Our daily experience makes it clear that the mind can affect physiology. Blushing from social embarrassment results from increased blood flow to the face, frightening movies can increase cardiovascular vital signs, and sexually stimulating visual material can increase blood flow to the penis. Similarly, psychological stress can lead to clear physiologic changes, most of which are potentially harmful. Chronically elevated blood pressure and heightened muscular tension leading to headaches or neck pain and increased incidence of chronic pain syndrome may be associated with stress. Pain and stress are interconnected, often generating a vicious cycle in which pain causes stress and subsequently stress causes more pain. Mind-body techniques can provide improved ability to cope with pain, decreased perception of pain, and an increased sense of wellbeing and relaxation. The psychological tendency to catastrophize has been associated with increased pain perception,[47] and mind-body techniques can help temper this anxious state.

The relaxation response is a physical state or reaction that counteracts the physiologic and emotional responses to stress and is essentially the opposite of the fight or flight response. It was first described by Herbert Benson and colleagues at Harvard Medical School in the 1970s.[48] Just as eliciting the stress response can generate unhelpful physiologic changes, eliciting the relaxation response can result in health inducing physiologic effects. The relaxation response is different than simply relaxing with a book or in front of the television. Although these activities may be considered "relaxing," they do not generate the physiologic changes associated with the relaxation response. The relaxation response is elicited by focusing the mind on a particular word, phrase, breath, image, or action and adopting a passive attitude toward one's thoughts. Modulation of cardiovascular parameters, muscular relaxation, and normalization of stress hormones such as cortisol, epinephrine, and norepinephrine are all associated with the relaxation response.

Mind-body techniques are varied and become easier to do with practice. Techniques include abdominal breathing, meditation, guided imagery, biofeedback, yoga, tai chi, qi gong, therapeutic arts, and even prayer. No mind-body technique is intrinsically more effective than another, and all can be used to decrease stress and elicit the relaxation response. Some involve movement and stretching, while others are practiced in seated or recumbent positions. They can be performed in groups, with an individual instructor, or alone. Patients may choose to try different mind-body techniques to find one, or several, that they prefer. Varied mind-body techniques have shown improvement in pain intensity and a suggestion of decreased need for opioids,[49] with meditation and hypnosis showing more benefit than other mind-body techniques. One challenge in the field of mind-body medicine is the lack of clarity regarding the needed "dose" of mind-body practice required for benefit. One study of a very brief (10 min) relaxation training experience did not show increased experimental pain tolerance compared to control.[50] Mindfulness Based Stress Reduction (MBSR) is a structured and standardized mind-body program that provides a large "dose" of mind-body practice. It is an eight-week training program with expectations for daily home practice. It usually requires a fee for participation. However, an online version is available at no cost (https://palousemindfulness.com). A randomized controlled trial of 342 adults aged 20–70 years with chronic low back pain found significant improvement in pain and functional limitation in those who participated in an MBSR program compared to usual care.[51] CBT was also assessed; MBSR and CBT were equally effective, and improvements persisted at 26 weeks. Similar improvements in pain, as well as the quality of life, were found for patients with chronic headaches.[52] Specific mind-body techniques are described in the ensuing paragraphs.

Progressive Muscle Relaxation

Progressive muscle relaxation is a commonly used technique for eliciting the relaxation response and relieving muscular tension. It is easy to learn and is accessible even to people who may not be familiar with or interested in meditation. It involves sequentially relaxing various muscle groups, often starting at the head and moving down the body to the feet. Participants may tense the muscle prior to relaxing it (for example, clenching the jaw and then releasing it) or simply bring their attention to a muscle group and intentionally relax it. Progressive muscle relaxation is often combined with guided imagery (see below). On its own, it has been shown to improve pain even with difficult populations such

as those with sickle cell disease.[53] It has also been used successfully to decrease headaches in children.[54] A sample progressive muscle relaxation script is provided in Appendix A.

Meditation

Moreover, 19% of the adult, civilian, noninstitutionalized United States population practices some form of meditation.[55] The term meditation refers to a broad variety of similar practices but may be quite distinct in intention. Depending on the culture and tradition of the meditator, meditation may be used to induce relaxation, increase vital energy ("qi" or "prana"), attain closeness to a deity, or induce a state of contemplation or ultimate consciousness. Many Western and Eastern religious faiths include meditative practices within their traditions, and in the past 40+ years, more secular versions of meditation have gained popularity. These forms of meditation are generally considered relaxation techniques, and they involve an intentional focus on the act of breathing, a sound, an object, a phrase, or a movement. The goal of these forms of meditation is generally to increase awareness of the present moment, elicit the relaxation response, reduce stress, and enhance personal growth.

Two common forms of meditation used in the West are MM and concentrative meditation. In MM, participants pay full attention to their breathing, focusing on each inhalation and exhalation. When thoughts, feelings, or sensations arise, the meditator simply notices and accepts them non-judgmentally and brings attention back to the breath. In concentrative meditation, attention is focused intently on one thing, such as an object (a candle) or a sound, word, or phrase, which is repeated silently with each breath cycle. Common phrases might include "peace" with inhalation and "love" with exhalation or "all will/be well."

Practicing focused attention in the present moment and nonjudgmental acceptance of experiences or thoughts decreases the mind's tendency to worry about the future or ruminate about the past. It has also been found useful in pain conditions. In one interesting study of experimental pain, subjects were taught MM, which they practiced 20 minutes daily for three days. The investigators measured pain sensitivity before and after meditation training and found decreased sensitivity after three days of meditation. The authors believed that the increased ability to tolerate pain was related to decreased anxiety and an increased ability to focus on the present moment.[56] A more recent study of 40 participants found that those assigned to a brief MM training had increased pain tolerance to experimental pain as well as a more rapid attenuation of pain intensity when compared to controls.[57] An interesting study addressed the question of whether mindfulness meditation-based analgesia is mediated by endogenous opioids.[58] The investigators performed a double-blind, randomized study of the effect of MM versus control on the impact of noxious heat while receiving either naloxone, an opiate antagonist, or saline. The meditation participants had decreased pain unpleasantness and intensity, and this effect was not negated by naloxone. This strongly suggests that the pain modulating effect of meditation is not related to endogenous opioids. A systematic review and meta-analysis of MM for chronic pain found improvements in pain, depression, and quality of life. However, the evidence was generally of low quality.[59]

Guided Imagery

Guided imagery is the generation of specific mental images to evoke a state of relaxation or physiologic change. It takes advantage of the communication links between the mind and the body and uses the imagination to generate intentional physiologic states, such as relaxation or relief of pain. It can be performed with a therapist and patient in person or by a patient alone, listening to a recording.

One study of fibromyalgia patients randomized subjects to either six weeks of daily guided imagery audiotapes or usual care. People in the guided imagery group had statistically significant improvements in their ability to cope with fibromyalgia, with a decrease in Fibromyalgia Impact Questionnaire score and increased self-efficacy for managing pain.[60] Interestingly, the imagery dose was not significantly associated with the outcome. This lack of dose-response relationship suggests that even using guided imagery infrequently might be beneficial. Guided imagery has also been shown to reduce headache intensity, duration, and frequency,[61] musculoskeletal pain,[62] and pain related to breast biopsy.[63]

Used with progressive muscle relaxation, guided imagery has been shown to reduce pain and fatigue in patients receiving chemotherapy[64] and pain related distress in terminal cancer patients.[65] There is evidence that guided imagery is helpful in the perioperative period. It has been shown to reduce the length of hospital stay[66] and decrease postoperative pain and preoperative anxiety.[67]

Hypnosis

Hypnosis involves leading the patient into a focused, trance-like state. By concentrating attention intensely on one specific thought, memory, feeling, or sensation and blocking out all distractions, patients become calm, relaxed, and open to hypnotic suggestion. Health inducing suggestions can be offered, including a decrease in anxiety or pain. Patients' free will remains intact during hypnosis, and they cannot be led against their will to perform actions that are dangerous to themselves or others.

There is evidence to support the use of hypnosis in various pain syndromes such as chronic pain, cancer, osteoarthritis, sickle cell disease, temporomandibular disorder, fibromyalgia, non-cardiac chest pain, and disability-related chronic pains.[68] A recent meta-analysis evaluating the impact of hypnosis with direct analgesic suggestion on pain showed that participants who were highly or moderately suggestible had significantly decreased pain.[69] Those who were minimally suggestible did not have a meaningful analgesic response. In a controlled study of 50 palliative care patients, those who received hypnosis had decreased pain and anxiety compared to controls, and these improvements were maintained at one and two years. The control group had a four times greater risk of increasing their pain medication usage at the two-year follow up.[70]

Yoga

Yoga originated in India but is now widely practiced worldwide and is generally used to improve relaxation, strength, and flexibility. Yoga's combined focus on mindfulness, breathing, and physical movements are health inducing for the mind and the body. Several styles of yoga are commonly practiced in the United States, including Hatha, Vinyasa, Ashtanga, Iyengar, Anusara, and Bikram, and each has unique intentions and techniques. Hatha yoga may be more appropriate for beginners, while Ashtanga yoga tends to be more physically demanding. "Power yoga" classes are appropriate for people seeking aerobic exercise, and they are often modifications of the Ashtanga style. Bikram yoga, often called "hot yoga," is practiced in a room heated to between 95 and 100 degrees, and Iyengar yoga is particularly concerned with bodily alignment.

Yoga is often used as a relaxation practice, but it has also been shown to be helpful in pain conditions. A recent Cochrane review

of yoga for chronic low back pain suggested a benefit for yoga in improving pain related function when compared to non-exercise controls.[71] These benefits persisted at three and six months. Yoga was associated with more adverse events than non-exercise controls, but none of the adverse events were serious. Veterans also showed that back pain was reduced after a yoga intervention,[72] but not all yoga studies for back pain have shown benefit.[73] Yoga has also shown benefit in chronic neck pain,[74] shoulder and arm pain in women with breast cancer,[75] chronic pelvic pain in women with endometriosis,[76] and even children with sickle cell crisis.[77] Benefits from yoga have been shown with both in person and telehealth sessions.[78]

An assessment of injuries attributed to yoga[79] found three categories of injury: soft tissue injury, axial nonbony injury, and bony injury (Box 61.1). Within the soft tissue group, overuse injuries were common. Within the axial group, exacerbation of degenerative joint disease was prominent; kyphoscoliosis, spondylolisthesis, and compression fractures were approximately equal contributors to the bony injuries. Hyperflexion and hyperextension of the spine were common causes of injury. Spinal hyperflexion may increase the risk of a compression fracture in high risk populations.[80]

Yoga therapy is an emerging field that aims to use the philosophy and practice of yoga to facilitate wellbeing, regardless of physical limitations. It focuses more on the individual than on the asanas (poses) and supports personal transformation within the experience of illness, pain, or disability.[81] A national survey of yoga therapists revealed that most yoga therapy is delivered in urban or suburban settings, and most therapists provided both therapeutic yoga classes and individual sessions. Common reasons for seeking out yoga therapy included anxiety, back or neck pain, and joint pain or stiffness.[82]

Tai Chi and Qi Gong

Tai chi and qi gong are ancient meditative movement techniques that combine standardized physical movements with meditation and relaxation breathing techniques. They have been used for thousands of years in China, and, as part of traditional Chinese medical theory, they are thought to unblock and balance vital energy ("qi"). In the United States, tai chi and Qigong are often used to relieve stress, improve balance and reduce pain. The practices use conscious, often slow, movements and focus on goals different from conventional Western exercise, such as developing consciousness within the body and enhancing the smooth flow of energy.

A recent study published in the American Journal of Public Health assessed the usage trends of tai chi/qi gong/yoga from 2002–2017 using National Health Interview Surveys. Use of these modalities, assessed collectively, increased from 5.8% in 2002 to 14.5% in 2017.[83] Stated reasons for use included the expectation that they would be beneficial, the focus on the whole person, and the fact that these modalities are "natural." The top three conditions for which people used these meditative movement modalities were acute and chronic pain, arthritis, and depression.

A systematic review and meta-analysis of tai chi for musculoskeletal pain assessed only randomized controlled trials. Fifteen trials met the inclusion criteria, and the quality of the studies was moderate. Tai chi was found to be more effective for pain and disability than no treatment or usual care.[84] Tai chi has been shown to decrease pain in fibromyalgia as effectively as aerobic exercise[85] as well as to decrease depression, improve fatigue, enhance sleep, and improve both physical and psychological quality of life in addition to improving pain.[86] It was shown to be equal to physical therapy in the treatment of knee osteoarthritis,[87] and to improve function and quality of life in this population.[88]

A review of the medical literature found significant beneficial health effects of tai chi and qi gong. The authors reviewed 77 articles reporting results of 66 randomized controlled trials, including over 6,000 patients of the health effects of tai chi or qi gong. Control groups included non-exercise controls, exercise controls, or both. The most convincing evidence for health benefits in this review was for bone density, cardiopulmonary fitness, fall prevention, balance, quality of life, and self-efficacy.[89]

Virtual Reality

Virtual reality uses computer technology to create a simulated but immersive environment. Using a head-mounted display and employing as many senses as possible, virtual reality creates three dimensional images that are highly realistic and place the participant "inside" the experience. Increasingly, virtual reality has been used in medical contexts to help manage pain and other conditions.

A recent comprehensive literature review of virtual reality for procedural pain and distress showed benefit even for patients undergoing extremely painful procedures such as wound care in burn patients.[90] It also showed benefit in cancer patients undergoing chemotherapy. Only mild side effects were observed. Virtual reality has also shown benefit in phantom limb pain,[91] acute experimental pain,[92] and in one study of morphine plus virtual reality, the combination was more effective for pain and anxiety management than morphine alone.[93] In addition to its benefit in acute and procedural pain, virtual reality has shown benefit in the management of chronic pain.[94,95]

Therapeutic Art and Music

Creative arts can be used in the therapeutic environment to relieve stress, anxiety, and pain in patients and caregivers.[96,97] Art therapy has been used to stimulate relaxation in the palliative care setting,[98] and as distraction from negative side effects of bone marrow transplant.[99]

A Cochrane review of music therapy in people with cancer assessed 30 trials for a total of 1891 participants. They included music from multiple sources, including recorded music and music provided by trained music therapists, and found that music interventions may have beneficial effects on pain, anxiety, mood, and quality of life in people with cancer.[100] Another more recent review that evaluated studies according to the Cochrane Collaboration Guidelines found similar results.[101] In addition, patients randomly assigned to music therapy plus usual care versus usual care alone after spinal fusion surgery showed a decrease in postoperative pain.[102] Music therapy has also shown reductions in pain, anxiety, and opioid use during burn dressing changes,[103] and postoperative reductions in anxiety and pain after thoracic surgery.[104] It may be more effective when the music is chosen by the patient rather than the practitioner.[105] Music therapy has been used successfully in the emergency department,[106] in the intensive care unit,[107,108] and for palliative care patients.[109]

Energy Medicine

Energy medicine modalities, sometimes called biofield therapies, are based on the idea that all living creatures have energy that can be manipulated in the pursuit of health by a trained practitioner.

A three year study of 118 chemotherapy patients investigated the role of Reiki, a form of energy medicine, in the management of anxiety, pain, and global wellness in cancer patients. Pain and

anxiety were evaluated with a visual analog scale (VAS). In the patients who received the full treatment course (4 Reiki sessions), mean VAS anxiety scores decreased from 6.77–2.28, which was a highly significant result; however, no control group was included, and significant bias was introduced. Mean VAS pain scores also decreased from 4.4–2.32, but this did not reach statistical significance.[110] A more recent meta-analysis of Reiki for pain also showed that it resulted in a statistically significant decrease in VAS pain score,[111] and it appears to have a similar pain-reducing impact in children undergoing bone marrow transplants, but rigorous studies are lacking.[112] A large scale effectiveness trial of Reiki for physical and psychological health revealed statistically significant improvements in pain, affect, fatigue, nausea, anxiety, depression, and overall wellbeing.[113]

While Reiki is likely safe and may be effective for pain and anxiety, higher quality studies are needed to solidify its clinical indications.

Manual Therapy

The term *manual therapy* is non-specific and refers to techniques that use the hands to diagnose and treat disorders of the musculoskeletal system (MSK). More specific terms include high velocity, low amplitude joint manipulation, joint mobilization, and soft tissue manipulation. These techniques are often used to treat various painful acute, subacute, and chronic musculoskeletal conditions, and multiple studies have demonstrated effectiveness.[114-122] Many studies show a significant effect on pain improvement in outcome measures, although in some cases, the effect size is small.[114,117,119,123] Spinal manipulation, one of the oldest forms of therapy for low back pain, has mostly been practiced outside of the medical profession until the latter part of the 20th century.[124] Today, manual therapy may be performed by physical therapists (PT, DPT), chiropractors (DC), massage therapists, osteopathic physicians (DO), and others and may include techniques such as chiropractic manipulative therapy (CMT), craniosacral therapy, and osteopathic manipulative techniques (OMTs). A 1991 RAND study estimated that 94% of all manipulation is performed by chiropractors.[125] While physical therapists have undoubtedly increased their utilization of this modality, it is likely that the vast majority of this therapy is still provided by chiropractors.

The evidence for the benefit of manual therapy in the treatment of patients with musculoskeletal pain continues to increase, and the risk of adverse events appears to be low; however, not all studies show clinical benefit or cost effectiveness. Non-pharmacologic pain management strategies may have both safety and cost benefits, and thus the American College of Physicians (ACP) guidelines now recommend spinal manipulation, massage, superficial heat, and acupuncture as first line options in patients with acute low back pain. A recent study by Thomas and colleagues on mild to moderate chronic low back pain in young adults compared spinal manipulation with spinal mobilization and sham cold laser (placebo). Their results showed no significant difference in change in self-reported disability scores between spinal manipulation, spinal mobilization, and placebo.[126] Thus it is not yet completely clear which manual medicine interventions may be most effective and if patients with greater pain related disability may benefit more or less than those who are less affected. Non-pharmacologic approaches are associated with reduced harm compared to pharmacologic approaches.[127] Therefore further research on the potential benefits of manual therapy approaches may benefit both patients and healthcare systems. Of note, the ACP guidelines state that providers should administer physical therapies with appropriate training, such as osteopathic physicians, chiropractors, and physical therapists. The Lancet reports similar European guidelines for the management of low back pain.[128]

A systematic review of randomized clinical trials of manual therapies evaluated the evidence for spinal manipulation or mobilization in treating several different conditions, including 13 musculoskeletal conditions and headaches. The authors reviewed 49 systematic reviews, 16 evidence-based clinical guidelines, and an additional 46 randomized clinical trials not yet included in systematic reviews and guidelines. They found spinal manipulation to be effective in adults for acute, subacute, and chronic back pain, migraine and cervicogenic headache, and cervicogenic dizziness, and thoracic manipulation or mobilization was determined to be effective for acute and subacute neck pain.[119] Other conditions that are reported to respond to manual therapy are costosternal pain,[129] lumbar spinal stenosis with neurogenic claudication,[130] pelvic girdle pain,[131] pain in extremity joints,[132,133] osteoarthritis,[134] and myofascial pain. Although anecdotally reported, the benefit of manual therapy for temporomandibular disorders and orofacial pain is unclear.[135]

Modern society continues to struggle with an opioid abuse crisis of epic proportion. A growing body of research demonstrates that MSK pain patients referred to or self-refer to practitioners of manual therapies have a lower likelihood of filling an opioid prescription than those seeking conventional care,[136-142] in some cases as much as a 60% reduction.[137]

Significant healthcare cost savings are realized using manual therapy practitioners: 2012 Optum Data for risk adjusted total episode cost by entry point for 1.4 million nonsurgical episodes of low back pain revealed that patients starting care with manual therapy providers (in this case, chiropractors) is the most common entry point and has the lowest cost per episode, including a 50% reduction in imaging costs.

Several models attempt to explain the mechanisms by which manipulation or manual therapy modulates pain and improves function. There are three primary models:

Structural model: States that misaligned structures, such as bones out of place, impinge on nerves and stress soft tissues, thereby stimulating nociceptors. Common terminology includes "subluxation," "osteopathic lesion," "pelvic obliquity," "leg length inequality," and "torsion." It is believed that correction of these misalignments via manual methods eliminates pain and improves function. The evidence base does not support the concept that structural misalignments are clinically significant in most instances, and the premise that manipulation or mobilization can correct structural misalignments has been largely disproven.[143-145]

Functional model: Muscular imbalance leads to abnormal joint loading, which in turn causes loss of joint function at the level of accessory motion, also termed "joint play."[146–148] Terminology includes "somatic dysfunction," "biomechanical lesion," "blockage," "fixation," "restriction," "muscular inhibition/facilitation," and "instability/stabilization." Syndromes include upper and lower crossed syndromes,[149,150] each characterized by specific patterns of muscular facilitation (tightness) and inhibition (weakness). For example, upper crossed syndrome is characterized by facilitation or "tightness" of the upper trapezius, levator, sternocleidomastoid, and pectoralis muscles, whereas the deep cervical flexors, lower trapezius, and serratus anterior muscles are inhibited and weak. Practitioners use a combination of manipulation and rehabilitative exercise with the intention of changing muscle activity and reducing nociceptive input. This is the current model presented

in most chiropractic, physical therapy, and osteopathic manual therapy programs.

Neurophysiologic model: This model is consistent with the emerging concept that the pain experience is a central nervous system output that is modulated by multiple factors such as stress, anxiety, fear avoidance, experience, and context in the brain's "neuromatrix."[151] Wellens and others proposed that manual therapy introduces a novel stimulation into the central nervous system that may help the brain downregulate the perceived threat of nociceptive stimuli, thereby decreasing the pain by descending inhibition and other peripheral and central mechanisms. This, in turn, may stimulate a change in the maladaptive motor responses produced by the brain in response to pain. Other reflexive reactions at the spinal cord level may affect temporal summation and downregulate the value (threat) of the nociceptive input even more.[152,153]

Bialosky et al.[154] propose that manual therapy affects the pain state by

- decreasing peripheral inflammation and nociception
- deceasing activation/temporal summation at the spinal cord level
- activating descending modulation via the brain and central nervous system

Even though this model is hypothetical, there is an impressive body of supportive literature.[155–158] Some of these studies describe neurophysiologic changes following spinal manipulation, including neuroplastic changes, alteration in motor neuron excitability, and increase in cortical drive. High velocity, low amplitude manipulation (HVLA) resulting in an audible "pop" or cavitation has been shown to down regulate the sensitivity of muscle spindles and/or other segmental sites of the 1a stretch reflex pathway.[159] Research by Reed in 2015 found that HVLA manipulation decreased sensory input from the paraspinal muscle spindles.[160]

Practitioners of manual therapy generally believe that musculoskeletal problems arise from abnormal repetitive movement patterns, prolonged static posture, trauma, lack of exercise, inadequate diet, and poor lifestyle choices, leading to diminished capacity and excessive and/or asymmetric musculoskeletal loads creating nociceptive input and impairing function. Examples of musculoskeletal asymmetry that can lead to painful conditions include chronic elevation of one shoulder when carrying a heavy purse, abnormalities in tissue mobility after prolonged immobilization, and forward head carriage associated with desk work, computer use, and prolonged sitting causing soft tissue overload.

The forms of manual therapy most frequently employed in clinical practice are manipulation and mobilization.

Manipulation (also called high velocity, low amplitude, or thrust manipulation) is the skilled introduction of a rapid rotational, shear, or distraction force via a thrust or impulse to an articulation, frequently associated with an audible popping sound caused by instantaneous joint cavitation.

Mobilization is a slower, deliberate process of articular movements of the joint intended to relieve pain, improve biomechanical elasticity, and enhance range of motion. It can be passive or actively assisted by the patient.

Soft tissue manipulation or mobilization is direct pressure, transverse friction massage, manual stretching, instrument assisted soft tissue mobilization (IASTM) with or without passive or active motion that seeks to relieve pain and improve function by "releasing" trigger points, mobilizing fascia, and reducing entrapment of peripheral nerves. The Graston technique is an example of a widely used IASTM technique. Active release is a manual technique coupled with active motion by the patient to address myofascial restrictions and relieve pain. An excellent description of peripheral neurodynamics, along with exercises and techniques to address entrapped peripheral nerves, is found here.[161]

Myofascial pain syndrome is a chronic musculoskeletal pain condition with a poorly defined and complex pathophysiology. It may emerge after tissue injury, chronic stress-related muscular contraction, or excessive strain on a muscle, tendon, or ligament. Tender regions of hyperirritable, contracted muscle fibers, called trigger points, may form in the affected muscle group and cause local and referred pain. Myofascial trigger points are palpable, tender nodules within the skeletal muscle that have characteristic referred pain patterns and physiologic activity that are different from those in normal muscle tissue.[162] Emerging research suggests that painful myofascial trigger points may be initiated by neurogenic mechanisms secondary to central sensitization and not necessarily by local injury.[163] Trigger points may be treated with physical therapy, manual or IASTM, massage, transcutaneous electrical stimulation, therapeutic ultrasound, selective voluntary contraction of antagonist muscles or muscle groups,[164] injection of saline or local anesthetic medications, dry needling, or application of vapor coolant spray combined with focused muscular stretching. Botulinum toxin has also been used.[165]

For some conditions such as chronic low back pain, manipulation appears to yield a greater effect, while mobilization and soft tissue manipulation may be more well tolerated in acute pain states or more delicate structures.

Adverse Effects From Manual Therapy

Walker[166] performed a randomized controlled trial including 183 adults, aged 20–85 years, with spinal pain. His team found that common adverse events following manual therapy are frequent but minor. They included increased pain, muscle stiffness, and headache. The relative risk was not significant for adverse event occurrence, and no serious adverse events were reported. Swait concluded that existing literature indicates that benign adverse events following manual treatments to the spine are common, while serious adverse events are rare.[167]

Some case reports claim that massage and manipulation of the lumbar spine can cause lumbar disc herniation (LDH).[168] However, a 10 year population-based self-controlled case series study concluded that while a strong positive association between acute LDH and both chiropractic and primary care visits exists, there was no evidence found of excess risk for acute LDH with early surgery associated with chiropractic compared with primary medical care.[169]

Some have expressed concern that manipulation of the neck increases the risk for cervical artery dissection (CAD) stroke. A large Canadian study that included more than 100 million person-years showed that these concerns are likely unfounded.[170] although debate on this topic persists.[171,172] A recent systematic review and meta-analysis of chiropractic manipulation and CAD conducted jointly by the Departments of Neurosurgery at Penn State Hershey Medical Center and Johns Hopkins University School of Medicine concluded: "There is no convincing evidence to support a causal link between chiropractic manipulation and CAD."[173] However, there are clear contraindications to manipulative therapy (Box 61.3).[174]

Massage

Massage is a widely used form of manual therapy that utilizes varied techniques applied to the muscles, ligaments, tendons, and related structures in the pursuit of pain relief, health, and wellness.

• Box 61.3 Contraindications to Manipulative Therapy

Relative Contraindications	Absolute Contraindications
Acute disc herniation	Unstable os odontoideum
Osteopenia	Healing fracture/dislocation
Spondyloarthropathy	Avascular necrosis
Anticoagulant medication	Bone infection
Bleeding/clotting disorder	Segmental instability
Psychological overlay	Cauda equina syndrome
Hypermobility/ligamentous laxity	Large abdominal aortic aneurysm
	Referred visceral pain
	Long term repeated manipulation with symptom relief lasting <1 day
	Recognized secondary gain or malingering

Massage may be performed with the hands, elbows, forearms, or feet, as well as with appliances such as warmed stones. There are many types of massage, each with unique techniques and goals, such as Swedish massage, trigger point massage, reflexology, and lymphatic drainage.

Massage is often used to address pain syndromes such as back pain, neck pain, and sports injuries, as well as to aid in stress reduction and generation of the relaxation response. It has been found to improve symptoms of osteoarthritis of the knee[175] and chronic low back pain, decrease medication use and medical costs,[176–178] and decrease the perception of cancer pain.[179]

It is not clear whether some forms of massage are superior to others or if the benefits of varied massage styles are equivalent. One recent study randomized 401 patients with non-specific low back pain to relaxation massage, structural massage, or usual care and assessed their symptoms with the Roland Disability Score and the Symptom Bothersome Score. Participants were blinded to the type of massage but not to massage versus usual care. Both massage groups had statistically significant improvements in both outcome measures at 10 weeks compared with those receiving usual care.[180] Cost effectiveness of massage therapy for pain management in the long term has not been established. Massage is generally safe for healthy populations. Contraindications include the presence of metastatic lesions, severe osteoporosis, thrombosis, infections or wounds, active inflammatory conditions, and bleeding disorders.

Chiropractic Manipulation

Doctors of Chiropractic (DC) focus primarily on the interaction between the structure and the function of the body, with particular attention paid to the spine. Historically, the primary goal was to correct musculoskeletal misalignments (subluxations) to relieve nerve pressure and thus alleviate pain and improve the body's innate self-healing capability. The primary modality of CMT is high velocity, low amplitude (HVLA) thrust manipulation (spinal adjustment). Adjustments generally involve the use of the hands or a device to apply an intentional, controlled, rapid force to a joint or body segment thought to have impaired alignment or restricted motion. Restored intersegmental motion or joint position is believed to improve both function and general health. Modern chiropractors reject the misalignment/subluxation hypothesis instead of focusing on restoring joint mobility. There are multiple chiropractic techniques, each with its own unique set of diagnostic and treatment protocols. Some use minimal force, whereas others use a more intense force. The most common technique encountered is termed "diversified" and encompasses HVLA maneuvers for all joints of the spine and extremities. Currently, no one technique is considered superior. In addition to manual therapies, chiropractors may incorporate pain education, ergonomic modification, relaxation techniques, dietary guidance, nutritional supplementation, physical therapy modalities, and rehabilitative exercise into their treatment plans. The combination of HVLA manipulation and rehabilitative exercise appears to provide the best outcomes.[181]

Most patients who choose chiropractic care do so because of back and neck problems. Patients are generally satisfied with their chiropractic care.[182] A 2018 study by Lisi et al. investigating integrating chiropractic care into private sector medical facilities concluded that delivery of chiropractic services, including CMT, was perceived to have high value among patients, medical providers, and administration. Patient clinical outcomes, patient satisfaction, provider productivity, and cost offset were identified as markers of clinic success.[183]

In a study by Goertz et al., 91 patients were randomized to either "standard care" or "standard care plus chiropractic care" (CMT). The authors concluded that "CMT in conjunction with standard medical care offers a significant advantage for decreasing acute low back pain and improving physical functioning compared with only standard care."[184]

Osteopathic Manipulation

Osteopathic medical education is similar to that found in allopathic medical schools, with the added focus on a holistic and preventive approach to medicine. In addition, osteopathic physicians learn OMT, which is not included in the allopathic medical school curriculum. OMT is a hands-on practice that attempts to restore normal musculoskeletal movement and function and decrease pain.

Osteopathic physicians may choose any specialty and can earn board certification from both osteopathic and allopathic medical boards. Most osteopathic physicians complete allopathic residencies and practice indistinguishably from allopathic physicians; however, some others focus their practice on osteopathic principles and techniques.

Osteopathic principles include working in partnership with patients to facilitate wellness and prevent disease and the concept that structure influences function. That is, a structural problem in one part of the body may affect function in that region and possibly others. Osteopaths generally believe that the body has an innate ability for self-healing, and OMT techniques are thought to support this process.

OMT procedures are directed at increasing mobility in restricted areas of musculoskeletal function and reducing pain. Some practitioners focus on pain relief, whereas others are more interested in the influence of increased mobility within the musculoskeletal system. The stated goal of OMT is to restore maximal, pain-free movement of the musculoskeletal system in postural balance.[185] Techniques include muscle energy technique, mobilization with and without impulses, indirect technique, myofascial release, and integrated neuromusculoskeletal technique.[185]

OMT has been demonstrated to be effective for neck pain[185] and migraine headache symptoms, with pain intensity, functional disturbance, and days of disability all showing improvement compared with control. A systematic review and meta-analysis of OMT for low back pain concluded that OMT significantly reduces low back pain symptoms, with the effect lasting at least three months.[186]

Orthopedic Manual Physical Therapy

Orthopedic manual physical therapy is the name given to manual therapy as practiced by physical therapists.[187,188] Manual therapy is part of the core physical therapy curriculum, with most practitioners gaining knowledge and skills through continuing education or fellowships.[188] Physical therapists trained in manual therapy use techniques such as stretching, mobilization, and muscle energy-related techniques to increase range of motion, improve function, modulate pain, decrease tissue inflammation, and facilitate tissue repair. Rehabilitative exercise and other physical therapy modalities such as electrical muscle stimulation and therapeutic ultrasound are also used.

Practitioners of manual medicine may be trained as physical therapists, osteopathic physicians, chiropractors, and to some extent, massage therapists, and strict distinction between practice styles and techniques is lacking. A standardized knowledge base with certification available to all relevant practitioners would be valuable. It is not clear whether one profession will eventually "own" manual medicine or whether a new specialty will emerge. One suggested model is to offer fellowships in manual medicine with board certification that would be available to physical therapists, chiropractors, osteopathic physicians, allopathic physicians, and massage therapists. A program designed to enhance competency as a primary contact practitioner who manages spine related disorders has recently been launched at the University of Pittsburgh. (https://www.psp.pitt.edu/index.html). The Primary Spine Practitioner certification program is open to chiropractors and physical therapists. From the program description: "The PSP functions as primary contact provider for patients with spine related disorders (SRDs). This involves taking responsibility for managing most patients without the need for special tests or specialist referrals. It also involves identifying the minority of patients who do require further diagnostic evaluations (X-ray, MRI, CT, EMG) or specialized interventions (injections, surgery). Further, the PSP serves as an inter-professional care coordinator, referring patients for the appropriate test or specialty service and following up after these referrals to continually guide the patient toward resolution of the SRD. To perform this role, the PSP requires a very specific and refined skill set."[189]

Manual Medicine and the Biopsychosocial Model

A role that a practitioner of manual medicine may find themselves in is that of a mechanic, with the MSK pain patient believing that the provider can come to the rescue and "fix" their problem without their active participation. The locus of control over the pain becomes assigned to the practitioner, and the patient may become dependent on the practitioner to experience a decrease in pain or pain related disability. This thinking reinforces the patient's view that they are "broken" or inadequate in some way and thus must rely on the practitioner to repair their issue or dysfunction. This may reinforce fear avoidance beliefs or catastrophizing, both potent contributors to central sensitization and chronic pain. While it is true that spinal manipulation may often rapidly relieve pain, the effects are usually short lived. The analgesic effect resulting from manipulation can provide a window of opportunity to empower the patient, aiding them in discovering their own resilience by showing them how they can restore impaired physical performance, reduce their disability,[153] and regain independence.

This can be achieved particularly for the chronic pain patient, with a powerful concurrent application of manual therapy with an appropriately dosed, well-designed rehabilitation program that includes pain education. Through appropriate patient education regarding the biopsychosocial aspects of pain, including information on the nocebo response, interpretation of actual or perceived threat, fear avoidance, catastrophization, and the use of exercise to illustrate to the patient their abilities, the skilled manual therapy practitioner can collaborate with other members of the pain management team to guide the patient to discover enhanced levels of function, fitness, and empowerment. This approach guides the patient to become the primary agent in their recovery.

Homeopathy

Homeopathy is based on the principle that the efficacy of a remedy is increased as the dose is decreased. Homeopathic remedies are serially diluted, often until the remedy no longer contains any molecules of the original medication. The diluent, often water, is thought by homeopaths to be "imprinted" by the original substance, thus imparting therapeutic efficacy. Homeopathy is used by 2% of the United States population, primarily for ear, nose and throat (ENT), musculoskeletal, and respiratory complaints.[191] Its use is much more common, as high as 35%, in the German population.[191] Rigorous clinical trials and systematic analyses of the research on homeopathy have concluded that there is no evidence to support homeopathy as an effective treatment for any specific condition.[192] Similarly, a Cochrane review of homeopathy for irritable bowel syndrome could not draw a conclusion about efficacy.[193] Although high quality research validating the efficacy of homeopathy is lacking, some small studies have shown benefit in conditions such as joint pain in breast cancer patients,[195] pelvic pain,[195] and other varied chronic conditions.[196] One double-blind, randomized controlled trial of homeopathy in rheumatoid arthritis showed that it was the homeopathic consultation rather than the remedy itself that led to positive outcomes.[197]

Biologically Based Products: Herbs, Nutraceuticals, and Nutritional Supplements

A large body of clinical evidence supports the usage of biologically based products for the alleviation of pain. This supportive evidence for pain reduction spans a wide variety of herbs, nutraceuticals, nutritional supplements, and food-derived topical products. The following products have the strongest evidence supporting their usage in the reduction of pain.

Capsaicin

Capsaicin is derived from chili peppers of the genus Capsicum, which includes the cayenne pepper commonly used in cooking. Topical application of creams and gels ranging from 0.025%–8% capsaicin concentration is utilized to provide pain relief. The primary mechanism through which capsaicin is believed to reduce pain is the depletion of substance P, a neuropeptide involved in the transmission of pain signals from nerve endings to the brain and the activation of inflammatory cytokines in joints. Thus capsaicin is involved in the neuronal modulation of pain.[198]

Many high quality, randomized, double-blinded, placebo-controlled trials have found that topical application of capsaicin is an effective treatment for osteoarthritis pain. A recent literature review found that capsaicin safely reduced osteoarthritis pain of

the hand, knee, hip, and shoulder compared to placebo.[199] Motivated by the relatively common sensation of burning experienced at higher concentrations, a trial assessed the topical application of capsaicin at a concentration of 1.25% in 100 patients with osteoarthritis of the knee.[200] Capsaicin at this lower concentration was effective at improving pain. While a mild burning sensation was common, no participants dropped out of the study for this reason. Consequently, lower concentrations of topically applied capsaicin appear to be another effective treatment option for mild to moderate osteoarthritis pain.

While most capsaicin research has focused on osteoarthritis pain, several studies have assessed its efficacy for neuropathic pain.[201–203] Transient application of a dermal patch containing 8% capsaicin has been shown to be an effective option for reducing neuropathic pain. In patients with painful diabetic peripheral neuropathy, a single 30 minute application of the 8% dermal patch provided 12 weeks of pain relief compared to a placebo.[204] It was non-inferior to oral pregabalin with a faster onset and greater treatment satisfaction. Following application, capsaicin causes increased sensitivity that, with repeated use, leads to reduced sensitivity and ultimately desensitization. The 8% capsaicin patches were developed to rapidly achieve desensitization and improve compliance and tolerability. The patch is generally administered in a physician's office; it is not prescribed for home use. The patch is applied for 60 minutes after application of a topical anesthetic to decrease patient discomfort. Occasionally an ice pack or other analgesic may be necessary. Treatment may be repeated every three months. A high quality Cochrane systematic review confirmed the benefit of high concentration capsaicin patches for peripheral neuropathy of varied etiologies.[205] The observed efficacy is similar to oral agents such as pregabalin, duloxetine, and gabapentin, with fewer adverse events.[206]

Boswellia Serrata

Extracts of the Boswellia serrata plant have been used as an important component of Ayurvedic medicine for thousands of years. Western science has validated the traditional usage of Boswellia serrata for pain as its extracts elicit powerful anti-inflammatory activity through its inhibition of the 5-LOX enzyme. Several forms of Boswellia serrata have been studied and used clinically.

A double-blind, placebo-controlled study of Boswellia for patients with osteoarthritis showed that Boswellia significantly improved pain, stiffness, and physical functioning compared to placebo.[207] It also reduced the levels of C-reactive protein, an inflammatory marker. No serious adverse events were reported. Boswellia is sometimes used alongside Curcumin, and the combination may be more effective than Boswellia alone.[208]

Glucosamine and Chondroitin

Numerous meta-analyses have determined that glucosamine, either combined with chondroitin or alone, is an effective treatment for osteoarthritis pain.[209–212] Despite the abundance of positive evidence for glucosamine and chondroitin, the large glucosamine/chondroitin arthritis intervention trial found mixed results which are often misinterpreted.[213] This five-arm trial compared glucosamine alone, chondroitin sulfate alone, glucosamine/chondroitin sulfate, and celecoxib to placebo. Participants in the glucosamine/chondroitin group did not demonstrate a statistically significant improvement compared to placebo in the primary outcome (20% improvement in WOMAC pain score) of the overall study sample of patients with osteoarthritis of the knee (mild [n = 1229] versus moderate to severe [n = 354]). However, 67% of the overall study sample in the glucosamine/chondroitin group experienced at least a 20% improvement in pain with a trend toward statistical significance (P = 0.09). The lack of statistical significance at P = 0.05 was thought to be because of the unexpectedly high improvement in the placebo group (60.1%). Furthermore, among the 354 participants with moderate to severe osteoarthritis of the knee, 79% of those in the glucosamine/chondroitin combination group experienced at least a 20% improvement in WOMAC pain score, which was statistically significant when compared to placebo (P = 0.002). Interestingly, participants with moderate to severe arthritis pain in the celecoxib group did not demonstrate a statistically significant improvement compared to placebo, a rarely reported finding. While a statistical comparison between the glucosamine/chondroitin and celecoxib groups was not reported in the paper, glucosamine/chondroitin was shown to be more effective than celecoxib in patients with moderate to severe osteoarthritis.

More recently, a multicenter randomized, double-blind non-inferiority trial of combined glucosamine and chondroitin versus celecoxib for knee osteoarthritis found comparable efficacy in reducing pain, stiffness, joint swelling/effusion, and functional limitation after six months. Adverse events were mild and similar between the groups.[214] While the findings from the greater than 50 randomized controlled trials of glucosamine/chondroitin for osteoarthritis pain have not been universally positive, consideration of the body of evidence suggests that glucosamine/chondroitin is a safe and at least moderately effective treatment for osteoarthritis pain. A daily dose of 1,500 mg glucosamine and 1,200 mg chondroitin has been studied most frequently and is the typical recommended dosage.

S-adenosyl-methionine (SAM-e)

The reduction of joint pain provided by SAM-e was first observed as side effects in clinical trials for depression. Produced from L-methionine and adenosine triphosphate, SAM-e is a methyl donor involved in a wide variety of metabolic processes. Although the mechanism of action is not completely understood, SAM-e has been shown to possess anti-inflammatory and analgesic effects without causing gastrointestinal damage in animal models. SAM-e has also demonstrated chondroprotective effects through the stimulation of chondrocytes and the subsequent increase in cartilage production.

A meta-analysis of 13 clinical trials revealed that SAM-e is comparable to ibuprofen and superior to placebo in reducing osteoarthritis pain.[215] A large randomized controlled trial published subsequent to this review compared the efficacy of SAM-e to celecoxib in patients with osteoarthritis pain.[216] This study found that SAM-e was as effective as celecoxib in relieving pain after 16 weeks of treatment. In one more recent study of mice with experimentally induced nerve injury, SAM-e attenuated sensory and cognitive symptoms compared to placebo saline. The authors postulated that the symptom improvement might be partly because of the modulation of DNA methylation in the central nervous system.[217] SAM-e has also been shown to attenuate morphine tolerance in rats.[218]

More high quality human trials are needed to confirm the benefit of SAM-e for joint pain. However, since it is more often used for depression, which can exacerbate pain, it should be considered for patients with coexisting pain and depression. The onset of pain relief is slower with SAM-e than some pharmacologic pain relievers, but it has no known side effects. Most clinical trials to date have used a daily dosage of between 400 and 1,600 mg.

Omega-3 Fatty Acids

Dietary omega-3 fatty acids, including α-linolenic acid (ALA), eicosapentaenoic acid (EPA), and docosahexaenoic acid (DHA), can interrupt the production of inflammatory compounds such as the prostaglandins E2 and LTB4, interleukin-1 beta (IL-1β), leukotriene B4, and tumor necrosis factor-alpha (TNF-α). Omega-3 fatty acids also inhibit the platelet-activating factor synthesis pathway, the cyclo-oxygenase pathway, and the 5-lipoxygenase pathway. As such, omega-3 fatty acids are known to play an important role in modulating the inflammatory cascade and the pathophysiology of autoimmune conditions. Chief among the conditions impacted by omega-3 fatty acids is rheumatoid arthritis.

Omega-3 fatty acids have been shown in numerous systematic reviews to reduce the pain and joint tenderness of rheumatoid arthritis.[219–221] Multiple studies have also found that omega-3 supplementation can reduce disease-related markers,[222,223] as well as dependence upon nonsteroidal anti-inflammatory drugs and antirheumatic drugs.[224–226] In addition to reduction of the pain associated with rheumatoid arthritis, omega-3 fatty acids have also been determined to be effective in reducing neck and back pain,[227] neuropathic pain,[228] and the pain from inflammatory bowel disease and dysmenorrhea.[229] It also reduced postoperative pain and postoperative C-reactive protein, a marker of inflammation,[230] and showed benefit in the prevention and treatment of oral mucositis in patients receiving chemotherapy.[231] In obese but not non-obese patients, omega-3 fatty acids were found to reduce the arthralgias caused by aromatase inhibitors when compared to placebo.[232] No significant toxicities have been associated with the use of omega-3 fatty acids, although patients on anticoagulant medications should be mindful of the potential for interaction.

The omega-3 fatty acids EPH, DHA, and ALA are not produced endogenously in human beings and must be obtained through the diet. Dietary sources of omega-3 fatty acids include salmon, sardines, and other cold-water fish, fish and krill oils, and plant oils from flaxseed or walnuts. While all forms of omega-3 fatty acids are important, EPA and DHA have direct anti-inflammatory effects and are more easily utilized by the body.[233] Conversion from ALA to EPA and DHA is poor, particularly in men.[234] As such, the optimal forms of omega-3 fatty acids taken for therapeutic purposes in pain conditions are EPA and DHA. Accordingly, most studies to date have investigated the effects of fish oils because of their high concentration of EPA and DHA. These studies show that a minimum daily dosage of 3 g of EPA and DHA is required for clinical efficacy in pain conditions. Benefits for pain generally become apparent after at least several weeks.

Summary

An integrative approach to the treatment of pain that incorporates complementary medicine approaches into the care plan can provide clinical benefit with minimal additional risk. Understanding the mind-body connection and its relevance to pain perception and treatment is important for the care of patients with acute and, especially, chronic pain. Biologically active products, mind-body therapies, and manipulative and body-based treatments can benefit patients with some pain conditions. Energy medicine and homeopathy have minimal and low quality evidence of benefit. Integrative medicine approaches have gained greater acceptance in healthcare. Still, further large, well-designed studies of diverse complementary medicine modalities are needed to confirm which modalities are best suited to which conditions.

Key Points

- Integrative medicine is a philosophy of care that integrates conventional medical approaches with complementary modalities.
- Commonly used complementary modalities include dietary supplements, yoga, meditation, acupuncture, and massage.
- The perception of pain is multifactorial, with nociceptive and affective components, which supports the use of an integrative approach.
- Psychosocial variables, including catastrophizing and negative affect, impact the severity and chronicity of pain.
- Acupuncture has shown benefit in migraines, neck disorders, tension-type headaches, and peripheral joint osteoarthritis.
- Mind-body modalities, such as meditation and guided imagery, are safe and effective modalities that have been shown to decrease pain.
- Yoga has shown benefit in the management of multiple pain syndromes, including low back pain, chronic neck pain, chronic pelvic pain, and sickle cell disease.
- Manual medicine approaches such as massage, chiropractic, physical therapy, and osteopathic manipulation have been shown to improve pain syndromes such as low back pain, myofascial pain syndrome, and arthritis.
- Nutritional supplements may have some benefit in the treatment of pain, particularly pain with an inflammatory component.

Appendix A

Find a comfortable position where you will not be interrupted. You may sit up or lie down, however you are most comfortable.

You will be focusing your attention on your body for the next few minutes. If your mind wanders, simply bring your attention back to your body.

Take a deep breath into your abdomen, trying to push your belly button out as you breathe in. Hold your breath for a few seconds, and then slowly breathe out. Take another deep breath, trying to push out your belly button as you take in a healing breath… Hold for a few seconds… then slowly release your breath.

As you exhale, imagine the tension in your body being released and flowing out of your body. And again, inhale… hold… and exhale. Feel your body beginning to relax.

Now tighten the muscles in your forehead by raising your eyebrows as high as you can. Hold for about five seconds. Moreover, abruptly release feeling that tension fall away.

Pause for about 10 seconds.

Now smile widely, feeling your mouth and cheeks tense. Hold for about 5 seconds, and release, noticing the softness in your face. Now just breathe slowly for about 10 seconds, feeling your face relax more and more with each breath.

Next, tighten your eye muscles by squinting your eyelids tightly shut. Hold for about 5 seconds, and release.

Pause for about 10 seconds, breathing slow, relaxing breaths.

Now lift your shoulders up as if they could touch your ears. Hold for about 5 seconds, and quickly release, feeling their heaviness. Pause for about 10 seconds, feeling your arms getting heavy and warm as you continue to breathe slow, relaxing breaths.

Tense your upper back by pulling your shoulders back, trying to make your shoulder blades touch. Hold for about 5 seconds, and release.

Pause for about 10 seconds, breathing slow, relaxing breaths.

Tighten your chest by taking a deep breath in, hold for about 5 seconds, and exhale, blowing out all the tension.

Breath in…and out. In…and out.

Let go of all the stress In…and out.

Now, tightly, but without straining, clench your fists. Hold for about 5 seconds, and release.

Pause for about 10 seconds.

Now, flex your biceps. Feel that buildup of tension. You may even visualize that muscle tightening. Hold for about 5 seconds, and release, enjoying that feeling of limpness. Breathing slowly in…and out.

Now tighten your triceps by extending your arms out and locking your elbows. Hold for about 5 seconds, and release. Pause for about 10 seconds, imagining that all your stress and tension is leaving your body through your fingertips.

Now tighten the muscles in your abdomen by sucking your abdomen in. Hold for about 5 seconds, and release. Pause for about 10 seconds breathing slowly deep into your abdomen, noticing your belly button moving away from your body with each inhale.

Gently arch your lower back. Hold for about 5 seconds, relax. Pause for about 10 seconds.

Feel the limpness in your upper body letting go of the tension and stress, hold for about 5 seconds, and relax. Your arms are heavy and warm… the tension is leaving your body through your fingertips.

Tighten your buttocks. Hold for about 5 seconds…, release, imagine your hips falling loose. Pause for about 10 seconds, breathing slow, relaxing breaths.

Tighten your thighs by pressing your knees together. Hold for about 5 seconds…and release.

Pause for about 10 seconds.

Now flex your feet, pulling your toes toward you and feeling the tension in your calves. Hold for about 5 seconds, and relax, feel the weight of your legs sinking down. Pause for about 10 seconds.

Curl your toes and tense your feet. Hold for about 5 seconds, release. Pause for about 10 seconds.

Now imagine a wave of relaxation slowly spreading through your body, beginning at your head and going all the way down to your feet.

Breathe in…and out…in…out….in…out.

Patient Education and Self-Management

DAVID A. WILLIAMS, SILVIE COOPER

The 2011 report from the United States Institute of Medicine concluded that pain care should be tailored to each person's experience and that *self-management* should be promoted as a central strategy to improve care.[1] The importance of self-management was again emphasized in the National Pain Strategy (NPS),[2] a blueprint for delivering optimal pain care, and in the Centers for Disease Control Guidelines for Prescribing Opioids for Chronic Pain,[3] the Healthy People 2020 report,[4] and within the Federal Pain Research Strategy.[5] The use of self-management for chronic pain management is also recommended in several clinical practice guidelines.[6–8] Despite these broad recommendations, self-management for pain is still not routinely implemented in clinical practice. This chapter reviews the current status of pain self-management in two sections. The first section defines pain self-management, identifies its components, and provides evidence of its efficacy. The second section addresses the use of self-management in the context of primary care and describes considerations for implementation, including face-to-face and digital options, as well as guided and unguided formats. The chapter concludes with future considerations for more broad scale implementation of pain self-management into routine clinical pain management pathways.

Pain Self-Management: Definition and Components

Definition

Pain self-management (i.e. self-care) can be highly beneficial but suffers from a bad reputation. Patients and clinicians alike often misinterpret the term "self-management" to reinforce perceptions that (1) the pain being experienced is not real and therefore "real" pain treatment (e.g. medications, surgery) will not be offered, (2) the clinician is abandoning the patient to deal with the pain on his/her own, or (3) the clinician is withholding "real" pain treatment out of fear of addiction and potential liability. Factually, none of these scenarios reflect the accurate use of or the clinical potential of pain self-management. A definition may prove helpful:

> *"Self-management refers to the individual's ability to manage the symptoms, treatment, physical and psychosocial consequences and [lifestyle] changes inherent in living with a chronic condition. Efficacious self-management encompasses the ability to monitor one's condition and to effect[sic] the cognitive, behavioral and emotional responses necessary to maintain a satisfactory quality of life. Thus, a dynamic and continuous process of self-regulation is established."*[9]

Self-management refers to all the things that a person can do on his/her own to address pain beyond visits to a health professional (which may be frequent or not at all). It does not replace traditional medical care but supplements current practices and bridges the gap between healthcare visits. One might think of pain self-management in the same way as one thinks about self-management for diabetes (e.g. lifestyle changes, dietary changes, monitoring glucose). For diabetes care, these behavioral changes do not replace medical management; they facilitate greater functioning and quality of life as an integral part of health care for a chronic condition.

Components of Pain Self-Management

Pain self-management programs (SMPs) share several key components. The most commonly featured components are[10,11] (1) functions of the patient-clinician relationship (e.g. shared decision making, patient education, goal setting, and action planning), (2) building self-efficacy (e.g. skill building, problem solving, and personalized tailoring), (3) self-monitoring (e.g. symptom monitoring and behavioral monitoring) and (4) social support (e.g. relationship maintenance and cultural considerations). Each component will be briefly described (Table 62.1).

TABLE 62.1 Components of Pain Self-Management Programs

Functions of the Patient-Clinician Relationship	Pain Education Shared Decision Making Goal Setting Action Planning
Self-Efficacy Building	Skill Building Problem Solving Personalized Tailoring
Monitoring	Symptoms Behaviors
Social Support	Maintenance Cultural

The Patient-Clinician Relationship

It may seem strange to include the clinician in a description of "self-management." It may also seem strange to use the term "patient" given that "self-management" implies that the "patient" is managing pain on his/her own and, therefore, not in a traditional "patient" role. As will be discussed, "self-management" can occur with just the efforts of the individual or can be "supported self-management" when it occurs in the context of professionally directed care.[12]

With the advent of sophisticated medical technologies and the increasing bureaucratization of medical care, communication between practitioners and patients has become increasingly hierarchical, administratively efficient, and impersonal. While such efficiencies can support the practice as a business, it tends to be woefully inadequate for addressing the needs of people with chronic pain.[13] A common complaint of both patients and clinicians is the lack of office time to address all the associated pain issues adequately.

Patients and their clinicians often bring two very different perspectives to the therapeutic relationship. Clinicians can offer a deep understanding of how pain develops, how best to treat it, and how and when to address concomitant comorbidities. In contrast, patients bring first-hand knowledge of what it is like to have the condition and how it affects daily life. Patients also know what seems to make sense to them and what they are willing to try. Integrating self-care into chronic pain care offers both the clinician and the patient a role to play if it is to be successful. Self-care is not simply shifting responsibility for pain treatment onto the patient. Instead, it capitalizes on a richer knowledge of the patient's circumstances that can influence pain and offers the benefits inherent in a clinician-patient dyad where treatment objectives are mutually identified.[14] It also acknowledges the chronicity of the pain where curative efforts need to be redirected toward promoting the wellbeing of the individual through continuous care and iterative adjustment to self-management strategies.[15] It is well-documented that patient-centered care that allows patients to take an active role in their care leads to better patient experiences and outcomes in the long term.[16,17]

The foundation of a good patient-clinician dyad is mutual respect and trust. By definition, chronic pain will be long term, and the dyad will need to work together to build a productive relationship over a lifetime, which will involve overcoming challenges and setbacks and the making of compromises when medical evidence and feasibility/desires conflict. Mutual respect and trust can facilitate *shared decision making,* which is needed for navigating the uncharted waters of the individuals' journey with chronic pain. The dyad is also supported by a shared knowledge of the mechanisms of chronic pain, a rationale for trying various treatments, and awareness of potential adverse responses. *Goals setting* and *action planning* within the dyad bolster the decision making process by making it objective and measurable. Without goals and action plans, it would be impossible to know whether the intended progress was being made or when additional fine-tuning was needed. Each dyadic function will be discussed further.

Shared decision making. The importance of therapeutic rapport is well-studied as a foundational element in behavioral change, adherence, and improved outcomes.[18] The traditional biomedical model emphasizes the clinician's role as a knowledgeable authority dictating the course of treatment to exact a cure for the presenting problem. The biomedical model can work well when a cure is likely, but it can be frustrating for both parties when cures are not the norm—such as with chronic pain.[19] In a patient-centric model, the clinician can still serve as a knowledgeable partner but more in the spirit of providing options, pros and cons of those options, and offering encouragement to the patient to identify what will work best at a particular point. Placing the clinician in this role better matches the evidence, which largely supports approaches requiring patient cooperation and involvement.[13,20] Unfortunately, most patients in primary care practices do not feel like an equal partner with decision making about their pain care.[21] Thus there is still work to translate the concept of "patient-centric care" into actual pain management practice.[22]

Pain neuroscience education. For the patient-clinician relationship to work well, both parties must share a common framework for understanding pain (i.e. pain, pain mechanisms, how those mechanisms are best treated, and why). Pain neuroscience, translated for a lay audience, offers the patient-clinician dyad a common language for discussing pain, a rationale for both pharmacologic and non-pharmacologic treatment options, and a foundation for generating personalized hypotheses about what would be effective. One study of online videos for pain neuroscience education suggested that pain neuroscience videos should contain seven key topics: [23] (1) the multiple sources that contribute to the pain experience, (2) the bioplastic nature of our nervous system and pain, (3) pain not being an accurate index of tissue status, (4) pain education as a form of treatment, (5) pain being created in and distributed from the brain, (6) pain's protective role, and (7) pathologic pain that can become overprotective and sensitized. Interestingly, most online videos claiming to provide pain education did not address any of the above topics, with only one addressing all topics (i.e. "Tame the Beast: It's Time to Rethink Persistent Pain"). The most commonly included topics were pain being created in and distributed from the brain and pain's protective role. The least frequently covered topics were bioplasticity and the overprotective/sensitization pathology of pain. Given the wide variance in quality of online educational materials, sharing educational resources between the dyad members can help ensure quality, create a shared understanding of pain, and helps reinforce the relationship between the two parties.

Goal setting. Goal setting might be considered the strategic part of the patient-clinician relationship.[24] Here, short and long term outcomes can be assessed and identified. Goal setting provides an opportunity to obtain three valuable tools for pain management: (1) a means of identifying relevant outcomes (e.g. personal goal attainment), (2) a means around which treatment can be tailored, and (3) a means of predicting the success of other treatments (e.g. a goal for increased step counts may predict improvements in pain interference).[25] Setting goals in the context of pain management adds structure to the management process and creates opportunities to evaluate progress. Goal setting refers to the choosing of goals and identifying the criteria by which a goal is evaluated. For example, if a patient sets a goal for pain reduction, it is important to identify how much pain reduction would constitute the achievement of that goal (e.g. complete remission?, 30%?). Setting goals that are reasonable and just slightly difficult to reach usually works best in pain management. Heapy et al. identified seven categories commonly associated with goal setting for pain self-management. These include goals for physical activity, functional status, wellness, recreational activities, house/yard work, socializing, and work/school activities.[26] Again, while an individual can set goals, including goal setting as part of the patient-clinician relationship offers an opportunity for the goal to be acknowledged publicly and allows the clinician to reinforce goal achievement.

Action planning. Whereas goal setting was the strategic component of pain self-management, action planning is the tactical component. By working on an action plan together, the dyad can identify specific behaviors that need to occur to turn goals into actions. Once actions are agreed upon, the patient then needs to act on the plan. This is known as "goal striving."[27] Depending upon the outcome of the actions, the clinician can then reinforce or assist in developing alternative plans. The clinician's involvement in action planning helps keep the clinician in touch with what the patient is attempting to accomplish and can serve as a reminder to ask about the entire treatment plan (i.e. both medications and self-management) on the next visit. Evidence suggests that when clinicians are active partners in encouraging and planning for self-management, patients learn more readily, manage symptoms and side effects better, and show better adherence to the overall treatment plan.[28]

Self-Efficacy Building. An objective of any self-management program is to have the individual with pain feel self-efficacious in performing the skills used to manage and control pain. The patient needs to go beyond simply learning about the skills to experiencing success through using the skills. This paves the way to self-efficacy, so he/she feels capable of managing pain in various situations in the future. Historically self-management skills have been taught in formal therapy supported by a therapist or coach. Once mastered, the individual would graduate therapy to become independent self-managers.

Nine non-pharmacologic therapies for chronic pain have sufficient evidence for broad implementation.[29] These can be grouped into three categories and include:

- psychologically based therapies (i.e. Cognitive-Behavior Therapy (CBT), Acceptance and Commitment Therapy (ACT), Mindfulness-based Stress Reduction (MBSR)),
- exercise and movement therapies (i.e. Exercise, Yoga, Tai Chi),
- manual therapies (i.e. manipulation, acupuncture, massage).

These therapies include skills that promote self-management to gain personal control over pain and symptoms, psychological flexibility to allow improved functioning in the context of pain, and empowerment to feel efficacious in managing pain between clinician visits or medication dosages.

The individual components of each of the above therapeutic options tend to overlap with one another and represent a set of skills to be learned, practiced, and mastered in support of better pain management more generally. Mastery of these *skills* can directly improve pain and functional status and provide an experientially based foundation for self-efficacy. Given that real-world applications of these skills can present challenges, training in *problem solving techniques* and methods of *personalizing* the skills to the unique circumstances of the individual can also help build self-efficacy to ensure long term success with pain self-management.

Skill building. There are many skills embedded in traditional therapies that can be learned and used on one's own. A sampling of some of these skills includes the following and can be grouped into those that are primarily intrapersonal in nature and more overtly observable and associated with one's lifestyle.

Intrapersonal Skills

- *Relaxation* – there are many methods of achieving mind and body relaxation (e.g. progressive muscle relaxation, visual imagery, meditation, biofeedback). All methods can work but require regular practice to establish a relaxation rhythm recognized by the body as a cue to relax.[30]
- *Sleep* – one night of poor sleep can interfere with coordination, mood, and mental agility for the next three days.[31] Behavioral sleep strategies and sleep hygiene skills can help individuals with pain get a better night's sleep despite the presence of pain.[32]
- *Mood management* – depression, anxiety, and anger are the big three emotions that can maintain pain and make it worse. These emotions need not be present at psychiatric levels to impact pain. Methods such as mindfulness meditation[33] and pleasant activity scheduling[34] can alter the background emotional milieu against which pain gets processed in the brain.
- *Stress management* – life can be stressful even without pain. When present, stress can make pain worse. Again, approaches such as pleasant activity scheduling[34] (e.g. engagement in daily brief, simple, pleasant activities such as going for a walk or spending time on a hobby) can help to reduce stress along with MBSR techniques.[35]
- *Reframing and cognitive restructuring* – when something is newly experienced, the mind creates a summary of that experience that is then recalled when interpreting the next encounter with a similar event. Using prior information in this manner facilitates faster mental processing and cognitive efficiency. While such efficiency can be helpful for day-to-day activities, this automatic thinking is problematic when it comes to chronic pain. Automatic catastrophic thinking, closed mindedness to potentially beneficial therapies, and low self-esteem are examples of unhelpful automatic thinking tied to pain. With chronic pain, automatic thinking can be challenged and altered to allow new possibilities for managing pain to emerge along with improved emotional responses to the reframed thinking.[36]
- *Resilience* – resilience refers to the personal strengths an individual can bring to bear on efforts to buffer the impact of pain. Such skills can be inherent or learned and include savoring each moment, finding gratitude, remembering positive events, conducting random acts of kindness, and learning one's signature strengths.[37]

Lifestyle Management

- *Exercise* – exercise benefits individuals whether or not they have pain and can include formal workouts, walking, water aerobics, or leveraging ongoing lifestyle activities.[38,39]
- *Pacing/graded activation* – activities can be paced either by time or broken into smaller tasks in a manner that reduces pain flare-ups, saves energy, and increases functioning and task completion.[40,41]
- *Diet and nutrition* – a healthy diet provides a solid foundation for wellness in general. Reduced weight can relieve burdened joints and make exercise more feasible. There is also some evidence that non-inflammatory diets, gluten-free, and hypocaloric diets can each have pain-reducing benefits.[42,43]
- *Acupressure* – acupuncture is an efficacious intervention for pain but requires a professional acupuncturist and, therefore, would not be considered a form of self-care. A personal version of acupuncture, acupressure, uses a similar philosophy but replaces the needles with the application of pressure (e.g. using the thumb, finger, or a blunt object). Evidence is emerging about the efficacy of this alternative approach for chronic pain self-management.[44,45]
- *Spirituality* – patient advocacy groups often mention the importance of spirituality in dealing with pain. Spirituality does not refer to any one theory or philosophy but references the importance of having a connection to something bigger than oneself and incorporates the formation of personal values and the search for meaning in life.

Problem solving. Individuals with pain face more challenges than people who are pain-free. Even minor tasks like carrying groceries up the stairs or driving to a relative's house for a visit can pose enormous feasibility challenges when in pain. There are structured problem solving processes that can be taught by a coach or adopted on one's own. Structured problem solving involves breaking a large problem down into smaller pieces to be addressed.[46,47] Structured problem solving comprises six steps. Step one involves identifying the problem. If there is more than one problem, then it needs to be broken into smaller pieces. Step two involves gathering information about the problem so it can be understood. Step three involves brainstorming a solution. For this step, all options can be on the table. Step four involves evaluating each of the brainstormed solutions in terms of whether the solution is (a) realistic and (b) favorable. Step five is the development of a work plan for addressing the problem. The work plan should include actionable items and the identification of potential barriers and means of addressing those barriers. Finally, Step six involves evaluating how the plan worked. If successful, congratulations. If unsuccessful, restart the process by revisiting Step one with a revised identification of the problem.

A common obstacle shared by many individuals with pain is how to incorporate the various pain management skills (reviewed above) into one's lifestyle. Many skills require consistent practice, the establishment of habit or a bodily rhythm, and the need to be integrated into an already crowded lifestyle. Knowing the skills but feeling blocked to implement them can have a deleterious effect on self-efficacy and ultimately the abandonment of self-management. While problem solving is not a pain management skill per se, it can help facilitate the mastery of the other pain management skills.

Tailoring and personalization. Similar to problem solving, tailoring and personalization involves molding generic pain management skills around the life of the individual with pain. Personalization can take many forms, such as selecting the elements of a skill found to be useful (e.g. using savoring resilience skills but not signature strengths). Skills can also be personalized in their timing/scheduling (e.g. using relaxation skills once a day for 20 min), modifying the skill to one's personal taste (e.g. using one's own music for relaxation rather than a scripted tape), or receiving personalized feedback on progress or barriers. Studies on the value of self-management personalization support the approach as a means of enhancing adherence and reinforcing one's self-efficacy for managing pain.[48]

Self-Monitoring

Monitoring how symptoms change over time and how specific behavioral changes can be more or less beneficial for a given symptom allows the individual to know what is working or what treatments can be stopped over the long term. Two types of self-monitoring will be described, monitoring for symptoms and monitoring behaviors.

Symptom monitoring. People have difficulty remembering how pain intensity fluctuates. If asked about pain intensity for the past week, people most likely recall the peak pain experienced for the week or report the pain intensity that occurred in the last several hours.[49–51] Being unable to objectively recount how pain was experienced over time makes treatment planning more difficult and makes it difficult to evaluate when and what treatments are working and which are not.

The most common symptoms monitored in the context of pain include pain intensity, the location of pain (using a body map), sleep problems, anxiety/depression, cognitive difficulties (e.g. memory and concentration), and fatigue. These symptoms represent a symptom cluster that commonly accompanies pain and other chronic diseases. This symptom cluster remembered by the acronym s.p.a.c.e. (sleep, pain, affect, cognition, energy) has been identified in both human and animal models as an index of "unwellness."[52] Monitoring s.p.a.c.e. over time can provide an ongoing account of how these symptoms interact, worsen, or improve compared to each other or with a given treatment.

Behavioral monitoring. Many of the self-management strategies require behavioral changes to be made. Thus monitoring or tracking the use of individual self-management skills can help with adherence and habit formation. For example, if an individual wishes to learn relaxation skills, it can be helpful to monitor time spent practicing relaxation daily. The same could be helpful if the individuals were trying to increase exercise time or monitor dietary intake. Behavioral monitoring helps establish routines but can also be used in combination with symptom monitoring to identify which behavioral changes are beneficial in altering the s.p.a.c.e symptom cluster.

Social Support

Good social support has been shown to buffer the impact of chronic pain on disability and reduce the amount of therapy needed.[53] This does not mean that people with pain need hundreds of friends; rather, just a few close acquaintances can be fine.[54] Although defined as a personal experience, people often need to share the experience of pain with others (i.e. to tell others about their journey with pain). Pain is often invisible, and therefore the only way to let others know what is being experienced is to verbally share it with others. Here we discuss two aspects of social support: relationship maintenance and cultural considerations.

Relationship maintenance. Pain is not experienced in a vacuum but rather in the context of relationships with others, such as family, friends, workplace employers/colleagues, and healthcare clinicians. Each of these relationships offers an opportunity for support both in physical terms (e.g. helping with tasks, offering physical assistance) or psychological (e.g. displaying empathy, offering encouragement, simply listening). Not all people know how to help someone with pain, nor do patients always know how best to ask for help. Communicating effectively with each social group is best done using assertive communication skills where each party gets heard, each has an opportunity to set priorities and limits, and compromise is always an option.[55]

Cultural considerations. Self-management must be considered through the lens of one's culture. Some components of self-management will work well in some cultures but not in others. For example, using assertive communication, taking time to meditate, engaging in water aerobics, or using acupressure could be viewed negatively or banned for some people in some cultures. Clinicians recommending self-management to their patients should be aware of such considerations and work with the patient (see "The Patient-Clinician Relationship" above) to set goals and develop action plans consistent with patients' culture. Self-management that includes a consideration of culture can positively affect outcomes and adherence.[56]

Evidence Supporting Pain SMPs

The United States Veterans' Administration has placed education and pain self-management as Step 1 of their "Stepped Care Model for Pain Management."[57] In this model, self-management functions as both a preventive strategy for general wellness and as a first line approach for persistent pain. If insufficient relief results, then progressively more intensive approaches can be tried in primary care (i.e. Step 2 - medications, psychological therapies). Step 3 involves secondary consultation (e.g. rehabilitative medicine, multi-disciplinary pain medicine teams, mental health/substance use interventions), and finally, Step 4, tertiary pain centers, includes interventional pain medicine or multi-disciplinary pain programs. A similar model was developed in the United Kingdom by the British Pain Society known as the Pain Care Pathway, which begins with diagnostics and treatment planning, including education and self-management before progressing to more intensive or invasive options.[58,59]

Finding the Relevant Comparator

Before one can decide whether pain SMPs are efficacious, it is important to ask the question, "efficacious for what?" Is the objective of pain SMPs to cure pain? No. Is the objective of pain SMPs to have superior outcomes to or replace interventional medicine? No. Is the objective to outperform or replace traditional therapies, such as medications, physical therapy, or CBT? Again, no. To understand the proper comparator for pain self-management, remember the intended purpose of self-management within the overall continuum of pain treatment options. If following a stepped care model (as mentioned above), the real-world comparator for pain self-management would be nothing given it is supposed to be offered prior to other treatments requiring therapists or treatments that do not actively involve patients. Perhaps the most informative clinical studies of pain self-management would be those that evaluate the optimal placement of self-management in the continuum of care and the characteristics of individuals most likely to benefit from that placement.

However, most of the evidence base supporting self-management consists of "horse races" between self-management and treatment as usual (TAU) or active interventions. All of these are comparators that occur at Step 2 or beyond in the model. For example, TAU often involves a wide array of medications and other active interventions from multimodal professional care (e.g. PT, CBT). Thus the published studies on self-management programs may actually underestimate the true effects given the comparators included treatments further up the stepped care hierarchy and likely selected patients with more refractory pain than would be expected to have benefited from the first step of a real-world stepped care model.

Review of the Evidence

A systematic review and meta-analysis of SMPs for low back pain examined 13 randomized control trials (RCTs).[60] In this study, pain SMPs were found to convey moderate effects for reducing pain intensity over one year. Similarly, moderate effects were shown for disability up to three months and then smaller effects at six months to one year. Of note, none of the 13 RCTs (combined n = 2188) reported any serious adverse events being associated with SMPs, suggesting its relative safety compared with other forms of pain treatment.

To benefit from self-management, participants need to actually participate and use the skills. In one study conducted in the UK, the retention rate for SMP was quite favorable, with the uptake of the program being 71% (n = 376). Following the seven week course, they still reported an 82% completion rate. Six months after precourse assessment, participants reported significantly improved activation, health status, depression and anxiety, decreased pain intensity and interference, and improved self-management skills.[61] A unique feature of this SMP that likely contributed to the retention and positive outcomes was that it was co-led by a physician and patient dyad.

Despite the study above, concerns over dropouts may be more the norm, especially in rural primary care populations. In one such study using bivariate analyses, early dropout was associated with being male, being younger, having a history of substance abuse, having a trauma history, receiving unemployment/disability benefits, being of low literacy, having higher catastrophizing scores, having higher daily opioid use, and holding a narrow biomedical understanding of pain. Logistic regression analyses revealed a reduced set of concerns, with the strongest predictors of dropout being a history of substance abuse, trauma, catastrophizing, and holding a biomedical understanding of pain.[62]

Overall, there appears to be support for the inclusion of self-management as an initial intervention for most forms of chronic pain. While it will not be sufficient for all individuals, it does appear to provide a good foundation for gaining some relief and improved function as an adjunct to traditional care. There also appears to be very little difference in effectiveness between the different forms of self-management, i.e. whether it is professionally delivered versus lay led, or whether it is individually administered or in group settings.[63]

Pain Self-Management in the Context of Primary Care

Chronic pain is the most common reason for seeking health care, and most cases are initially seen in a primary care context.[64] Unfortunately, these clinicians may not be the best equipped to manage such a complex condition. Eighty percent of American medical schools have no formal pain education in their curriculum, and those that do, report five or fewer hours of mostly basic science education related to pain.[65] Many residency programs similarly miss the mark by continuing to emphasize an outdated biomedical model of care focused on interventions for "curing" pain rather than multi-disciplinary management.[13] It is well known that the traditional model often fails to provide adequate relief for most, has a high rate of adverse events, and in the case of the more invasive approaches, lacks sufficient evidence to support their use.[66–68]

Self-management can offer primary care clinicians a means by which to diminish the pain experience and increase function with little cost and few adverse events. Unfortunately, the uptake of self-management in primary care practices has been slow and may require a cultural shift where the acceptance of pain as a biopsychosocial and perceptual experience requiring individualized and targeted care [69] is adopted by a host of stakeholders including patients, clinicians, payors, and healthcare systems.[70,71]

Reengineering the Point-of-Care

Better integration of SMPs into primary care may require the point-of-care to be slightly reconfigured.[72] From the clinician's perspective, high-quality primary care pain management programs need these six elements.[28]

Local linkages between the Primary Care Clinician (PCP) and community self-management resources (e.g. exercise classes, pools, yoga).
The PCP requires healthcare organizations that place value on multi-disciplinary pain care.
The PCP needs to truly place value on self-management and appreciate the benefits of patient empowerment in successful pain care, both in terms of patient outcomes and economic benefit.
The PCP needs a structure for delivering self-management that includes roles and tasks of team members for educating patients, assessing needs, setting goals, and developing action plans.
The PCP needs administrative support for incorporating evidenced pain care into daily practice.
The PCP needs clinical informatics systems that remind clinicians of self-management resources and skills being used by patients and their individual outcomes.
A second qualitative study captured the patients' perceptions and those of the clinician about barriers associated with patients' ability to engage with pain self-management. These barriers included:[73]
Patients felt that clinicians waited too long to recommend or offer advice on self-management strategies.
Patients felt that clinicians were rushed and failed to listen carefully to their concerns.
Patients felt that clinicians offered only generic self-management information, if any at all.
Patients felt that they were on their own to learn about self-management and felt unsupported in this aspect of pain care.
Clinicians felt conflicted about offering self-management when they still believed in the biomedical model and the possibility of "curing" chronic pain.
Clinicians felt conflicted about offering self-management advice when they were not familiar with the quality of the information.
Clinicians found it challenging to discuss the biopsychosocial model of care and felt that many patients would not be ready or willing to participate.
Both clinicians and patients agreed there was an over-emphasis on medications for pain and a need for greater acceptance of alternatives.
Both clinicians and patients agreed that for self-management to work, there also needed to be greater continuity of care where self-management was genuinely incorporated into the flow of primary care practice.

From what has been discussed, many of these barriers can be overcome by properly placing self-management at the front-end of a practice's approach to pain care. There is also an apparent mismatch between clinicians' comfort level in recommending self-management and the patient's desire for such approaches to be used between office visits and a primary care practice.

Explaining Self-management to Patients

Another ongoing challenge for primary care clinicians has been broaching pain self-management with patients. There is fear that the concept of self-management will be rejected, the recommendation will damage the relationship, or PCPs may not feel comfortable explaining why self-management is real pain treatment.[74] Over the past three years, faculty within the Chronic Pain and Fatigue Research Center at the University of Michigan have participated in a statewide initiative to educate primary care physicians about optimal pain management, including the use of self-management. The following is an example of how the rationale for self-management can be presented to patients.[75]

How to ERASE SPACE

When pain is chronic, there is rarely a problem in a specific set of damaged tissues where the pain seems to be felt (e.g. in the leg or back). Instead, chronic pain is considered to result from how pain is "processed" within the brain.[76] Unlike acute pain, chronic pain is often accompanied by the s.p.a.c.e. symptom cluster (described above), which includes problems with sleep, pain, affect, cognition, and energy. Pain processing involves mechanisms that also contribute to these other symptoms; thus pain and these other symptoms tend to show up together. Neurobiologically, pain and these other symptoms share the same neurotransmitter system in the brain (e.g. glutamate, GABA, norepinephrine, serotonin) and overlapping cortical representation (e.g. amygdala, insula, prefrontal cortex, hippocampus, anterior cingulate).[77] Given this shared neurophysiology, patients with chronic pain tend to present at the clinic with a complex list of problems. However, these problems tend to all come from the same source, which accounts for this complexity.[78] Shared neurophysiology offers opportunities for better pain treatment. While our pain drugs may offer only modest relief for pain, we do have relatively good treatments for sleep, mood, and fatigue. Targeting these other symptoms can have indirect benefits on pain (e.g. addressing poor sleep can also be beneficial in reducing pain).[52]

Many of the self-management skills used for pain (described above) are generic illness management strategies and can thus benefit each symptom within the s.p.a.c.e. symptom cluster. For example, exercise has demonstrated benefits not only for pain but also sleep,[79] mood,[80] fatigue,[81] and cognitive functioning.[82] The various self-management approaches can be grouped into categories addressing emotions (e.g. pleasant activity scheduling, stress management), reflections (e.g. reframing, relaxation), actions (e.g. exercise, pacing), sleep (e.g. behavioral and sleep hygiene), and environmental factors (e.g. social support, communication). The self-management categories can be remembered by the acronym ERASE. Thus when clinicians are addressing the rationale for using self-management for pain, the goal for patients is to use self-management approaches to ERASE the SPACE symptom cluster (Table 62.2).

Reimbursement

Perhaps the biggest barrier to integrating self-management into routine pain care is the issue of reimbursement. Historically, resistance to self-care was generated from the misconception that psychosocial constructs were of lesser importance than "real biologic" causes of pain and might connote patient fabrication of concerns. Self-management was also perceived as inefficient given the need for clinician involvement in shared decision making, goal setting, action planning, and monitoring (see above). To proponents of the biomedical model, where psychosocial factors represent non-essential add-ons, such opposition is understandable. However, the lack of benefit often associated with the biomedical model supports a need to reconsider how best to utilize clinicians' time. Neuroscience supports the notion that chronic pain is a perceptual problem rather than tangible damage of peripheral tissues. Clinicians are realizing the need to treat the perception of pain

TABLE 62.2 ERASE SPACE

Self-Management Categories	CHRONIC PAIN SYMPTOM CLUSTER (s.p.a.c.e.)				
	Sleep Problems	Pain Intensity and Distribution	Affect: Depression Anxiety	Cognition: Memory Concentration	Energy: Fatigue
Emotions	Examples: Pleasant activity scheduling, stress management, journaling				
Reflections	Examples: Relaxation, mindfulness, reframing				
Actions	Examples: Exercise, pacing, diet/nutrition, acupressure				
Sleep	Examples: Behavioral sleep strategies, sleep hygiene				
Environment	Examples: Social support, ergonomics, assertive communication skills				

and how it is processed rather than focusing on trying to fix broken body parts that might be associated with pain.

Recently, payors discovered that more diagnostics and more procedures were not producing better outcomes, and as a result, priorities are beginning to shift away from curing chronic pain to its management.[13,14] When patients are encouraged to understand self-management in the context of ongoing care, clinicians work in a synchronized collaborative manner to tailor treatment to the individual patient, and reliance on specialists is reduced, and outcomes improve.[83] Focusing on self-management extends clinicians' reach rather than simply usurping precious clinical encounter time. In doing so, patients are empowered to productively communicate with clinicians about treatment preferences and utilization of self-management strategies and assess the benefits of these strategies before progressing to other more costly or invasive treatments.[16,84–86] Recently, the United States Department of Health and Human Services report on Pain Management Best Practices included recommendations for broader reimbursement for non-pharmacologic therapies, including self-management approaches.[87]

Even when a practice completely adopts the rationale for self-management, finding the time and staff to properly administer SMPs in the office environment remains problematic. The education, goal setting, and action planning activities all take time that does not fit neatly into the 15 min office visit. Utilizing other team members (e.g. nurses, physical therapists, occupational therapists) to deliver face-to-face coaching can be effective,[88–94] but still may not be a feasible option in many practices. Digital pain self-management is gaining popularity and can help primary care practices expand their reach between office visits. These digital programs (also called e-Health or mHealth) can involve interactive voice responses, telephonic coaching, website-based self-management, and smartphone app-based approaches.

Digital SMPs

Digital SMPs are usually offered in either guided (with a therapist/coach) or unguided (self-directed) formats. Unguided formats can either be static content only sites or semi-automated ones assisted by logic-driven personalized messaging.

Only a handful of studies have been able to directly compare the benefits of guided versus unguided approaches. However, a meta-analytic study suggested that the guided interventions work best when a human coach can help with motivation, clarification of difficult concepts, personalization, and adherence.[95] At least one digital intervention, using a version of ACT (i.e. ACTonPain), explored this question in a three arm RCT (i.e. guided vs. un-guided, vs. usual care). The guided version revealed the best outcomes overall but at a significantly greater cost. A health economics analysis of this study suggested that depending upon a society's willingness to pay, the unguided version may be preferable, given it still produced significantly better outcomes than the usual care group but at much reduced cost.[96]

Digital Pain Self-Management: Pros and Cons

With digital self-management for pain, it can be a bit like the "Wild West." There are over 900 digital products targeting pain management,[10] with the majority of those being developed without the guidance of a pain expert.[97] There have been some attempts to evaluate the health information quality of websites using either the JAMA score criteria or the HONcode system. One study using these methods to evaluate websites about fibromyalgia found that overall, the quality of health information on most websites was rated as poor and difficult to understand.[98] Not-for-profit organizations tended to have the best information. An additional concern about most online self-management resources is that the majority of sites have been made available to the public without ever being tested for efficacy.[10,97,99]

Given the variability in quality, it is not surprising that many clinicians have been hesitant to refer their patients to digital self-management resources. One study found that only half of the healthcare clinicians surveyed would recommend online self-management to their pain patients.[100] The reasons for not using this resource included a lack of confidence in self-management generally and lack of knowledge about the quality and availability of existing resources.

From the patient perspective, ideal digital SMPs should offer information and knowledge about pain and its treatment, methods for obtaining balance between managing pain and normal life activities, and a means of communicating and engaging with others and receiving social support.[101] digital self-management resources are far from this ideal. A review of current smartphone apps for pain management found that most included only 4/14 potential techniques with some of the more comprehensive programs offering 8/14.[10] The most frequently offered technique was meditation and guided relaxation, followed by the ability to monitor symptoms and self-tailoring strategies. Only a few apps offered features supporting social support or clinician communication, and none offered the ability to tailor for cultural needs. Digital

self-management apps offer some but not most of the components typically found in traditional face-to-face versions of SMPs. Clinicians may want to augment their practices with these resources but will need to carefully vet the scope and quality of the digital resources they are offering their patients.

Within the cornucopia of digital products, there are a few that have been developed by experts and evaluated in RCTs. These studies generally support digital benefits being similar to those seen with traditional in-person self-management. A systematic review of unguided digital SMPs demonstrated significant short- and long term improvements in pain intensity and depression and short term improvements on catastrophizing and self-efficacy.[102] The review concluded with the recommendation to increase the availability of efficacious digital self-management options for routine care.

Future Directions

Self-management appears to be best positioned at the front-end of pain care in either face-to-face or digital formats and as either guided or unguided experiences. Cost savings appear possible when delivered in an unguided digital format without compromise to outcomes for many individuals. Self-management, however, is best used in the context of an overall model of care that can be scaled up in intensity or back depending upon need. Self-management is not likely to be sufficient for most as monotherapy but can be used as an extension of care between office visits.

Perhaps one of the trickiest problems with self-management remains the issue of engagement. Engagement can be conceptualized as coming in two forms: simple engagement versus "effective engagement."[103] If using a self-management website, an individual might log in just to browse. This would be simple engagement (i.e. the individual is present). However, they may not be actively engaged with the self-management skills offered on the site. The person would need to spend time on the site, learning and applying the skills for self-management. This distinction between simple and effective engagement might account for the often unintuitive association between website usage and outcomes [104,105] (e.g. little engagement can be associated with good outcomes and high engagement with poor outcomes). Outcomes are not likely to change simply by having sustained engagement without effective involvement. In order to enhance effective engagement, future digital SMPs will need to utilize a "person-based" approach to development that considers users' knowledge, skills, behaviors, motivation, culture, and context for using the program. There are opportunity costs of using the digital product rather than engaging in other activities. The costs and benefits need to favor the digital product if effective engagement is to occur. Effective engagement is also more likely if the content is matched to the educational level or literacy of the participant. Tailored messaging that utilizes knowledge about the participant's context or situation can enhance motivation for effective engagement. Unguided self-management can be effective, but the effect sizes are smaller than when a coach is used. Coaches add an element of supportive accountability and the sense that the participant is not having to deal with pain completely on their own. Finally, effective engagement can be enhanced simply by having a trusted clinician recommend its use. While many digital resources are freely available, a recommendation from a trusted healthcare clinician is likely to increase engagement with the resource.[103]

As alternatives to opioids continue to be required and a desire to incorporate a more person-centric multi-faceted approach to pain management persists, self-management will remain an important element of care. Improved clinician and payor education could increase the perceived value of the approach. Improved reimbursement will similarly contribute to broader acceptance of the approach. Finally, investment in informatics infrastructures to support the delivery, tracking, and sustainability of self-management over time has been a key missing element that could facilitate more wide scale deployment and adoption of pain self-management.

Key Points

- Pain self-management is best placed at the initiation of a comprehensive pain management program.
- Self-management is what patients use to manage pain between office visits to healthcare clinicians and more traditional care.
- Self-management does not replace or compete with traditional forms of pain treatment.
- Self-management needs to be better incorporated into routine pain care.
- The traditional primary care practice may need to be redesigned to make optimal use of pain self-management by adding informatics for monitoring progress and staff who can support patients when needed.
- Digital resources can augment self-management, but the quality of sites and apps varies greatly and needs to be vetted.
- Guided /coached self-management is slightly more efficacious than unguided resources, but patients can still benefit from the latter at a lower cost.
- Clinicians need to ask patients about their use of self-management with the same enthusiasm as medications and other more traditional forms of pain care.

PART 6

Neural Block and Interventional Techniques

63

Neurolytic Agents, Neuraxial Neurolysis, and Neurolysis of Sympathetic Axis for Cancer Pain

HEATHER A. COLUMBANO, AMIT GULATI, ROBERT W. HURLEY

Neurolytic therapy, for the appropriate patient, may result in significant improvement of quality of life and possibly improved function. Few other interventional pain therapies have such extreme risk/benefit profiles requiring targeted patient selection and meticulous procedural technique. Evaluating neurolysis as a therapeutic option is usually reserved for end-stage therapy, primarily for patients with refractory cancer pain resulting from the possibility of severe side effects. For instance, neuraxial neurolysis can provide profound pain relief for patients with pain related to invasive tumors involving the pelvis, but this approach often also leads to loss of bowel or bladder function and may well also produce weakness in the lower extremities. It should also be emphasized that relief from neurolytic blocks is usually not complete, as most patients with cancer pain have multiple sources of their pain. Neuraxial neurolysis is an important treatment modality for patients *in extremis*. Neurolytic agents available in the United States for common use in the neuraxis include ethanol and phenol. The five criteria for neurolysis[1] are (1) the presence of severe pain, (2) the failure of less invasive techniques to relieve the pain, (3) the presence of well localized pain, (4) the relief of pain with diagnostic local anesthetic blocks, and (5) the absence of undesirable effects after diagnostic blocks (Box 63.1).

Neurolytic blocks can be peripheral, neuraxial, or visceral. Of the three, visceral blocks are most commonly performed. In the case of peripheral neurolytic nerve blocks, blocking mixed motor and sensory nerves can cause motor deficits leading to loss of functionality for the patient. In addition, peripheral neuritis and deafferentation pain are potential painful consequences, whereas the block itself is not predictably permanent.[1] Finally, the patient may also be dissatisfied with the subsequent numbness of the area and complain of symptoms of *anesthesia dolorosa*. Neuraxial neurolytic blocks, including intrathecal and epidural alcohol or phenol neurolytic blocks, are rarely used today because neuraxial analgesics including opioids, local anesthetics, and clonidine can effectively and safely be used to treat cancer pain. Where an intrathecal drug delivery system can provide widespread pain relief that can be adjusted to accommodate many scenarios, a successful neurolytic block may have to be repeated with changes in the pathologic condition, such as the presence of new metastatic lesions. In such cases, it is impractical to perform subsequent subarachnoid neurolytic injections because of their attendant risks, whereas an indwelling intrathecal (and occasionally epidural) drug delivery system will cover new areas of pain and continue to be useful. In contrast, neurolytic blocks have a less financial burden than implantation of intrathecal drug delivery systems.

• Box 63.1 Criteria for the Use of Neurolytic Blockade

- Pain is severe and unremitting
- Pain is unresponsive to medical management
- Pain is relieved with diagnostic blocks using local anesthetic
- No undesirable effects appear during local anesthetic blocks
- Pain is well localized
- Pain affects the patient's function
- Patient is not a candidate for neuraxial medication delivery systems
- Patient has failed neuraxial medication delivery
- The patient can perform informed consent or has appropriate advance directive

While neurolytic blocks are effective in treating visceral pain syndromes, there may be less efficacy or shorter duration of effect when treating somatic pain syndromes or lymphatic pain syndromes. Stretching, compressing, invading, or distending visceral structures can result in poorly localized, noxious visceral pain. Patients experiencing visceral pain often describe the pain as vague, deep, squeezing, crampy, or colicky. Other signs and symptoms include referred pain (e.g. shoulder pain that appears when the diaphragm is invaded by a tumor) and nausea and vomiting because of vagal irritation.

Visceral pain associated with cancer may be relieved by oral pharmacologic therapy, which classically includes combinations of nonsteroidal anti-inflammatory drugs (NSAIDs), opioids, and co-adjuvant therapy (i.e. anti-convulsants and tricylic antidepressants). NSAIDs have fallen out of favor with some clinicians for the treatment of chronic pain because they have been implicated in thrombotic events. Besides pharmacologic therapy, neurolytic blocks of the sympathetic axis are also effective in controlling visceral cancer pain and should be considered as important adjuncts to pharmacologic therapy for the relief of severe visceral pain. These blocks rarely eliminate cancer pain because patients frequently experience somatic and neuropathic pain. Therefore oral pharmacologic therapy must

be continued in the majority of patients with advanced stages of their disease. The goals of performing a neurolytic block of the sympathetic axis are to maximize the analgesic effects of opioid or nonopioid analgesics and reduce the dosage of these agents to alleviate side effects. This chapter reviews the technical approaches and pharmacologic agents used for neurolytic blocks, neuraxial neurolysis, and neurolysis of the sympathetic axis for cancer pain.

Neurolytic Agents (Table 63.1)

Alcohol

Ethyl alcohol (ethanol) is the classic neurolytic agent first reported by Dogliotti in 1931 for intrathecal injection.[2] Anhydrous ethanol is commercially available undiluted (approximately 100% concentration) but will absorb a small amount of water from the air upon exposure to the atmosphere. Although neurolytic blocks have been shown to require a concentration of 33% or greater to effect neurolysis,[3] the most common concentrations used are ≥80% when diluted with contrast medium or local anesthetic. The neurolytic action of alcohol is produced by the extraction of neural cholesterol, phospholipids, and cerebrosides, and the precipitation of mucopeptides.[4] These actions result in sclerosis of the nerve fibers and myelin sheath, leading to demyelination.[5] The basal lamina of the Schwann cell sheath remains intact, allowing for new Schwann cell growth, thereby providing the framework for subsequent nerve fiber growth. This framework encourages the regeneration of axons, but only if the cell bodies of these nerves are not completely destroyed.[6] The pathway of degeneration is nonselective and can be observed in peripheral nerves and spinal nerve roots following intrathecal injection. Areas of demyelination can be seen in posterior columns, Lissauer's tract, and the dorsal root, followed by Wallerian degeneration to the dorsal horn.[7] Intrathecal alcohol injection results in rapid uptake of alcohol and variable injury to the surface of the spinal cord.

Ethanol is quickly absorbed from the cerebrospinal fluid (CSF) so that only 10% of the initial dose remains in the CSF after 10 min and only 4% after 30 min.[8] The rapid spread from the injection site means larger volumes are required than for phenol, which in turn may result in local tissue damage.[9] In the case of celiac plexus blocks, alcohol is rapidly absorbed into the bloodstream. It has been shown that serum ethanol levels up to 54 mg/dL can occur after a celiac plexus block.[10] However, following the intrathecal administration of alcohol, it is unlikely there will be significant vascular uptake. Ethanol has a specific gravity of less than 0.8, and CSF has a specific gravity of slightly greater than one. Within the CSF, alcohol is hypobaric and will move against gravity, "floating" upward. Therefore positioning of the patient is an extremely important factor to consider when planning the procedure.

The use of ethanol as a neurolytic agent has been associated with a disulfiram-like effect, acetaldehyde syndrome. Case reports include patients taking moxalactam, a β-lactam antibiotic that inhibits aldehyde dehydrogenase, documented disulfiram-like effects, and another taking 1-hexyl carbamoyl-5-fluorouracil, an anticancer drug, experienced similar symptoms.[11] The patients experienced flushing, hypotension, tachycardia, and diaphoresis within 15 min of alcohol administration. The symptoms resolved 4–6 h later, and efforts were undertaken to stabilize hemodynamics. Both cases occurred after celiac plexus blocks. The pain practitioner needs to recognize medications that may cause disulfiram-like effects, such as chloramphenicol, β-lactams, metronidazole, tolbutamide, chlorpropamide, and disulfiram, after peripheral neurolytic blocks with alcohol.[12]

Perineural administration of ethanol is associated with burning dysesthesias in the distribution of the nerve. This sensation is often extremely unpleasant for the patient and can last from a few minutes to a few weeks. To alleviate this outcome, local anesthetic is administered prior to the use of ethyl alcohol. The use of this initial dose of local anesthetic can also provide diagnostic guidance on the correct location for the neurolytic that has enormous importance. The administration of ethanol for the purpose of neurolysis can have catastrophic consequences. It has been associated with both transient and permanent paraplegia in both celiac plexus and intrathecal blocks. It has been postulated that these effects are secondary to vasospasm of the spinal arteries by the direct action of alcohol or direct damage to the spinal motor nerves.[9]

TABLE 63.1 Characteristics of Chemical Neurolytic Agents

	Alcohol	Phenol
Physical properties	Low water solubility	Absorbs water on air exposure
Stability at room temperature	Unstable	Stable
Concentration	100%	4%–8%
Diluent	None	Glycerin
Relative to CSF	Hypobaric	Hyperbaric
Injection sensation	Burning pain	Painless, warm feeling
Onset of neurolysis	Immediate	Delayed (15 min)
CSF uptake ends	30 min	15 min
Full effect of neurolysis	Three to five days	One day

CSF, Cerebrospinal fluid.

Phenol

Phenol has a benzene ring with one hydroxyl group substituted for a hydrogen atom. It is usually prepared by the hospital pharmacy because it is not commercially available in premixed liquid form. Phenol is poorly soluble in water and, at room temperature, forms only a 6.7% aqueous solution. It has a shelf life of approximately one year if refrigerated and shielded from light exposure. When phenol is exposed to room air, it oxidizes and turns a reddish color. Phenol is frequently prepared with sterile water, sterile saline, or glycerin. When prepared with glycerin, it has limited anatomic spread, and, hence, injections are well localized. In rats, the aqueous solution of phenol has a greater ability to penetrate the perineurium and produce greater endoneurial damage than glycerin preparations, but there is no difference in the results following intraneural injection.[13] Unlike alcohol, phenol injection has an initial local anesthetic effect. It is not associated with localized burning but instead creates a sensation of warmth for a short time after injection. The distribution of this sensation can help the practitioner verify proper needle placement similar to a diagnostic local anesthetic injection. Concentrations of 4%–10% are typically used for neurolysis. When phenol is prepared in glycerin, it has a specific gravity of

1.25, making it hyperbaric. Preparations of phenol in glycerin are highly viscous, which may make administration through a small (22- or 25-gauge) spinal needle difficult.

Putnam and Hampton first used phenol as a neurolytic agent in 1936. Mandl used it for a sympathetic ganglion block in animals in 1947.[14] Phenol was first used as a medication in an intrathecal injection in humans in 1955.[15] It was once believed that phenol's neurolytic effects might be because of local ischemia because of its greater affinity for vascular tissue than neural tissue.[16,17] Racz found that, unlike epidural injection, tissue destruction resulted after intrathecal injection even though the vasculature was intact in the areas of spinal cord destruction.[18] This finding points toward direct neurotoxic effects rather than effects secondary to local ischemia. Phenol's effects may be a combination of direct neurotoxic and ischemic effects.[19] Originally, it was surmised that phenol had a selective effect on small-diameter, unmyelinated nerve fibers, such as c-fiber afferents and lightly myelinated A-δ afferents. Subsequent studies have shown that phenol concentrations determine the type and extent of nerve disruption. Dilute intrathecal phenol can produce a transient local anesthetic blockade, whereas increased concentrations can produce significant neural damage.[20] At concentrations <5%, phenol results in protein denaturation of axons and surrounding blood vessels. At concentrations >5%, phenol can produce protein coagulation and nonselective segmental demyelination.[9] Nathan confirmed the nonselective effects of phenol using histologic studies combined with evidence of electrophysiologic changes to Aα and Aβ fibers.[21] Smith showed that intrathecal phenol injections in cats and humans primarily destroyed axons in dorsal rootlets and the dorsal columns of the spinal cord. It was also noted to exert some effects on the ventral root axons.[22] Maher and Mehta noted that motor blocks by phenol were possible at concentrations greater than 5%, whereas intrathecal injections of less than 5% produced mostly sensory blocks.[23] At higher concentrations, the extent of damage can increase significantly, with the potential of axonal nerve root damage and spinal cord infarcts. Injections of high concentration phenol have also been associated with arachnoiditis and meningitis.[24]

Systemic doses of phenol over 8.5% are associated with toxic side effects. These effects initially are convulsions, followed by central nervous system depression, and, finally, cardiovascular collapse. Chronic long-term exposure may be associated with renal toxicity, skin lesions, and gastrointestinal effects. However, phenol is not classically used in long-term settings, and the customary doses of less than 100 mg are unlikely to produce any systemic effects.[5]

Compared to alcohol, phenol seems to facilitate axonal regeneration in a shorter period. Electrophysiologic studies comparing peripheral nerve destruction in cats showed that those injected with phenol had returned to normal by two months, whereas at the end of the same period, those injected with alcohol still demonstrated depression of compound action potentials.[25]

Glycerol

Glycerol is a colorless, odorless, viscous, liquid, polyol compound. It has three hydroxyl groups that result in high water solubility, and it is hygroscopic in nature. The glycerol backbone is central to all lipids known as triglycerides. When placed on nervous tissue, myelin disintegration and axonolysis occur in both myelinated and unmyelinated fibers. In the uninjured nerve, the c-fiber and lightly myelinated fibers are the most sensitive to neurolysis, requiring higher concentrations to destroy the heavily myelinated fibers. However, this order is altered in the injured nerve; the heavily myelinated fibers become very sensitive to the neurolytic properties of glycerol. In 1981 Hakanson was the first to use glycerol for neurolysis of the trigeminal ganglion.[26] The success is most likely related to a combination of the viscous nature of glycerol and resultant lack of spread into other sensitive structures, the low concentration required to destroy the abnormally firing myelinated fibers while preserving the uninjured sensory afferents. The use of glycerol for neurolysis is now primarily restricted to the neurolysis of the Gasserian ganglion.

Neurolytic Blocks

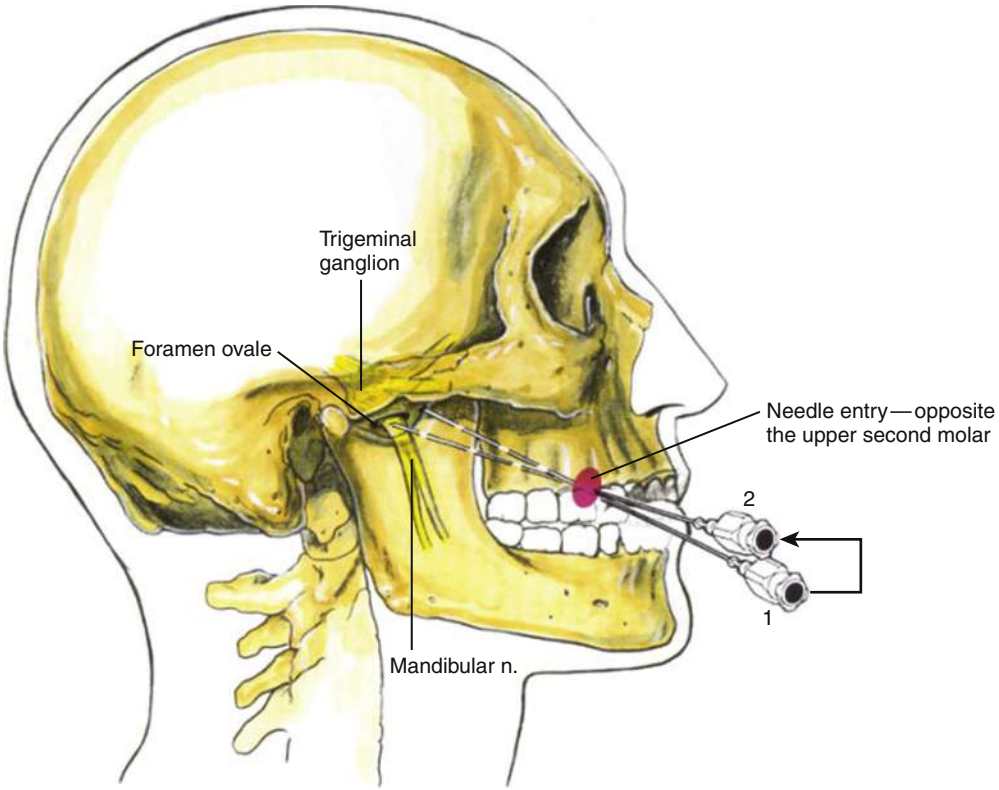
Neurolytic agents can be injected surrounding the peripheral nerves, along the neuraxis within the intrathecal or epidural spaces, or adjacent to visceral sympathetic nerves. Each of these sites of injection is associated with specific benefits, risks, and complications. Peripheral neurolysis can include injection into the trigeminal ganglion, truncal, upper, and lower extremities.[1]

Head and Neck

Gasserian Ganglion Neurolysis

Peripheral nerves in the head and neck are destroyed for a variety of reasons. These include blockade of the trigeminal ganglion for trigeminal neuralgia that is not responsive to medical management and for relief of cancer pain secondary to invasive tumors of the orbit, maxillary sinus, and mandible, and blockade of individual peripheral nerves in the head.

The Gasserian ganglion is formed from two trigeminal roots that exit the ventral surface of the brainstem at the midpontine level.[27] The roots pass forward and in a lateral direction, in the posterior fossa of the cranium, across the border of the petrous temporal bone. It then enters the Meckel's cave in the middle cranial fossa. The Gasserian ganglion contains the ophthalmic, maxillary, and mandibular divisions. A smaller motor root joins the mandibular division as it exits the foramen ovale. It should be noted that a dural pouch, the trigeminal cistern, lies behind the trigeminal ganglion. In Gasserian ganglion block, the needle is inserted approximately 2.5 cm lateral to the side of the mouth and advanced, perpendicular to the middle of the eye (with the eye in the mid-position) in a cephalad direction toward the auditory meatus.[28] When contact is made with the base of the skull, the needle is withdrawn and "walked" posteriorly toward the foramen ovale (Fig. 63.1). A free flow of CSF is usually noted, and fluoroscopy is then used to confirm the correct needle placement. Very small amounts (i.e. 0.1 mL increments) of local anesthetic or neurolytic agent (commonly glycerol) are injected to a total of 0.4–0.5 mL. Because of their different baricity, the patient remains supine if alcohol is used but placed in a sitting position with the chin on the chest prior to the injection of phenol. This maneuver localizes the phenol around the maxillary and mandibular divisions of the trigeminal nerve, avoiding the ophthalmic division and the risk of keratitis from loss of the conjunctival reflex. If glycerol is used, the patient is kept in a "seated"/head-up position. The pterygopalatine space is highly vascular, and significant hematoma of the face and subscleral hematoma of the eye can occur. Veins in the subtemporal region can be punctured, causing hemorrhage in the temporal fossa. Local anesthetic injection can lead to spinal anesthesia because the ganglion lies within the cerebrospinal fluid. Blockade of the motor fibers of the trigeminal nerve can interfere with mastication.[29] Oculomotor palsy, which results in



• **Figure 63.1** Trigeminal ganglion block: anatomy and technique. (Reprinted with permission from Brown D. *Atlas of Regional Anesthesia*. 3rd ed. Philadelphia: Saunders, an imprint of Elsevier; 2006: Figure 20-5.)

diplopia and strabismus, is usually temporary. Abducens palsy is also temporary, although cases of permanent lateral rectus palsy have been reported.[30] Spread of the neurolytic agent into the facial nerve results in paralysis of the facial muscles and inability of the eyelid to close, resulting in keratitis or corneal ulceration. Blockade of the greater superficial petrosal nerve may result in a lack of tear formation and conjunctivitis. Blockade of the acoustic nerve may result in deafness or dizziness. The delayed effects of Gasserian ganglion neurolytic block include trophic problems such as keratitis, ulcerations in the nose, and erosions in the mouth. These disturbances usually occur after trauma to the area. Another delayed complication is anesthesia dolorosa seen more commonly with alcohol and phenol neurolysis. Because the neurolytic block of the Gasserian ganglion is associated with myriad devastating complications, many neurosurgeons and pain medicine physicians choose to perform radiofrequency rhizotomy of the ganglion instead.[30] The technical difficulty and complications associated with Gasserian ganglion block led some investigators to perform peripheral branch (supraorbital, infraorbital, and mandibular nerves) injections with 10% phenol to relieve the pain of tic douloureux.[31]

Other Neurolytic Blocks of the Head and Neck

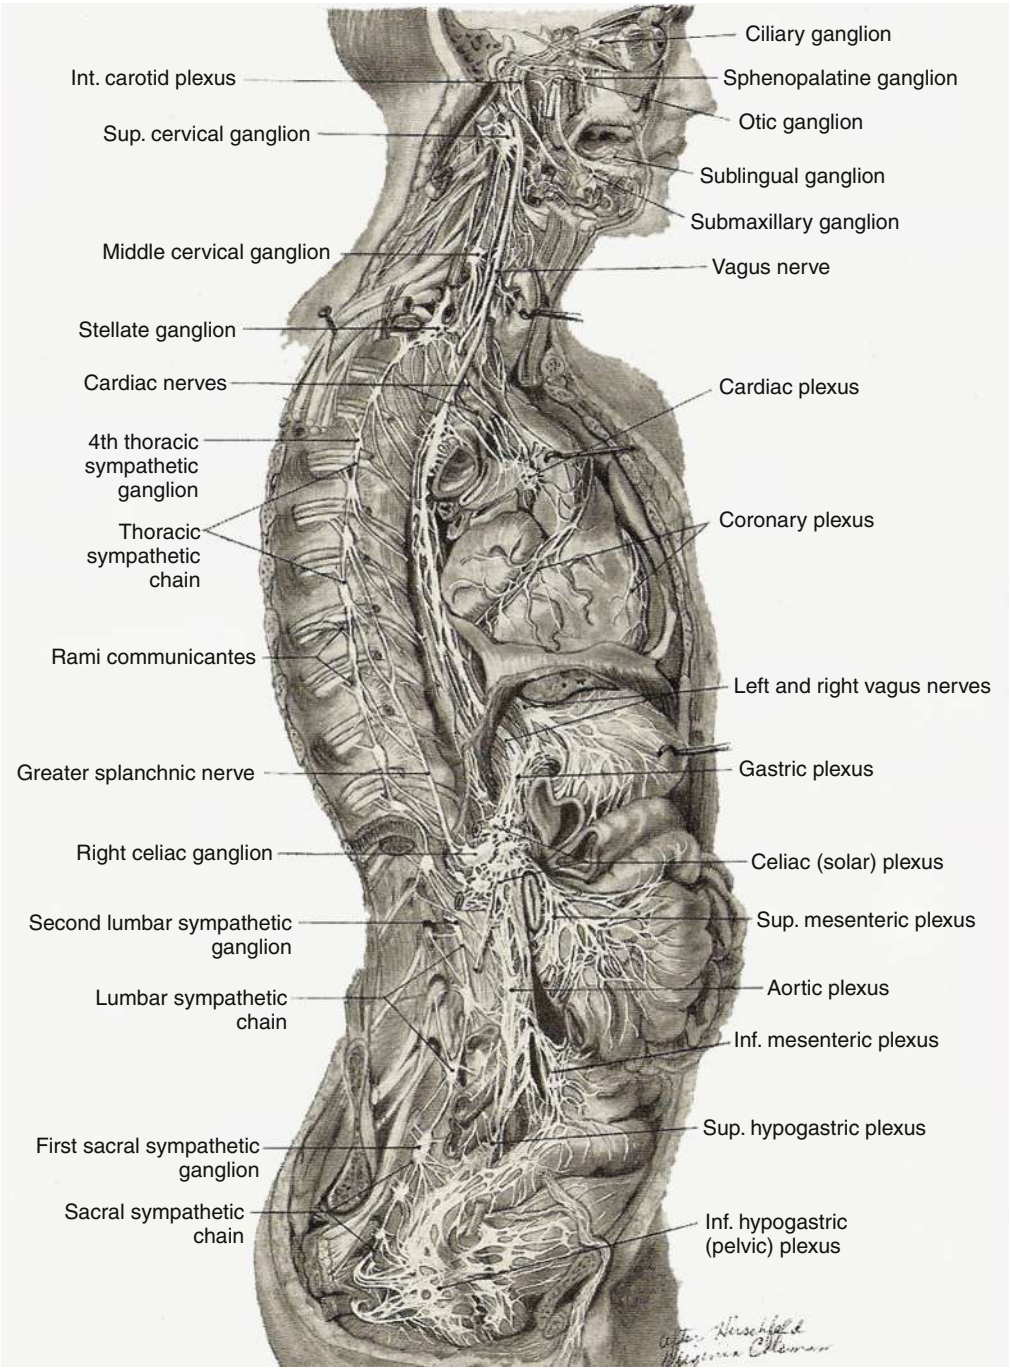
Neurolytic blocks of individual cranial nerves and their branches have also been performed, and complications are related to nerve location and the tissues it innervates. Neurolytic block of the maxillary nerve at the foramen rotundum or of the infraorbital nerve may cause ulceration and sloughing of the alar of the nose and the cheek, ischemic necrosis of the palate, or sloughing of the posterior portion of the superior ridge of the maxilla.[30] Blockade of the mandibular nerve at the foramen ovale may result in weakness of the muscles of mastication in the blocked side, whereas blockade of the facial nerve causes weakness or paralysis of the facial muscles. Blockade of the glossopharyngeal nerve is rarely performed because of the proximity of the nerve to the vagus, spinal accessory, and hypoglossal nerves. The close location of the other nerves led investigators to recommend blockade of the glossopharyngeal nerve under fluoroscopic control[32] or to use radiofrequency rhizotomy.[33] The sensory area of innervation of the glossopharyngeal nerve includes the nasopharynx, eustachian tube, uvula, tonsil, soft palate, base of the tongue, and part of the external auditory canal.[1] Paralysis of the pharyngeal muscles is a consequence of blockade of the glossopharyngeal nerve.

Paravertebral Sympathetic Neurolysis

Stellate Ganglion Block and Neurolysis

Clinically Relevant Anatomy

The cervical sympathetic trunk contains the superior, middle, and inferior cervical ganglia. In 80% of the population, the lowest cervical ganglion is fused with the first thoracic ganglion, forming the cervicothoracic (stellate) ganglion. The cervical sympathetic chain lies anterior to the prevertebral fascia, which encloses the prevertebral muscle (Fig. 63.2). The sympathetic chain is enclosed within the alar fascia, a thin fascia that separates the cervical sympathetic chain from the retropharyngeal space. The carotid sheath is connected to the alar fascia by a mesothelium-like fascia. The fascial plane that encloses the sympathetic chain may be in direct communication with several spaces and structures, including the brachial plexus, vertebral artery, endothoracic fascia, and the thoracic wall muscle at T1–T2. At the C6 level, the cervical sympathetic

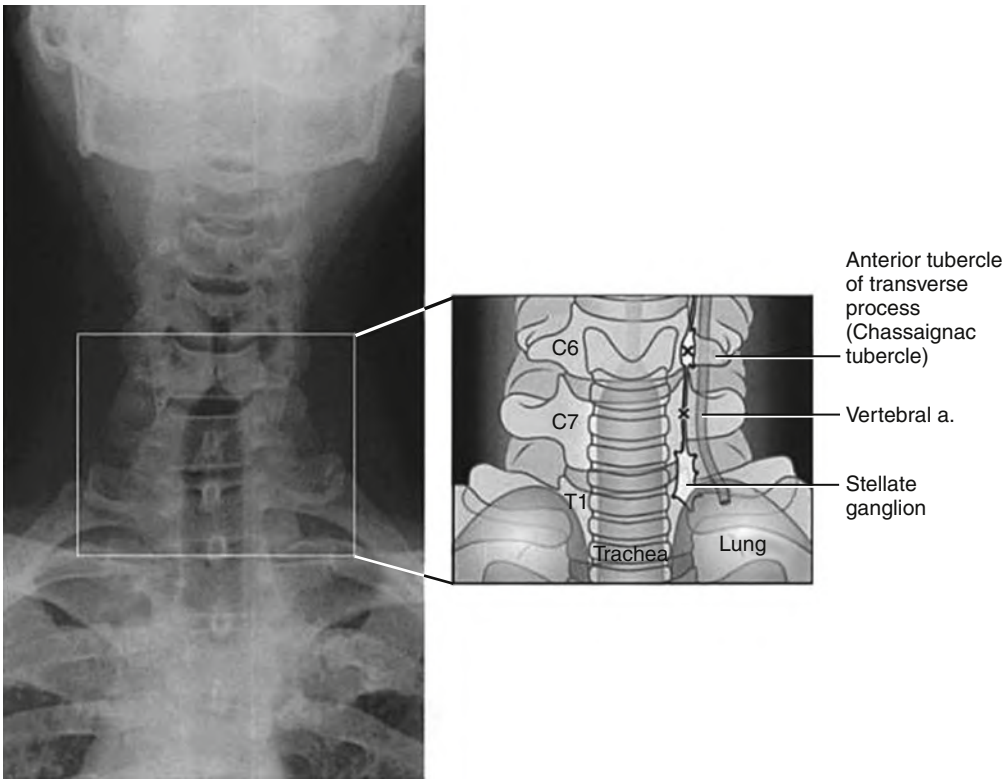


• **Figure 63.2** The peripheral autonomic nervous system. (From Bonica JJ. *The Management of Pain*. Philadelphia: Lea & Febiger; 1953.)

trunk is located posterolaterally to the prevertebral fascia on the surface of the longus colli muscle (LCM).[34] The carotid vessels are anterior, whereas the nerve roots that contribute to the inferior portion of the brachial plexus are lateral to the ganglion. The vertebral artery passes over the ganglion and enters the vertebral foramen posterior to the anterior tubercle of C6. The communications of the fascia covering the stellate ganglion with several structures, as noted previously, and the proximity of the stellate ganglion to the vertebral and carotid vessels, phrenic nerve, and the recurrent laryngeal nerve explain some of the potential complications of the stellate ganglion block (Fig. 63.3).[35]

Indications

SGB is commonly used for the diagnosis and management of sympathetically mediated pain and vascular insufficiency of the upper extremity. In addition, more esoteric indications that have been advocated include the treatment of a variety of medical conditions, such as phantom pain, postherpetic neuralgia, cancer pain, cardiac arrhythmias, orofacial pain, and vascular headache.[7] Recently, cervical sympathetic blockade has been suggested as an effective method for prevention and treatment of cerebral vasospasm, hot facial flushes, and post-traumatic stress disorder.[36–38]



• **Figure 63.3** Stellate ganglion anatomy. The relative position of the stellate ganglion, the vertebral artery, and the inferior cervical vertebrae. The relative positions of the C6, C7, T1 vertebral bodies of the Chassaignac tubercle (anterior tubercle of C6 transverse process) and the vertebral artery are illustrated. The vertebral artery traverses within the bony foramen at the C6 level, but the presence of a bony foramen at C7 is variable, and here the artery often courses unprotected anterior to the C7 transverse process. (Adapted from Janik IE, Hoeft MA, Rathmell J. Anatomic variation of Chassaignac tubercle measured by computed tomography: implications for stellate ganglion block. Presented at the annual fall meeting of the American Society of Regional Anesthesia and Pain Medicine; November 7-10, 2002, Phoenix, AZ; and Rathmell JP. Atlas of image-guided intervention in regional anesthesia and pain, 2005, Figure 10-2.) Rathmell JP; Atlas of Image Guided Intervention in Regional Anesthesia and Pain Medicine, Lippincott Williams and Wilkins: Philadelphia, 2005; Figure 10-2.

Available Techniques

Several techniques of stellate ganglion block have been described. These include insertion of the needle at the level of C6, placement of the needle at C7, and the posterior thoracic approach.[35] With C6 placement, the needle is placed in contact with either the C6 tubercle or the junction between the C6 vertebral body and the tubercle (Fig. 63.4). The needle is withdrawn 1–2 mm, and an initial test dose of 0.5–1 mL is injected, or volumes of 5–10 mL can be injected. If the patient is positioned in reverse Trendelenburg, the injectate travels caudad and reaches the stellate ganglion and the upper thoracic sympathetic ganglia.[36] A smaller volume of drug is adequate when the needle is placed at the level of C7. However, there is an increased incidence of vertebral artery injection with this approach because the artery lies anterior to the C7 transverse process. There is also an increased risk of pneumothorax because the dome of the lung is closer to the injection site. These risks are reduced when an oblique approach aiming at the uncinate process of C7 is taken.[37,38] The posterior thoracic approach requires fluoroscopic guidance to identify the lamina of T1 or T2, and dye injection is recommended to document the spread of the drug. In this approach, the needle contacts the lamina of T1 or T2, is moved laterally off the lamina, and is advanced to pass the costotransverse ligament at a depth of 2 cm beyond the lamina. Either loss of resistance is used, or dye is injected to confirm proper needle placement.

• **Figure 63.4** Anteroposterior fluoroscopy shows a block needle placed at the anterior base of the C6 transverse process. Injected contrast material is seen within the longus colli muscle.

Kapral published an ultrasound guided technique involving the use of ultrasound to visualize the stellate ganglion.[39] Since the initial technique was developed, many modifications have been made to increase the safety, efficacy, and speed of the block.[34,40] The patient is positioned supine with the neck slightly hyperextended, and an ultrasound probe is placed at the level of C6, providing a cross-section of the anatomy at this level (Figs. 63.5–63.6). Visible are the trachea, esophagus, thyroid gland, carotid artery, jugular vein, LCM, and transverse process of C6. A 22G × 2 inch needle can be advanced in plane with the ultrasound probe paratracheally toward the LCM while avoiding the other structures and stopping once the tip reaches the prevertebral fascia. The needle is inserted under continuous ultrasound guidance and directed to the anterior surface of the LCM via a short-axis, out of plane approach. When the tip of the needle is visualized, either directly or indirectly (tissue movement) as the target is approached, 1–2 mL of saline is injected to confirm the placement of the needle under the prevertebral fascia and facilitate clear separation of the tissue planes (Fig. 63.7). If the injectate is observed above the fascia or within the muscle, the needle must be carefully repositioned. If the spread is appropriate, 5–10 mL of local anesthetic is deposited under direct visualization and can be seen spreading along the prevertebral fascia.[41]

A lateral approach has recently been described and validated.[22] The patient is placed in the lateral decubitus position with the side to be treated uppermost. Preparation and ultrasonography are performed as described previously. The ultrasound transducer is centered on the C6 transverse process and not the anterior aspect of the neck. With the transducer placed as shown in Fig. 63.8, only the anterior tubercle of the C6 transverse process is visible adjacent to the projected entry point of the needle, and no visceral or neural elements are present between the entry site and the anterolateral surface of the LCM. The needle track is entirely intramuscular and passes through the sternocleidomastoid muscle, the anterior scalene muscle, or both. The internal jugular vein is occasionally seen within the projected needle track,

but it can readily be collapsed by placing light pressure on the transducer.

Skin anesthesia is performed immediately posterior to the ultrasound transducer. Under continuous ultrasound guidance, the needle is inserted via a short-axis, in plane technique (Fig. 63.9). The advantage of the lateral approach, besides avoiding trespassing through the thyroid, is totally controllable, visible progression of the needle from the skin entry point to the target. Verification of needle position and performance of the rest of the procedure are the same as the anterior approach.

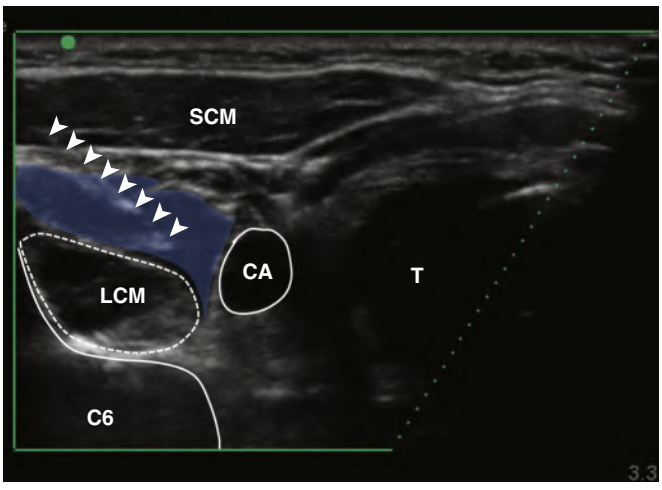
Injection of 5 mL of a local anesthetic typically results in C3-T1 prevertebral spread and complete blockade of the CST and stellate ganglion. If anesthetic blockade of the upper cervical ganglion is not desirable, it would be prudent to limit the volume of the injectant to 3 mL.

Complications

Blind paratracheal injection produces unreliable results and is associated with various side effects and complications, such as intravascular injection, formation of hematomas, temporary paralysis of the recurrent laryngeal nerve, diskitis, and esophageal injury.[39-44] Narouze and associates further emphasized the risks inherent with a blind approach[43] by pointing out that blind injection at the C6 level on the left side may cause inadvertent esophageal puncture or may traverse the thyroid.

Fluoroscopic guidance may prevent adverse outcomes related to intravascular, nerve root, or neuraxial injection. However, visualization of the soft tissue, vessels, and cervical sympathetic ganglia makes guidance with ultrasound superior to fluoroscopic guidance. Subfascial injection of 5 mL of an injectant reliably produces cervical sympathetic blockade. Ultrasound guidance may prevent the complications and adverse outcomes associated with either blind or fluoroscopically guided techniques.

The complications of intravascular injection of local anesthetic are well known. These include loss of consciousness, apnea, hypotension, and seizures. Local anesthetic blocks of the stellate ganglion have been performed for complex regional pain syndrome, vascular insufficiency of the upper extremities, and hyperhidrosis of the face and upper extremities. Neurolytic blockade of the stellate ganglion has been performed for complex regional pain syndrome when there is consistent relief after diagnostic block with local anesthetic and without prolongation of the duration of pain relief. The overall incidence of complications is 0.17%.[45] The exact incidence of pneumothorax is not known. Aside from Horner's syndrome, hoarseness, blockade of the brachial plexus, subarachnoid and epidural spread, and cord infarction have been reported.[46] Brachial plexus block is secondary to the needle being inserted too lateral or from the spread of the drug along the prevertebral fascia. Ptosis can be corrected by suspension operation of the upper eyelid. Additionally, retropharyngeal hematomas have been reported, ranging from minimal patient discomfort to complete loss of airway.[47,48] An unusual reported complication is transient locked-in syndrome, in which the patient is paralyzed and cannot breathe or speak but can only move their eyes because of accidental intravascular anesthetic injection.[49] These complications led other investigators to use alternative techniques to cervicothoracic sympathectomy, including radiofrequency rhizotomy and thoracoscopic sympathectomy.



• **Figure 63.9** Lateral ultrasound-guided approach. The needle *(arrowheads)* is placed under the prevertebral fascia. Local anesthetic *(semitransparent figure)* spread superficially to the longus colli muscle *(LCM)* and posteriorly to the carotid artery. Lumbar Sympathetic Neurolysis

Paravertebral sympathetic blocks are performed for the treatment of complex regional pain syndromes, vascular insufficiencies of the lower extremities, phantom limb pain, and other conditions such as hyperhidrosis. Percutaneous thoracic paravertebral sympathetic neurolysis is rarely performed because of the high incidence of pneumothorax. A thoracic surgeon who does a surgical sympathectomy under direct vision usually performs treatment of this region. Lumbar paravertebral sympathetic neurolysis can be more safely performed. In this technique, the needles are placed in the anterolateral surface of L2 or L3. Fluoroscopy is used to confirm the vertebral level of placement, correct position of the needle tip, and adequate spread of the dye along the anterolateral aspect of the vertebral bodies. Although a single needle technique can be used, two needles (one at L2 and the other at L3) are recommended for chemical neurolysis so that a smaller volume can be injected per needle. One to 2 mL of local anesthetic is injected, and if it is followed by a temperature increase, 3–4 mL of 6%–10% phenol is injected per needle. The reported complications of the block include subarachnoid injection secondary to injection near the dural cuff at the intervertebral foramen, sensory and motor block resulting from nerve root injury, paresthesia, and backache. The ureter can be injured from the needle or phenol-induced thrombosis of the branch of the ovarian artery supplying the ureter. Genitofemoral neuralgia occurs in 7%–20% of patients and may last four to five weeks.[50] Postsympathectomy dysesthesias result in numbness and pain in the thigh and may last several months. The use of guidance (fluoroscopy, computed tomography [CT], or ultrasound) is mandatory when neurolytic block of the sympathetic chain is performed. Alternate nonchemical neurolytic techniques, including radiofrequency rhizotomy of the lumbar sympathetic nerves, have been employed to avoid the complications from spillage of the neurolytic agent. However, this technique did not result in long-term relief,[51] although other studies have found benefits.[52,53] Compared with phenol neurolysis, incomplete neurolysis appears to be more common with radiofrequency rhizotomy,[54] but the incidence of postsympathectomy neuralgia was higher in the phenol group (33% vs. 11%).

Neurolytic Blocks of the Trunk and Extremities

Intercostal Neurolysis

Peripheral neurolysis is a controversial subject. Although some argue that it has no real use in pain management, it has found a role in intercostal neurolytic blocks for the management of malignant chest wall pain. The use of peripheral neurolysis follows successful diagnostic blocks using local anesthetics. Peripheral neurolytic blocks are frequently associated with neuritis and deafferentation pain, in addition to postinjection dysesthesias (Box 63.2). Although these complications are unpleasant, they may be preferable to the patient's current pain, or the patient may succumb to their primary disease before these complications fully manifest themselves.[55] Intercostal blocks are used in the treatment of thoracic or abdominal wall pain and as an adjunct in surgery.[56,57] Complications include pneumothorax, intravascular injection, intrapulmonary injection with consequent bronchospasm, and neuraxial spread (Table 63.2). The incidence of pneumothorax detected by radiograph is 0.082%–2%.[58] Clinically significant pneumothorax occurs at a low rate, and chest tube insertion is rarely required. Another reported complication is total spinal anesthesia after intraoperative intrathoracic injection.[59] The intrathoracic injection at a medial location resulted in the injection of the local anesthetic into a dural cuff or into the nerve itself, with the proximal spread of the drug. Bronchospasm from the intrapulmonary injection of phenol has been reported.[60] Persistent paraplegia from the intercostal block with 7.5% phenol has been reported, with the authors suspecting the damage occurred via the spread of phenol through the intervertebral foramen and subsequent destruction of motor and sensory nerve roots.[61] Similar to the advantages of its use in other peripheral nerve blocks, ultrasound has made intercostal nerve block a safer technique in that the pleura is visualized, preventing its puncture and avoiding pneumothorax.[62]

• Box 63.2 Limitations of Peripheral Neurolytic Blocks

- Motor deficits are likely when mixed sensory-motor nerves are blocked.
- Neuritis/deafferentation pain may occur and can be more severe than preexisting pain.
- Neurolytic blocks are not permanent.
- Sensory loss following peripheral neurolysis can, in some cases, become more distressing than the original pain.

TABLE 63.2 Complications After Truncal Blocks

Block	Complications
Intercostal	Pneumothorax
	Intravascular injection
	Bronchospasm (intrapulmonary injection)
	Neuraxial block
Somatic	Hypotension
	Urinary retention
Lumbar	Subarachnoid injection

Ilioinguinal and Iliohypogastric Neurolysis

Ilioinguinal and iliohypogastric nerve blocks are used in the perioperative management of pain after inguinal herniorrhaphy. Preoperative wound infiltration can decrease pain scores and analgesic requirements after inguinal herniorrhaphy. The preemptive analgesic effect of the preincisional infiltration of local anesthetic before herniorrhaphy has not been firmly established. In the pain clinic, ilioinguinal and iliohypogastric nerve blocks are performed in the diagnosis and treatment of inguinal and suprapubic pain after lower abdominal surgery or inguinal hernia repair. Complications of the block include unintentional blocks of the lateral femoral cutaneous and femoral nerves. The incidences of these complications are not known. Neurolytic blocks of these nerves are presently being supplanted by pulsed radiofrequency treatment (this is not a neurolytic procedure) and radiofrequency rhizotomy.[63] The advantage of radiofrequency techniques includes the ability to first stimulate the nerves to provide exact localization in a manner similar to sensory and motor testing of medial branch nerves in facet joint denervation. Diagnostic blocks are recommended before neurolytic (chemical or thermal) procedures are performed.

Neurolysis of Other Peripheral Nerves

Neurolytic injections have been reported to be useful in patients with palpable painful neuromas (0.2–0.5 mL of 5% phenol),[64] patients with poststernotomy pain secondary to scar neuroma (2–3 mL of 6% phenol),[65] and patients with painful surgical scars (1 mL of absolute alcohol).[66] Neuritis has not been reported after these peripheral neurolyzes.

Nerve root destruction in the extremities is rarely performed because of the attendant paralysis of the extremity. Mullin reported neurolytic blockade of the brachial plexus with 10 mL of 10% phenol in a patient with a painful arm secondary to Pancoast tumor.[67] The patient had short term pain relief with minimal motor blockade. The complications from neurolysis of peripheral nerves include painful dysesthesias and sensory and motor blockade. The exact incidences of these complications are not known but are high enough that this treatment is not recommended.

Neurolysis for Myofascial Pain and Spasticity

Neurolytic blocks of peripheral nerves are useful in patients with acquired spasticity to facilitate rehabilitation and restore the normal position of the limb for maintenance of hygiene. Examples of these blocks include obturator block to relieve hip adduction, musculocutaneous nerve block for elbow flexion, and posterior tibial nerve block for plantar flexion.[68] Peripheral nerve blocks with phenol have been performed in patients with spasticity to improve their gait and balance and assist in their rehabilitation. In this technique, the motor or mixed nerves are targeted preferentially. A nerve stimulator is used for nerve identification. Injections of small volumes of 3%–5% phenol are effective in relieving the hypertonicity of affected muscles, and relaxation of the muscle usually lasts two months. During this time, extensive physical therapy is employed for functional training of the limb. It appears that ethanol treatment can extend the therapeutic benefit. In a randomized controlled trial of 20 patients evaluating phenol (5%) versus ethanol (50%) in neurolysis of tibial motor branches for gastrocnemius spasm after stroke, ethanol maintained its effect for six months in nine of the 10 patients, whereas phenol lasted the same amount of time in seven of the 10 patients.[69] The reported complications include focal motor weakness in 15% of patients and dysesthesias in 10% of patients, but there were no differences

between those that received ethanol and those that received phenol. The motor weakness usually lasts one week, whereas the dysesthesias last several days to weeks. Others have reported a rare complication of arterial occlusion of the patient's upper limb after phenol block of the brachioradialis and musculocutaneous nerves.[70] Of note, the development and widespread use of botulinum toxin has made neurolysis a therapy of last resort for this condition.

Neuraxial Neurolysis

Intrathecal Alcohol

A neurolytic intrathecal procedure should be performed at the level where the targeted dorsal root leaves the spinal cord and not at the level where it passes through the intervertebral foramen. The latter is not recommended because of a mismatch of the spinal cord level and vertebral bone level (especially as one progresses from the thoracic spinal cord to the lower lumbar). An accurate determination of the level to be blocked should be evaluated according to dermatome and sclerotome charts, as well as selective local anesthetic intrathecal blockade.[71] The patient should be positioned laterally so that the rootlets (dorsal root entry zone [DREZ]) are above the injection site.[72] This positioning is necessary given that alcohol will float in the CSF because of its hypobaric nature.[73] The patient should also be turned 45 degrees toward the prone position (Fig. 63.10). This will raise the targeted area (DREZ) horizontally so it will be superior to the ventral nerve rootlets, and it makes contact with the neurolytic.[72] After proper patient positioning, a short beveled (e.g. small Touhy, 22-gauge) needle is placed into the predetermined level slowly until arriving at the epidural space. This is best confirmed using a loss of resistance to air and guided by fluoroscopy. After ascertaining that the epidural space has been reached, the needle should be advanced slowly while aspirating continuously until it reaches the intrathecal space and contrast dye administration (Fig. 63.11). The physician should then inject a low volume/high concentration of rapidly acting local anesthetic to provide anesthesia and clinical feedback of needle location. The lack of pretreatment with local anesthetic will result in significant discomfort and the possibility of patient movement. Using a 1 mL syringe, the alcohol is injected in 0.1 mL increments, with at least 60–90 s between repeat administrations. The maximum dose per nerve is usually 0.3 mL, and the total alcohol volume should not exceed 0.5–0.7 mL when several nerve roots are neurolyzed.[74]

After injection, the patient should remain in the same position for 15 to 30 min. This immobilization allows the alcohol to exert its maximal effect at the desired location, with minimal spread to

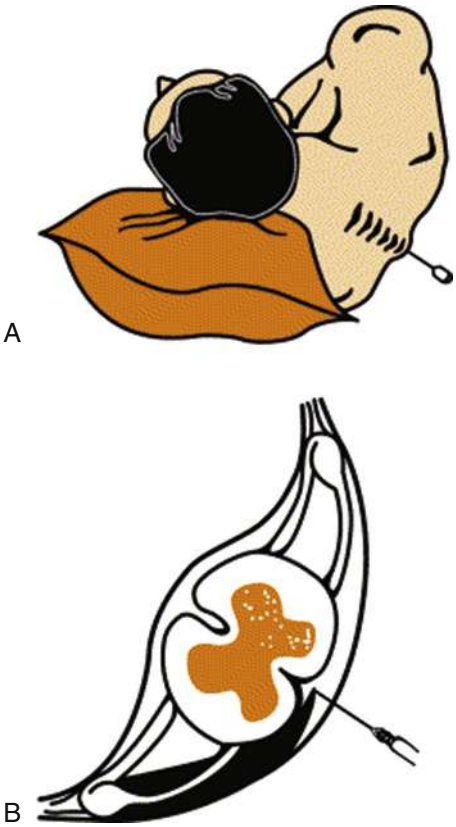
adjacent levels. After the 30 min period, a neurologic exam should be performed. The patient's pain should be reassessed three to five days after the alcohol injection to determine the effectiveness of the procedure.

Intrathecal Phenol

The same considerations that occur prior to the injection of alcohol also apply to phenol. The pain location should be determined with dermatome and sclerotome mapping and isolated with a diagnostic injection of local anesthetic or contrast dye under fluoroscopy. There are two fundamental differences between alcohol and phenol administration. When using phenol, the patient's targeted anatomy must be facing down, the patient must be leaned 45 degrees supine, and the spinal needle diameter must be larger because of the increased viscosity of phenol. The hyperbaric nature of phenol in glycerin requires positioning so the phenol sinks to targeted DREZ and rootlets. A short, 20-gauge needle should allow the thick phenol solution to be injected in most situations. However, if this proves difficult, warming the injectate in a warm water bath before drawing may ease the flow of the injection.

Although positioning can be challenging, a common technique involves slightly elevating the head of the bed, with the bed under the target flexed and the patient turned 45 degrees supine (Fig. 63.12). Using supporting devices, such as pillows, towels, and foam, and a judicious amount of intravenous sedation can facilitate a reasonable level of comfort to prevent failure of the technique resulting from patient movement. Unlike alcohol, phenol does not require pretreatment with local anesthetic to provide analgesia of the site. However, the diagnostic value (needle localization) of the local anesthetic is still imperative. Similar to alcohol neurolysis, phenol is injected in 0.1 mL increments, with 60–90s between subsequent injections. Phenol is injected up to a total dose of 0.5–0.7 mL. The feeling of warmth from the phenol is fleeting and may provide some pain relief. Although there is less diffusion with phenol than alcohol, the patient should be maintained in position for 30 min after phenol administration. The full effect of phenol manifests over approximately 24 h.



• **Figure 63.12** **A,** Proper positioning of a patient with left-sided pain for intrathecal phenol in glycerin. Epidural Neurolytic Block

Epidural neurolysis is used for abdominal cancer pain of both visceral and mixed somatic and visceral origin. Epidural neurolysis remains popular compared to intrathecal neurolysis because of its increased safety index, ease of repeated injections, and its greater efficacy on thoracic and cervicothoracic junction pain. However, it often provides less complete anesthesia of the patient's painful areas compared to intrathecal administration. Although the traditional technique is described in this chapter, one study demonstrated that the use of a transforaminal approach, when necessary, provided excellent results.[75] Selecting the appropriate size needle depends on the agent used, as discussed previously. If alcohol is used, the physician may use an epidural catheter for delivery. An epidural catheter approach provides advantages of repeated injections and can be performed without accessing the epidural space multiple independent times. However, the indwelling catheter can be an entry site for epidural infection. The most appropriate catheter to use is a soft-tipped styletted catheter that can be maneuvered with precision and allows confirmation of position with the injection of a small amount of contrast and local anesthetic.

Unlike the intrathecal administration of neurolytic agents, needle or catheter tip location should be chosen near the vertebral bone that corresponds to the dermatomal levels manifesting in the patient's pain area to deposit the medication over the appropriate nerve roots. The injections should be performed under sterile conditions. It has been recommended that injections be repeated over several days to improve efficacy and outcome. Once the needle and patient positioning have been established, contrast-enhanced fluoroscopic imaging and a local anesthetic test dose can be performed to confirm proper needle depth and location. The appropriate volume of injectate depends on the level of the neurolysis being performed. Doses ranging from 2–5 mL are usually adequate, with doses increasing as location moves more caudally. Racz and colleagues endorse daily injections until noticeable changes in pain levels no longer occur, or the patient is pain-free after 24 h. For up to three days after the initial placement of an epidural catheter 3–5 cm into the epidural space, ethanol can be injected daily. Before each daily administration, the researchers reconfirmed placement with a local anesthetic test dose.[76] Using 0.2 mL increments, they administered 3–5 mL of alcohol over 20–30 min. Although initial relief was achieved in all cancer patients, results are less significant in patients with chronic nonmalignant pain.[77] In four studies, the results of thoracic epidural neurolysis revealed a significant improvement in cancer pain.[6] Pain relief, ranging from 65%–100%, was achieved in 80% of patients. Pain relief varied among populations and reflected the severity of disease. Nonetheless, many patients were pain-free until their death. In the patients who survived, the duration of pain relief varied from less than one month to more than three months.

Neuraxial neurolytic procedures for cancer pain are now rarely used because intrathecal opioid pumps have supplanted it. Intrathecal medication infusion pumps have the advantage of managing pain from the progression of the disease or future sites of painful metastases, which are common occurrences in a patient with malignancy.

Other Complications Associated With Intrathecal and Epidural Neurolysis

Although ease of administration is a factor, there does not appear to be an increased margin of safety of epidural neurolysis compared to intrathecal neurolysis. A study by Katz showed that two weeks after the lumbar epidural injection of phenol in a group of primates, predominant posterior nerve root damage was noted, in addition to the anterior nerve root and spinal cord damage. These test subjects also demonstrated lower extremity motor weakness on physical examination.[78] Complications with neurolysis range in frequency from 1%–14%, and in severity between incomplete block to limb weakness or bladder/rectal paresis.[5] Like most interventional pain procedures, the most common complication is the failure of the procedure to provide significant pain relief. Poor pain relief can have numerous etiologies. It is not unusual for patients to have high expectations for pain relief and have those expectations not met by neurolysis. Therefore the pain physician needs to have clear communication and discuss rational expectations with the patient prior to the procedure to prevent these disappointments. Another cause of inadequate pain relief may be as simple as an incomplete block that can be remedied with a repeat dose. If tumor growth is extensive or crosses several dermatomes, neurolysis may be less effective. Unfortunately, there is always the possibility that the block works well, but that local spread of the neurolytic agent may have produced peripheral damage.

There are complications because of entry into the anatomic space where these medications are administered. They include postdural puncture headache, meningitis, arachnoiditis, and neural damage from trauma. Postdural headaches usually resolve quickly, within one to five days. Complications related to neurolytic agents include loss of motor function because of neurolysis of the ventral rootlets, loss of touch and proprioception, and loss of sphincter tone. Of these potential complications, loss of bowel or bladder sphincter tone is relatively common. The complications resulting from the neurolytic agents are usually transient. According to Gerbershagen, who observed the duration required for resolution of neurolytic complications, 28% resolved within three days, 23% within one week, 21% within one month, 9% within four months, and 18% longer than four months.[79] Complication rates appear to be similar between alcohol and phenol as shown by Swerdlow, who analyzed complications in a series of 145 patients.[80]

Complications can be specific to the location along the spine where the neurolysis is performed. At the cervical level, damage can occur to the brachial plexus, most often manifesting as limb paresthesia. Complications at the thoracic level are the least common relative to the cervical and lumbar level. Below the L1 spinal level, injections may travel into the cauda equina, where anterior and posterior roots are not separated. This factor may make the degree of motor or sensory effect difficult to predict.

Changes in opioid use may occur after a neurolytic block. Patients who have typically been on high doses of opioids for long periods will have reduced requirements for pain control with successful neurolysis. Rapid discontinuation of opioids will cause withdrawal side effects; without pain as a stimulus, pre-neurolysis opioid doses may produce excessive sedation and respiratory depression. Careful observation of the patient in the hours to days post successful neurolysis can circumvent these problems.

Neurolysis of the Sympathetic Axis for Cancer Pain Management

Celiac Plexus Block

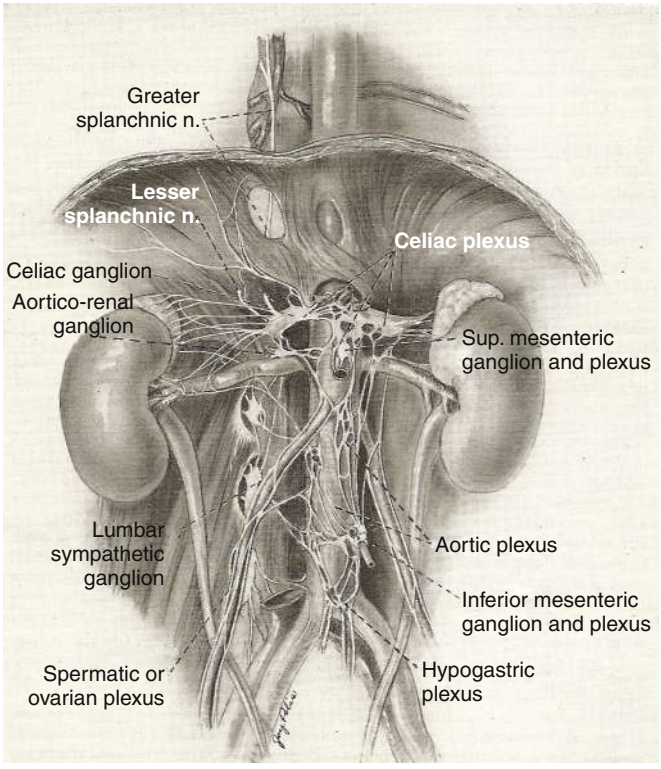
Clinically Relevant Anatomy

The celiac plexus is situated retroperitoneally in the upper part of the abdomen. It is at the level of the T12 and L1 vertebrae, anterior to the crura of the diaphragm. The celiac plexus surrounds the abdominal aorta and the celiac and superior mesenteric arteries (Fig. 63.13). The plexus is composed of a network of nerve fibers from both the sympathetic and parasympathetic systems. It contains two large ganglia that receive sympathetic fibers from the three splanchnic nerves (greater, lesser, and least). The T5–T9 preganglionic fibers coalesce to form the greater splanchnic nerve; T10 and T11 constitute the lesser and T12 the least splanchnic nerves.[81]

The plexus also receives parasympathetic fibers from the vagus nerve. Autonomic nerves supplying the liver, pancreas, gallbladder, stomach, spleen, kidneys, intestines, and adrenal glands, as well as blood vessels, arise from the celiac plexus. The sensory (afferent) fibers do not synapse in the plexus but rather traverse it and ascend to spinal levels through the splanchnic nerves.

Indications

Neurolytic celiac plexus block (NCPB) has been used for malignant and chronic nonmalignant pain. NCPB is indicated for the management of pain related to cancer of the pancreas, stomach, duodenum, and proximal part of the small bowel. In addition, metastatic tumors in the lymph nodes may cause similar pain and might be amenable to NCPB. In the case of benign conditions,



• **Figure 63.13** Celiac plexus anatomy (From Bonica JJ. *The Management of Pain*. Philadelphia: Lea & Febiger; 1953.)

analgesic prognostic CPB is performed and may be repeated as needed. Alternatively, if the reduction in pain was significant but lasted only short term, NCPB may be attempted.

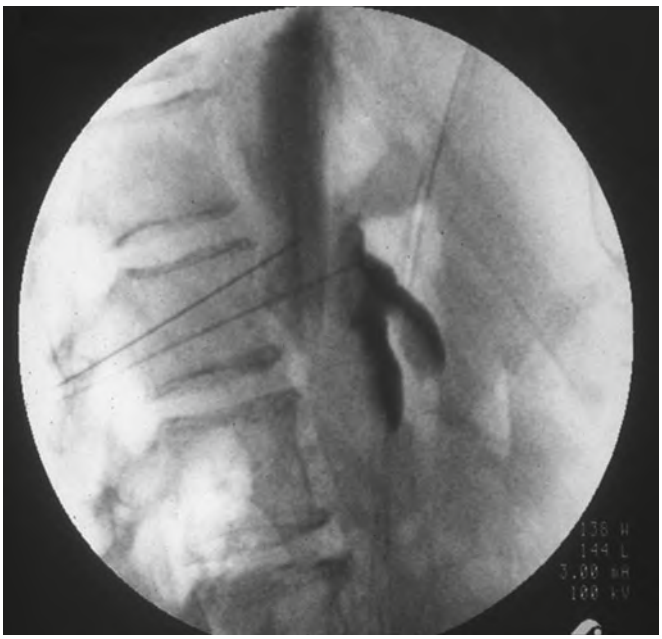
In patients with acute or chronic pancreatitis, celiac plexus block has been used with variable success.[82] Likewise, patients with upper abdominal cancer who have a significant visceral pain component have responded well to this block.[83]

Evidence for Celiac Plexus Block

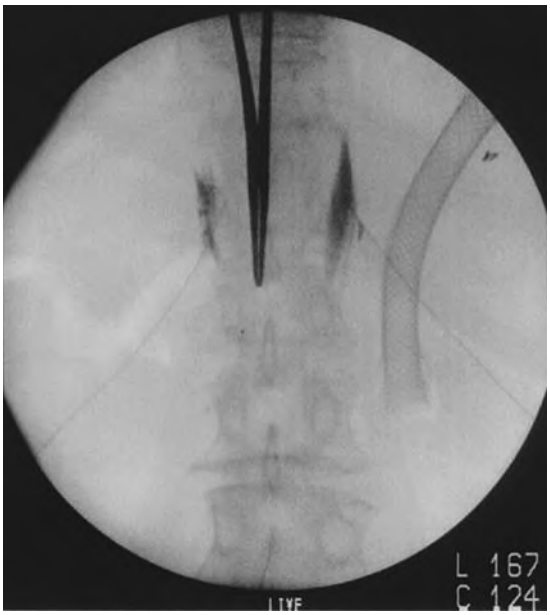
The Cochrane collaboration performed a systematic review of all randomized controlled studies investigating the effectiveness of celiac plexus block in the management of pancreatic cancer pain. They concluded that despite a small amount of evidence for an increase in pain relief, the improved side effect profile because of the reduced need for opiates is desirable.[84] It must be considered that many of the studies comparing the various interventional procedures with oral pharmacotherapy included NSAIDs. If more protocols in the future exclude NSAIDs, there may become a bigger statistical difference between the interventional and pharmacotherapy groups. A randomized, controlled study showed that CPB was effective in treating feeding intolerance in patients with critical illness when intravenous drug therapy failed to improve gastrointestinal dysfunction.[85]

Available Techniques

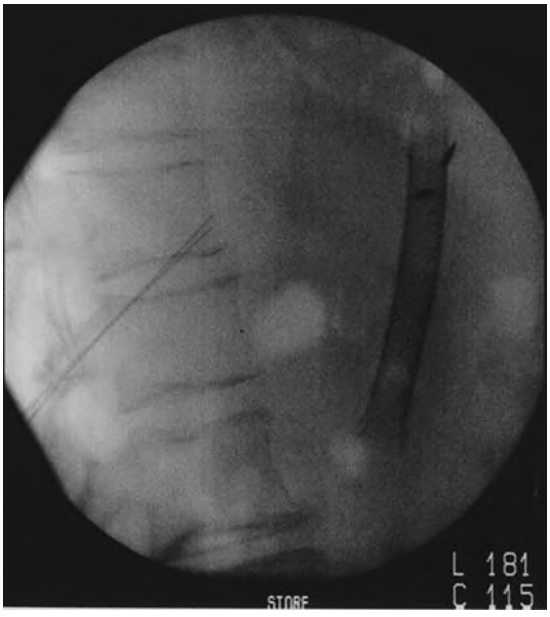
Three approaches to block nociceptive impulses from viscera in the upper abdominal region include the retrocrural (or classic) approach, the anterocrural approach, and neurolysis of the splanchnic nerves.[86–89] Regardless of the approach, the needle or needles are inserted at the level of the first lumbar vertebra, 5–7 cm from the midline. Then the tip of the needle is directed toward the upper third of the body of L1 for the retrocrural and toward the lower third of the body of L1 for the anterocrural technique (Fig. 63.14). In the case of the retrocrural approach, the tip of the needle is advanced no more than 0.5 cm anterior to the anterior border of L1, and with the anterocrural approach (Fig. 63.14), the tip of the needle is advanced through the aorta on the left side until no more blood flow is noted through the needle. This is why the anterocrural approach is also known as the transaortic approach. In the case of a splanchnic nerve block, the needle is directed toward the body of T12 (Fig. 63.15). In this case, perfect needle positioning is achieved when the tip of the needle is at the anterior portion of the T12 vertebral body on the lateral view (Fig. 63.16).



• **Figure 63.14** Neurolysis of the celiac plexus, retrocrural versus anterocrural positions of the tip of the needle on the lateral view. Note that for a retrocrural technique, the tip of the needle is in the upper third of L1 and about 1 cm beyond its anterior border. The spread of the contrast medium is cephalad. The tip of the needle is in the lower third of L1 and about 3 cm beyond its anterior border for an anterocrural technique. In this case, the spread of contrast medium occurs caudad.



• **Figure 63.15** Neurolysis of the splanchnic nerves with needle position on the anteroposterior view. Note that the spread of the contrast medium is limited to the lateral portion of T12.



• **Figure 63.16** Neurolysis of the splanchnic nerves with needle position on the lateral view. Note that the tip of the needle is advanced until it is at the same level of the anterior border of T12 to avoid potential puncture of the pleura.

CT (Figs. 63.17 and 63.18.) and ultrasound techniques (Figs. 63.19.14–63.21) have allowed pain specialists to perform neurolysis of the celiac plexus via a transabdominal approach. This approach is frequently used when patients cannot tolerate either the prone or lateral decubitus position or when their liver is so enlarged that a posterior approach is not feasible. CT guidance allows an anterocrural technique to be performed without piercing the aorta, thus adding an element of safety in this case (see the section "Complications"). Ultrasound guided percutaneous CPB may have several benefits compared to other modalities. It may be performed at the bedside and has no radiation hazards. In addition, the supine position is more comfortable for patients. It allows real-time visualization of the spread of the injectant. Its disadvantages include poor visualization of deeper structures, including the pancreas, and interference by air in the intestinal loops. Similar to anterior CT guidance, it may be associated with perforation of the stomach, intestine, pancreas, or liver.

Drugs and Dosing

For neurolytic blocks performed via the retrocrural or anterocrural approaches, 50%–100% alcohol is used. Injected by itself, alcohol can produce severe pain. Thus it is recommended that 5–10 mL of 0.25% bupivacaine first be injected 3–5 min before injection of the alcohol or at the time of the injection by diluting 100% alcohol to a 50% concentration with the same amount of local anesthetic (0.25% bupivacaine). Phenol in a 6% to 10% final concentration may also be used; it has the advantage of being painless on injection, and both agents seem to have the same clinical efficacy. The

dose of alcohol or phenol administered varies with the approach to be used. For the retrocrural approach, 20–25 mL of alcohol is injected on each side. Consequently, the need to inject this high volume precludes the use of phenol in the retrocrural approach. For the anterocrural approach, 8–10 mL of either neurolytic agent is used per side. For splanchnic nerve blocks, 6–8 mL of phenol per side is recommended.

Complications

The incidence of complications from NCPBs was evaluated by Davis[90] in 2730 patients who had blocks performed from 1986–1990. The overall incidence of major complications (e.g. paraplegia, bladder, and bowel dysfunction) was one in 683 procedures. However, the report does not describe which approach or approaches were used to perform the blocks.

Complications associated with celiac plexus block appear to be related to the technique used: retrocrural,[87] transcrural,[88] or transaortic.[89] In a prospective, randomized study of 61 patients with cancer of the pancreas, Ischia and colleagues[86] compared the efficacy and incidence of complications associated with these three approaches with those of celiac plexus neurolysis. Orthostatic hypotension occurred more often when the retrocrural (50%) or splanchnic (52%) technique was used, thus suggesting associated neurolysis of the sympathetic chain. In contrast, the anterocrural approach produced a 10% incidence of hypotension. Conversely, transient diarrhea was more frequent with the anterocrural approach (65%) than with the splanchnic nerve block technique (5%) or the retrocrural approach (25%). The incidence of dysesthesia, interscapular back pain, reactive pleurisy, hiccups, or hematuria was not statistically different among the three groups.

The following paragraphs discuss several aspects involved in the diagnosis and management of specific complications.

Malposition of the needle is avoided with radiologic imaging before injection of a neurolytic agent in as much as the tip of the needle may be intravascular, in the peritoneal cavity, or in a viscus. Imaging guidance techniques currently used include biplanar fluoroscopy, CT, and ultrasound. However, no study has evaluated the superiority of one technique over the others. Wong and Brown[91] suggested that the use of radiologic imaging does not alter the quality of the block or the incidence of complications based on a retrospective study of 136 patients with pancreatic cancer pain treated with a celiac plexus block with or without radiologic control of the position of the tip of the needle. However, it is not clear how many of these patients underwent radiologic imaging. Assuming that half the patients did not, the upper 95% confidence limit for complications would be 5%.[92]

Orthostatic hypotension may occur up to five days after the block. Treatment includes bed rest, avoidance of sudden changes in position, and replacement of fluids. Once the compensatory vascular reflexes are fully activated, this side effect disappears. Wrapping the lower extremities from the toes to the upper part of the thighs with elastic bandages has been successful in patients in whom orthostatic hypotension developed and thus enabled them to walk during the first week after the block.

Backache may result from local trauma during needle placement and subsequent retroperitoneal hematoma or from irritation of retroperitoneal structures by alcohol. Patients with a backache should have at least two hematocrit measurements at a 1 h interval. If there is a decrease in the hematocrit, radiologic imaging is indicated to rule out a retroperitoneal hematoma. Urinalysis positive for red blood cells suggests renal injury.

Retroperitoneal hemorrhage is rare. However, in patients with orthostatic hypotension, the possibility of hemorrhage must be ruled out before assuming that it is a physiologic response to the block. Patients with backache and orthostatic hypotension develop after a celiac plexus block should be admitted to the hospital for serial hematocrit monitoring. If the hematocrit level is low or decreasing, patients should undergo radiologic evaluation to rule out injury to the kidneys, the aorta, or other vascular structures. Surgical consultation should be obtained as soon as feasible.

Diarrhea may occur as a result of sympathetic block of the bowel. Treatment includes hydration and antidiarrheal agents. Oral loperamide is a good choice, although any anticholinergic agent may be used. Matson and colleagues[93] reported nearly fatal dehydration from diarrhea following this block. In debilitated patients, diarrhea must be treated aggressively.

Abdominal aortic dissection has also been reported.[94,95] The mechanism of aortic injury is direct damage with the needle during the performance of the block. As expected, the anterocrural approach is more frequently associated with this complication. Thus this approach should be avoided in patients with atherosclerotic disease of the abdominal aorta.

Paraplegia and *transient motor paralysis* have occurred after celiac plexus block.[96–102] These neurologic complications may be because of spasms of the lumbar segmental arteries that perfuse the spinal cord.[103] In fact, canine lumbar arteries undergo contraction when exposed to both low and high concentrations of alcohol.[103] Thus these data suggest that alcohol should not be used if there is evidence of significant atherosclerotic disease of the aorta because the circulation to the spinal cord may also be impaired and be dependent only on lumbar artery flow. However, there is also a report of paraplegia after the use of phenol,[96] which suggests that other factors (e.g. direct vascular or neurologic injury or retrograde spread to the spinal cord) may come into play. These complications further support the need for radiologic imaging when performing these blocks.

Efficacy

Three randomized controlled trials[86,104,105] and one prospective study[106] have evaluated the efficacy of celiac plexus neurolysis in relieving pain caused by upper abdominal cancer. In a prospective, randomized study, Ischia and coworkers[86] evaluated the efficacy of three different approaches to celiac plexus neurolysis for pancreatic cancer. Of 61 patients with pancreatic cancer pain, 29 (48%) experienced *complete* relief of pain after the neurolytic block. The remaining 32 patients (52%) required further therapy for residual visceral pain secondary to technical failure in 15 patients and neuropathic or somatic pain in 17 patients. The second trial,[104] which compared the procedure with oral pharmacologic therapy in 20 patients, concluded that celiac plexus neurolysis results in an equal reduction in visual analog scale (VAS) pain score as does therapy with a combination of NSAIDs and opioids. However, opioid consumption was significantly lower in the group of patients who underwent neurolysis than in the group receiving oral pharmacologic therapy during the seven weeks of the study. The incidence of side effects was greater in patients who received oral pharmacologic therapy than those who underwent neurolytic block. Regarding the third randomized controlled study, the results of Wong and collaborators[105] are welcome in light of a lack of properly designed comparative studies between neurolytic techniques and comprehensive medical management (CMM). However, several issues in the design and results of this study need to be highlighted:

- Patients enrolled in the study did not have severe pain at study entry. Mean pain scores at baseline were 4.4 ± 1.7 in the NCPB group and 4.1 ± 1.8 in the CMM group. This is a surprising finding in patients with this type of malignancy and may reflect ethnic and racial differences in pain perception and reporting by the population enrolled in the study.
- Although the authors reported a significant statistical reduction in pain scores one week after therapy when comparing the NCPB group with the CMM group, the difference between the two groups may not be clinically important. Patients assigned to the NCPB group reported mean pain scores of 2.1 ± 1.4, whereas those randomized to the CMM group reported pain scores of 2.7 ± 2.1 at that time interval. Moreover, statistical difference was found only when the percent reduction from baseline in the NCPB and the CMM group was analyzed separately (53% reduction from baseline in the NCPB group, $P = 0.05$, versus a 27% reduction observed in the CMM group, $P = 0.01$).
- It is critically important to note that most patients (93%) took opiates during the first week of therapy, with similar amounts of opiates being administered to the two treatment groups. Opiate consumption increased with time with no differences between groups at the different time intervals during the study. The incidence of side effects was not different between the two treatment groups at any point in time.
- Likewise, quality of life measurements and the physical and functional wellbeing subscales of the Functional Assessment of Cancer Therapy for Prostate Cancer did not differ between the two groups at any evaluation point.

Two important questions stem from these results:

- Can the authors truly conclude that the major finding of the study was that NCPB significantly improves relief of pain in patients with advanced pancreatic cancer compared to those who received optimized CMM?
- Based on these results, are we justified to submit a patient with advanced pancreatic cancer to NCPB, given the potential side effects and complications associated with this procedure?

We do not believe that the authors can conclude that NCPB significantly improves pain relief in patients with advanced pancreatic cancer. This is partly because the levels of analgesia achieved by the patients assigned to either group after one week of therapy can be considered clinically acceptable. Additionally, statistical difference was found only when the authors analyzed the percent reduction in pain from baseline in each of the treatment groups.

Likewise, based on these results, we do not believe that we would recommend NCPB to a patient with advanced pancreatic cancer because in this not so perfect world, complications do occur, as has been addressed earlier.

Given these reservations, does this mean that we should not perform NCPB in patients with pancreatic malignancy? As with every clinical study, the results of Wong and associates apply only to the population studied and under the conditions of the study protocol design. The critical issue is that *all* patients had nonresectable disease, which suggests that the patients were likely to have other pain components such as somatic or neuropathic, which are not responsive to NCPB.[86] This is because neurolytic blocks of the sympathetic axis are effective in treating visceral pain only. Moreover, previous studies have suggested that in patients with evidence of disease outside the pancreas, such as celiac or portal adenopathy, the success rate of this block decreases significantly.[106] In the study by De Cicco and collaborators, long-lasting

pain relief was described in nine of nine patients (95% confidence interval of 60–100) when contrast medium spread into the four quadrants and in 10–21 patients (95% confidence interval of 26–70) when contrast medium spread into three quadrants. None of the 75 patients with spread of contrast agent into two or one quadrants experienced long-lasting pain relief.[106] Thus the presence of adenopathy secondary to metastasis is a poor prognostic factor for the success of the block. This decrease in effectiveness is not because of a mechanical factor such as big lymph nodes blocking the spread of the neurolytic agent. Rather, it is simply a marker of more extensive disease that often includes nonvisceral pain components and is, therefore, less amenable to NCPB. The results of the study by Wong and collaborators further support the notion that NCPB should not be performed in patients with advanced unresectable carcinoma of the pancreas. This block should be reserved for patients without evidence of disease outside the viscera so that one is guaranteed that the patient has a visceral pain component only.

A prospective, nonrandomized study[107] compared 41 patients treated according to the World Health Organization guidelines for relief of cancer pain with 21 patients treated by NCPB. The authors concluded that this technique could play an important role in managing pancreatic cancer pain.

Since one of the three randomized, controlled studies compared different approaches to the celiac plexus and had no control group,[86] and the other study compared the procedure with an analgesic drug,[104] it is not possible to estimate the success rate of this technique. In contrast, the results of a meta-analysis that evaluated the findings of 21 *retrospective* studies with a total of 1145 patients concluded that adequate to excellent pain relief can be achieved in 89% of patients during the first two weeks following the block.[108] Partial to complete pain relief continued in approximately 90% of the patients who were alive at the three-month interval and in 70%–90% of patients during the three-month interval before death. Its efficacy was similar in patients with pancreatic cancer as in those with other upper intra-abdominal malignancies. However, these results are based on *retrospective* evaluation, which may not yield reliable information or be subject to publication bias. In addition, the statistical techniques used for the analysis must account for the heterogeneity produced by patient selection criteria, technical differences in performance of the blocks, choice of neurolytic agents and doses used, diversity in the tools for evaluation of pain, goals of therapy, and other factors. Thus the meta-analysis must be interpreted with caution because the report may be overly enthusiastic.

Oral pharmacologic therapy with opioids, NSAIDs, and co-adjuvants is used frequently for the treatment of cancer pain. However, the evidence suggests that chronic use of high doses of opioids has a negative effect on immunity.[109] Thus analgesic techniques that lower opioid consumption may have a positive effect on patient outcomes. Lillemoe and colleagues[110] showed in a prospective, randomized trial that patients with nonresectable cancer of the pancreas who underwent splanchnic neurolysis lived longer than those who did not undergo neurolysis. These findings may result from lower opioid use in the neurolysis patients, who had better-preserved immune function and experienced fewer side effects (e.g. nausea and vomiting), thus allowing them to eat better. Although the study by Wong and colleagues[105] did not show that patients randomized to the neurolytic arm of the study lived longer, this may be explained by their high intake of opioids during the study period, which negated the effect of the blocks. The effects of this procedure on long-term survival will need further experimental investigation.

Superior Hypogastric Plexus Block

A variety of visceral and somatic causes can lead to pelvic pain. Such conditions may include endometriosis, inflammatory disease, postoperative adhesions, and cancer. Frequently, the pain is diffuse and vague, a condition called visceral pain and may be interrupted with a targeted sympathetic blockade. Cancer patients with extension of tumor into the pelvis may experience severe pain that is unresponsive to oral or parenteral opioids. In addition, excessive sedation or other side effects may limit the acceptability and usefulness of oral opioid therapy. Therefore a more invasive approach is needed to control pain and improve the quality of life of these patients.

Pelvic pain associated with cancer and chronic nonmalignant conditions may be alleviated by blocking the superior hypogastric plexus.[111–114] Analgesia of the organs in the pelvis is possible because the afferent fibers innervating these structures travel in the sympathetic nerves, trunks, ganglia, and rami. Thus sympathectomy for visceral pain is analogous to peripheral neurectomy or dorsal rhizotomy for somatic pain. One study[114] has suggested that visceral pain is an important component of the cancer pain syndrome experienced by patients with cancer of the pelvis, even in advanced stages. Thus percutaneous neurolytic blocks of the superior hypogastric plexus should be considered more often for patients with advanced stages of pelvic cancer.

A Japanese study group investigated 35 patients with abdominal or pelvic pain (or both) with a large visceral component. They performed three blocks at one time on all the patients: celiac plexus, inferior mesenteric, and superior hypogastric. They reported a 100% immediate success rate, with all patients' VAS pain scores dropping to zero. The statistically significant decrease in pain scores following the procedures persisted for three months. They also found a significant decrease in opiate use following the intervention that persisted for the first month.[112] This again underscores the need for selecting patients with visceral pain for neurolysis.

Clinically Relevant Anatomy

The superior hypogastric plexus (SHP) is situated in the retroperitoneum; it extends bilaterally from the lower third of the fifth lumbar vertebral body to the upper third of the first sacral vertebral body (Fig. 63.2). The plexus lies anteromedial to the psoas muscle and caudal to the bifurcation of the iliac vessel. The SHP sends out multiple branches to various smaller plexuses supplying sympathetic innervation to all the pelvic viscera except the ovaries and fallopian tubes. It extends distally as the hypogastric nerves, which form the inferior hypogastric plexus.

Available Techniques and Approaches

The technique for the blockade has been described elsewhere.[111,114,115] The patient is placed in the prone position with a pillow under the pelvis to flatten the lumbar lordosis. Two 7-cm needles are inserted with the bevel directed 45 degrees medially and 30 degrees caudad so the tips lay anterolateral to the L5-S1 intervertebral disk space. Aspiration is important to avoid injection into the iliac vessels. If blood is aspirated, a transvascular approach can be used (see the section "Complications"). Accurate placement of the needle is verified by biplanar fluoroscopy. Anteroposterior (AP) views should reveal the tip of the needle to be at the level of the junction of the L5 and S1 vertebral bodies. This is an important safety step to avoid the potential spread of

the neurolytic agent toward the L5 roots (see "Complications"). Lateral views will confirm the placement of the needle's tip just beyond the vertebral body's anterolateral margin. Injection of 3–5 mL of water-soluble contrast medium is used to verify accurate needle placement and rule out intravascular injection. In the AP view, the spread of contrast material should be confined to the midline region. In the lateral view, a smooth posterior contour corresponding to the anterior psoas fascia indicates that the needle is at the appropriate depth. For a prognostic hypogastric plexus block or patients with non-cancer related pain, local anesthetic alone is used. For therapeutic purposes in patients with cancer related pain, phenol is typically used as the neurolytic solution.

Mastering this technique is difficult because the transverse process of L5 makes it difficult to access the anterior portion of the L5-S1 region. Consequently, a transdiscal approach has been suggested (Figs. 63.22–63.24). However, this approach may be associated with the inherent risk of puncturing the intervertebral disk.[113]

More recently, an ultrasound guided anterior approach was described that permits visualization of the iliac vessels and vertebral body.[116] It may be prudent to confirm the spread of contrast dye with fluoroscopy, especially before the instillation of neurolytic solutions, when the needle was placed under ultrasound guidance.

With a curved-array transducer and the patient supine, the aorta is traced caudally until it bifurcates into the iliac arteries (Fig. 63.25). The use of color Doppler facilitates proper identification. Medial and posterior to the bifurcation, the fifth lumbar vertebral body may be visualized. The target is over the anterior and most caudal portion of the fifth lumbar vertebral body. The planning of the trajectory is based on the location of the vessels (Fig. 63.26). The area over the possible needle entry point is prepared and draped. Using sterile technique, a 22-gauge spinal needle is advanced either out of plane or in plane to the anterolateral border of the vertebral body. Following placement, it may be

prudent to confirm accuracy with digital subtraction angiography before injection of local anesthetic. The typical volume used is approximately 10 mL on each side. Neurolytic agents may be used after confirmation of pain relief with local anesthetic. Administration of antibiotics beforehand is recommended.

Indications

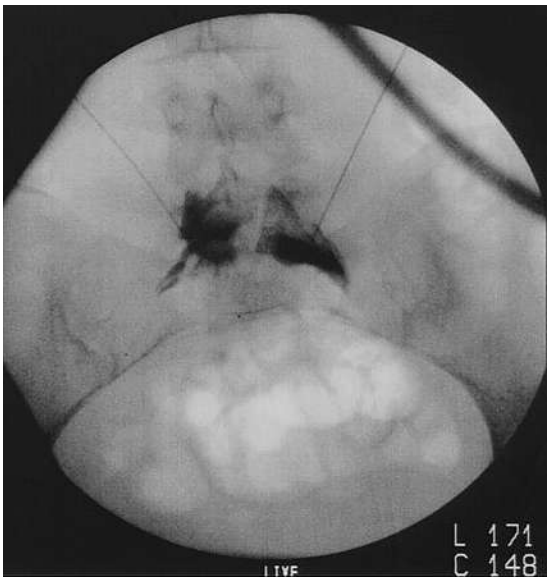
Blockade of the SHP provides relief of pain originating from pelvic viscera secondary to various types of cancer and endometriosis. Superior Hypogastic Plexus Block (SHPB) has also been reported to provide relief from postprostatectomy penile pain, urethral pain, and post-uterine artery embolization pain.[117-120]

Complications

The combined experience of over 200 cases from the Mexican Institute of Cancer, Roswell Park Cancer Institute, and M.D. Anderson Cancer Center indicates that neurologic complications have not occurred as a result of this block.[115] However, extreme care should be exercised because placing the tip of the needle in the upper middle portion of L5 may be associated with retrograde spread to the nerve roots. If such spread is not recognized, injection of the neurolytic agent could result in predictable neurologic deficits (Figs. 63.27 and 63.28).

Efficacy

The effectiveness of the superior hypogastric plexus block was originally demonstrated by a significant decrease in pain via VAS pain scores. In their study, Plancarte and colleagues[111] showed that the block was effective in reducing VAS pain scores in 70% of patients with pelvic pain associated with cancer. The majority of the patients enrolled had cervical cancer. In a subsequent study,[114] 69% of the patients experienced a decrease in VAS pain scores. A mean daily reduction in opioid use of 67% was seen in the success group (736 ± 633 reduced to 251 ± 191 mg/d) and 45% in the failure group (1443 ± 703 reduced to 800 ± 345 mg/d).[114] In a later multicenter study,[115] 159 patients with pelvic pain associated with cancer were evaluated. Overall, 115 patients (72%) had satisfactory pain relief after one or two neurolytic procedures. Mean opioid use decreased by 40% from 58 ± 43 to 35 ± 18 mg/d of morphine equivalents three weeks after treatment in all the patients studied. This decrease in opioid consumption was significant in both the success group



• **Figure. 63.27** Improper needle placement for intended superior hypogastric neurolysis. Note the spread of contrast medium to the L5 nerve root.

(56 ± 32 reduced to 32 ± 16 mg/d) and the failure group (65 ± 28 reduced to 48 ± 21 mg/d).[115] Success was defined in the two studies as the ability to reduce opioid consumption by at least 50% in the three weeks following the block and a decrease in VAS pain scores to below four of ten.[103,114]

In a case report, Rosenberg and colleagues[121] reported on the efficacy of superior hypogastric plexus block in a patient with severe chronic nonmalignant penile pain after transurethral resection of the prostate. Although the patient did not receive a neurolytic agent, a diagnostic block performed with 0.25% bupivacaine and 20 mg methylprednisolone acetate was effective in relieving the pain for more than six months. The usefulness of this block for chronic benign pain conditions has not been adequately documented.

Thus SHPB may be performed for the relief of pelvic pain under imaging guidance through either an anterior or posterior approach. The major advantage of an anterior approach is patient comfort. Although CT and fluoroscopy guided approaches have been described, they have the disadvantage of excessive radiation exposure. An ultrasound guided anterior approach may be used for needle placement with subsequent fluoroscopic contrast confirmation. The safety, reproducibility, and efficacy of this technique still need to be established.

Ganglion Impar Block

The ganglion impar is a solitary retroperitoneal structure located at the level of the sacrococcygeal junction. This unpaired ganglion marks the end of the two sympathetic chains. Visceral pain in the perineal area associated with malignancy may be treated effectively by neurolysis of the ganglion impar (Walther's).[122] Patients who will benefit from this block frequently have vague, poorly localized pain that is frequently accompanied by sensations of burning and urgency. However, the clinical value of this block is not clear because the published experience is limited.

Clinically Relevant Anatomy

The ganglion impar is an irregularly shaped terminal ganglion of the sympathetic chain that is usually located close to the midline. The variably shaped ganglion is approximately 4 mm long. It may be located anywhere from the anterior surface of the sacrococcygeal junction to the lower coccygeal vertebral bodies. The exact location follows a gaussian distribution centered on the first to second coccygeal vertebrae.[123] The ganglion impar has gray nerve fiber communication from the ganglion to the spinal nerve but appears to lack white nerve fibers, which communicate pulses from the spinal nerves to the ganglion in the thoracic and upper lumbar regions.[122] Visceral afferents innervating the perineum, distal part of the rectum, anus, distal end of the urethra, vulva, and distal third of vagina converge at the ganglion impar.

Indications

GIB is indicated for sympathetically mediated pain in the region of the anus, distal part of the rectum, urethra, and vagina. Coccygodynia following trauma, infection, degenerative changes, and subluxation has also been relieved temporarily with this block.[124-132]

Available Techniques and Approaches

The original technique was described by Plancarte and collaborators.[122] The technique calls for the patient to be placed in the lateral decubitus position with the hips fully flexed. A standard 22-gauge, 3.5 inch spinal needle is bent 1 inch from its hub to form a 30 degree angle. The needle is then introduced under local anesthesia through the anococcygeal ligament with its concavity oriented posteriorly. Under fluoroscopic guidance, it is directed along the midline at or near the sacrococcygeal junction while placing a finger in the rectum to avoid puncturing this structure. Retroperitoneal location is verified by observation of the spread of 2 mL of water-soluble contrast medium. An alternative needle geometry, in which the needle is bent to the shape of an arc, has been proposed by Nebab and Florence.[133]

An easier technique is the trans-sacrococcygeal approach (Fig. 63.29),[134] in which the tip of the needle is placed directly into the retroperitoneal space by inserting a 20-gauge, 1.5 inch needle through the sacrococcygeal ligament under fluoroscopic guidance so that the tip of the needle is just anterior to the anterior portion of the sacrum. This technique avoids invasion of more caudal structures (rectum) by the needle and the need to insert a finger in the rectal lumen.

For diagnostic blocks, local anesthetic alone is used. For neurolytic blocks, 6% phenol is recommended. Cryoablation of the ganglion impar has also been described for repeated procedures via a trans-sacrococcygeal approach in a patient with chronic benign pain after abdominoperineal resection.[135]

Technique of Ultrasound Guided Ganglion Impar Block

The patient is positioned prone with a pillow underneath the pelvis, and the hips externally rotated to provide exposure of the perineum. The skin is prepared with a suitable antiseptic solution and draped in a sterile manner. A preliminary scout scan is performed in the transverse and longitudinal views with a linear-array transducer in a sterile sleeve to visualize the sacrum and coccyx. The coccyx is then brought to the middle of the field in a longitudinal view, and a suitable trajectory is planned (Figs. 63.29 and 63.31). While keeping the coccyx in the longitudinal view, a skin wheal is raised with 1% lidocaine at the point of needle entry just caudal to the transducer. A Quincke-type spinal needle is then directed from the caudad to the anterior part of the first coccygeal vertebral body via an in plane technique with real-time visualization of the needle (Fig. 63.32). The tip of the needle may not be visualized clearly beneath the coccyx because of the acoustic shadow. Alternative methods are to use an out of plane technique for the trans-sacrococcygeal or paracoccygeal approaches. This provides a smaller trajectory, but needle visualization is poorer.

Further confirmation is provided by a lateral fluoroscopic view, which should show the needle to be suitably positioned just anterior to the coccyx and posterior to the rectum. Under fluoroscopic guidance, 0.5–1 mL of contrast agent is injected to confirm the proper spread of the dye, which appears as a "comma sign," before injecting a local anesthetic, steroid, or neurolytic substance (Fig. 63.29). Injection of a local anesthetic to confirm pain reduction before steroid injection or neurolytic intervention may be recommended. The total volume required is usually about 2–4 mL.

Efficacy

Three studies evaluated the efficacy of ganglion impar blocks in a prospective, nonrandomized, noncontrolled fashion. Plancarte and colleagues[122] evaluated 16 patients with advanced cancer (cervix, nine; colon, two; bladder, two; rectum, one; endometrium, two) and persistent pain despite treatment (pharmacologic management resulted in a 30% global reduction in pain). Localized perineal pain was present in all cases and was characterized as burning and urgent in eight patients and of mixed character in the other eight. Pain was referred to the rectum (seven patients), perineum (six patients), or vagina (three patients). Eight patients reported complete pain relief after a neurolytic block via a transanococcygeal approach, whereas the remainder experienced a significant reduction in pain (60%–90%). Blocks were repeated in two patients, and follow up was conducted for 14–120 days, depending on survival.

Swofford and Ratzman[136] reported on the efficacy of the transsacrococcygeal approach. Twenty patients with perineal pain unresponsive to the previous intervention were studied, 18 with a bupivacaine/steroid block and two with a neurolytic block. In the bupivacaine/steroid group, five patients reported complete (100%) pain relief, 10 reported a greater than 75% reduction in pain, and three reported a greater than 50% reduction in pain. Neurolytic blocks resulted in complete pain relief. Duration of the pain relief varied from four weeks to long-term.

Vranken and colleagues[137] studied the effect of a ganglion impar block for long-lasting, treatment-resistant coccydynia. Twenty patients, including 17 females and three males, diagnosed with coccydynia (spontaneous, seven; fracture, three; injury, 10) received a 5 mL injection of 0.25% bupivacaine. There was no reduction in pain or increase in quality of life associated with the procedure. Thus based on this study, it would appear that this block is not effective for the treatment of coccydynia.

Complications

Although there is always a risk of damaging structures adjacent to the ganglion impar, no complications have been reported with this technique. Plancarte and coauthors[138] reported one case in which epidural spread of contrast medium within the caudal canal was observed. In this case, repositioning the needle resolved the problem. Although published experience is limited and criteria for predicting success or failure are not available, patients with poorly localized perineal pain with a burning character are considered candidates for a ganglion impar block. The procedure is safe, and no complications have been reported.

Conclusion

Neurolysis of the celiac plexus/splanchnic nerves, superior hypogastric plexus, or ganglion impar may be used in patients with visceral pain of the upper part of the abdomen, pelvis, and perineal region, respectively. Use of this technique in patients who do not have a significant visceral pain component is not warranted. The presence of disease in the corresponding lymph nodes is a poor prognostic marker for these blocks. The incidence of reported complications is low. However, they may occur and have significant implications on the quality of life of the patient. Thus strict adherence to the technique is important to prevent potential problems.

Key Points

- Chemical neurolytic therapy should only be considered after other pain modalities have been exhausted. These therapies are usually reserved for patients with a terminal disease. Very clear therapeutic goals and limitations need to be communicated between patient and practitioner.
- Chemical neurolytics can offer patients the ability to decrease their systemic pain medications that can improve their quality of life and allow them the opportunity to communicate with loved ones during difficult times.
- Alcohol and phenol are the primary agents used in intrathecal and epidural chemical neurolysis. Alcohol is associated with burning upon injection, so it is preceded by local anesthetic injection. Phenol injection is relatively painless and is associated with a feeling of warmth. Glycerol is used or trigeminal neurolysis.

- Pain location should be pinpointed with sclerotome, dermatome mapping, and radiologic survey. For neuraxial injections, the patient's positioning for injection is determined by patient comfort and by which agent is to be injected. Alcohol is hypobaric and "floats" in CSF, whereas phenol is hyperbaric and "sinks" in CSF.
- The most common complication is poor pain relief. Often, pain relief may require several injections. Other complications related to intrathecal or epidural neurolytics are loss of motor function, loss of touch or proprioception, and loss of bowel or bladder sphincter tone.
- Neurolytic blocks of the sympathetic axis are used for the control of chronic upper abdominal and pelvic pain in patients with cancer.
- A study has shown that even in the best-case scenario, the duration of full pain control with a neurolytic block is two months.
- The goals of a neurolytic block are to maximize the analgesic effect of pharmacotherapy and reduce the dosage of these agents to alleviate side effects.
- A *stellate ganglion block* has historically been used to treat numerous pain related and unrelated conditions. Evidence of its efficacy is limited. Blind injections are inaccurate and risky. Ultrasound guidance is the preferred method to ensure accuracy and safety.
- The *celiac plexus* is situated retroperitoneally in the upper part of the abdomen at the level of the T12 and L1 vertebrae, anterior to the crura of the diaphragm. The celiac plexus is supplied by the greater, lesser, and least splanchnic nerves originating from T5 to T12.
- Three approaches to block the celiac plexus include the retrocrural (or classic) approach, the anterocrural approach, and neurolysis of the splanchnic nerves.
- An analgesic or NCPB is less effective in managing nonmalignant abdominal pain.
- Pelvic pain associated with cancer and chronic nonmalignant conditions may be alleviated by blocking the *superior hypogastric plexus*.
- A *ganglion impar block* provides relief of coccygodynia and pain involving the lower part of the rectum, anus, urethra, and vagina.
- Visceral pain in the perineal area associated with malignancy may be treated effectively by neurolysis of the *ganglion impar*.

Head and Neck Blocks

ANTOUN NADER, JEE YOUN MOON, MARY LEEMPUTTE, KENNETH D. CANDIDO

Head and neck blocks consist of blockade of the atlanto-axial joint, third occipital nerve, occipital nerve, sphenopalatine ganglion, trigeminal nerve, and glossopharyngeal nerve. This chapter will discuss the rationale for these blocks, the relevant anatomy, and the technique in performing the blocks. There has been tremendous progress in the performance of these blocks, mirroring the progress of other peripheral nerve blocks: from landmark technique to use of fluoroscopy and, recently, ultrasound. Discussion on the efficacy of many of these blocks is not complete, reflecting the state of published studies.

Atlanto-Axial Joint Blockade

The primary indication for performing an atlanto-axial (A-A) nerve block is for the diagnostic and therapeutic evaluation of suboccipital pain that occasionally radiates into the temporomandibular joint area that is exacerbated by head rotation. Whiplash injuries and cervicogenic headaches are two of the more common indications for this block. The A-A joint (Figs. 64.1 and 64.2, previously Figs. 52.1 and 52.2) lacks posterior articulations and therefore is neither a bona fide facet joint nor a true zygapophyseal joint. Furthermore, there is no intervertebral disc between the atlas (C1) and the axis (C2), nor is there an intervertebral foramen at that level to accommodate an exiting nerve root. At the A-A joint, the head flexes, extends, and rotates in a horizontal plane, up to 60 degrees, giving the joint significant responsibility for both the stability and the mobility of the head and neck. The joint can be injured by seemingly trivial insults and trauma. The resulting pain syndrome can be significant, manifesting as dull, continuous, and achy pain in the posterior neck and suboccipital region. More severe injuries, such as those caused by motor vehicle accidents, might subject the joint to acceleration-deceleration type injuries, with sequelae exceeding pain and dysfunction. Indeed, paralysis and even death could result from ligamentous disruption, analogous to an odontoid fracture. The fibers of the respective spinal nerves C1 and particularly C2 contribute to the formation of the occipital nerves (greater and lesser), which are a frequent target for the practicing pain physician in contemporary practice. An extremely important anatomic concept involves the relationship of the vertebral artery to the A-A joint; whereas the artery is medial to the atlanto-occipital (A-O) joint,[1] it is found lateral to the A-A joint. Therefore needles directed at the joint during nerve block need to be oriented slightly more medially, cognizant of the danger of aiming toward the interlaminar space or even toward the foramen magnum.

Technique of Atlanto-Axial Nerve Blockade (Figs. 64.3 and 64.4, previously Figs. 52.3 and 52.4)

Blockade of the A-A joint requires fluoroscopic assistance to ascertain that the advancing needle does not encroach upon the critical anatomical structures such as the vertebral artery and the spinal cord. Appropriate medical history is obtained, and a targeted physical examination is performed. After establishing no bleeding problems or infectious issues and baseline vital signs taken and recorded, the patient is placed prone. Baseline vital signs are obtained and recorded. It is recommended that an intravenous peripheral line be established for prophylactic purposes. Bolsters are typically placed beneath the chest to elevate the shoulders off the procedure table, permitting the patient to flex the neck and rest the forehead upon a neurosurgical donut or pillow. After performing a careful sterile skin preparation and draping, the fluoroscopic unit is oriented in an anterior-posterior direction to identify the atlas and the foramen magnum, implementing a moderate cranial tilt of the unit until all structures are clearly visualized. The A-A joint is located lateral and inferior to both the foramen magnum and the atlas (Fig. 64.2). After a local anesthetic skin wheal, an 18-gauge skin core is made using a sharp cutting needle to permit the passage of a blunt, 22-gauge, styletted Whitacre type subarachnoid needle. (A curve placed at its distal tip to allow steering of the needle once it has been advanced through the skin and subcutaneous tissues.) The needle is advanced under continuous fluoroscopic guidance, rotating the beam of the unit until the needle appears in a tunnel or "gun barrel" view, which is represented as a dot advancing toward the posterolateral aspect of the A-A joint. The needle should be directed slightly medially to avoid the vertebral artery, which is situated laterally, but not too medially, as this would potentially engage the spinal cord. Occasionally, but not always, a "popping" sensation will be appreciated as the needle traverses the joint and enters it from posterior to anterior (Fig. 64.3). The fluoroscopic unit must then be rotated laterally (Fig. 64.4) to confirm the needle placement at the appropriate depth between the atlas and axis. Once placement has been verified, gentle aspiration of the needle is undertaken to assess for the presence of cerebrospinal fluid (CSF) or blood. If CSF or blood is not present, a small (i.e. 1 mL) volume of radiocontrast media may be incrementally injected under real-time fluoroscopy. If the needle is indeed situated within the confines of the joint, a bilateral concavity will be demonstrated, which is indicative of an intact joint capsule. However, if the joint capsule has been ruptured, the dye may be seen to spread into the peridural space. Long acting local anesthetics (bupivacaine, ropivacaine) should not be injected. Rapid runoff of the dye may signify vascular injection and is to be guarded against, particularly if it is suspected that the needle may have entered the laterally situated vertebral artery. If this occurs, the needle should be redirected medially, re-aspiration of the needle in four quadrants undertaken, and re-injection of contrast material prior to considering injecting local anesthetics or adjuvants. Even without directly injecting into the vertebral artery (even minuscule volumes of dilute local anesthetics injected here can lead to grand mal seizures), ataxia following A-A block is not uncommon and is likely because of vascular uptake of local anesthetics in this extremely vascular region.[2]

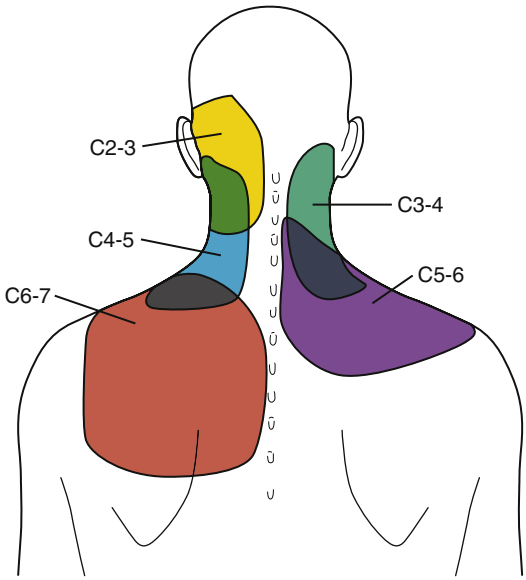
Third Occipital Nerve Blockade

Diverse pain syndromes result from disorders of the cervical intervertebral discs, the facet joints (zygapophyseal, or Z-joints), or both. When confronted by individuals with headache and neck and/or shoulder pain, the clinician is compelled to seek a diagnosis based largely upon history and physical examination. The physical examination is complicated by significant variability and overlap in the innervation patterns related to the sensory distribution of the cervical medial branch nerves (Fig. 64.5, previously Fig. 52.5). The third occipital nerve has been implicated in chronic headache pain, primarily as attributed to cervicogenic headache. There is little doubt that syndromes related to dysfunction of the medial branch nerves of the upper cervical spine have at times been misdiagnosed as being because of tension-type and other forms of headache. Consequently, these patients who have been misdiagnosed have ultimately failed to derive analgesic benefit from medication administration and other conservative treatment measures.

The third occipital nerve (TON) is the superficial branch of the C-3 dorsal ramus. It is the only medial branch nerve that



• **Figure 64.5** Map of areas invested by the sensory nerves of the cervical medial branches. (From Cooper G, Bailey B, Bogduk N. Cervical zygapophysial joint pain maps. *Pain Med.* 2007;8:344–353.)

innervates the facet joint at C2–C3 (Figs. 64.6–64.8, previously Figs. 52.6–52.8). Therefore successful blockade of the TON and the resultant block of the facet joint at C2–C3 has been associated with relief of headache pain in individuals suffering from "third occipital headache."

Anatomical Considerations

The C2–C3 joint is the first joint of the cervical spine possessing a true joint capsule and synovium, and this is the first level where an intervertebral disc and a foramen exist to accommodate the exiting C3 nerve root. In this regard, the C2–C3 joint is distinct from the atlanto-occipital (AO) (C0–C1) and atlanto-axial (AA) (C1–C2) joints superior to it. This level then represents a sort of transitional zone between the rotational joint of the neck (AA)

and the lower cervical facet joints, which function not in the neck and head rotation but in neck flexion and extension.

Facet joints contain free and encapsulated nerve endings. In addition, nerves in the zygapophyseal joint (Z-joint) contain substance P and calcitonin gene-related peptide. The capsule of the Z-joint contains low threshold mechanoreceptors, mechanically sensitive nociceptors, and silent nociceptors. Each of these may respond to noxious stimulation, including moderate to severe levels of osteoarthritis, with the result being a nociceptive stimulation perceived as headache or neck pain.

The clinical anatomy of the cervical dorsal rami was described by Bogduk following dissections of five adult cadavers.[2] He pointed out some 30 years ago that classic textbook descriptions of the cervical dorsal rami had been limited in scope and detail. While dissecting the medial branches, he was able to place wires superficially and parallel to the nerves and then perform radiographic analyses of the wires in relation to the cervical vertebral skeleton. It was noted that the semispinalis capitis muscle covers the cervical medial branches, while the lateral branches of C3-C7 lie superficial to the tendons of origin of that muscle. The TON penetrates the semispinalis capitis. The C3 dorsal ramus, a short nerve, was noted to arise from the C3 spinal nerve in the C2-C3 intervertebral foramen and then curve dorsally through the intertransverse space. At this point, the C3 dorsal ramus was noted to divide into three major branches: the two medial branches, the lateral branch, and a communicating branch. In three out of five of his specimens, the two medial branches of C3 were noted to arise from a common stem, and in the other two specimens, they had their own respective origins. The TON was the principal and constant medial branch of the C3 dorsal ramus.[2] After arising from the C3 dorsal ramus, the TON was found to curve dorsally and medially around the superior articular pillar of the C3 vertebral body, crossing the C2-C3 Z-joint either just below the joint itself or at the joint level. The TON runs transversally medially through the fibro-adipose tissue below the obliquus inferior and dorsal to the lamina of the C2 vertebra.

A branch of the TON supplies the semispinalis capitis, which lies superficial to it. A communicating branch to the greater occipital nerve (GON) is also given off. This branch arises just above the level of the C2 spinous process. The TON then passes dorsally and pierces the semispinalis capitis and the splenius capitis, turning rostrally to pierce the trapezius, which lies over it. The more medial terminal branch supplies the skin of the rostral neck and the occiput below the external occipital protuberance. More lateral branches travel toward the mastoid process, communicating with the cutaneous rami of the GON and lesser occipital nerves (LON). Because of the transverse direction of the GON and the TON, these two nerves may be injured by parasagittal incisions made in the upper part of the neck.

The target branch for the nerve block, the TON, wraps dorsally and medially around the middle of the waist of the articular pillar of C3 (center of the bony trapezoid). As it moves more medially, the TON invests the multifidus muscle. There is a communicating branch that typically arises from the C3 dorsal ramus, running rostromedially across the posterior part of the C2–C3 Z-joint.[2] The anatomic target for locating the nerve percutaneously is to utilize lateral fluoroscopy to identify the waistline of the articular pillars of C2 and C3 and to advance a needle or radiofrequency cannula toward the Z-joint at C2–C3. As Bogduk stated, "needles or electrodes introduced obliquely, ventromedially onto the dorsolateral aspect of the articular pillar, will rest on the medial branch. The relationship of the nerve to bone at this site is constant because the medial branches are bound to the periosteum by an investing fascia and are held against the articular pillar by tendons of the semispinalis capitis."[2] This target is both removed from any major arterial (vertebral artery) or other vascular structure, as well as from the exiting spinal nerve and spinal cord and is, therefore, both an appropriate target in terms of affording access to the medial branches, as well as one which provides for an approach likely to minimize unwanted trespass into non-targeted tissues.

The Third Occipital Nerve and Headache Pain

Osteoarthritis of the C2–C3 Z-joint and trauma related to motor vehicle accidents are causes of persistent occipital or suboccipital headache pain. As there is no clear-cut clinical evaluative technique or diagnostic tool for determining patients who suffer from a headache because of disease of this joint or from neck trauma (or that mediated by the TON), it is somewhat intuitive and logical that blockade of the TON should be performed in cases of persistent headache that are unresponsive to conventional medication management.[3]

Bogduk and Marsland conducted fluoroscopically guided TON blocks in ten consecutive patients presenting with occipital or suboccipital headache.[3] They elected to place their needles at the lower half of the silhouette of the C2–C3 Z-joint, recognizing the landmark on X-ray as a convexity arising upwards from the concavity of the C3 articular pillar, lying horizontally opposite the level of the C2 spinous process and C2–C3 disc space (Figs. 64.9–64.11). All procedures were performed with patients in the prone position and with a bolster beneath the upper chest and shoulders to permit head flexion forward toward the procedure table. Injected was 0.5 mL of 0.5% bupivacaine into three distinct sites; in the middle of the Z-joint at C2–C3, one injection at the lower end of the joint, and one between the first two needle placements (for bilateral blocks, the total volume was 3 mL; 1.5 mL per side). Seventy percent of patients manifest total pain relief lasting the duration of the bupivacaine following unilateral blocks.[3] The 30% failures did not have positive responses to the bilateral blocks that were performed on their behalf. Bogduk stated that blockade of the medial branch nerves, particularly the TON, is easier for patients to tolerate than intraarticular injections since they are more easily performed and are associated with less pain during their performance than are the articular injections. Furthermore, it is apparent that local anesthetic injected into a joint may not actually stay within the joint space, potentially limiting any diagnostic information that might otherwise be derived from the procedure. Finally, markedly degenerated joints might not readily accommodate an advancing needle tip, rendering the choice of this articular approach potentially useless overall.[2] If the ventral margin of the joint space is penetrated, there is also a distinct possibility that entrance into the epidural or subarachnoid spaces may occur, with potentially devastating consequences.

While no one knows for certain how likely it is that pain in the occipital and suboccipital area emanates from the C2–C3 Z-joint and while various studies show greatly disparate findings, several compelling attempts at determining the incidence (a measure of the risk of developing some new condition within a specified period) or prevalence (the total number of cases in the population, divided by the number of individuals in the population) need to be reviewed.

One such study on the role of the cervical zygapophyseal joint in neck pain involved 24 consecutive patients who presented with undiagnosed neck pain and had controlled diagnostic blocks with volume local anesthetic injections.[4] For individuals with occipital or suboccipital headache and neck pain, the lower half of the lateral margin of the C2–C3 Z-joint was selected as the injection site. Complete pain relief was considered to occur if the patients, having received the bupivacaine blocks and then going home to perform their activities of daily living, noted at least 2 h of total analgesia. Failure to derive pain relief resulted in patients undergoing additional cervical medial branch blocks at contiguous levels. Nineteen out of 24 patients had positive results, with nine

of these ultimately having pain isolated to the C2–C3 level. This would mean that in 47% of patients who had diagnostic block-proven cervical Z-joint pain, the TON was the nerve responsible for mediating the pain. Although this study has not been replicated, it is tempting to use this information as a general rule of thumb when approaching individuals with neck pain resulting from degenerative disease of the cervical spine and when planning nerve blocks based upon the correlation of symptoms with joint pain maps.[5,6] If it is known that in one-half of cases, the level responsible for a given pain problem is at the C2–C3 joint, then it might save time, expense, and patient discomfort to rapidly move toward ruling in or ruling out that level and the TON at the outset as part of the diagnostic workup. However, as noted below, these figures may be overreaching in terms of the actual prevalence of C2–C3 related pain. While TON block may be performed easily and simply and typically is done with little likelihood of encountering significant complications, side effects do occur commonly. Indeed, any patient presenting for this type of procedure must be duly apprised that successful blockade of the TON (or GON) will likely result in the temporary development of ataxia and some gait unsteadiness. For this reason, bilateral blocks at these levels should likely either be staggered, or else the benefit/risk ratio must be significant enough that performing bilateral blocks is warranted.

The subject of joint pain maps merits special mention, as noted above (Fig. 64.5, previously Fig. 52.5). Multiple attempts have been made to delineate the specific cutaneous area of sensation, and hence pain, invested by each respective facet joint and medial branch.[5-9] In the report by Fukui et al.[8] the site of Z-joint intraarticular injection and electrical stimulation (selected cases) was chosen based upon any focal paraspinal tenderness. They observed that with injections performed at C2–C3 (n = 14), symptoms were referable to the upper posterior cervical region (64%), the occipital region (50%), and/or the upper posterolateral cervical region (50%).[8] Windsor et al.[9] electrically stimulated the cervical medial branches, including the TON in nine patients suffering from chronic neck pain. They used the lateral mid-point of the C2–C3 Z-joint to indicate the location of the TON. Relatively reproducible referral patterns were identified for the TON nerve distribution as well as for the other medial branch nerves studied.[9]

However, what is immediately obvious when reviewing these studies is that there is considerable overlap in the areas served by each of the respective segments, much more so than that observed with attempts at mapping spinal nerve dermatome distributions. This produces a diagnostic conundrum, as it is entirely conceivable when approaching cervical spine pain that even perfectly performed techniques, using standardized and accepted anatomical landmarks, may result in failures to derive anti-nociception with the resultant confusion on behalf of the patient and treating physician.

Since both the intervertebral disc and facet joint are fairly equivalently represented as sources of neck pain (approximately 40% each as sources of neck pain, according to two separate studies), a missed diagnosis might lead a pain physician in the wrong direction when seeking to provide pain relief to a given individual.[10,11] Mapping studies may help pinpoint discrete areas of pain referral sources that are then amenable to local anesthetic blockade and/or radiofrequency lesioning techniques. In one such study, joint maps were created by distending the respective joint capsules at segments from C2–C3 to C6–C7. This was done by sequential injections of contrast media, which could be subsequently identified using fluoroscopy. Each joint was noted to produce a characteristic, distinguishable pain pattern from which pain charts could be constructed (Fig. 64.5, previously Fig. 52.5).[6] Although only four total subjects comprised this evaluation, that number is not too disparate from the original small group of subjects selected to develop the original dermatome charts in neurologically impaired individuals, which has persisted, largely unchallenged, for more than six decades.[12] In 10 subjects who received injections based upon maps such as those derived and described above, 90% had complete concordance of the predicted pain level and the positive response to the blocks.[7] The C3–C4, C4–C5, and C5–C6 levels were most commonly affected, with only 10% (1/10) of patients having pain that was documented to result from processes occurring at the C2–C3 (TON) level. Therefore these percentages are less indicative of the possibility of the C2–C3 level being primarily involved in head and neck pain than they are of alternative levels lower in the cervical spine. However, a study by Barnsley and Bogduk from 1993 demonstrated that, following cervical medial branch injections performed in 16 patients suffering from chronic neck pain, 33% (3/9) patients who had complete pain relief were patients for whom the TON was treated.[13] Thus it remains unclear how likely the TON is to be implicated in individuals suffering from chronic head and neck pain. The closest studies performed to identify the prevalence of TON induced headache and neck pain may have been those performed by Lord and Barnsley et al.[14,15] In the first study, 100 consecutive patients underwent double blind, controlled diagnostic blocks of the TON. On two separate occasions, the nerve was blocked using either lidocaine or bupivacaine. The diagnosis of TON nerve involvement was only made if the double diagnostic blocks both relieved the symptoms, with the bupivacaine injection-induced pain relief outlasting that provided by the lidocaine. The prevalence of TON headache in chronic neck pain following whiplash was found to be 27%, while the prevalence of TON headache after whiplash was noted to be 38%.[14]

In the second study, 50 consecutive patients with chronic neck pain and whiplash injury underwent double blind, controlled diagnostic medial branch blocks using 0.5 mL lidocaine (2%) or bupivacaine (0.5%) randomly. In 12/27 patients (44%), the source of symptoms was identified as being isolated primarily to the C2–C3 Z-joint.[15]

These findings corroborate the impression that although there may be substantial overlap in cutaneous innervations of the central and peripheral nervous systems, these joint maps are essential tools to assist one in determining the appropriate approach to a given pain process in any individual. They also demonstrate variability in assessing the relative incidence and relative prevalence of C2–C3 Z-joint pain, depending upon technique of assessment and use of varying provocation maneuvers to assess the joint and the medial branch nerve (TON).

Rationale for Blocking the Third Occipital Nerve

The TON block is useful in both the diagnostic as well as the therapeutic phase of treating cervicogenic headaches. Evidence of efficacy for both local anesthetic blocks as well as for radiofrequency ablation (RFA) of the cervical medial branches has accrued over the past several decades. Nevertheless, it is only relatively recently that the use of medial branch nerve blocking techniques and RFA techniques have received scientific support in the literature. Indeed, two separate attempts at meta-analysis have shown somewhat disparate results. The first such paper, published in 2001, suggested that radiofrequency neurotomy used for treating pain from the cervical Z-joints after flexion-extension injury was only supported by limited scientific data.[16] However, a mere six total studies satisfied the authors' criteria for inclusion; thus it is entirely possible that the data suffer lack of suitable cohort studies to make a true assessment of its validity. The second review performed in 2007 liberalized the inclusion criteria somewhat and found that the support for medial branch cervical block was moderate (Level III), as was the support for cervical medial branch neurotomy.[17] Here, the authors relied upon the Agency for Healthcare Research and Quality criteria, which included some non-randomized trials. They also incorporated studies from the Cochrane Musculoskeletal Review Group, which were randomized trials. One of the important points noted was that the evidence for performing cervical intraarticular facet joint injections was limited both for short-term as well as for long-term analgesia efficacy. This corroborates Dr. Bogduk's earlier assertions that not only are medial branch techniques more likely to target the real source of pain associated with cervical degenerative facet conditions but also that articular procedures have an inherently high failure rate since there is no guarantee that injected local anesthetic will remain in the confines of the joint (see above).

The rationale for blocking the TON is two-fold:

1) To provide a diagnostic evaluation of the C2-C3 facet joint as the source of pain in the occipital and suboccipital areas.
2) To provide an indication as to whether or not neuroablative techniques applied over that nerve might be fruitful in treating pain on a long-term basis.

The present authors suggest performing double diagnostic blocks using 0.5 mL of local anesthetic solutions, typically 0.5% ropivacaine plain, before undertaking neurotomy of the TON. Ropivacaine is used for two major reasons. It has intrinsic vasoconstrictor properties, and therefore no epinephrine is necessary. It also has a cardiovascular safety profile superior to bupivacaine and poses a less theoretical risk for use in outpatient procedures. Unintentional injection into vascular structures, including the vertebral artery, is less likely to result in serious morbidity when ropivacaine is used, in contradistinction to bupivacaine. Ropivacaine also provides a duration of analgesia that exceeds that provided by shorter acting agents such as lidocaine or mepivacaine. Regarding assessing efficacy, it is likely that longer acting amino-amide local

anesthetics may provide greater information than shorter acting drugs since the effect of the shorter acting drugs may be so fleeting as to provide confusing or inexact clinical information. However, whether or not this is true remains the subject of some clinical controversy.

Double diagnostic blocks have been described for assessing the efficacy of cervical medial branch blocks.[18] Barnsley et al. compared single versus double diagnostic blocks in 55 adult patients having neck pain for longer than three months. They randomly used 0.5 mL of either 0.5% bupivacaine or 2% lidocaine. The duration of analgesia was assessed in a double blind fashion. They found that the false positive rate (a test result that is read as positive but actually is negative; a test that shows evidence of a disease when it is not present) of single-blocks was 27% (16/60).[18] They also found that the most common positive levels were at C2–C3 and C5–C6.[18] Lord et al. found that comparative blocks of the medial branches using either lidocaine, bupivacaine, or normal saline in randomized, double blind, placebo-controlled fashion in 50 patients had a specificity (the statistical probability that an individual who does not have the particular disease being tested for will be correctly identified as negative, expressed as the proportion of true negative results to the total of true negative and false positive results) (TN/TN + FP) of 88%, but only marginal sensitivity (the proportion of individuals in a population that will be correctly identified when administered a test designed to detect a particular disease, calculated as the number of true positive results divided by the number of true positive and false negative results) (TP/TP + FN) (54%).[19] Hence some of the 46% of patients who are not placebo responders would incorrectly be labeled as placebo responders if diagnoses were based solely upon comparative blocks.[19]

Slipman et al. retrospectively reviewed 18 patients with chronic persistent daily headaches lasting a mean of 34 months following whiplash injury who underwent intraarticular C2–C3 facet joint injections.[20] They noted that in 61% of cases, headache frequency diminished from daily to less than three headaches/week. Although this work is retrospective, the results nevertheless demonstrated further rationale for targeting the TON in chronic headache conditions refractory to conventional conservative care and management. Furthermore, since the injections were articular and not at the medial branch (TON), the information gleaned from this report may not be useful in determining candidacy for radiofrequency neurotomy.

Technique for Third Occipital Nerve Block

C2–C3 medial branch (TON) procedures are usually performed with the patient in the prone position using continual live fluoroscopic guidance throughout the injection phase (Figs. 64.9–64.11, previously Figs. 52.9–52.11).[21] A bolster is placed beneath the shoulders and chest to elevate the thorax off of the table and to permit gentle head and neck flexion forward. An intravenous cannula is placed, and vital signs are monitored using standard American Society of Anesthesiologists (ASA) basic monitors. After performing a sterile skin preparation, scout films are obtained of the neck, seeking to identify the scalloped margins of the lateral vertebral bodies. Then, skin wheals are raised over the intended target(s) using a hypodermic needle and 1–3 mL of lidocaine. Using short-beveled, 22-gauge, 2.5–3.5 inch needles, the targeted lateral scalloped margins of the vertebral bodies are advanced upon until bony contact is made. At this point, the fluoroscopy unit is rotated laterally to assess the relationship of the advancing needle tip to the TON target in the center of the C2–C3 Z-joint (see above). The needle tip must be recessed posteriorly away from the C2–C3 intervertebral foramen as well as from the known location of the vertebral artery. If no bony contact has been made and 2 cm of the needle has been placed into the skin, then a reassessment of the approach and direction is undertaken while still in the A-P fluoroscopy mode. Once the needle is appropriately seated on the bone at the target (Fig. 64.4, previously Fig. 52.4), the A-P view is once again undertaken to verify that the needle(s) is in the correct position vis-à-vis the lateral vertebral body margin.

Ultrasound guided approaches are rapidly gaining in popularity for all forms of interventional pain procedures, but most clinicians have not yet reached the level of sophistication to supplant fluoroscopy use for this particular procedure. At this point, aspiration tests are performed to verify the absence of blood or cerebrospinal fluid, and the patient is queried to ascertain that no paresthesia has been elicited. If there are none and vital signs remain stable, 0.5 mL of 0.5% ropivacaine is injected. No glucocorticoid is added to the solution, as Manchikanti et al.[22] have demonstrated little if any value of adding steroid to the blocks. While this one study demonstrated no added benefit of corticosteroid use in diagnostic/therapeutic cervical medial branch injection versus not using steroids, many clinicians continue to employ them in daily practice. It can only be stated that this is an area of some controversy, and if the risk-benefit ratio favors using steroids in a given individual suspected of having an inflammatory component to their pain, then there may be little harm in employing them in judicious doses. After completing the injection phase, the needle(s) is cleared and withdrawn, and a sterile dressing is applied over the injection site. The patient should be observed for no less than 30 min as it is quite common that most patients will become ataxic or unsteady of gait following successfully performed procedures. Discharge instructions should be clear and precisely instruct patients to seek emergency medical care if they develop any delayed onset side effects or complications from the procedure, as unlikely as that may be.

Radiofrequency Neurotomy

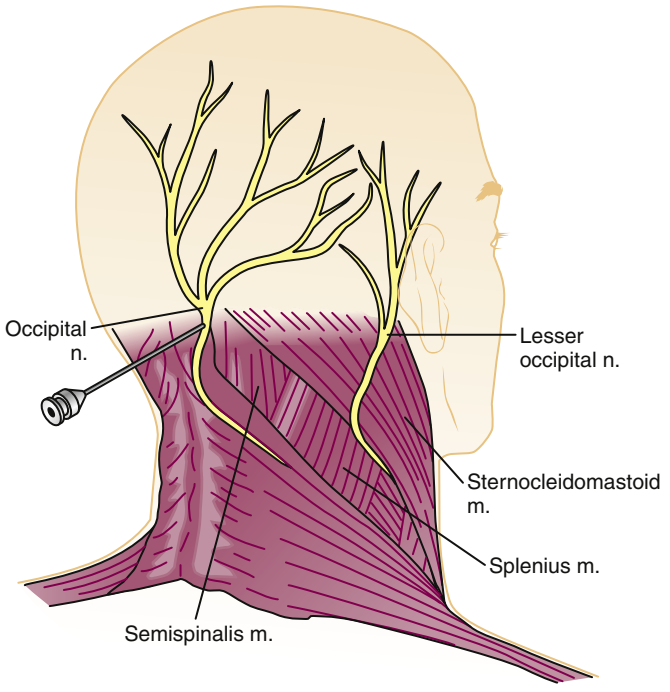
In selected patients, radiofrequency of the TON may be considered for long-term therapeutic benefit. In a study published in 1995, Lord et al. demonstrated the efficacy of performing RFA of the TON in only 40% of patients (4/10), with only three having long-lasting pain relief.[23] They used 10 cm needles with either 4 mm or 6 mm exposed tips. No stimulation test was performed to assure concordance of needle placement with the nerve. Instead, the authors relied solely upon fluoroscopic anatomic cannula placement. The mean duration of the C2–C3 neurotomy procedure was stated to have been 1.5 h.[23] The rather meager success rate was in sharp contrast to the 70% success they noted for lower cervical medial branch procedures. The authors stated that radiofrequency of the cervical medial branches "carries a high rate of technical failure."[23] In 1996 Lord et al.[24] suggested that RFA of the cervical medial branches, performed in 24 patients with a median duration of pain of 34 months following motor vehicle accidents, provided a median duration of analgesia persisting 263 days. This contrasted sharply with the median analgesia of eight days in a control group of patients. However, they excluded individuals with C2–C3 Z-joint pain based upon their rather dismal results from the previous study noted above. In a subsequent study published by the same group of investigators, complete pain relief was found in 71% of 28 patients following

a single RF procedure, persisting a mean duration of 219 days. When failures were excluded from consideration, the mean duration extended out to 422 days (60 weeks).[25] Again, excluded from the study were individuals suffering from TON-mediated C2–C3 pain. Govind et al. in 2003 used three large gauge electrodes to perform RFA procedures of the TON. Following controlled diagnostic blocks, 51 nerves in 40 patients were treated with RFA. Eighty-eight percent (43/49) achieved successful outcomes using this approach, with a median duration of 297 days (42 weeks). Side effects included ataxia, stated to be "slight" numbness, and temporary dysesthesias.[26] Their improved success was attributed to the use of three needles, the use of Ray electrodes instead of SMK electrodes (smaller), and the assurance that each of the three lesions was made at a distance no greater than one electrode width from an adjacent lesion.[26]

Cohen found that the only factor predicting the success of RFA, defined as at least 50% pain reduction lasting at least six months, was paraspinal tenderness.[27] Although the authors state that C2–C3 pain was included in this analysis, they never indicated how many individuals were treated this way nor what the success rate was for TON RFA.

Greater and LON Blockade (Figs. 64.12 and 64.13, previously Figs. 52.13 and 52.14, and Fig. 64.14).

The GON arises from the dorsal primary rami of C2, with occasional contributions from C3. The nerve penetrates the fascia inferior to the superior nuchal crest, where it runs alongside the occipital artery for a variable distance. The sensory area innervated by the nerve includes the medial portion of the posterior scalp, with radiation ventrally up to the vertex. The LON arises from the ventral primary rami of C2 and C3 and passes superiorly and laterally from the occiput to the lateral edge of the sternocleidomastoid muscle. Here the nerve divides into cutaneous branches that innervate the lateral portion of the posterior scalp and the cephalad surface of the ear pinna. Along with the great auricular nerve,



• **Figure 64.12** The anatomy and site of nerve blocking for the greater occipital nerve.

• **Figure 64.14** Schematic anatomy of the nerves in the occipital area. *GON,* Greater occipital nerve; *LON*, lesser occipital nerve; *TON,* third occipital nerve.

the GON and LON provide most sensory afferent information for the occipital area and are responsible for transmitting information derived from C2-C3 facet joint derangements to the referral area described.

Occipital nerve blocks have become an increasingly popular method of managing headaches of diverse etiologies, even though the scientific support for doing so is limited. GON blocks have been shown to be ineffective for chronic tension-type headache when prilocaine and dexamethasone were used in a group of 15 patients.[28] They have been used with various degrees of success for postconcussive headaches[29] (80% successful in then patients), atypical orofacial pain,[30] and especially for migraine headaches,

when they are often combined with trigger point injections,[31] or supraorbital nerve blocks,[32] in both cases affording a very high degree of success for ameliorating pain and brush allodynia. A novel use of GON block has been in the successful treatment of patients with abnormal head movements who also suffered from tinnitus and dizziness associated with a previous history of trauma.[33] Further, the injection of botulinum toxin type A (50 units) was suggested to be more effective than the use of bupivacaine in reducing short-term and long-term pain in patients with chronic headache in the occipital area. Although often, the diagnosis of headache because of occipital neuralgia is not too difficult to make,[34] there are cases of refractory headache that require advanced evaluation techniques. Although some suggest performing computed tomography (CT)-guided C2–C3 nerve blocks as a prelude to considering patients who may be candidates for percutaneous rhizotomy,[35] fluoroscopically guided techniques of C2–C3 nerve block have been used and have precluded the requirement to seek more advanced imaging for guidance (Figs. 64.8 and 64.9). Besides, ultrasonography has recently become a more popular image modality for the occipital nerve block at the upper part of the posterior neck, which is named the proximal approach.

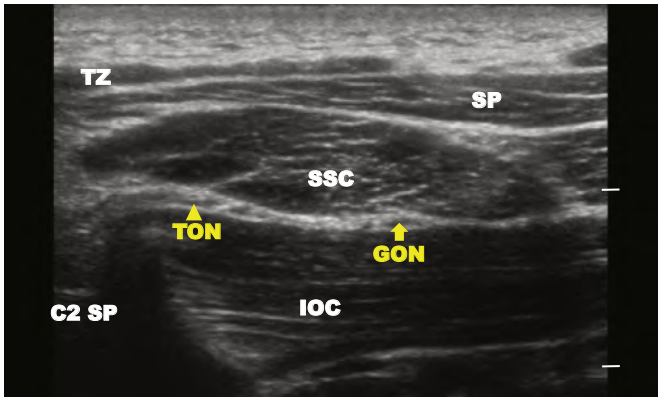
Technique of Blocking the Greater and Lesser Occipital Nerves

Some have erroneously described occipital nerve blocks as merely a field block of local anesthetic and steroid layered somewhere in the posterior part of the occiput, without regard to anatomic landmarks or consequences of errantly placed medications. Indeed, there are cases of sudden unconsciousness reported following LON block, some resulting from occipital artery injection and at least one the result of unintentionally injecting local anesthetic into a previous bone defect from a craniotomy.[36] In addition, it is possible that unconsciousness might occur after the GON block has been made too far inferiorly toward the foramen magnum. Additionally, if practitioners are not careful and discriminating in their choices of frequency of GON block and use judicious doses of agents, including corticosteroids, additional complications like the development of Cushing syndrome may result.[37] Our technique of blockade of the occipital nerves is to perform the procedure with the patient in the sitting position, with the forehead forward, resting on either a Mayo stand, the edge of a padded table, or on a gurney. If possible, the occipital artery is palpated at the superior nuchal ridge. Using ultrasound guidance may help identify the artery, which is often not robust or bounding and, subsequently, not always readily discernible as a distinct structure. As it is virtually impossible to completely disinfect the scalp injection site, we utilize alcohol wipes or a Betadine-soaked pledget to soak the area with a disinfectant prior to inserting the needle, without expectations of complete asepsis. Next, we insert a fine-gauge (25-gauge, 1.5 inch) cutting needle immediately medial to the artery and advance it perpendicular to the skin until the needle tip touches the periosteum (Fig. 64.14). Once the occipital bone has been contacted this way, the needle is retracted about 1 mm and is redirected slightly cephalad. After gently aspirating, 5 mL of local anesthetic (0.5% bupivacaine or ropivacaine) with 4 mg of dexamethasone or 6 mg of betamethasone is injected in a fan-like manner, taking care not to direct the needle too far medially toward the foramen magnum. The LON may be blocked, as can the greater auricular nerve, by removing the needle and placing it into the skin about 3–4 cm lateral to the entry point for GON block, while also directing it inferiorly instead of superiorly as for GON block (Fig. 64.14). After gentle aspiration, 5 mL of the same combination of local anesthetic with or without corticosteroid as noted previously may be injected, again in a fanlike distribution, to block the nerve. After completing GON and LON blocks, it is important to gently massage the tissues of the scalp to assist in the spread of the agents while maintaining pressure over the injection site(s). This will minimize ecchymosis or hematoma formation from this highly vascular area. Often, an ice pack is applied for 20–30 min post-procedure to further minimize swelling and inhibit vascular absorption of the local anesthetic agents, particularly if bilaterally blocks have been performed.

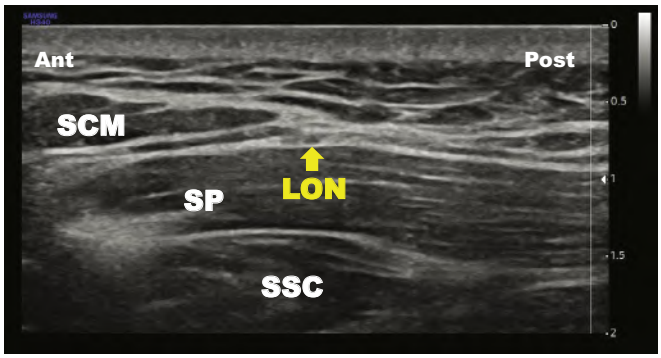
Ultrasound Guided Proximal Approach for the Greater and Lesser Occipital Nerve Block

For ultrasound guided GON block, the patient is asked to be in a prone position with the neck flexed. The first key ultrasonography landmark is the bifid C2 spinous process, where the inferior oblique capitis muscle originates. The linear probe must be located obliquely from the bifid C2 spinous process to the C1 transverse process, where the inferior oblique capitis muscle inserts (Fig. 64.14). The GON is typically identified lying superficial to the inferior oblique capitis muscle and beneath the semispinalis capitis muscle (Fig. 64.15). In this ultrasound image, the third occipital nerve is detected medially to the C2 bifid spinous process. A 22- to 25-gauge, 1.5–3.5 inch needle is introduced from lateral to medial to avoid piercing the tight trapezius fascia via an in-plane approach under real-time ultrasound guidance. While advancing the needle from superficial lateral to deep medial direction, the vertebral artery should not be injured, which is located deeply and medial to the inferior oblique capitis muscle. The needle tip should be visualized in the fascial plane between the inferior capitis and semispinalis capitis muscles. After gentle aspiration, the combination of local anesthetic with or without corticosteroid, as noted previously, may be injected under real-time ultrasound guidance.

For ultrasonography guided LON block, the patient is asked to be in a lateral position. The LON emerges from the superficial branches of the cervical plexus (from ventral rami of C2 and



• **Figure 64.15** Oblique ultrasonography image at the posterior neck for the proximal approach of the GON block. The probe is located between the C2 spinous process and the C1 lateral mass. The greater occipital nerve is detected at the superficial fascial layer of the inferior oblique capitis muscle. *C2 SP*, Spinous process of the C2 spine; *GON*, greater occipital nerve; *IOC*, inferior oblique capitis; *SP*, splenius capitis; *SSC*, semispinaliscapitis; *TON*, third occipital nerve; *TZ*, trapezius.



• **Figure 64.16** Transverse ultrasonography image at the posterior lateral neck. The lesser occipital nerve emerges from the superficial cervical plexus at the upper and posterior margin of the sternocleidomastoideus muscle. *Ant*, Anterior; *LON*, lesser occipital nerve; *Post*, posterior; *SCM*, sternocleidomastoideus; *SP*, splenius capitis; *SSC*, semispinalis capitis.

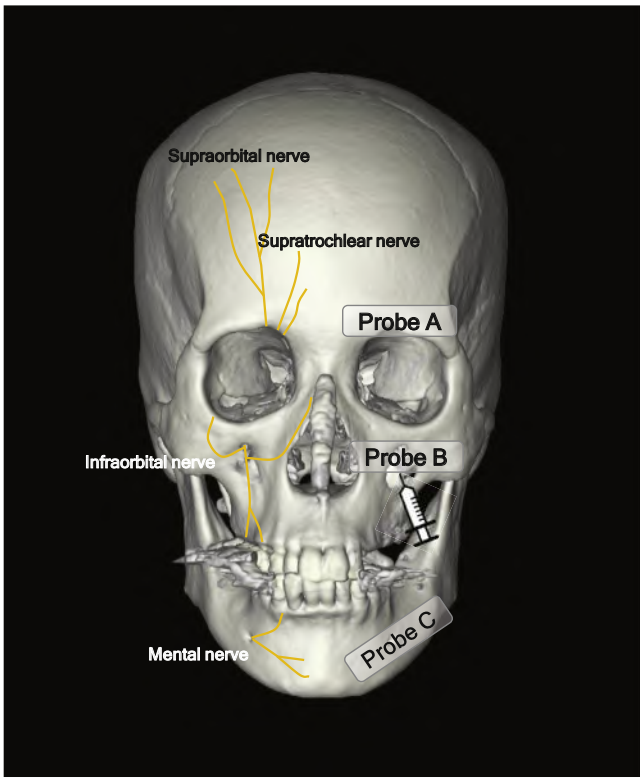
C3). Therefore the first step begins with obtaining the transverse image at the posterior border of the sternocleidomastoid (SCM) muscle, which is seen caudally to the mastoid process. By moving the high-resolution linear probe cranially and caudally along the posterior border of the SCM muscle, the LON is identified as a small hypoechoic oval-shaped structure, which has emerged from the superficial cervical plexus beneath the upper part of the SCM muscle (Fig. 64.16) and runs upward to the lateral occiput. The 25-gauge, 1.5 inch needle is advanced from posterior to anterior (or anterior to posterior) via an in-plane approach. The needle tip should be visualized above the superficial fascial layer of the SCM muscle. After gentle aspiration, the combination of local anesthetic with or without corticosteroid, as noted previously, may be injected under real-time ultrasound guidance.

Facial Pain Nerve Blockades

Supraorbital, Infraorbital, Mental Nerve Blocks (Figs. 64.17 and 64.18)

Peripheral branches of the trigeminal system may be readily accessible through percutaneous needle techniques.

Supraorbital nerve block is useful in the treatment of painful conditions of the frontal nerve, a branch of cranial nerve V1. The nerve leaves the superior orbital fissure to enter the orbit, passing ventrally under the periosteum of the roof of the orbit. The frontal nerve gives off two corollary branches: the supraorbital and the supratrochlear nerves. The supraorbital nerve is larger and more laterally situated than the supratrochlear nerve, and it supplies sensory fibers to the forehead, upper eyelid, and anterior scalp. The nerve is typically blocked by injecting a small volume of dilute local anesthetic, with or without corticosteroid added, into the supraorbital notch (foramen). A 22- to 25-gauge, 1.5 inch needle is typically employed for the block, which is readily accomplished once the notch is palpated and after a sterile skin prep is performed. The goal of needle insertion is to avoid placing the needle tip through the notch, which would assuredly elicit paresthesia of the supraorbital nerve as it pins the nerve against the periosteum. It is more desirable to guide the needle toward the foramen, and, once periosteum is contacted, the needle should be slid slightly medially so that its tip is abutting the rim of the foramen. Following a negative aspiration, 3–4 mL of local anesthetic with 2 mg of dexamethasone

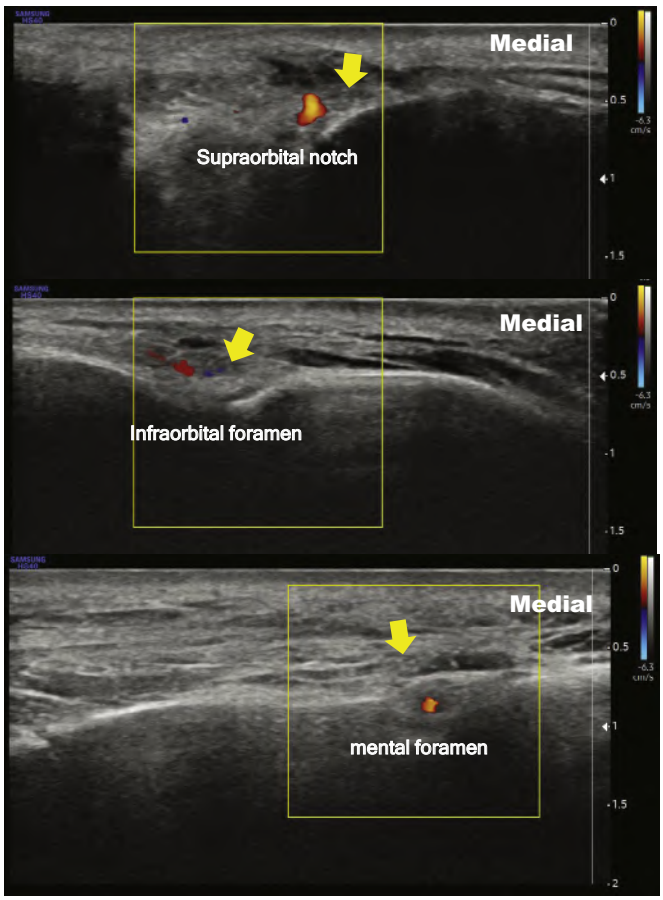


• **Figure 64.17** Schematic anatomy of the nerves on the face and the locations of the transducer (probe) to block each branch.

or 6 mg of betamethasone may be incrementally injected. The needle should be flushed and withdrawn, and a dressing should be applied over the injection site. Supraorbital nerve block has been successfully employed in the treatment of hemicrania continua.[38] Supratrochlear nerve block may be performed at a point slightly medial to the insertion site described earlier for supraorbital nerve block, using the same needle type and volumes and concentrations of local anesthetics and adjuvants. The indications, contraindications, complications, and side effects of this block are virtually identical to those mentioned above.

For the ultrasound guided supraorbital nerve block, the patient is asked to be in a supine position. A target point is usually at 1/3 of the ipsilateral supraorbital margin, where the supraorbital notch could be identified. Using the 6–13 MHz linear transducer, a transverse image is obtained by gently adjusting and tilting the transducer up and down around the eyebrow, whereby the supraorbital notch is revealed on the ultrasound image (Fig. 64.18A). The supraorbital nerve emerges from the superficial notch with the supraorbital artery when the power Doppler mode is used. A short length of needle can be introduced using an out-of-plane or an in-plane approach. After gentle aspiration, the combination of local anesthetic with or without corticosteroid, as noted previously, may be injected under real-time ultrasound guidance.

Infraorbital nerve block is used to block the peripheral contribution of the maxillary nerve, typically affected by conditions of chronic facial pain such as those resulting from complex regional pain syndrome and occasionally herpes zoster. The infraorbital nerve enters the orbit via the infraorbital fissure and passes along the floor of that structure in the infraorbital groove. It exits the skull through the infraorbital foramen, innervating the lower eyelid, lateral nose, and part of the superior lip. A branch of the nerve,



• **Figure 64.18** Transverse ultrasonography images of the trigeminal nerve branches. **Upper** (Probe A)**.** The supraorbital artery *(red)* and nerve *(yellow arrow)* emerge from the supraorbital notch. **Middle** (Probe B)**.** The infraorbital artery *(red)* and nerve *(yellow arrow)* emerge from the infraorbital foramen. **Lower** (Probe C). The mental nerve *(yellow arrow)* emerges from the mental foramen with the inferior alveolar artery *(red)*.

the superior alveolar nerve, innervates the upper incisors, canine, and contiguous soft tissue.

Infraorbital block is performed with the patient in the supine position and the head maintained in a neutral position. The infraorbital foramen is palpated, and a mark is placed over it using a marking pen. A sterile skin prep is performed, after which a fine-gauge (25- or 27-gauge) 1.5-inch needle is advanced into the foramen while maintaining a slight medial direction of the advancing needle tip. This maneuver minimizes the pinning of the infraorbital nerve against bone and potentially traumatizing the nerve. Even taking such precautions, the nerve may be stimulated, resulting in paresthesia to the teeth or lateral naris. After aspirating for the presence of blood, a small volume (3 mL) of local anesthetic, with or without a nonparticulate corticosteroid, is incrementally injected. After clearing the needle, it is withdrawn, and a small bandage is applied over the injection site. The patient should be observed for 20 min and examined for an expanding hematoma of the face, which, if present, is usually readily treated with pressure and occasionally with an ice pack.

For ultrasound guided infraorbital nerve block, a transverse image is obtained to identify the infraorbital nerve exiting from the infraorbital foramen (Fig. 64.18B). The infraorbital nerve emerges from the foramen with the infraorbital artery when the power Doppler mode is used. Because the axis of the infraorbital foramen is oriented caudally and medially, a lateral to medial approach is recommended to reduce the risk of penetration of the foramen. The short length of the needle can be introduced in the lateral to medial direction using the in-plane approach to target the infraorbital nerve. After gentle aspiration, the combination of local anesthetic with or without corticosteroid, as noted previously, may be injected under real-time ultrasound guidance.

Inferior Alveolar (Mental) Nerve Block

The inferior alveolar nerve is a distal branch of the mandibular nerve. The nerve exits the mental foramen at the level of the second molar tooth, having divided into an incisor branch and a mental branch. After exiting the foramen, the nerve sends a ramus superiorly, innervating the lower lip, inferior oral mucosa, and the chin (mental branch). This nerve block has been used in the treatment of mental neuralgia, facial herpes zoster, and cases of trigeminal neuralgia (TGN) of the V3, where the nerve is readily accessible for cryolesioning.[39] There is both an extraoral and an intraoral technique of mental nerve block. The intraoral technique is less painful for patients and provides a similar degree of successful block than the latter agent.[40] When evaluated in 123 patients using a standardized alveolar nerve block method, the block provided analgesia/anesthesia to the first molar (92%), first premolar (55.3%), and canine (38.2%) teeth of the lower jaw.[41] Additionally, levobupivacaine 0.5% with epinephrine 1:200,000 (5 μg/mL) was shown to be equipotent and equally effective to the same concentration and dose of bupivacaine when used for inferior alveolar nerve block. Because of its inherent reduced systemic and cardiac toxicity, levobupivacaine may replace the latter agent for peripheral nerve blocks of the trigeminal system.[42]

Inferior alveolar nerve block is performed with the patient in the supine position and the head maintained in a neutral position. After palpating the mental foramen and performing a sterile skin prep, a small (25- or 27-gauge) 1.5 inch needle is advanced toward the foramen using a slight medial approach, as noted earlier for infraorbital nerve block, to minimize the likelihood of pinning the exiting nerve against periosteum. Using the 6–13 MHz linear transducer, a transverse image shows the mental nerve exiting from the mental foramen with the inferior alveolar artery when the power Doppler mode is used (Fig. 64.18C). Paresthesia may nevertheless be obtained while performing the needle insertion, and patients need to be appraised of this possibility. After a negative aspiration test, 3 mL of local anesthetic with or without a nonparticulate corticosteroid are incrementally injected using a blind technique or under real-time ultrasound guidance. The needle is cleared and withdrawn, and a small bandage is applied over the injection site. The patient should be observed for approximately 20 min to guard against the development of a hematoma, which is typically amenable to compression or the application of an ice pack.

Sphenopalatine Ganglion Blockade

The sphenopalatine ganglion (SPG) is also referred to as the pterygopalatine ganglion, nasal ganglion, or Meckel's ganglion. It represents the largest collection of neurons outside of the brain and inside the calvarium. It has long been targeted for its role in the generation of trigeminal autonomic cephalgia. This broad term includes cluster headaches, paroxysmal hemicrania, and short-lasting unilateral neuralgiform headache attack with conjunctival injection and tearing (SUNCT). The SPG contains

both sympathetic and parasympathetic pathways, dysfunction of which can cause acute migraine headaches, posttraumatic headaches, and facial neuralgias, including Sluder's, Vail's, and Gardner's syndromes.[43–45] In addition, irritation of the SPG may also result in facial and neck pain because of its connection with the facial nerve, lesser occipital nerve, and cutaneous cervical nerve. The superior cervical ganglion connects to the SPG through the sympathetic trunk, explaining its role in treating head, face, neck, and upper back pain.[46]

The ganglion resides in the pterygopalatine fossa. The fossa is bordered anteriorly by the maxillary sinus, posteriorly by the medial pterygoid plate, medially by the palatine bone, and superiorly by the sphenoid sinus. The pterygomaxillary fissure allows passage of a needle into the fossa, whereas the pterygopalatine foramen is medial to the ganglion and posterior to the middle turbinate. The fossa is approximately 1 cm wide and 2 cm high and resembles a V-shaped vase on a lateral fluoroscopic image. The SPG is covered by a 1–1.5 mm thick layer of connective tissue and mucous membrane and is approximately 5 mm in size and triangular in shape. A large venous plexus overlies the fossa. Foramen rotundum and the pterygoid canal are located on the superolateral and inferomedial aspects of the fossa, respectively. The maxillary artery resides in the fossa. The ganglion is "suspended" from the maxillary nerve by the pterygopalatine nerves and is medial to the maxillary nerve. Posteriorly the ganglion is connected to the vidian nerve, which is formed by the deep petrosal (sympathetic from the upper thoracic spinal cord) and greater petrosal (parasympathetic from the superior salivatory nucleus) nerves. The ganglion has efferent branches and forms the superior posterior lateral nasal and pharyngeal nerves. Caudally, the greater and lesser palatine nerves exit the ganglion. Sensory fibers arise from the maxillary nerve, pass through the SPG, and innervate the upper teeth, nasal membranes, soft palate, and some parts of the pharynx. A small number of motor nerves are believed to travel with the sensory trunks.

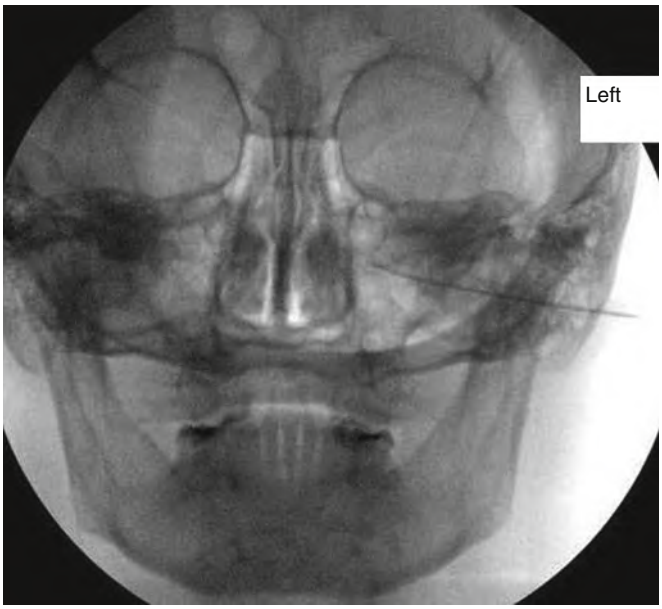
Nerve Block Techniques

There are several techniques to block the SPG, one of which is the topical application approach. With the patient in the supine position and the head maximally extended, as in the sniffing position, the practitioner applies 3 mL of 4% viscous lidocaine, or a long acting local anesthetic, absorbed onto cotton-tipped pledgets. The pledgets are advanced slowly and deliberately to minimize the chance of causing epistaxis in a direction that is directly perpendicular to the floor. The path taken with the pledgets is along the superior border of the middle turbinate of each nostril until the tip contacts the mucosa overlying the SPG. The pledgets are left in place for 30 min while the patient's vital signs are monitored, and then they are removed and discarded. Side effects are typically related to iatrogenic epistaxis, as local anesthetic toxicity is exceedingly rare using this approach.

Another technique is the infrazygomatic approach to SPG blockade, which can be technically challenging. It can be performed without fluoroscopy, but fluoroscopic guidance is highly recommended, as this will anecdotally improve the success of the block and the speed at which it is performed and will decrease potential complications. Noninvasive monitors should be used to record vital signs. Place the patient in the supine position. Sterilely prep and drape the appropriate side of the face. Obtain a lateral fluoroscopic image. Palpate the mandibular notch and anesthetize the skin. If the notch is not palpable, identify the notch on a lateral fluoroscopic view. Identify the pterygopalatine fossa (which appears as a "V") on the lateral image and superimpose the right and left fossae. This is accomplished by manipulating the C arm or the head. The block can be performed with a 3.5 inch, 22-gauge, short-bevel needle with the distal tip bent at a 30-degree angle or with a curved, blunt, 10-cm, 20- or 22-gauge needle. The technique described reflects the use of a blunt needle. Anesthetize the skin and insert a 1.25 inch, 16-gauge angiocatheter through the skin and advance until it is just medial to the ramus of the mandible. This can be checked on an A-P image. Pass the block needle through the angiocatheter and advance it medial, anterior, and slightly cephalad. Obtain a lateral image to check the direction of the needle. Your target is the midportion of the pterygopalatine fossa (Fig. 64.19, previously Fig. 52.20). Get an A-P view and advance the needle toward the middle turbinate, stopping when the tip is adjacent to the palatine bone (Fig. 64.20, previously Fig. 52.21). If resistance is encountered at any point, withdraw and redirect the needle. Given the small size of the fossa, frequent A-P and lateral images may be required to redirect the needle. Once in the fossa, inject 0.5–1 mL of nonionic, water-soluble contrast and observe for intravascular spread or intranasal placement of the needle. Once correct placement has been confirmed, inject 1–2 cc of local anesthetic, with or without steroids.

Two therapeutic choices are available after a successful diagnostic block: conventional radiofrequency lesioning (RFTC) and pulsed radiofrequency (PRF). An insulated radiofrequency needle with a 3–5 mm active tip is placed using the infrazygomatic approach. Once in place, sensory stimulation is performed at 50 Hz up to 1 volt. If the tip of the needle is adjacent to the SPG, the patient should perceive paresthesia at the root of the nose at less than 0.3 volts. If the paresthesia is felt in the hard palate, the needle should be redirected cephalad and medial. Paresthesia in the upper teeth indicates stimulation of the maxillary nerve, and the needle should be more caudal and medial. Motor stimulation is not necessary. After appropriate sensory stimulation, RFTC can be performed at 67°C for 90 s times two cycles. Before lesioning, 2–3 mL of local anesthetic should be injected. To avoid inadvertent

• **Figure 64.19** Lateral fluoroscopic image of a 22-gauge, curved, blunt block needle in the pterygopalatine fossa.



• **Figure 64.20** Posteroanterior fluoroscopic image of a 22-gauge, curved, blunt block needle just lateral to the middle turbinate. Sensory stimulation confirmed that the tip of the needle is on the sphenopalatine ganglion.

lesioning of other nerves around the SPG, a 3 mm active tip is a better choice. For pulsed radiofrequency, the size of the active tip is not important as the electromagnetic field is projected from the tip of the needle and not from the shaft. With pulsed radiofrequency, two to four 120 s cycles are performed at 45 degrees. Local anesthetic is not required for pulsed radiofrequency. The choice of whether to do a conventional or a pulsed radiofrequency lesion after a successful block is up to the discretion of the pain practitioner. Bradycardia ("Konen" reflex) has been noted during both conventional and pulsed radiofrequency lesioning and can be prevented with pretreatment with atropine or glycopyrolate.[47]

Trigeminal Nerve Blockade

Trigeminal nerve blocks encompass a set of procedures with emerging benefits in the treatment of facial pain. Classically considered in cases of refractory TGN, this approach has proven effective in acute and chronic settings. Recent prospective work has suggested that pain relief not only occurs quickly but can last on the order of months.[48] While still emerging, the literature to date indicates that complications are extremely rare. Thus while this block is feasible and effective, it requires appropriate patient selection and a thorough understanding of procedural intricacies.

Trigeminal nerve blocks are generally considered for cases of refractory TGN after unsuccessful medical management or surgical decompression. They may also be indicated for patients with acute herpes zoster outbreaks and subsequent postherpetic neuralgia, in addition to cancer palliation and acute facial pain exacerbations. When facial pain has proven chronic, trigeminal neural blockade is used diagnostically prior to neurolysis.

Contraindications to trigeminal blocks parallel those of peripheral nerves, including infection and malformation (e.g. vascular) at the procedure site. No injection should be performed in those patients who refuse or are not fully consented regarding risks and benefits. The physician should proceed with caution in patients on anticoagulant medications for arrhythmias, DVT, and cardiac stents. Coagulopathies may also be seen in those with liver failure or other hematologic abnormalities. Typically, peripheral blockade is avoided in parturients. However, if performed, decreased doses should be used because of increased susceptibility to local anesthetics.

The trigeminal ganglion (or Gasserian ganglion) is the sensory ganglion of the trigeminal nerve (CN V), which lies in Meckel's cave in the middle cranial fossa and gives rise to three branches: ophthalmic (V1), maxillary (V2), and mandibular (V3) nerves.

The ophthalmic nerve (V1), a sensory nerve, divides into three branches (lacrimal, frontal, and nasociliary nerves) before exiting the skull and entering the orbit through the superior orbital fissure. It carries sensory information from the forehead, eyebrows, upper eyelids, and anterior area of the nose.[49] The maxillary nerve (V2), a purely sensory nerve, exits the skull through the foramen rotundum, passes through the pterygopalatine fossa, and reaches the floor of the orbit through the infraorbital foramen to become the infraorbital nerve. It carries sensory information from the lower eyelid, cheek, nose, upper lip, upper teeth and gums, palate, roof of the pharynx, and the maxillary, sphenoid and ethmoid sinuses, and meninges.[50] Of note, its blockade is also achieved by the sphenopalatine block (see the previous section). The mandibular nerve (V3), a mixed sensory and motor (for mastication muscles) nerve, exits the middle cranial fossa through the foramen ovale and descends between the lateral and medial pterygoid muscles, posterior to the lateral pterygoid plate. It delivers sensory branches that supply the anterior part of the ear, the temporal area, the anterior two-thirds of the tongue, teeth, mucosa, and bone of the mandible.[51]

The pterygopalatine fossa (PPF) is a pyramidal-shaped space bounded by the maxillary bone anteriorly, lateral pterygoid plate of the sphenoid bone posteriorly, and the orbital apex superiorly. The PPF contains the maxillary nerve (V2), maxillary artery, and sphenopalatine ganglion and communicates with the infratemporal fossa via the pterygomaxillary fissure. Injection in the pterygopalatine fossa will result in a blockade of the maxillary (V2) branch of the trigeminal nerve and sphenopalation ganglion blockade. Injectate placed in the upper part of the PPF can travel posteromedially through the foramen rotundum to reach the Gasserian ganglion in the middle cranial fossa, resulting in blockade of all three branches of the trigeminal nerve.[52]

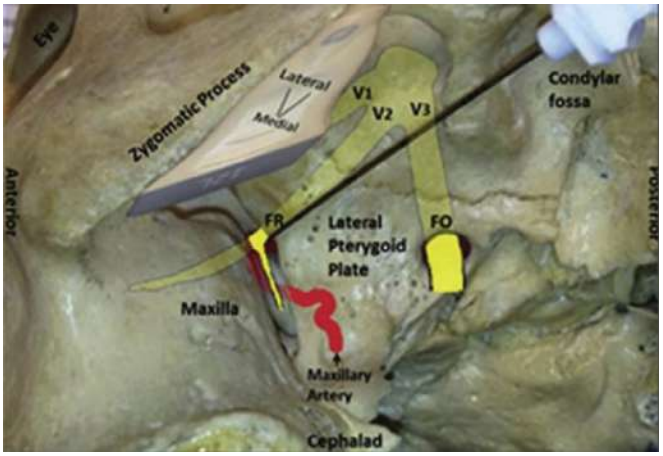
Injection posterior to the lateral pterygoid plate will preferentially block the mandible branch of the trigeminal (V3) nerve

Pterygopalatine Fossa Injection/Maxillary Nerve Block Technique (Fig. 64.21)

Blockade of the maxillary nerve in the PPF can be accomplished with the assistance of both ultrasound and fluoroscopy/CT scan guidance.

Ultrasound Techniques (Fig. 64.22)

Pterygopalatine Fossa injection can be easily performed in a procedure room with the patient in a lateral decubitus position. A 1 mL insulin syringe may be used for subcutaneous topicalization with 0.3–0.4 mL of lidocaine 1%. A 3–5 mL syringe and a 21–22-gauge echogenic needle are commonly used to inject the 5 mL of local anesthetic and steroid mixture. The injectate that may be used includes a mixture of 4 mL bupivacaine and dexamethasone (1 mL). A high-frequency linear array ultrasound is used for



• **Figure 64.21** Skull image illustrating the posterior-to-inferior approach to the ultrasound-guided maxillary nerve block. The ultrasound transducer is placed below the zygomatic bone. The pterygopalatine fossa is anterior to the lateral pterygoid plate. (From Anugerah A, Nguyen K, Nader A. Technical considerations for approaches to the ultrasound-guided maxillary nerve block via the pterygopalatine fossa: a literature review. *Reg Anesth Pain Med.* 2020;45(4):301-305.)

the visualization of superficial structures such as a facial nerve. Other supplies include a sterile probe cover with sterile lubricant. Face-mask and sterile gloves are also recommended.

The patient should be placed in the lateral decubitus position with standard ASA monitoring. After skin preparation, ultrasound is used to identify the lateral pterygoid muscle, the lateral pterygoid plate, and the maxillary bone.

Infrazygomatic Approach

A sterile sheath should cover the transducer probe, which is positioned longitudinally on the side of the face immediately below the zygomatic process, superior to the mandibular notch and anterior to the mandibular condyle.

Posterior to Anterior Approach

With the infrazygomatic posterior to anterior approach, the needle is inserted in-plane and directed anterior to the coronoid process. The needle is advanced from a posterior to an anterior and a lateral to a medial direction. The tip is placed deep into the lateral pterygoid muscle. The target position is immediately anterior to the lateral pterygoid plate at the pterygomaxillary fissure,[53] and the injectate should be observed passing through the fissure. Caution should be taken to identify the superficial facial nerve and artery and the deep maxillary artery that enters the fossa through the fissure (Fig. 64.23).

Anterior to Posterior Approach

The infrazygomatic anterior to posterior approach is also in-plane. Here, the probe is placed below the zygomatic process, and the needle is inserted toward the area between the uppermost part of the lateral pterygoid plate and the maxillary tuberosity. The provider then advances anterior to posterior and lateral to medial through the lateral pterygoid muscle until contact is made with the lateral pterygoid plate. The needle is carefully withdrawn and directed medially to advance 1–2 mm into the pterygopalatine fossa.[53]

Suprazygomatic Approach (Fig. 64.24)

The suprazygomatic approach initially described in the pediatric population[54] utilizes an out-of-plane approach with the ultrasound probe placed below the zygomatic process with an inclination of 45 degrees in the frontal and horizontal planes. The needle is inserted perpendicular to the skin at the area of the frontozygomatic angle above the zygoma. It is advanced to reach the greater wing of the sphenoid at approximately 20 mm depth. The needle is then withdrawn, reoriented, and advanced 35–45 mm deep to the pterygopalatine fossa. Ultrasound guidance in 70% of cases showed LA solution spread into the intermediate (anterior) part and 22% into the deep part of the PPF.

Fluoroscopic Techniques

Maxillary and Mandibular Nerve Blocks

The trigeminal nerve branches may also be blocked using a coronoid approach. The benefit of accessing the V2 and V3 nerves using this approach is the facility in doing so, the ease of reproducibility, and the possibility, albeit not recommended, of doing the procedure absent the requirement for radiologic guidance. The coronoid approach is a useful technique for accessing V2 as it leaves the foramen rotundum. From a technical ease standpoint, coronoid trigeminal block far surpasses the classic technique of Gasserian ganglion block; therefore it is probably our technique of choice in all situations where a V1 block is not essential for diagnosis or management of facial pain.

With the patient in the supine position, the head is turned to the side opposite of the intended block. The coronoid notch is easily identified by asking patients to open and close their mouths and with palpation anterior and inferior to the external auditory meatus. Once the landmarks are identified, the patient is asked to maintain the mouth in a neutral position, while a 22-gauge, 3.5 inch Whitacre or other blunt tipped block needle is advanced perpendicular to the skin of the side of the face, just below the zygomatic arch directly in the center of the coronoid arch. Once the lateral pterygoid plate is contacted (at about 4–5 cm from the skin), the needle is withdrawn about 22 mm. Withdrawing the needle slightly as such improves the likelihood of successfully blocking the mandibular nerve (V3) in addition to V2. A total of 5–10 mL of local anesthetic, with or without corticosteroid, is used for diagnostic/therapeutic block, whereas the same volume of alcohol may be carefully injected using the same approach if neurolysis is desired. The mandibular (V3) branch may be separately blocked here, or it may be blocked in tandem with V2 as described previously. If the nerve is to be blocked, as noted previously for the V2 block, the simplest and likeliest chance for success is via the coronoid approach. If one desires to block the nerve separately, then, once the needle contacts the lateral pterygoid plate, it should be redirected posteriorly and inferiorly until it passes the inferior aspect of the plate. At a point corresponding to approximately 1 cm deeper than the contact point of the lateral pterygoid plate, there will typically be a V3 paresthesia elicited. A usual dose of local anesthetic or neurolytic agent is 3–5 mL using continual, intermittent aspiration tests because of the high degree of vascularity in the area. Because the mandibular nerve (V3) has motor branches, it is not inconceivable that a well-performed local anesthetic or neurolytic procedure might result in paresis or weakness of the muscles of mastication and some facial asymmetry resulting from muscle weakness. This may be more than a nuisance and should be clearly described during the informed consent process with the patient.

Mandibular and maxillary nerve blocks are typically used to ameliorate pain related to TGN, but indications for surgical analgesia include using mandibular block as an adjunct for cervical plexus block for carotid endarterectomy surgery have been described.[55] Although most clinicians continue to use fluoroscopic guidance in most instances of mandibular nerve block, the technique of CT-guided block has been described and may be a suitable alternative if this modality is considered necessary to delineate the relevant anatomy.[56] Continuous catheter techniques of mandibular block have also been described for cancer pain management and analgesia after mandibular fracture repair.[57] Neural complications after mandibular nerve injury are not uncommon and involve the lingual nerve more commonly than the inferior alveolar nerve, often lasting much longer than other common peripheral nerve injuries such as neuropraxia.[58] These injuries may represent neurotoxicity as a central etiology, according to one recent review undertaken in 52 patients who had received these blocks.[59] Otherwise, intravascular injection, hematoma, dizziness, and ataxia occur with some frequency after these procedures and should be discussed with patients during the informed consent process.[60]

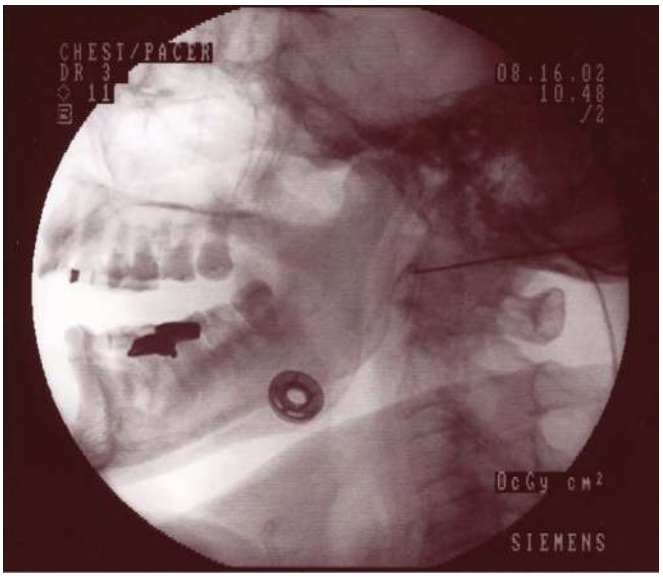
For maxillary nerve block using the coronoid approach, it is important not to advance the block needle more than 0.25 cm once the pterygoid plate has been contacted to minimize the chance of causing neural injury.[61] And as for mandibular nerve block described earlier, a CT-guided technique and a continuous catheter technique of maxillary nerve block have both been described, the former to increase the likelihood of success,[62] and

the latter to extend the duration of analgesia in a group of patients undergoing radical maxillary sinusotomy.[63]

Glossopharyngeal Nerve Block

The glossopharyngeal nerve (GPN) (cranial nerve IX) is infrequently implicated in painful conditions of the face and neck. Nevertheless, because of the lack of familiarity of many pain practitioners with the anatomy and implications of glossopharyngeal nerve dysfunction, it is an important entity to consider in cases of recalcitrant pain, particularly of the tongue, mouth, and pharynx. GPN block may be suitable for conditions such as glossopharyngeal neuralgia and pain from malignancy.[64] The nerve may be affected by tumors of the tongue, hypopharynx, and palatine tonsils. The block is also used during the anatomic evaluation method of differential nerve block. The GPN is a mixed cranial nerve carrying both motor and sensory fibers. The nerve is attached by three or four filaments to the medulla oblongata in a groove between the olive and inferior peduncle. Motor fibers, from cells of the nucleus ambiguus, innervate the stylopharyngeus muscle, while the sensory branches, from cells of the superior and petrous ganglia, innervate the tongue (the posterior third), palatine tonsil, fauces, and mucous membranes of the mouth and pharynx. A branch of the GPN, the carotid sinus nerve, is important in the regulation of blood pressure, pulse, and respiration, as this branch innervates the carotid body and carotid sinus. Sympathetic efferent fibers from the nucleus ambiguus are both preganglionic motor fibers and preganglionic secretory fibers of the sympathetic system. Parasympathetic fibers pass to the otic ganglion, and postganglionic fibers innervate the parotid gland. In conjunction with the vagus and spinal accessory nerves (cranial nerves X and XI), the GPN exits the jugular foramen near the internal jugular vein. All three cranial nerves and the hypoglossal nerve (cranial nerve XII) lie between the internal jugular vein and the internal carotid artery. The styloid process of the temporal bone is a major landmark for successfully blocking the GPN. GPN block is performed with the patient in the supine position, and the head turned slightly opposite to the affected side.

Our practice includes the use of fluoroscopic imaging to help delineate and define the ipsilateral mastoid and the ipsilateral angle of the mandible, as the styloid process is typically found equidistant between those two respective structures. Fluoroscopy also permits real-time imaging of the pattern of injection of contrast media so that in cases where the needle tip has penetrated either the carotid or jugular systems, this activity should be observable and intravascular injection subsequently preventable. Once baseline scout films have been obtained, intravenous access assured, and baseline vital signs documented, the skin overlying the styloid process should be prepped and draped in a sterile fashion. A small skin wheal may be made over the styloid process using a 25-gauge 1.5 inch needle and 1% plain lidocaine, 3–4 mL. Next, a 22-gauge, 1.5–2 inch blunt tipped block needle may be advanced perpendicular to the skin toward the process, aiming for its posterior aspect. The usual depth of contact of the styloid varies from about 1.5–4 cm. Once the needle tip has slipped posteriorly off of the process, 1 mL of iodinated contrast media should be incrementally injected under live continuous fluoroscopy (Fig. 64.25, previously Fig. 52.19). Then, barring any intravascular spread, a short-acting (lidocaine, mepivacaine) and dilute (1% concentration) local anesthetic with epinephrine



• **Figure 64.25** Lateral fluoroscopic image for a glossopharyngeal nerve block. Note that the tip of the needle is at the base of the styloid process.

1:200,000 (5 μg/mL) in a volume of 5–8 mL should be incrementally injected in divided doses. If indicated, a modest dose of nonparticulate corticosteroid (dexamethasone, betamethasone) may be added to the injectate. Patients need to be monitored for a minimum of 30 min following the block to verify that there has been no systemic response to the injected local anesthetic solution. Even taking these precautions and using fluoroscopic guidance does not completely eliminate the possibility of local anesthetic spillover onto the vagus nerve (with resultant ipsilateral vocal cord paralysis, or bradycardia, asystole, reflex tachycardia, and syncope) or the spinal accessory nerve (weakness of the trapezius muscle).

An intraoral approach can also be utilized when there is an anatomic distortion externally by previous surgery or tumor. The patient is placed in a supine position with the mouth wide open, and the tongue is retracted downward and medially using a tongue depressor or a laryngoscope blade. The nerve will be located at the inferior portion of the tonsillar pillar and is accessed via the palatoglossal fold. Once the fold is identified, a topical local anesthetic spray or pledget with 1 mL of saline with epinephrine is applied for hemostasis. A 22- or 25-gauge needle with a slight distal bend (25 degrees) is advanced to a depth no more than 0.5 cm into the mucosa. After negative aspiration, 2–3 mL of local anesthetic (0.2% ropivacaine) with or without steroid is injected. With the intraoral approach, there is a potential for vessel trauma and neurotoxicity, but much less than might occur with the extraoral approach.

Ultrasound-guided Glossopharyngeal Nerve Blockade

For this procedure, the patient should be placed in a lateral position with a thin pillow under the head. The ultrasound probe is used to locate the mastoid and mandibular angle. About 1.5 cm above the posterior edge of the mandibular angle, the probe is used to visualize the styloid process until this image is optimized. Color flow Doppler can be used to identify the internal carotid

artery and vein below or behind the styloid process. Using an in-plane approach, a 22 G 3.5 inch needle is directed for lateral puncture of the mandible. When the tip reaches the styloid process, it is slid back. After negative aspiration, lidocaine 0.5% and methylprednisolone 40 mg are injected with real-time ultrasound guidance.

Summary and Conclusions

With fluoroscopy and especially ultrasound, there has tremendous progress in the performance of these blocks. The safety of these blocks increased as a result. Therefore clinicians should learn and adapt these safer techniques. Additionally, the efficacy of these blocks should be investigated so that their role is firmly established.

Key Points

- Ultrasound-guided greater and lesser occipital nerve blocks are safely and effectively performed for managing some types of head and neck pain.
- Ultrasound-guided supraorbital, infraorbital, and mental nerve blocks should be considered for diagnostic and therapeutic purposes in some types of facial pain.
- Detailed knowledge of the anatomy of the facial structures will improve the success of trigeminal ganglion, sphenopalatine ganglion, and glossopharyngeal nerve blocks.
- There is considerable overlap in the areas served by the upper cervical nerves. It is conceivable that even perfectly performed techniques may result in failures to achieve complete pain relief.
- Expected side effects (e.g. numbness in the distribution of the targeted nerve) versus complications of trigeminal ganglion rhizotomy should be fully explained to and comprehended by the patient before proceeding.
- The use of pulsed radiofrequency for trigeminal-mediated pain syndromes should be considered prior to using thermal radiofrequency after a successful diagnostic block.
- The practitioner should be prepared to treat bradycardia, which is commonly seen with trigeminal and sphenopalatine ganglion procedures.
- Given the complexity of the facial pain syndromes, the sphenopalatine ganglion block should be considered for diagnostic and therapeutic purposes.

Interlaminar and Transforaminal Therapeutic Epidural Injections

ARIANA M. NELSON, HONORIO T. BENZON, MAGDALENA ANITESCU, MARC A. HUNTOON

The International Association for the Study of Pain (IASP) continues to deliberate the classification of chronic pain as a disease symptom or etiology.[1] Semantics aside, pain is undoubtedly a public health crisis as the Institute of Medicine's report estimates that over 100 million American citizens are living with chronic pain.[2] Of this group, chronic low back pain is the most prevalent, and this diagnosis more than doubles a given patient's healthcare expenditures.[3] Besides the higher costs to society, numerous adverse social, emotional, and financial consequences befall the individual patient.[2]

Radiculopathy is a syndrome of neurologic conductive loss (sensory or motor) arising from any compressive force on the nerve root.[4] Radiculopathy is not uniformly associated with radicular pain. Radicular pain, or pain in the distribution of a spinal nerve, is a consequence of inflammation driven by glial production of cytokines and is sometimes termed radiculitis to emphasize the inflammatory component of the disease state.[5,6] Diagnosing radicular insult as the putative source of pain can be challenging, as neither magnetic resonance imaging (MRI) nor physical examination findings correlate precisely with symptom severity or response to treatments.[7–9]

From primary care physicians to spine surgeons, most clinicians concur that conservative non-interventional management is the best initial approach.[10] Because the natural history of radiculopathy secondary to disc herniation is favorable,[11–16] the goal of successful treatment of radicular pain is to reduce pain and restore function while minimizing risk or harm to the patient. Many guidelines exist to guide nonsurgical best practices,[17,18] all of which concur that physical therapy and/or structured exercise programs and oral analgesics should be first line treatments. When these fail, the next step in the management of low back or radicular pain is often epidural steroid injection (ESI).

From 2000 to 2014, the number of injections billed to the United States Medicare system increased to 2.2 million per year. Although total lumbar interlaminar ESI (IL-ESI) and caudal epidural injections decreased by 2% per 100,000 Medicare beneficiaries, this was offset by a 609% increase in lumbar transforaminal ESIs (TFESIs) and 93% increase in cervical epidural steroid injections (CESI) per 100,000 Medicare beneficiaries.[19] Although operative (e.g. spine surgery) management is still far more expensive, two-thirds of non-operative (e.g. ESI) costs can be attributed to spine imaging rather than injection therapy.[20]

Early ESI studies were replete with methodologic deficiencies.[21–23] Many observational studies were encouraging and were only followed by randomized controlled trials (RCTs) that demonstrated no clinical benefit of the evaluated procedure.[24–26] The heterogeneity of studies performed in the lumbar, thoracic, or cervical space further complicates the evaluation of overall epidural efficacy given the anatomic differences between regions of the human spine.

ESIs for treatment of radicular syndromes appear, at the very least, to transiently improve pain.[27] In the short term, ESIs may also have a surgery-sparing effect.[28] As always, patient selection is the most important component of any successful interventional procedure, and providers should carefully assess the patient's history, physical examination findings, and imaging results. This is quite feasible in theory, but the uncertainty surrounding nonsurgical best practices, including concern for serious complications of ESIs,[26,29,30] poses a significant challenge for interventional physicians offering epidural steroid injections to patients.

History

In 1934 Mixter and Barr were the first to suggest that intervertebral disc herniation might be responsible for radicular pain via mechanical compression on the exiting spinal nerve root.[31] Four years before this hypothesis germinated, Evans proposed treating sciatica with injections of 120 mL of 2% procaine via the transsacral canal.[32] Decades later, in 1951, Lindahl and Rexed examined resected dorsal nerve roots from patients with radicular pain and found lymphocytic infiltration and edema, suggesting that inflammation is responsible for radicular symptoms.[33]

Early work in the post-WWII era on injectable corticosteroids (CSs) was a Nobel Prize-winning effort that culminated in the synthesis of the drug hydrocortisone.[34] Soon after, CSs were used in joint injections,[35] and in 1952 Robecchi and Capra reported the first ESI.[36] In the subsequent year, Li'evre et al. described a case series of 20 patients with positive results from epidurally administered hydrocortisone.[37]

Between 1960 and the late 1980s, interlaminar and caudal approaches to the epidural space predominated, largely via non-image guided techniques using surface landmarks and "loss-of-resistance" techniques.[38] In 1988 a study found that a large

percentage of these "blind" epidural injections were either not in the epidural space or were not communicating with the target area of nerve inflammation.[39] In a subsequent review, Johnson and colleagues described 5,489 consecutive image guided injections that resulted in only four complications and only ten patients requiring sedation, thus reassuring providers that ESI procedures could be performed on an outpatient basis. They proposed the use of an epidurogram of contrast dye that allowed more accurate localization within the epidural space while also demonstrating that the injectate reached the target area.[40] In 1986 Benzon discussed the efficacy of ESIs for low back pain and nerve root irritation. He noted that patients with acute radicular pain have better results than those with chronic pain.[41] Although ESIs are most widely performed for radicular pain, they may also be used to treat spinal cysts, spinal fractures, and postherpetic neuralgia[42] and are among the most common procedures performed in pain clinics.[43]

Pathophysiology

Key factors in the provocation of radicular symptoms include mechanical compression of the spinal nerve root or inflammation due to proinflammatory mediators such as prostaglandins and cytokines.[44] CSs, through their anti-inflammatory effects, reduce these inflammatory changes in or around the nerve,[45] thereby decreasing pain and improving function.[12,46]

The nociceptive neural fibers in the outer third of the annulus fibrosus are small unmyelinated C-fibers activated by peptidergic neurotransmitters such as calcitonin gene-related peptide and substance P. In discography-proven pain-generating discs, these nerve fibers sprout farther into the disc, usually accompanied by neovascularization and further degradation of the disc matrix.[47] This *de novo* innervation appears to originate from the vertebral end-plate region, which may be the progenitor of the pathologic pain attributed to the disc itself.[48,49] Modic changes at the end-plate correlate with radiologic spine degeneration but may not have an association with axial or extremity pain.[50] The disc is relatively avascular, and therefore cellular fuel enters and waste exits via passive diffusion. Homeostatic attempts by the body to improve disc nutrition may explain why new blood vessels (and associated nerve fibers) invade the injured disc from the vertebral end-plate region.

The processes that lead to disc degeneration may ultimately lead to disc herniation. Herniated nucleus pulposus results in the local release of cytokines and other inflammatory mediators that cause chemical radiculitis.[51] Burke and associates[52] found increased levels of the inflammatory cytokines interleukin (IL)-6 and IL-8 in disc material taken from patients with known disc disease. Cytokines tumor necrosis factor-α (TNF-α), IL-1α, IL-1β, IL-6, and IL-17 are also thought to promote extracellular matrix degradation, chemokine production, and changes in the intervertebral disc (IVD) cell phenotype, all of which can lead to degeneration of IVD tissues.[51] Olmarker et al.[53] found that the application of disc material onto spinal nerve roots induced functional and morphologic changes in these nerves. In addition, disc cells express TNF-α, which, when applied to spinal nerve roots, causes similar changes to those observed after the application of disc material.[51,54] Selective inhibition of TNF-α reduces the intraneural edema seen in this context,[55] lending further credence to the theory that exposure of the nerve root to disc material can be responsible for radicular pain irrespective of anatomic perturbation.

Epidural Injection Techniques

The approaches used to access the epidural space include interlaminar, caudal, and transforaminal. Published studies and guidelines generally agree that all three approaches afford similar clinical benefits but differ markedly in complication rates.[56–59] For all injections, the patient was placed in the supine position, the skin was cleansed with a chlorhexidine-based solution unless contraindicated, draped in a sterile fashion, and the skin and subcutaneous tissues along the proposed needle trajectory were anesthetized with 0.5%–2% lidocaine. Non-particulate steroids are increasingly used for transforaminal injections due to the risk of arterial thrombosis from particulate steroid introduction.[60] The procedure should be aborted if paresthesia or cerebrospinal fluid aspirate occurs, and these risks will be discussed in greater detail later in the chapter.

Cervical Transforaminal Epidural

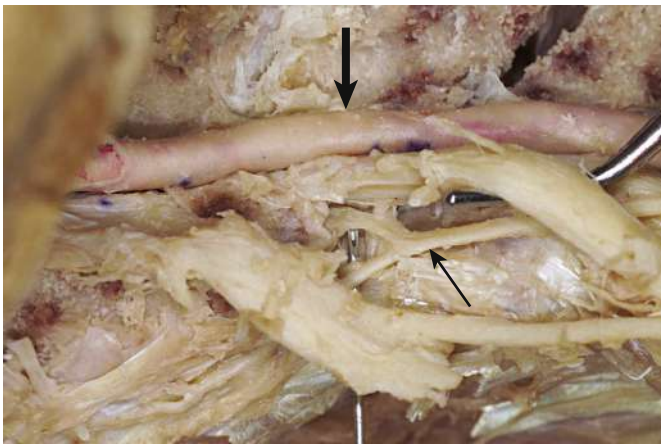
An oblique lateral radiograph is adjusted to maximize the breadth of the intervertebral foramen with the superior articular process (SAP) visualized as a straight line at the posterior aspect of the foramen. A spinal needle was advanced to contact the SAP in the posterior foramen. From the SAP, the needle is "walked off" into the posterior aspect of the foramen, superior to the midpoint. The proceduralist ensures that the needle tip remains superior to the midpoint of the posterior foramina, that is, above the midsagittal plane of the cervical articular pillar in anteroposterior (AP) view, to protect against vascular injury of critical arteries located in the inferior half of the posterior aspect of the intervertebral foramen (Fig. 65.1).[61,62] Local anesthetic (LA) test dosing may be used to rule out arterial location of the needle tip, and digital subtraction imaging should be used to substantiate the absence of vascular uptake prior to CS administration. Although we discuss this technique in this chapter, extreme caution must be applied, and rigorous patient selection and consent are required as the risk of vascular penetration at the cervical level is associated with high morbidity and even mortality.

Lumbar Transforaminal Epidural

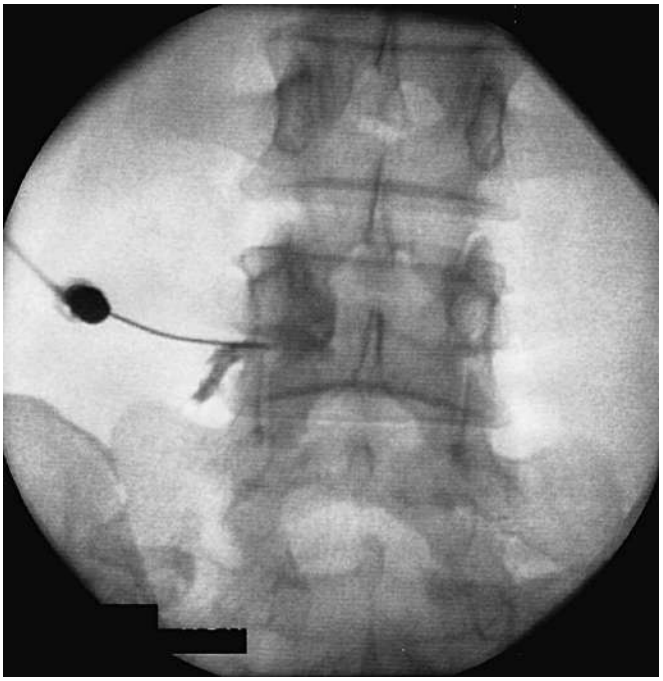
An oblique view is obtained from the lateral surface of the SAP and marked at the six o'clock position along a line that bisects the sagittal plane of the pedicle (Fig. 65.2).[25] Either a cutting-type needle or a blunt needle with a side port opening may be used; some authors contend that a blunt needle may be less apt to enter blood vessels.[63] The needle is advanced incrementally in one of three approaches: the sub-pedicular, the "safe triangle" as proposed by Bogduk and Cherry,[64] or the Kambin triangle (Fig. 65.3).[65] There was no difference in the amount of contrast dye required to visualize epidural spread based on the approach.[66] Injection of contrast medium should demonstrate a neurogram and medial spread into the epidural space (Fig. 65.4). Digital subtraction imaging is useful to substantiate the absence of vascular uptake (Fig. 65.5) as a LA test dosing to detect arterial administration of CSs.

Cervical Interlaminar Epidural

This is most safely performed at the C7-T1 or T1-T2 levels, as the posterior epidural space is 1.5–2 mm greater at these levels than at more superior cervical levels.[67] It is also prudent to review



• **Figure 65.1** Anatomic cadaver dissection demonstrating the vertebral artery (*pink, large arrow*) and the exiting left C5 spinal nerve lifted by the probe. The needle tip is pushing on a spinal branch of the ascending cervical artery (*small arrow*) at the outer aspect of the C4-5 intervertebral foramen.



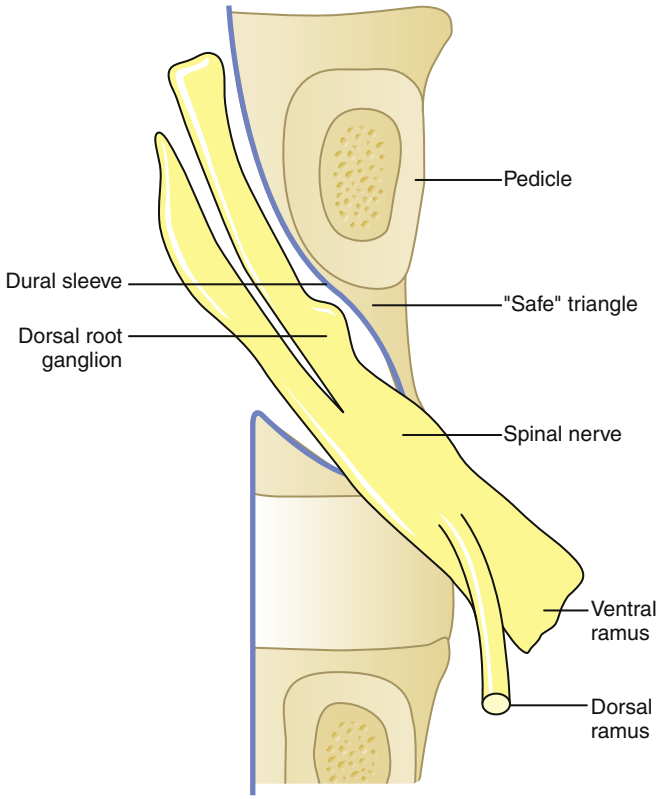
• **Figure 65.2** Needle placement for a left l4 transforaminal epidural block. The needle has been "walked off" the lateral edge of the superior articular process and is at approximately the midsagittal plane relative to the pedicle above.

a patient's MRI prior to the procedure to ensure that the epidural absolute distance is greater than 10 mm at the proposed injection site.[68,69] Caudocephalad angulation of the fluoroscope is used to visualize the interlaminar opening in maximal diameter, and an epidural needle is advanced toward the inferior laminar bone at the target level. After contact with the inferior lamina, the needle is walked superiorly until the needle is superior to the lamina. At this point, a loss-of-resistance (LOR) syringe is attached, and the needle is advanced with the operator correlating the tactile LOR technique with a fluoroscopic view of the lateral or the increasingly popular contralateral oblique orientation (Fig. 65.6).[70]

Resistance to pressure increases as the needle moves toward the anterior extent of the spinous processes, and a subtle LOR will be detected as the tip enters the epidural space, after which contrast dye and CS may be injected. Occasionally, there are discontinuous areas of the ligamentum flavum in the cervical epidural levels,[67] causing the LOR to be more subtle than in the inferior vertebral levels. An alternative technique uses a needle advanced at a 45-degree angle until the epidural space is accessed, after which a catheter can be threaded cephalad through the needle to the target level.[71]

Lumbar Interlaminar Epidural

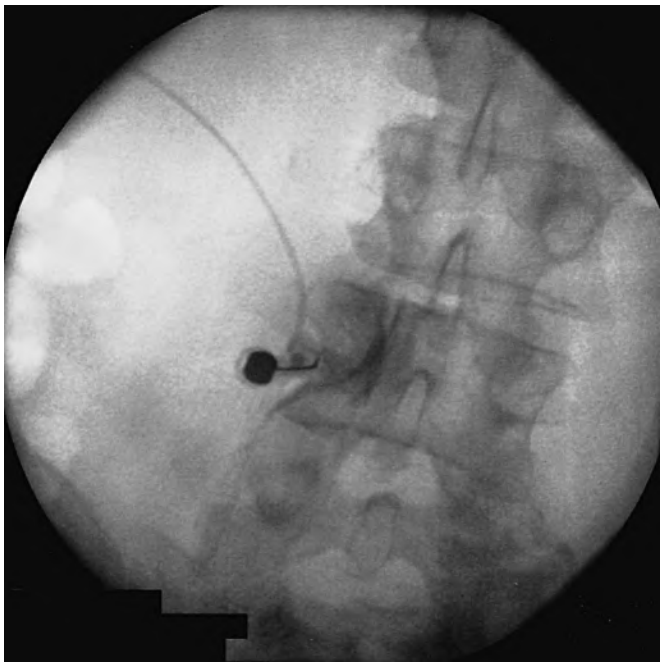
An epidural needle is advanced toward the interlaminar vertebral target, and the epidural space is identified using the LOR technique. The interventional physician may choose to traverse the ligamentum flavum and enter the epidural space in the lateral fluoroscopic view to ensure appropriate placement. Contrast dye demonstrating an epidurogram in both AP (Fig. 65.7) and lateral fluoroscopic views provide support for correct needle placement, after which CS may be administered.



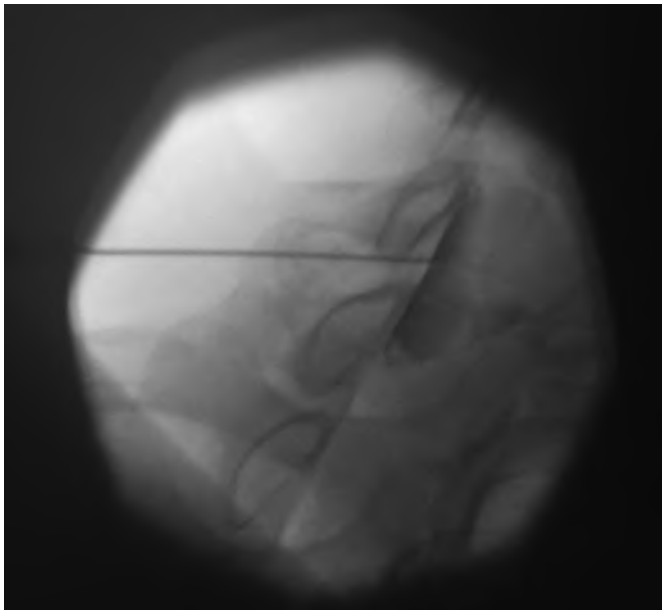
• **Figure 65.3** The "safe" triangle depicts the confines of the classic transforaminal epidural technique. The needle is safely placed inferior to the pedicle's inferior border, superior to the tangentially exiting spinal nerve, and lateral to the dural sleeve.

Caudal Epidural

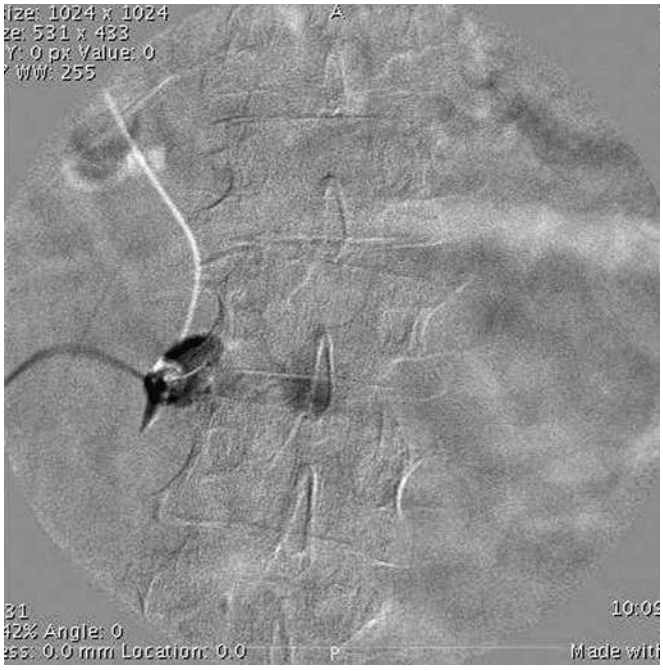
Many techniques have been described for accessing the epidural space via the sacral hiatus. Both cutting and blunt-tipped needles can be used for access, and the procedure can be performed blindly or with fluoroscopic or ultrasonographic guidance. The



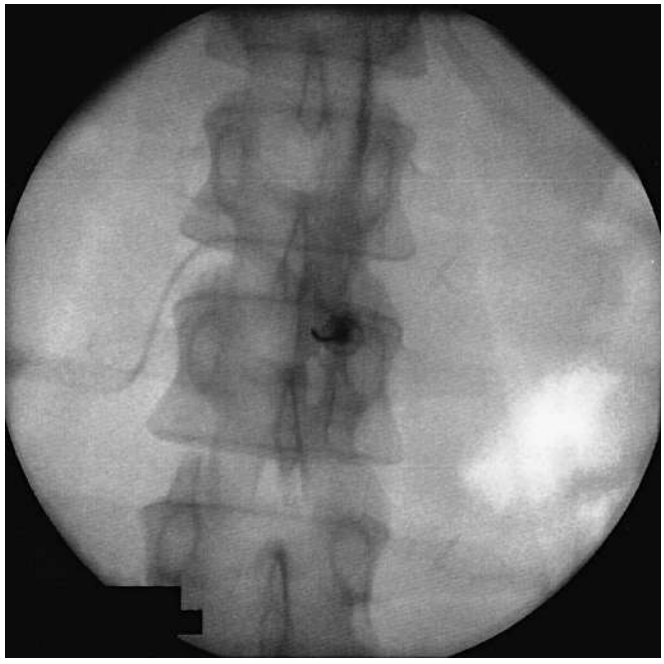
• **Figure 65.4** Spread of contrast dye is seen along the medial border of the pedicle and outlining the exiting spinal nerve.



• **Figure 65.6** An interlaminar cervical epidural procedure demonstrates a characteristic filling pattern along the pedicular column in contralateral oblique fluoroscopic visualization.



• **Figure 65.5** Digital subtraction sequence of a left L2 transforaminal epidural injection. The contrast dye outlines the exiting spinal nerve and displays no vascular uptake despite the high likelihood of proximity to the great segmental medullary artery of Adamkiewicz (see Figure 60.9).



• **Figure 65.7** An interlaminar epidural procedure demonstrates one-sided spread at the same level and cephalad to the injection.

caudal ESI may be performed in patients even after posterior spine instrumentation and is therefore often used for post-surgical patients that will not have a reliable LOR with an interlaminar approach but also have stenosed foramina that cannot safely accommodate a TFESI.

Pharmacology

Corticosteroids (CSs) are key mediators in the maintenance of normal physiology and in the complex adaptive mechanisms that protect an organism amid internal or external stressors.[72] CSs maintain the function and integrity of many physiologic and bio-

chemical processes, including regulation of protein, carbohydrate, and lipid metabolism.[73,74] Naturally occurring CSs are classified into three functional groups: glucocorticoids, mineralocorticoids, and adrenal androgens.[75] Glucocorticoids (GCs) act primarily to enhance the production of high-energy fuel and glucose and to reduce other metabolic activity.[73,76] Synthetic injectable GCs have been used to relieve vertebrogenic, arthritic, and radiculopathic pain.[46]

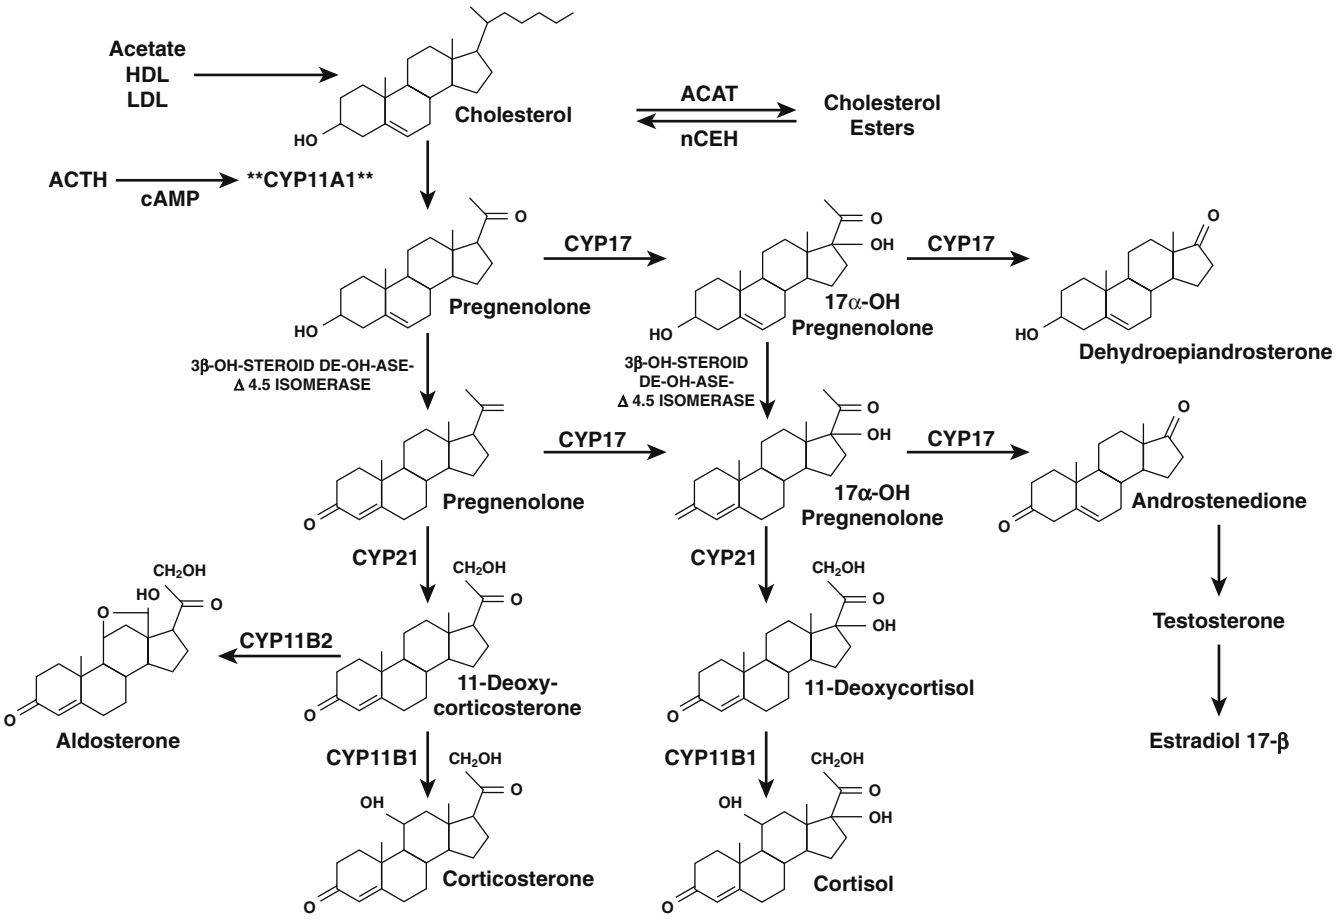
GCs stimulate hepatic gluconeogenesis, increase hepatic glycogen content, and inhibit insulin-mediated peripheral blood glucose uptake. They modulate protein metabolism by decreasing peripheral protein synthesis and stimulating protein catabolism while stimulating protein and enzyme synthesis in the liver.[73] GCs regulate lipid metabolism largely by potentiating catecholamine-enhanced activation of cellular lipase, resulting in lipolysis.[74] Hemodynamically, GCs modulate α-adrenergic receptor synthesis and cell density,[77] prevent α-adrenergic receptor desensitization and uncoupling,[78] and inhibit nitric oxide synthase.[79] Through these mechanisms, GCs maintain vascular responsiveness to circulating vasoconstrictors and, in high doses, may restore circulatory function in shock (hemorrhage, endotoxin, anaphylaxis, trauma). Similarly, in acute inflammation, they maintain adequate microcirculation by reducing capillary endothelial permeability and preventing edema formation.

All CSs are produced in the cortex of the adrenal gland, which comprises three distinct zones.[75,80] GCs are produced primarily by the middle zone, the zona fasciculata, an area occupying over 70% of the cortex, and in smaller amounts by the inner zone, zona reticularis. Cortisol is the primary glucocorticoid and accounts for approximately 80% of GC production. Circulating plasma lipoproteins provide the most cholesterol for steroid synthesis. Cholesterol uptake is upregulated in response to adrenocorticotropic hormone (ACTH) secreted by the pituitary gland. The first and rate limiting step in steroid biosynthesis is the conversion of cholesterol to pregnenolone (Fig. 65.8).[80] Cortisol secretion is controlled by the hypothalamic-pituitary-adrenal (HPA) axis and depends on three factors:

1. Negative feedback by serum cortisol levels. Cortisol exerts a negative feedback inhibition on corticotropin-releasing hormone (CRH) secretion by binding to specific steroid receptors in the central nervous system (CNS).[81] It also inhibits both ACTH secretion and pro-opiomelanocortin (POMC) gene transcription.
2. Circadian pattern. It is estimated that human cortisol production is approximately 5–10 mg/m^2 per day.[82,83] This amount is equivalent to 20–30 mg/day of hydrocortisone or 5–7 mg/day of oral prednisone.[82] Peak levels of ACTH and cortisol secretion occur between 4 a.m. and 8 a.m., with the lowest levels of secretion occurring between 8 p.m. and 12 a.m.[75]
3. The CNS controls secretion. During non-stress periods, cortisol production is influenced by CNS activation, CRH, and ACTH release, which vary based on baroreceptors, chemoreceptors, nociceptors, and emotional afferent signals. Baroreceptor and chemoreceptor afferent inputs to the medulla are transmitted via the pons to the hypothalamus. Nociceptive afferent signals activate the medulla and thalamus, which, along with emotional triggers, directly activate the hypothalamus via the paleocortex limbic system. The activated hypothalamic paraventricular nucleus then stimulates the synthesis of CRH, which is secreted into the hypophyseal portal system to the anterior pituitary, causing ACTH release.[81] Cortisol can increase 5- to 10-fold during stress, to a maximal level of approximately 100 mg/m^2 per day.[75,84]

Cortisol circulates in the blood in three forms: the physiologically active free cortisol (5%), cortisol bound to CS binding globulin (CBG) (90%), and the remaining 5% as cortisol bound to albumin or cortisol metabolites.[73] CBG, also known as transcortin, has a high affinity for cortisol but is present in small amounts, while albumin binds cortisol with less affinity but is abundant. Total cortisol blood levels, including the unbound percentage, increase during stress.[81] CBG levels increase in high-estrogen states, during pregnancy, and during the administration of contraceptives.[73] Most synthetic GCs have less affinity for CBG (approximately 70% binding), leaving more free cortisol. As a physiologically active form, this explains their propensity to produce cushingoid symptoms even at low doses. Cortisol is metabolized in the liver, with subsequent renal excretion of metabolites. Stress due to physical (trauma, surgery, exercise), psychological (anxiety, depression), or physiologic (hypoglycemia, infection) origin increases cortisol levels within minutes. Similarly, pain, fever, and hypovolemia cause a sustained increase in ACTH and cortisol secretion.[84] An increase in ACTH and cortisol levels in response to surgery persists for 24–48 h and is associated with the extensiveness of the procedure. Adult adrenal glands produce approximately 50 mg of cortisol/24 h during minor surgeries and 75–150 mg/24 h during major surgeries.[85] The mechanism of the HPA axis, when stimulated to produce cortisol, is the body's response to elevated levels of circulating cytokines, appearing within minutes of trauma/surgery. CSs improve survival in stress by reducing the duration of shock, decreasing the severity of inflammation, improving vessel contractility and hemodynamics, and preventing inflammatory cell recruitment, proliferation, and release of pro-inflammatory mediators.[86]

CSs are predominantly used in interventional pain management because of their anti-inflammatory effects and temporary relief of pain symptoms. Mechanisms include effects on cytokines, inflammatory mediators, inflammatory cells, nitric oxide synthase, and adhesion molecules. Cytokines are important mediators of inflammation, and the pattern of their expression largely determines the magnitude and persistence of the inflammatory response.[87] Steroids have potent inhibitory effects on cytokine transcription and synthesis, especially those relevant to chronic inflammation (IL-1, IL-3, IL-4, IL-5, IL-6, IL-8, TNF-α, and granulocyte-macrophage colony-stimulating factor).[88,89] They also inhibit the synthesis of the IL-2 receptor and oppose the induction of IL-2 and T-lymphocyte activation and proliferation. The primary anti-inflammatory effect of steroids appears to be the suppression of transcription of genes involved in inflammation such as collagenase, elastase, plasminogen activator, cyclooxygenase (COX)-2, prostaglandin E_2 (PGE_2), phospholipase A_2, and most chemokines.[90,91] In addition, GCs interfere with macrophage activity by impairing phagocytosis, intracellular digestion of antigens, and release of IL-1 and TNF-α.[73] By inhibiting chemokine expression, GCs prevent the activation and recruitment of inflammatory cells, including eosinophils, basophils, and lymphocytes.[90] By increasing lipocortin (annexin) 1, a phospholipase A_2 inhibitor, GCs decrease the production of inflammatory mediators such as leukotrienes, prostaglandins, and platelet-activating factor and upregulate transcription of anti-inflammatory genes.[89,91–93] In addition, GCs cause an expansion in the number of circulating neutrophils secondary to decreased adherence to vascular endothelium,



• **Figure 65.8** Steroidogenesis in the adrenal cortex. termed demargination, and stimulation of bone marrow production.[94] GCs inhibit the production of T lymphocytes by down-regulating T-cell growth factors IL-1β and IL-2, and they inhibit the release of various T-lymphocyte cytokines.[73] GCs suppress ectopic neural discharge in neuromas or severed nerves,[95] and the topical application of methylprednisolone blocks transmission of C-fibers but not the A-β fibers.[96] This suggests a direct neural membrane stabilizing effect. Last, GS receptor sites have been found on 5-hydroxytryptamine (5-GC) and noradrenergic neurons within the dorsal horn substantia gelatinosa. These are known pathways of pain transmission and suggest that CSs may modulate nociceptive transmission via direct action on the spinal cord.

Several synthetic steroid preparations are available and are widely used in interventional pain procedures. They vary in anti-inflammatory potency, mineralocorticoid activity, solubility, and duration of action. Short-acting synthetic steroids, such as hydrocortisone and the inactive cortisone (converted by the liver to the biologically active cortisol), have durations of action of 8–12 h; the intermediate-acting steroids, prednisone, prednisolone, methylprednisolone, and triamcinolone, have durations of action of 24–36 h. The longest acting steroids, dexamethasone and betamethasone, have durations of action longer than 48 h. Although the choice of steroid used by interventional pain physicians is frequently based on anti-inflammatory potency and duration of action, the steroid particulate size and potential for aggregation have become major determinants of CS selection given reported catastrophic neurologic sequelae. Table 65.1 summarizes the properties of commonly used injectable CSs.

Corticosteroid Alternatives

Because CSs have dose limitations and side effects, many researchers are interested in the systemic or epidural delivery of specific anti-inflammatory agents as an alternative therapy. Korhonen and colleagues[97] used intravenous infliximab, a TNF-α inhibitor, to treat patients with disc herniation and radicular pain and found that pain scores were reduced at the one year follow up when compared with controls. Etanercept, another TNF-α inhibitor, has also

TABLE 65.1 Properties of Commonly Used Injectable Corticosteroids[a]

Steroid	Commercial Name	Equivalent Potency (mg)	Relative GC Potency	Solubility	Maximum Particle Size (microns)	Particles >10 microns (%)	Particle Aggregates

shown promising efficacy as a systemic treatment for lumbosacral radicular syndromes.[98] Cohen and associates[99] performed a novel RCT evaluating patients with subacute lumbosacral radiculopathy that showed significant patient improvement with epidural etanercept. However, a follow up multicenter RCT showed that epidural etanercept did not improve pain compared to steroids or placebos.[100] A subsequent well-conducted RCT demonstrated that epidural etanercept was more effective than dexamethasone for leg and lower back pain due to spinal stenosis.[101] Therefore the evidence is mixed for this therapy.

Previously, both human and animal data suggested that epidural local anesthetic may be similar to CSs in analgesic effect.[102–110] In 2008, Manchikanti and colleagues[102] performed a double-blind RCT comparing LA alone with LA and non-particulate betamethasone in fluoroscopically guided cervical IL-ESI. More than 70% of patients in both groups reported pain relief, and there was no difference in pain relief or functional status between the groups. An RCT in patients with unilateral leg pain due to nerve root compression evaluated TF-ESIs with either 40 mg methylprednisolone, bupivacaine, or LA alone and showed no difference in any outcome measure at three months.[105] The similarity of steroids to LA injection was confirmed by Manchikanti et al. who showed that epidurally administered bupivacaine with steroids or alone are both effective modalities in treating LBP and lower extremity pain.[108]

In a study evaluating alternatives to CSs, Burgher et al.[111] studied the differences between clonidine and triamcinolone (CS) in TF-ESIs for acute lumbosacral radiculopathy. While no differences were seen between groups in pain intensity at one month, both groups showed significant improvement in pain scores at two weeks and one month compared to baseline ($P < 0.05$). The CS group showed more functional improvement at one month compared to the clonidine group ($P = 0.022$). Although adverse effects occurred, none resulted in serious complications.

Evidence-Based Medicine for Corticosteroid Epidural Injections

Several well-designed studies have corroborated the short-term benefit of ESIs.[24,26,112–114] Given the favorable natural history of most patients with radicular pain, especially those related to a disc protrusion, a thorough understanding of the benefits and risks associated with ESIs for radicular pain syndrome is needed.[13,14,16] Head-to-head studies are necessary to compare interlaminar, transforaminal, and caudal approaches to the epidural space, which may be relevant given the unique risks to the patient of each approach. A selection of these studies concerning interlaminar, transforaminal, and caudal ESIs is reviewed in this section (Tables 62.2–62.5).

In response to a systematic review by Koes et al.,[22] Karppinen and colleagues[115] hypothesized that the poor efficacy reported in ESIs might result from insufficient penetration of CS into the locus of nerve root irritation when administered via an IL-ESI. They conducted an RCT in patients with radicular pain to test the efficacy of a single TFESI (80 mg methylprednisolone with bupivacaine 5 mg/mL, 2–3 mL) compared with a 0.9% saline injection. Leg pain was significantly better in the methylprednisolone bupivacaine group at two weeks, with a 45% reduction in pain versus 24% in saline ($P < 0.01$). Back pain was better in the methylprednisolone bupivacaine group at three months; back and leg pain was better in the saline group at six months, and no difference was noted at one year. Carette and colleagues[116] performed an RCT of lumbar IL-ESIs with either methylprednisolone or saline in patients with lumbar radiculopathy and signs of nerve root irritation or compression. The ESIs were not fluoroscopically guided, which may have led to a high frequency of misplaced injections.[39] The study did not show a statistically significant change in functional improvement as assessed by the Oswestry Disability Index (ODI), but it did find a reduction in leg pain at six weeks in the

treatment group. In a similar study, Arden and colleagues[24] performed an RCT to examine the efficacy of lumbar IL-ESIs with either 80 mg of triamcinolone and 10 mL of 0.25% bupivacaine or a placebo group of normal saline in 228 patients with unilateral lower extremity pain and signs of nerve root irritation (Table 65.2). The treatment group showed significant improvement in self-reported function and 75% improvement in ODI at three weeks. No statistically significant differences existed between the groups at six weeks or beyond in any outcome measure.

Bush and Hillier[112] performed an RCT of caudal ESIs without fluoroscopic guidance in patients with intractable radicular pain, signs of lumbar nerve root irritation, and a positive straight leg raise test. The treatment group received 25 mL (80 mg triamcinolone and 0.5% procaine), and the placebo group received 25 mL of saline. The treatment group showed a statistically significant improvement in lifestyle and pain reduction at four weeks ($P = 0.02$). At one year, both groups showed statistically significant resolution of their symptoms, further demonstrating the positive natural history of radicular pain.

The different technical approaches to the epidural space also complicate studies due to variable efficacy and risks. The efficacy of the transforaminal approach versus the interlaminar approach is not well-established; one study showed that the two approaches are similar in terms of pain relief and functional capacity.[59] Lipetz and colleagues proposed that after TFESI for lumbar radiculopathy, only one-third of patients experienced significant and long-lasting pain relief after the first injection (Table 65.3).[117] According to an RCT by Makkar et al. on patients with unilateral

TABLE 65.2 Selected Studies—Interlaminar Epidural Steroid Injections

Authors	Patients	Design/Technique	Outcome Measure	Conclusion

lumbar radiculopathy, the TFESI and para-sagittal interlaminar approaches are equivalent and superior to midline interlaminar in terms of effective pain relief and a decrease in disability; they are supported by significantly better pain relief at six months, as assessed by visual analog scale (VAS) and ODI scores.[58] TFESI is a potentially efficacious treatment for patients with spinal canal stenosis,[118] and lumbar spinal stenosis,[114] but the risk of arterial injury is increased compared with other approaches. Sencan et al. postulated that the interlaminar approach might be preferred due to the ease of the procedure, while the transforaminal approach may be preferred for patients with predominantly neuropathic pain.[119] Other studies suggest better efficacy of the transforaminal approach over the interlaminar approach when the radicular pain is limited to one nerve root.[57] The interlaminar approach may also palliate pain from lumbar central spinal stenosis, but the effect is limited, especially in severe stenosis.[120] Any patient with severe canal stenosis is not a candidate for IL-ESI due to lack of posterior epidural space and risk of cord injury. Therefore approaches are limited to transforaminal or caudal in these patients. Patients with prior spine instrumentation are not candidates for IL-ESI due to scarring of the epidural space. Therefore approaches are limited to transforaminal or caudal in these patients as well.

In part due to the inability to use the IL-ESI approach after posterior neuraxial surgery, other methods of steroid administration have been evaluated and compared to fluoroscopic ESIs. A 2020 retrospective study by Bureau and colleagues examined computed tomography (CT)-guided injectate dispersal patterns and therapeutic efficacy of cervical TFESI versus intraarticular facet steroid injection. They concluded that steroids injected into the extraforaminal or juxta-articular facet space had a better safety profile and were more efficacious than cervical TFESI.[121] Dashfield and colleagues[122] performed an RCT comparing caudal ESI with targeted steroid placement during spinal endoscopy for chronic sciatica (Table 65.4). Each group received 10 mL of 1% lidocaine with 40 mg triamcinolone. The results showed a significant benefit in patient outcomes for both groups, but no significant difference between the groups. Jang et al.[123] studied ultrasound guided selective nerve root block (US-SNRB) versus fluoroscopically guided IL-ESI and TFESI for radicular pain in the lower cervical spine. According to the Numeric Rating Scale and the Neck Disability Index, significant improvements in pain were found in all groups at one, three, and six months. The study suggests that US-SNRB should be considered as an approach for therapeutic ESI. Bahar-Ozdemir conducted a prospective observational study to determine whether the current psychiatric condition of the patient can affect the results of lumbar TFESI. The study concluded that psychiatric conditions could negatively affect the pain and disability of patients

before and after ESI, but these patients should still be offered interventional treatment.[124]

The efficacy of surgical procedures for many spinal conditions has come under scrutiny largely because of disparate geographic practice patterns, inconsistent outcomes,[14] and cost-benefit analyses. Patients widely accept the surgical treatment of acute radiculopathy, but studies comparing surgery with comprehensive nonsurgical care usually reveal equivocal findings, with some favoring non-operative care,[125] some stating that operative treatment is effective,[11,12,16,126] and most studies demonstrating clinically similar outcomes between groups given the favorable natural history of radicular pain (Table 65.5).[13,14,16]

Short-term outcome data from the Comprehensive Spine Pain Outcomes Research Trial (SPORT) regarding nonsurgical versus surgical care of lumbar disc herniation[13] demonstrated no statistically significant superiority of surgical discectomy over conservative care. Thus the use of conservative treatments, including ESIs, will likely continue to increase (Fig. 65.9A–C). However, in a systematic review of the 10 year outcomes of SPORT, results of the four and eight year as-treated analyses showed significantly greater improvements in patients treated surgically.[126] Unfortunately, the long-term outcomes of lumbar disc herniation are challenging to treat, regardless of approach.[114] In addition, SPORT agreed with previous trials[11,15,126] that the natural history of discogenic radicular pain consists of slow improvement over time. Outcomes of patients undergoing surgical versus nonsurgical treatments for lumbar spinal stenosis continue to be similar in terms of decreased pain burden and change in functional status, but complication rates increase with surgical management.[127] When surgical options are unavailable, ESI can be an effective treatment.[128] Follow up data from a controlled trial of lumbar TF-ESIs suggest that non-operative care may be effective in decreasing the need for disc surgery over time, with lower morbidity.[129] Findings from epidemiologic studies of cervical radicular pain demonstrate similar results.[130,131]

A study of 192,777 patients who received CESI for radiculopathy, cervical disc herniation, or stenosis found that within five years, one in five patients underwent surgery.[132] Patients with stenosis or disc herniation were more likely to have surgery than patients with isolated radiculopathy. Patients with repeated injections were less likely to continue surgery,[132] which is consistent with a study by Riew et al. who found a significant reduction in the frequency of lumbar spine surgery in patients treated with up to four TF-ESIs.[133] In follow up data, Riew[129] discovered that patients in the bupivacaine-betamethasone group versus the bupivacaine-only group had no significant differences in avoiding operative treatment. However, Gerling et al.[113] found that ESIs did not have a surgical-sparing effect for patients with degenerative spondylolisthesis, again demonstrating the importance of patient selection for intervention.

There are known predictors of eventual operative management, such as male sex and prior opioid use,[125] and there is also a likely association between biomarkers and response to ESI. Schaaf proposed that 35% of pain patients were responders, which correlated with baseline plasma levels of certain substances, namely, lower levels of chondroitin sulfate-846 and higher neuropeptide Y and serotonin levels as compared with non-responders.[134] Patients have a higher risk of requiring reoperation if a microdiscectomy is completed within the six weeks following lumbar ESI.[135] Therefore it is important for pain providers to communicate their plan for intervention if a surgery is being considered. More research is needed to assess and validate the predictive ability of patient attributes, as this is crucial for selecting surgical candidates.

Patients show clinical improvement after both interlaminar CESIs[136] and cervical TF-ESIs.[137,138] Therefore the selection of approach is at the discretion of the individual provider. Few randomized, placebo-controlled studies of CESIs, interlaminar or transforaminal, have been conducted to date.[61] One 2019 study comparing interlaminar and transforaminal approaches for cervical radicular pain showed no difference in efficacy.[139] Another study noted decreased efficacy of cervical IL-ESI treatment in patients with severe foraminal stenosis or high spinal level cervical disc herniation.[140] The latter is logically valid given that cervical IL-ESI is not typically superior to the C7-T1 interspace. However, larger studies with longer follow up periods are still needed, especially given the differing complication rates of the two approaches.

Contrast Media Use in Epidural Steroid Injections

Contrast media (CM) is employed in interventional pain procedures to confirm the correct placement of the needle tip and the absence of intravascular uptake. In most instances, the volume

TABLE 65.5 Selected Studies: Surgical vs Non-operative Treatment

Authors	Patients	Design/Technique	Outcome Measure	Conclusion
Weinstein, et al.[13]	S = 245 N = 256	RA, assigned to surgery or non-operative care	Rate of operative intervention	Both surgical and non-operative groups improved over two years
Karademir, et al.[16]	ESI = 70	R, review of patients with symptomatic lumbar intervertebral disc herniation	VAS Oswestry 3- Modified Ashworth Scale	Surgical treatment recommended for patients with persistent low back pain for more than six weeks
Atlas, et al.[11]	S = 217 N = 183	PO, ten year outcomes of patients with lumbar disc herniation	Rate of operative intervention	Surgically treated patients have more complete relief after ten years. Improvements were similar regardless of treatment
Oster, et al.[126]	54 articles reviewed in full	Meta-analysis, ten years clinical outcomes of Spine Patient Outcomes Research Trial	Short Form-36 Health Status Questionnaire 2- Oswestry	Surgical treatment was greater at three months and two years compared to non-operative treatment in the observational cohort. No difference in the RCT cohort. Surgically treated patients had greater improvements at four and eight years
McCormick, et al.[15]	Percutaneous lumbar disc decompression = 70 One year follow up = 40 Eight year follow up = 25	PO, patients with discogenic lumbosacral radicular pain	NRS Oswestry Rate of operative Intervention	Percutaneous lumbar disc decompression has relief over long-term follow up
Zaina, et al.[127]	26 articles reviewed in full	Meta-analysis, surgical vs. non-operative treatment in patients with lumbar spinal stenosis	Oswestry Zurich Claudication Questionnaire	Surgical vs. non-operative approach was similar in treating lumbar spinal stenosis. Surgical treatment includes side effects not reported in non-operative management
Gomes, et al.[128]	ESI = 32	PO, dogs with degenerative lumbosacral stenosis	Rate of operative intervention	Surgical decompression can lead to a more favorable outcome. ESI is a long-term alternative treatment
Kleimeyer, et al.[132]	192,777	R, C, ESI for diagnoses of cervical disc herniation or stenosis, or radiculopathy	Time of ESI to surgery	Over one-fifth of patients continued to surgery in five years. Patients with repeat injections are at a lower risk to continue to surgery
Gerling[113]	Control = 192 Epidural injection = 74	R, surgical candidates with degenerate spondylolisthesis	Short Form-36 Bodily Pain score Self-reported preference for surgery	No relationship between ESI and improved clinical outcomes over a four year period
Lilly, et al.[125]	277,941	R, patients with lumbar intervertebral disc herniations	Rate of operative intervention	Non-operative treatment can be used successfully for the majority of patients. Predictors of treatment failure include male sex and prior opioid use
Bhattacharjee, et al.[135]	12,786	R, microdiscectomy patients	Rate of operative intervention	Six month reoperation rates increase with patients who received injections six weeks prior to surgery
Bush, Hillier[137]	68	PO, serial periradicular/ epidural corticosteroid injections	Rate of operative intervention	All patients had relief without surgery at an average of 39 months

• **Figure 65.9** Data from the Spine Pain Outcomes Research Trial demonstrate no significant difference between bodily pain scores (**A**), physical function (**B**), and Oswestry Disability Index (**C**) over a two month study period in which surgery was compared to conservative care of patients with radicular pain. (Weinstein JN, Tosteson TD, Lurie JD, et al. Surgical vs. nonoperative treatment for lumbar disc herniation: the spine patient outcomes research trial (SPORT): a randomized trial. *JAMA*. 2006;296:2441–2450.)

injected is 1–3 mL and may be repeated. Overall, CM should be used in ESI procedures. Cervical and lumbar IL-ESIs should be performed using image guidance and a test dose of CM. Additionally, dye injection to evaluate needle placement of cervical and lumbar TFESI should be conducted with real-time fluoroscopy.[141]

Several developments have impacted the continued use of radiocontrast agents for ESIs. These include gadolinium (Gd) deposition/retention in the brain following repeated administration of gadolinium-based contrast agents (GBCAs),[142–144] and encephalopathy from unintentional intrathecal injection of GBCA.[145,146] Another concern with CM for interventional procedures relates to hypersensitivity reactions (HRs) and iodinated contrast medium (ICM).[147] See more on contrast agents in Chapter 73.

High signal intensities in the dentate nucleus and globus pallidus in patients exposed to linear GBCAs were first reported by Kanda et al.[142] They noted that the dentate nucleus-to-pons and globus pallidus-to-thalamus signal intensity ratios in patients who had undergone contrast-enhanced examinations were significantly greater than those who underwent unenhanced examinations. Other investigators have also demonstrated the deposition of Gd in the skin and bones of patients exposed to CM.[148,149] However, brain deposition/retention in this instance pales in comparison to catastrophic sequela from unintentional IT gadolinium injection. Factors to consider when choosing a specific GBCA include diagnostic efficacy, rate of adverse reactions, dosing and concentration, radio-opacity, and the propensity to deposit in organs such as the brain. While gadobutrol has the highest radiographic conspicuity (pixel value difference with respect to background), it contains the highest molar concentration of Gd.[150] This increased concentration likely increases the risk of encephalopathy after unintentional IT Gd injection. More research is needed to determine the clinical significance of gadolinium brain deposition after small extravascular injections, typical of interventional pain procedures.

Cases of encephalopathy after unintentional IT injection of gadolinium have been reported after interventional pain procedures.[30,146,151,152] The risk of unintentional IT injection after an IL-ESI is well known (0.2%) but also occurs with TF-ESIs (0.04%).[153] In one report, seizures, impaired consciousness, and intubation resulted from gadobutrol (1.5 mL) unintentionally injected into the intrathecal space prior to an ESI.[146] Another patient developed pain and spasms in the lower extremities after injection of 2 mL gadobutrol for an IT catheter contrast study.[152] Both patients fully recovered. However, a 2019 publication reported a patient who required intubation within 12 h of unintentional intrathecal gadoteridol injection during the minimally invasive lumbar decompression procedure. The patient died 18 days later.[30] Encephalopathy after unintentional Gd injection is of grave concern to the interventional pain physician given the potentially catastrophic sequelae.

Of the iodinated CM, iohexol and iopamidol are FDA-approved for intrathecal use and are used for spine interventional pain procedures. In the absence of HRs to ICM, these agents provide an alternative when interventional pain procedures with a high risk of IT injection are performed in the spine.

Immediate contrast reactions can be non-immunoglobulin E (IgE)-mediated or IgE-mediated. The pathways of non-IgE-mediated reactions include a direct membrane effect on the basophil or mast cell, complement activation, or bradykinin generation.[154] Most HRs to CM are anaphylactoid in nature, also called idiosyncratic or non-allergic hypersensitivity.[155,156] The American College of Radiology classified the reactions as allergic-like and physiologic in nature and the severity of reactions from mild to moderate to severe.[157] The greatest risk factor for HR to CM is a previous history of HR, but other predisposing factors include asthma, atopy, severe cardiovascular disease, female sex, and drug allergy.[158,159]

Clinical trials show the overall and severe adverse reaction rates to low osmolar ICM to be 0.2%–0.7% and 0.01%–0.02%, respectively.[160–162] The incidence of HR is higher with ICM than with Gd. A review and meta-analysis of nine trials (716,

978 administrations) showed that the overall and severe rates of allergic-like reactions were 9.2 (0.092%) and 0.52 (0.0053%) per 10,000 administrations, respectively.[163] Similar to ICMs, HRs-to-GBCAs are mostly mild in nature. The most frequent allergic-like symptoms are urticaria and respiratory or throat symptoms.[164] The risk factors are the same as those for ICM: previous HR (recurrence rate 30%), female sex, allergies or asthma, number of exposures, inpatient status, and imaging target (abdomen and/or pelvis).[159,164–166] In terms of structure, HRs are more common with macrocyclic GBCAs than with linear GBCAs, partly because of their higher osmolality.[156] Macrocyclic GBCAs may also be used in patients who have had moderate or severe HRs to ICM, and linear GBCAs are also an option for spinal injections. Regardless of the gadolinium agent employed, caution should be exercised to avoid unintentional injection of Gd into the IT space.

In a case series, six patients with a history of previous HR to intravenous ICM for diagnostic procedures did not have breakthrough reactions when ICM was injected into the epidural space without pretreatment. Patients had a history of HR to ICM and were given iodinated contrast during an interventional pain procedure. Regardless of patient history in reaction to high volume contrast from prior CT, the authors ascribed the lack of breakthrough reactions during ESIs to the small (1–3 mL) volumes of CM injected, slow absorption from the epidural space, and concurrent administration of steroids.[147] Patients should be observed for at least 30 min after the procedure, especially in patients with a history of HRs. For patients with mild reactions, physicians may determine if pretreatment of these patients is necessary. While most interventional pain radiologists do not pretreat, anesthesiologists often opt for pretreatment. In cases of mild reactions, the use of steroids for pretreatment should be a risk-benefit analysis based on the patient's comorbidities. This is based on the assumption that ICM has been elected because GBCA use is contraindicated for the procedure (i.e. interlaminar epidural injection).

Complications of Epidural Steroid Injections

Complications of ESIs can be ascribed to the procedure or injection. Complications from the procedure include neurologic injury, infection, and bleeding/hematoma. Complications from the injectate include neurologic injury and systemic side effects.[167] A 2004 closed claims study revealed that ESIs accounted for 40% of all chronic pain management claims. Of the 114 ESI claims in the study, 25% were nerve injuries, 21% infections, 18% headaches, and 8% were deaths or brain damage.[168] The nerve injuries resulted in paraplegia or quadriplegia, either from injection into the spinal cord or compression due to epidural abscess or hematoma. Infections included meningitis and epidural abscesses. Death or brain damage occurred only in ESIs involving administration (achieved or attempted) of LA to the epidural space and, in some cases, with co-administration of opioids.

A follow up publication from the Closed Claims group noted that cervical procedures accounted for 22% (64/294) of chronic pain treatment claims, the most common being needle trauma to the spinal cord, neural ischemia after intra-arterial injection, and dural puncture.[169,170] Spinal cord damage was noted in 59% of patients, with direct needle trauma as the leading cause (31%). In 67% of cervical intervention claims, general anesthesia or sedation was employed compared to 19% of claims without spinal cord injuries. In patients with spinal cord injuries, 25% were unresponsive during the procedure compared to 5% of patients with cervical interventions but did not have spinal cord injury. Appropriate sedation allays anxiety and reduces the risk of sudden movement but still allows reporting of pain or paresthesia when there is needle-to-nerve contact. In contrast, heavy sedation eliminates the patient's ability to communicate warning signs of cord injury and is not recommended during neuraxial procedures.[170] Back pain after lumbar spine intervention is usually mild, localized, and resolves within two to three days. Back pain is attributed to tears in the ligaments, fascia, or bone with localized bleeding, immobility of the spine, relaxation of the paraspinal muscles under anesthesia, flattening of the normal lumbar convexity, and stretching and straining of the lumbosacral ligaments and joint capsules.[171] Other findings of the Closed Claims group included the use of radiographic guidance in 76% of claims and the use of contrast in 57% of claims with spinal cord injury. After reviewing the records for each case, the reviewers concluded that the appropriate use of radiographic guidance would have prevented spinal cord injury in 45% of claims with injury compared to 17% of claims without injury.[169]

A more recent analysis of malpractice claims regarding outpatient interventional pain procedures involved the Controlled Risk Insurance Company.[172] The analysis identified 126 closed claims, of which 34 were lumbar and 31 were cervical IL-ESIs. The common alleged events included improper performance of the procedure (n = 38), nonsterile technique (n = 17), unintentional dural puncture (n = 13), and needle misdirected to the spinal cord (n = 11). The commonly reported outcomes included worsening pain (n = 26), spinal cord infarct (n = 16), epidural hematoma (n = 9), and postdural puncture headache (n = 9). Perceived deficits in technical skills were present in 83% of claims.

Postdural Puncture Headaches

Although rare, postdural puncture headaches (PDPHs) may occur after diagnostic lumbar puncture. Benzon et al. studied the incidence of PDPHs in patients who received dural punctures and noted that 13 of 142 (9%) developed headaches. Treatment for postdural headache consists of intravenous and oral fluids, analgesics, bed rest, and, if necessary, an epidural blood patch.[173] The clinician should be alerted to the presence of intracranial pathology in patients with classic PDPH with a postural component, in which headache worsens with standing or sitting and improves in the supine position and is accompanied by typically associated signs and symptoms such as nausea, vomiting, and neck stiffness.[174]

Vascular Injury

Intraarticular C1-C2 (lateral atlantoaxial joint) injections are now uncommon because of reports of stroke due to injection of the vertebral artery.[175] Several cases of CNS injuries involving the brain or spinal cord have been described after TF-ESIs. Events involving the brain consist of cerebellar infarction, cortical blindness from edema of the occipital cortex, or death from brain stem hemorrhage.[176–178] These events have been ascribed to embolism of particulate steroid, trauma to the vertebral artery, or vasospasm from the injected contrast or steroid. Spinal cord events included paraplegia or quadriplegia.[179–184] Cases involving particulate steroids were permanent, while non-particulate injectates (CM or LA) caused temporary events (lower extremity paralysis or blindness for three weeks).[179,184] One case of permanent injury after

use of non-particulate steroid was attributed to either vasospasm from the needle tip or injectate and/or anterior spinal artery obstruction from a thrombus formation, intimal flap formation, or dissection.[183] Kim et al. found that approximately 30% of transforaminal injections demonstrated intravascular spreading patterns during real-time fluoroscopy, which was significantly more likely in the cervical than the lumbar spine ($P < 0.001$). The authors suggest using at least 3 mL of contrast agent during neurogram to ensure that the needle tip is outside the vasculature.[185]

Regarding particle size, methylprednisolone acetate and compounded betamethasone preparations were noted to be the largest size, triamcinolone acetonide was intermediate, and betamethasone sodium phosphate/betamethasone acetate was the smallest.[176,186] If a non-soluble steroid is preferred, the recommended preparation is commercial betamethasone. Commercially available betamethasone (Celestone Soluspan^{R}) contains 3 mg/mL betamethasone sodium phosphate, which is non-particulate and short-acting, and 3 mg/mL betamethasone acetate, which is long-acting and particulate.[186] Dexamethasone was noted to be purely non-particulate in one study[176] and to contain small particles in another study.[186] In addition, the particles were noted to aggregate very quickly. These particles are large enough to occlude possible vascular routes of embolism. Studies investigating the routine use of dexamethasone are needed to determine its safety and efficacy.

For cervical TF-ESIs, the routes of embolization of the particulate steroid include the vertebral artery, ascending cervical artery, deep cervical artery, and the radicular artery accompanying the nerve root.[62,186–188] For lumbar TF-ESIs, the routes include the radicular artery, a low-lying artery of Adamkiewicz, or in rare cases, the Desproges-Gotteron artery. The artery of Adamkiewicz is in the upper half of the foramen 97% of the time and has never been observed in the most inferior fifth of the foramen[187] and may be present at any level of the lumbar spine, although more common at high lumbar levels (Fig. 65.10). Similarly, the Desproges-Gotteron artery may be present in the Kambin triangle, even at the L5 vertebral level. It may explain the rare instances of paralysis that have been reported at low lumbar levels. A cadaver study revealed that the ascending cervical and deep cervical arteries supply medullary arteries to the anterior spinal artery and that the ascending cervical and deep cervical arteries anastomose with the vertebral artery.[62] Also noted was the close proximity—within 2 mm of the needle tip—of the ascending cervical and deep cervical arteries to the cervical SAP, which is a landmark for cervical TF-ESIs, as referenced earlier in the chapter (Fig. 65.1). An ultrasound study confirmed the presence of many vessels at or in the projected pathway of selective nerve root blocks at C5–C7.[188] These findings explain reported embolisms to the brain or segmental infarct of the spinal cord from TF-ESIs. The contrast or particulate steroid can be injected into the radicular artery, which connects to the anterior spinal artery. The injection of methylprednisolone into the vertebral artery of pigs resulted in the animals becoming unconscious and requiring ventilator support, whereas animals that received dexamethasone showed no evidence of injury.[189] In another study the injection of different steroids into the carotid artery of rats, resulted in cerebral hemorrhage with the following incidences: eight of 11 for methylprednisolone, zero of eight for dexamethasone and saline, and three of six for the carrier.[190] The findings for the carrier may be attributed to a reaction to the preservative. Although rare, it is still possible for vascular injury to occur even with the use of a water-soluble steroid such as dexamethasone.[183]

Solvent Toxicity

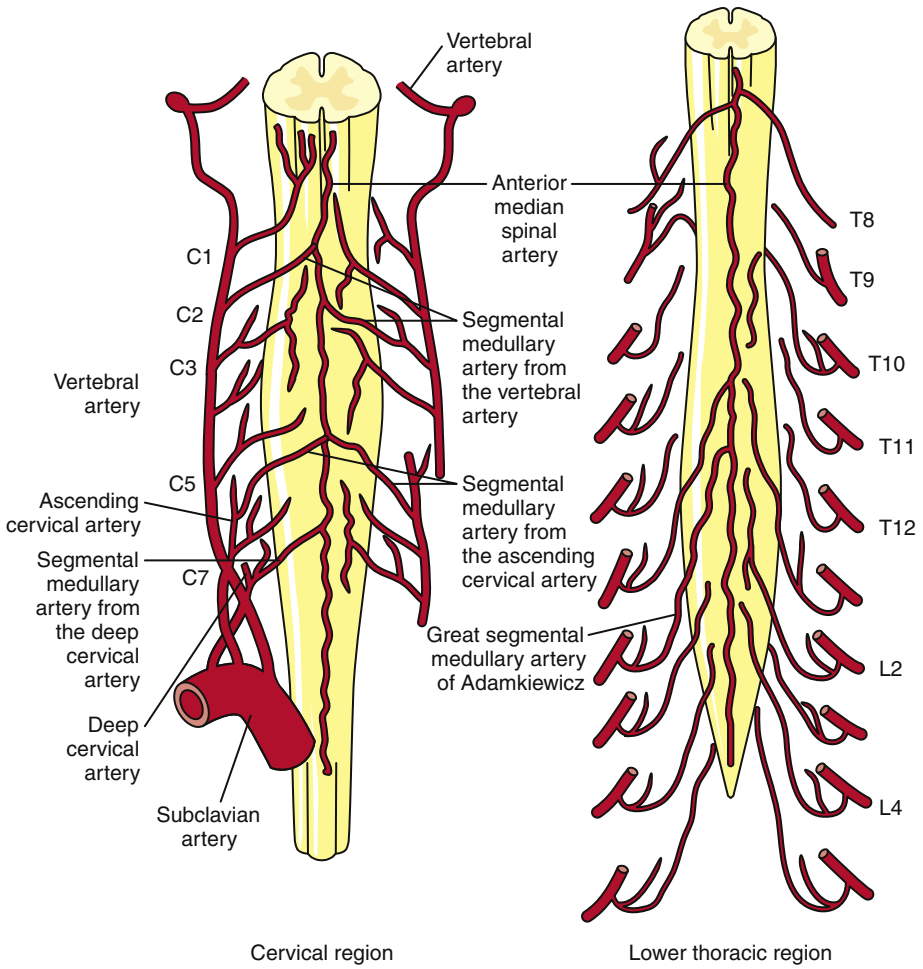
Steroids contain a vehicle and preservatives to prolong their shelf life. These include benzyl alcohol, polyethylene glycol, myristyl γ-picolinium chloride (MGPC), and benzalkonium chloride (BKC).[191] The neurotoxicity of benzyl alcohol was deduced after a primigravida developed flaccid paralysis after unintentional subarachnoid injection of 40 mL of 0.9% NaCl containing 1.5% benzyl alcohol. The patient recovered after 30 h and had complete recovery after six months.[192] In contrast, no motor block was noted after injection of 40 mL of 2.5% benzyl alcohol into the caudal space of a patient with pelvic cancer pain.[193] Animal studies also showed no neurotoxicity from benzyl alcohol. Regarding polyethylene glycol (PEG), in an isolated nerve preparation, 30% PEG decreased the amplitudes of the compound action potentials of the A, B, and C-fibers, while 40% abolished the potentials.[194] Concentrations greater than 40% could not be studied because of their viscosity. All compound action potentials recovered within a 2 h washout. Intravitreal injection of 1 mL of 0.38, 0.76, or 1.52 mg/mL MGPC resulted in disarrayed and swollen fibers in the retina of rabbits 24 h after injection. Loss of retinal layers occurred at six weeks.[195] The conjunctival application of BKC resulted in a 30% decrease in stromal nerve fiber density with a 0.01% concentration and 60% decrease with 0.1%.[196] It should be noted that the concentrations of the vehicles and preservatives used in these studies, other than BKC, were several-fold higher than their concentrations in the commercial depot steroid preparations.[191] The collective data on animal studies exonerate the preservatives in the commercial depot steroids as being neurotoxic when injected into the epidural space.[197–199] Additionally, the steroid is typically diluted with 1–3 mL saline or LA before ESI, further decreasing concentrations of the preservatives. Concerns regarding adverse events due to preservatives prompted clinicians to order compounded steroids without any vehicle or preservatives. However, the use of contaminated compounded steroids led to multistate cases of fungal meningitis.

Injectate Contamination

Clinicians who use compounded steroids often sense that they avoid neurotoxicity from the preservatives and that they are cheaper than commercial depot steroids. However, compounded steroids pose practical issues. For example, a New England company's production of a contaminated compounded steroid led to a multistate outbreak of fungal infections.[200] This devastating event led to increased federal supervision of compounding companies. In 2012, more than 590 cases of fungal meningitis were reported after ESI of contaminated compounded methylprednisolone. In response to these adverse events, the Pharmacy Compounding Accreditation Board (PCAB) was created to evaluate compounding companies and hold them accountable to nationally accepted quality control, quality assurance, and quality improvement standards. That year, only 2% of compounding companies participated in the PCAB program. PCAB accreditation will ensure the preparation of sterile and safe medication, but further legislative and regulatory changes are needed to prevent future adverse events.[191]

Epidural Abscess

This is a rare complication of ESIs. A study showed no infection after 4265 epidural injections in 1857 patients over a seven year period.[201] However, infections after ESIs have been reported, and

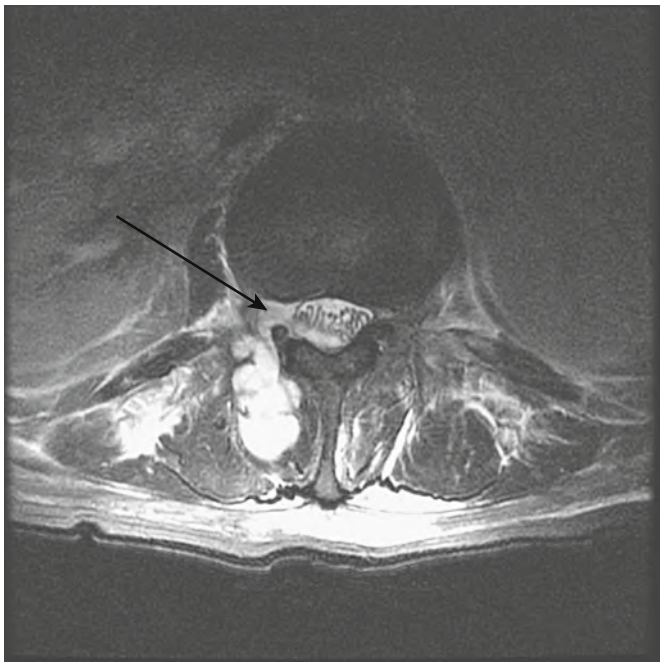


• **Figure 65.10** Artist's adaptation of an earlier drawing from Gillilan. *Left panel*, Contributions of several segmental medullary vessels to the anterior median spinal artery; *right panel*, great segmental medullary artery of Adamkiewicz entering at the L2 intervertebral foramen on the left side. (From Gillilan LA. The arterial blood supply of the human spinal cord. *J Comp Neurol.* 1958;110:75–103.)

although suspicion is raised due to patient history and physical, the definitive diagnosis is achieved with MRI (Fig. 65.11). A retrospective review of a prospectively maintained database of 1182 cervical ESIs and 4617 lumbar ESIs revealed three cases of infection, all in the lumbar group.[202] An analysis of 128 cases of purulent meningitis showed eight cases of paraspinal abscess originating from injections, one due to an ESI, and the remaining seven due to facet or paravertebral injections.[203] Factors resulting in infection include breaks in sterile techniques, skin disinfectant failures, contaminated instruments and injectates, and hematogenous dissemination. Immunocompromised patients are at an increased risk of infection. A review of 14 cases of epidural abscess or meningitis reported in the literature revealed that eight of the 14 patients were immunocompromised. In their review the authors noted that the cultures of blood, cerebral spinal fluid, or pus in all patients were positive for *Staphylococcus aureus*.[204] In addition to immunocompromised patients' susceptibility to infection, adrenal suppression can occur from the injected steroid.[205] The American Society of Anesthesiologists and the American Society of Regional Anesthesia and Pain Medicine (ASRA) published a practice advisory on prevention, management, and diagnosis of infectious complications after neuraxial techniques.[206,207] Some of their recommendations on aseptic techniques include removal of jewelry (e.g. rings and watches), hand washing, wearing of caps, wearing masks covering both mouth and nose, sterile gloves, sterile draping of the patient, use of individual packets of antiseptics for skin preparation, use of antiseptic solutions (e.g. chlorhexidine with alcohol) for skin preparation, and allowing for adequate drying time. An expanded discussion of infections is presented in Chapter 74.

Disease-Modifying Anti-rheumatic Drug Complications

Nonbiologic and biologic disease-modifying anti-rheumatic drugs (DMARDs) are used to slow rheumatoid arthritis disease progression. Nonbiologic DMARDs include methotrexate, sulfasalazine, hydrochloroquine, leflunomide, and doxycycline. Biologic agents include etanercept, golimumab, infliximab, abatacept, certolizumab, rituximab, tocilizumab, anakinra, secukinumab, ustekinumab, belimumab, and tofacitinib. There is an increased risk of perioperative infection in patients taking more than one DMARD.[208,209] National rheumatology associations caution that the risks of postoperative infection must be balanced against the possibility of arthritic flare from discontinuation of therapy. The guidelines advise the continuation of DMARDs, such as methotrexate, perioperatively. Biologics should be stopped before



• **Figure 65.11** An accumulation of abscess material (*arrow*) is seen tracking epidurally and into the perispinal soft tissues. (From Hooten WM, Kinney MO, Huntoon MA. Epidural abscess and meningitis after epidural corticosteroid injection. *Mayo Clin Proc.* 2004;79:682–686.)

surgery; the interval depends on the pharmacokinetics of the specific drug.[210–213] Anti-TNF drugs should not be used during the preoperative period for at least one week prior to, and one week after surgery,[209] or stopped for three to five times the half-life of the relevant drug prior to surgery.[210] Resumption is advocated when the wound is healed, usually around 14 days, and in the absence of infection. There have been no reports of infection after epidural administration in a patient taking a DMARD drug. However, there has been a case of spinal and paraspinal inflammatory reaction (mass) after ESI in a patient who was taking methotrexate, adalimumab, and prednisone.[214] Several cultures of the lesions in the paravertebral soft tissue, ligamentum flavum, and pedicle were negative for fungal, aerobic, and anaerobic organisms. This case demonstrates the adverse reaction in immunocompromised patients, even with strict observance of aseptic techniques.

Hematoma

Bleeding and spinal hematoma are the consequences of epidural injections. ASRA Pain Medicine guidelines on interventional pain procedures in patients on anticoagulants are discussed in Chapter 74. In patients at high risk for a cardiovascular event, a shared decision making process should be followed before anticoagulant discontinuation. It has been recommended that the $CHADS_2$ (C-congestive heart failure, H-hypertension, A-age >75, D-diabetes mellitus, S-stroke, or transient ischemic attack) score be determined.[215] In this scoring system, one point each was given for the presence of congestive heart failure, hypertension, age ≥75 years, and diabetes mellitus, and two points for the history of stroke or TIA. A patient with a CHADS2 score of three should prompt the consideration of low-molecular-weight heparin (LMWH) bridge therapy, after discontinuation of the anticoagulant, with stoppage of LMWH 24 h before the procedure.

Endocrine Complications

The most common side effects or complications from ESIs are endocrine-related.[216,217] ESIs with triamcinolone and methylprednisolone cause reductions in cortisol levels for more than three weeks.[218] A study by Park et al. in patients receiving ESIs for six months or longer showed no incidence of Cushing's syndrome, but two patients (11.8%) developed adrenal insufficiency (AI). An unanticipated adrenal crisis due to AI would be rare but dangerous.[219] Therefore regular monitoring of adrenal function is suggested in patients who have received long-term ESIs.

ESIs can increase the blood sugar levels. In a study of diabetic patients, the investigators found significant increases in fasting blood sugar on post-procedure days one to three after 40 mg triamcinolone and on post-procedure day one after 20 mg of dexamethasone. Analgesia in both groups was similar.[220] The elevation of blood glucose after ESIs has been shown in other studies: a 75% increase in one study,[221] prolonged elevations for up to three days in another study,[222] and up to four days in another study.[220]

Abnormal vaginal bleeding after ESIs has been reported anecdotally. In a large paired observational retrospective cohort study of 8,166 ESIs, the authors noted that subjects were 2.8 times more likely to have abnormal vaginal bleeding during the post-injection period compared to the pre-injection period.[223] Additionally, bleeding prompted endometrial biopsies in 52% of cases; benign findings were noted in 100% of premenopausal women.

ESIs have been shown to affect bone mineral density. A systematic review of eight articles that studied 7,233 patients revealed an association between ESIs and decreased bone mineral density, and increased vertebral fracture risk.[224] The significant decreases were related to a cumulative methylprednisolone dose of 200 mg over one year and 400 mg over three years. The risk of osteoporosis and osteopenia was diminished in patients who were on anti-osteoporotic medication during the ESIs.

Neurologic Complications

The Multidisciplinary Working Group, a consortium of pain medicine organizations, under the auspices of the FDA-Safe Use Initiative, proposed safeguards to prevent neurologic complications after ESI (Table 65.6).[141,225] Moderate to heavy sedation is not recommended. The recommendation to perform the cervical IL-ESI at C6-C7 or C7-T1 is prompted by the wider diameter of these interspaces and the presence of gaps in the ligamentum along the higher cervical levels.[225] The use of a particulate steroid in cervical TF-ESIs is not recommended. However, it may be used in lumbar TFESI if an initial injection of a non-particulate steroid (e.g. dexamethasone) is ineffective.[141,225] Additionally, particulate steroids have a higher incidence of neurologic complications at the cervicothoracic level.[226] IL-ESIs without contrast is an option in patients with a history of moderate/severe HR (The topic of contrast is discussed in Chapter 73.). Digital subtraction imaging (DSI) was not approved by the group. Although DSI improves the detection of intravenous injection compared with negative aspiration assessment, it also increases radiation exposure and cannot distinguish between the arterial or venous spread. A case of paraplegia has also been reported, even with a reassuring DSI study.[227]

The multi-disciplinary working group recommendations were confirmed and amplified by the BENELUX (Belgium, Netherlands, Luxemburg) group.[228] They also recommended an LA test dose prior to injection, limiting the volume of injection to 4 mL, and TF-ESIs to be performed in the Bogduk "safe triangle" (upper

TABLE 65.6 Statements and Clinical Considerations of the Multispecialty Work Group to Reduce Neurologic Injuries after Transforaminal Epidural Steroid Injections

1. Cervical IL-ESIs are associated with a rare risk of catastrophic neurologic injury.
2. TF ESI using particulate steroid is associated with a rare risk of catastrophic neurovascular complications.
3. All cervical IL-ESIs should be performed using image guidance, with appropriate anteroposterior (AP), lateral, or contralateral oblique views and a test dose of contrast medium.
4. Cervical TF-ESIs should be performed by injecting contrast medium under real-time fluoroscopy and/or digital subtraction imaging, using an AP view, before injecting any substance that may be hazardous to the patient.[a]
5. Cervical IL-ESIs are recommended to be performed at C7-T1, but preferably not higher than the C6-C7 level.
6. No cervical IL-ESI should be undertaken, at any segmental level, without reviewing, before the procedure, prior imaging studies that show there is adequate epidural space for needle placement at the target level.
7. Particulate steroids should not be used in therapeutic cervical TF injections.
8. All lumbar IL-ESIs should be performed using image guidance, with appropriate AP, lateral, or contralateral oblique views, and a test dose of contrast medium.
9. Lumbar TF-ESIs should be performed by injecting contrast medium under real-time fluoroscopy and/or digital subtraction imaging, using an AP view, before injecting any substance that may be hazardous to the patient.[a]
10. A non-particulate steroid (e.g. dexamethasone) should be used for the initial injection in lumbar transforaminal epidural injections.
11. There are situations where particulate steroids could be used in the performance of lumbar TF-ESIs.
12. Extension tubing is recommended for all TF-ESIs.
13. A face mask and sterile gloves must be worn during the procedure.
14. The ultimate choice of what approach or technique (IL vs. TF ESI) to use should be made by the treating physician by balancing the potential risks and benefits of each technique for each patient.
15. Cervical and lumbar IL-ESIs can be performed without contrast in patients with documented contraindications to the use of contrast agents (e.g. significant history of contrast allergy or anaphylactic reaction).
16. TF-ESIs can be performed without contrast in patients with documented contraindications to use. However, particulate steroids are contraindicated in these circumstances, and only preservative-free, particulate-free steroids should be used.
17. Moderate to heavy sedation is not recommended for ESIs, but if light sedation is used, the patient should remain able to communicate pain or other adverse sensations or events.

[a]An organization voted against statements four and nine; preferred that digital subtraction imaging should be mandatory before transforaminal injection of a potentially hazardous substance.

AP, Anteroposterior; *ESI*, epidural steroid injection; *IL*, interlaminar; *TF*, transforaminal.

aspect of the foramina) or the Kambin triangle. A test dose of LA, if intravascular, may result in neurologic signs and symptoms within 30–60 s, prompting redirection of the needle. A study demonstrated that patients with signs of systemic toxicity from the test injection of LA could prompt abandonment of the procedure, which suggests a protective effect of test dosing in avoiding neurologic complications.[229] Regarding the injection site, other authors recommend injecting at Kambin's triangle, that is, the inferior aspect of the foramen as this area is less vascular.[230] However, this triangle does not absolutely guarantee avoidance of vasculature, as the Desproges-Gotteron artery may be present even at low lumbar levels. Injury to this artery is a potential etiology of reported cases of paralysis using dexamethasone via the transforaminal route in the Bogduk "safe triangle." The lowest doses recommended by the BENELUX group were 40 mg methylprednisolone, 10–20 mg triamcinolone, and 10 mg dexamethasone. A major difference is the group's permission to inject non-particulate steroids transforaminally at the L3 level or lower.

Summary

The evidence seems to support the use of interlaminar, caudal, and transforaminal CS injections for radicular pain and painful radiculopathy secondary to spinal stenosis or disc pathology for short-term analgesia. Most studies suggest modest benefits for variable periods of two weeks to three months.[24,26,112–114] Recent studies suggest that particulate and non-particulate injections result in a similar duration of relief.[141] The short-term benefit of ESIs and the favorable natural history of radicular pain may be complementary factors with respect to the clinical improvement that is typically observed in patients. The impact of other conservative therapies, such as medications, exercise, physical therapy, and cognitive behavior strategies, combined with epidural CSs has not been studied in a robust fashion.

Given the waxing and waning nature of radicular symptoms, ESIs may provide prolonged functional benefits when used for exacerbations. However, ESIs are associated with complications, most of which are preventable. Pain medicine physicians should be aware of these complications, observe measures to avoid them, diagnose issues without delay, request expert consultation as necessary, and treat the patient accordingly. Identifying the origin of spine pain and instituting appropriate treatments should be performed by providers with expertise in pain management.

Key Points

- The natural history of discogenic radicular pain is favorable for conservative management.
- Randomized, placebo-controlled trials have shown short-term benefits with ESIs via multiple techniques.
- The best practice for nonsurgical radicular pain syndromes is yet to be defined; few comparative, nonsurgical trials have been conducted.

- Because of the rare but catastrophic nature of complications of interventional epidural treatments and the favorable natural history of radicular pain, safety should be a primary concern.
- Systemic side effects of ESIs include decreased bone mineral density, reduced blood cortisol levels over three weeks, and increased blood glucose levels.
- Neurologic complications occur after transforaminal epidural injections of steroids, the most common of which is vascular injury due to embolization of particulate steroids through the accompanying radicular artery, ascending cervical, and deep cervical arteries. The cervical arteries anastomose with the segmental medullary arteries and connect it with the anterior spinal artery.
- A multi-disciplinary pain working group recommended the initial use of a non-particulate steroid when transforaminal ESIs are employed for cervical radicular pain and painful radiculopathy.
- Caution is recommended when using gadolinium as the contrast agent because it is linked to nephrogenic systemic fibrosis, gadolinium deposition/retention in the brain, and encephalopathy/death from an unintentional intrathecal injection.
- Future research should investigate alternative pharmacologic agents or techniques to address the pathophysiology of radicular pain syndromes; the use of these agents via continuous or prolonged delivery is of interest.

66 Radiofrequency Treatment

KOEN VAN BOXEM, MAARTEN VAN EERD, THIBAUT VANNESTE, XANDER ZUIDEMA, JAN VAN ZUNDERT

The use of electric current for pain management has a long history. As early as the second half of the 19th century, brain lesions were made in animals with the application of direct current, and empirical rules for quantifying lesion size based on current and time were developed.[1,2] One of the first uses in humans was for the management of trigeminal neuralgia in 1931 when a direct current was delivered through a needle with a 10 mm uninsulated tip placed in the Gasserian ganglion.[3] This technique produced lesions of unpredictable size.[4] The use of high frequency electric current was later found to produce lesions with a more predictable size.[5] Because frequencies of 300–500 kHz were also used in radio transmitters, the current was called radiofrequency (RF) current. Later, temperature monitoring was suggested to be the most important parameter to obtain a standardized lesion size.[6]

In pain management, RF was first used for percutaneous lateral cordotomy to relieve unilateral pain in cancer patients.[5] A few years later, RF treatment of trigeminal neuralgia was described.[7] The first use of RF current for spinal pain was reported by Shealy,[8] who performed RF lesioning of the medial branch for lumbar zygapophyseal joint pain. Another application for spinal pain was introduced by Uematsu,[9] who described RF lesioning of the dorsal root ganglion (DRG).

At the end of the 1970s, percutaneous cordotomy and RF treatment of the Gasserian ganglion were the only widely accepted RF procedures. A turning point came in 1980, when small-diameter electrodes, known as the Sluijter Mehta Kit (SMK) system, were introduced for the treatment of spinal pain.[10] The system consists of a 22-gauge disposable cannula with a fine thermocouple probe inside for measurement of temperature. The smaller electrode size resulted in diminished discomfort during the procedure. Because there was less risk for mechanical injury to major nerve trunks, targets in the anterior spinal compartment were no longer off-limits, and procedures such as RF lesions adjacent to the DRG (RF-DRG) and lesions of the communicating ramus,[11,12] and sympathetic chain became part of the treatment armamentarium.

Over the years, the concept that the clinical effect of RF current was caused by the formation of heat had not been challenged. A selective effect of heat on thin nerve fibers was thought to interfere with the conduction of nociceptive stimuli.[13]

The role of heat was finally questioned for several reasons. First, the classic concept presupposes a strict configuration: the RF lesion must be made in between the nociceptive focus and the central nervous system (CNS). However, RF lesions were also successful when performed distal to the nociceptive focus and the CNS. For example, in the treatment of acute radicular pain from a herniated disk, the electrode is placed distal to the nociceptive focus.[14] Second, RF-DRG induces only transient sensory loss, which is possibly heat related, whereas the pain relief may be of much longer duration.[15] Finally, no differences in outcome were noted when two different tip temperatures (i.e. 40°C and 67°C) were applied.[16] It is against this background that pulsed radiofrequency (PRF) treatment was developed.[17] PRF delivers strong, fluctuating electric fields while the temperature effects are kept to a minimum. PRF was conceived as a novel, potentially safer mode of administration of RF energy.[18–20] It can be specifically useful for treatments in which RF lesioning is not indicated, such as peripheral neuropathies, atherogenic pain, painful trigger points, and application to the DRG in patients with neuropathy or radicular pain.

Radiofrequency Generator System

A modern RF generator has the following components:

- Continuous online measurement of impedance
- Nerve stimulation
- RF delivery mode
- Pulsed current delivery mode
- Monitoring of voltage, current, and wattage during the RF procedure
- Temperature monitoring

Electrical impedance is measured to confirm the continuity of the electrical circuit. After placement of the needle under fluoroscopic control, nerve stimulation is performed to confirm the proper position of the electrode. Stimulation is carried out at 50 Hz to ensure proximity of the electrode to sensory fibers; 2 Hz stimulation is performed to detect muscle contractions, which indicates that the position of the needle is too close to motor fibers. If an electrode is actually resting on a nerve, the minimum stimulation level required to produce a discharge is 0.25 V.[21] At a distance of 1 cm from the nerve, 2 V would be required. Thus the stimulation threshold is an indicator of the distance of the electrode from the nerve. Temperature is measured with a thermocouple electrode. A thermocouple electrode consists of a junction of two dissimilar metal elements and produces a voltage proportional to temperature.

Theoretical Aspects of Radiofrequency Treatment

Continuous Radiofrequency Treatment

The generator establishes a voltage gradient between the (active) electrode and the (dispersive) ground plate. RF current flowing through the tissue results in an alternating electric field. This electric field creates an electric force on ions (electrolytes) in the tissue

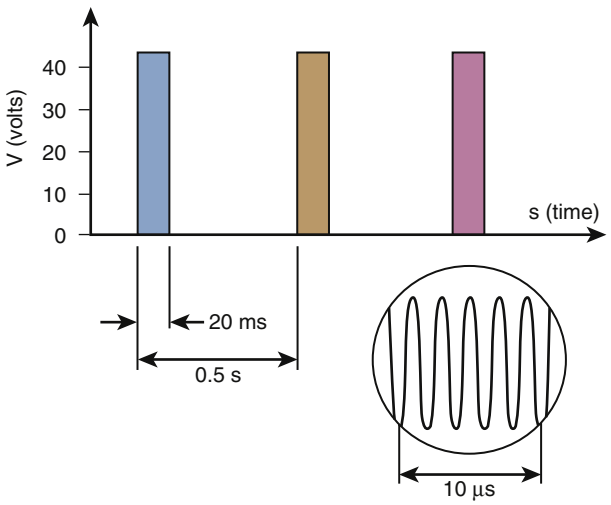
that causes the ions to move back and forth at a high rate. Frictional dissipation of the ionic movement within the fluid medium results in tissue heating. The lesion size depends on the temperature of the tip of the electrode, and tip temperature depends on the amount of power delivered. Other factors influence lesion size, for instance, heat and the type of tissue. Heat is removed from the lesion area by conductive heat loss and blood circulation (heat "washout"). The larger the heat washout, the smaller the lesion will be for a given tip temperature. The type of tissue factors influences heat washout. For example, bone is an effective heat insulator, and therefore RF lesions close to the bone will have less washout. Similarly, segmental blood vessels, which lie in close relationship to the DRG, may cause more heat washout and thereby reduce the size of the lesion.[22]

Pulsed Radiofrequency Treatment

The treatment effect of PRF is based on the dual effect of exposure of the tissue to RF fields (Fig. 66.1). Besides the ionic friction that causes the production of heat, there is an independent electric field effect. The mechanism of this electric current effect is thought to be an alteration in synaptic transmission in a neuromodulatory type of effect.[18,19,23] Alterations have been found in peripheral sensory neurons,[24] the DRG,[25,26] neurotransmitters and microglia in the dorsal horn,[27] descending inhibitory pain pathways, and the CSF.[28,29]

Practical Considerations

Although no clinical complications have been reported, this technique is considered minimal neurodestructive.[30] Therefore it may be wise to avoid ultralow sensory thresholds (<0.05 V) because such values may reflect intraneural electrode placement.[22] In a small proportion of procedures, the mean tip temperature exceeds 42°C at some point during the PRF procedure. In this case, power output should be decreased as a precaution. This can be done by lowering the voltage or by decreasing either the duration of the active cycle (typically 20–30 ms) or the frequency of the cycle (typically 2 Hz).



• **Figure 66.1** Schematic drawing of the duty cycle during pulsed radiofrequency treatment. There are two active cycles per second of 20 ms each. During the active phase, radiofrequency current is delivered at the normal frequency of 500,000 Hz. (Based on Sluijter ME. *Radiofrequency: Part I.* Meggen, Switzerland: Flivopress; 2001, with permission of the publisher.)

It is not desirable to adjust the voltage during a PRF procedure to reach the mean tip temperature since the mean tip temperature does not affect the outcome of the procedure.[31] Because there is a large variation in heat washout, large and unpredictable variations in voltage will occur. There is no optimal duration of treatment. However, durations of 240 s are often reported. Typical PRF treatment settings are 45 V for 240 s at 2 Hz and 20 ms pulse width.

Cooled RF

The use of cooled radiofrequency treatment was first described for the treatment of low back/sacroiliac joint pain. Later, it was introduced for the treatment of chronic knee pain.[32–34]

Cooled electrodes increase lesion size by removing heat from adjacent tissue and allowing power delivery to be increased without tissue scarring and high impedance.[35] A randomized controlled trial (RCT) study showed a higher success percentage and possibly a longer effect with the use of cooled radiofrequency for the treatment of knee pain.[36] There is an increasing interest in the use of cooled RF.

Indications for Radiofrequency Treatment

Radiofrequency Treatment Procedures On The Head

Radiofrequency Treatment of the Gasserian Ganglion

Trigeminal Neuralgia

Patients with trigeminal neuralgia have brief episodes of sharp, shooting pain in one or more of the trigeminal divisions that are typically provoked by touch. This so-called trigger area need not be in the division where the patient experiences pain. In the classic case, the patient is free of pain between episodes. However, residual pain has been reported in 42% of cases.[37] These patients have been described as having a combination of trigeminal neuralgia and atypical facial pain. Trigeminal neuralgia predominantly occurs in older age groups (50+ years), although it may occasionally be seen in very young patients. It is thought to be caused by vascular compression of the trigeminal root. In patients with multiple sclerosis, it occurs frequently and may indeed be the first symptom of the disease. In a study evaluating the clinical characteristics of patients with trigeminal neuralgia, 22 had multiple sclerosis. Six of them had atypical trigeminal neuralgia, and 16 had signs of brainstem involvement.[38] It is not clear whether the pain is caused by plaques in the CNS in these patients, but clinically there was no distinction between patients with and without brainstem involvement. Trigeminal neuralgia may also be caused by a primary brain tumor (acoustic neuroma), which should always be excluded before symptomatic treatment is considered (red flag).

Treatment. In younger patients, posterior fossa craniotomy with microvascular decompression (MVD) is the treatment of choice.[39] This treatment has a high rate of success and avoids the sensory loss that is one of the consequences of thermocoagulation of the ganglion. This procedure has a low complication rate. Complications are mostly serious neurologic deficits.[40] In patients with multiple sclerosis, the procedure should be combined with partial sectioning of the trigeminal nerve.[41] This could be an indication of a more central mechanism in these patients. Pain relief is substantially longer after microvascular decompression than after thermocoagulation of the ganglion. If the pain recurs, recurrent vascular compression is seldom found during reoperation.[42] In such cases, partial sectioning of the nerve could be performed. However, other forms of treatment such as thermocoagulation are generally recommended because the incidence of

complications of MVD is distinctly higher after reoperation.[42,43] The outcome of thermocoagulation in operated patients is less favorable.[44] PRF seems a safer alternative that was shown to be effective in case reports.[45,46] An RCT comparing RF with PRF found a much shorter duration of efficacy for PRF.[47] More recently, an RCT that compared short RF, long RF, and PRF showed that all groups experienced significant differences in pain than baseline. No differences were found between the groups.[48] A retrospective study and an additional RCT found that high voltage PRF resulted in a longer-lasting pain relieving effect than standard voltage PRF.[49,50] The choice between MVD, RF, and PRF treatment of the Gasserian ganglion is a clinical decision in which age, physical condition, and personal preference of the patient have to be taken into account.

Evidence. Following the Grading of Recommendations, Assessment, Development and Evaluation (GRADE) system on assessing the quality of evidence, there is a low quality of evidence that RF of the Gasserian ganglion reduces the pain of patients suffering from idiopathic trigeminal neuralgia for at least six months. There is evidence of very low quality that PRF is effective in the treatment of trigeminal neuralgia.[51] However, there is extensive experience with RF treatment of trigeminal neuralgia. A review of 25 years' experience in 1600 patients undergoing percutaneous RF trigeminal rhizotomy for idiopathic neuralgia indicated acute pain relief in 97.6% and continued complete pain relief at five years' follow up in 57.7%.[52] Comparisons with other techniques are based mainly on retrospective evaluations.[53–59]

Comprehensive considerations for the usage of continuous radiofrequency (CRF) or pulsed radiofrequency (PRF) treatment in idiopathic trigeminal neuralgia are outlined by Guo et al.[60]

Procedure. The technique for placing a radiofrequency needle in the Gasserian ganglion is as follows:

The oval foramen is visualized first by using a tunnel view technique. To attain this, the direction of the x-rays should be reversed from the normal configuration because the image intensifier is too bulky to avoid contact with the patient's chest (Fig. 66.2). The position of the C-arm should be adjusted until the oval foramen is identified just medial to the mandibular processes and just lateral to the maxilla.

The shape of the foramen varies with the angle of the x-rays in the horizontal plane. A more vertical direction will transform the foramen into a round, almost circular shape. A more horizontal direction will make the foramen flat, like a split. The C-arm should be adjusted so that the foramen optimally has an oval shape. The skin entry point is now marked over the target point and is located lateral to the corner of the mouth. The entry point may be just superior to the mandible, but it also may be much more superior, close to the maxilla (Fig. 66.3).

Adverse Events and Complications. RF treatment of the Gasserian ganglion is associated with very low morbidity and virtually no reported mortality.[61] Reports vary considerably regarding recurrence of pain. This may be because of variations in technique. If a dense sensory loss is produced, there is a low incidence of recurrence.[7,62] However, loss of facial sensation and the accompanying paresthesia account for 80% of the side effects of the procedure with an incidence of 18.8%.[61] If RF treatment with a less intense lesion is performed, it might be associated with a lower incidence of paresthesia but potentially earlier recurrence. Other complications include corneal hypesthesia (6.6%), masseter weakness and paralysis (4.1%–6.2%), anesthesia dolorosa (0.6%–1%), keratitis (0.6%–1.2%), transient paralysis of cranial nerves III and IV (0.8%), CSF leak (0.11%), hearing loss (0.13%), and meningitis (0.02%).[52] A much less frequent complication is permanent palsy of the abducens nerve.[63]

No complications have been reported with PRF treatment of the Gasserian ganglion.[45–50]

Radiofrequency Treatment of the Pterygopalatine (Sphenopalatine) Ganglion

The pterygopalatine ganglion is a parasympathetic ganglion located in the pterygopalatine fossa just beneath the maxillary nerve. It is in or close to the foramen that connects the pterygopalatine fossa to the nasal cavity. Preganglionic fibers reach the ganglion from the facial nerve through the greater superficial petrosal nerve and the nerve of the pterygoid canal. There are also connections through the deep petrosal nerve that joins with the greater superficial petrosal nerve to form the Vidian nerve (Fig. 66.4). Many afferent fibers originating from the nasal mucosa, the soft palate, and the pharynx cross the ganglion on their way to the maxillary nerve and eventually to the Gasserian ganglion.

Cluster Headache

Treatment and Evidence. The rationale for RF treatment of cluster headaches is based on parasympathetic symptoms during an attack.[64] Following the GRADE system, there is a very low quality of evidence that RF of the pterygopalatine ganglion reduces intensity and frequency of cluster headache attacks up to 18 months.[51,64–66] A retrospective study of 56 patients with episodic and 10 patients with chronic cluster headache treated by RF treatment of the pterygopalatine ganglion and followed 12–70 months. In the group with episodic cluster headache, 60.7% experienced complete pain relief, while only three out of ten patients with chronic cluster headache had the same result.[64] Another retrospective study of 15 patients reported significant improvement in both mean attack intensity and mean attack frequency for up to 18 months.[65]

Since cluster headache is a very rare but severe clinical condition, the authors recommend that RF of the pterygopalatine ganglion could be used in patients with cluster headache refractory to conservative treatment.

Persistent Idiopathic Facial Pain

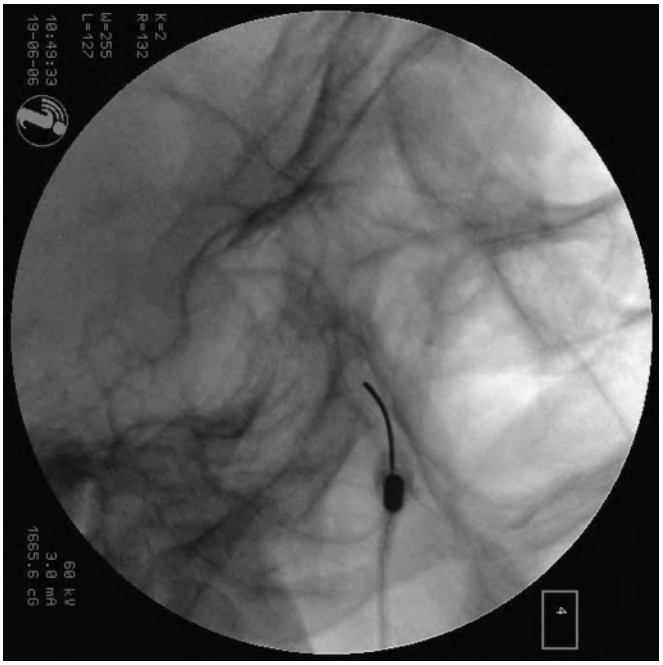
In a retrospective study assessing the effect of RF treatment of the pterygopalatine ganglion on persistent idiopathic facial pain (PIFP), 60% (nine out of 15 patients) showed considerable pain relief. However, repeated RF treatment procedures were needed in most cases.[67] Treatment of atypical facial pain in the second division of the trigeminal nerve using RF of the pterygopalatine ganglion has also been described.[66] A case report on PRF treatment of the pterygopalatine ganglion for posttraumatic headache described 17 months of pain relief.[68] Analysis of PRF treatment of the pterygopalatine ganglion in 30 patients suffering from chronic head and facial pain showed complete relief of pain in 21% and mild to moderate relief in 65%.[69] In a case series ($N = 8$) on refractory chronic short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) and with cranial autonomic symptoms (SUNA) reported an average improvement in pain of 57% (30%–100%), with an average duration of six (2–10) months.[70]

Evidence for the use of PRF is weak, but given the safe character of this treatment, the authors recommend the use of PRF for these aforementioned conditions.

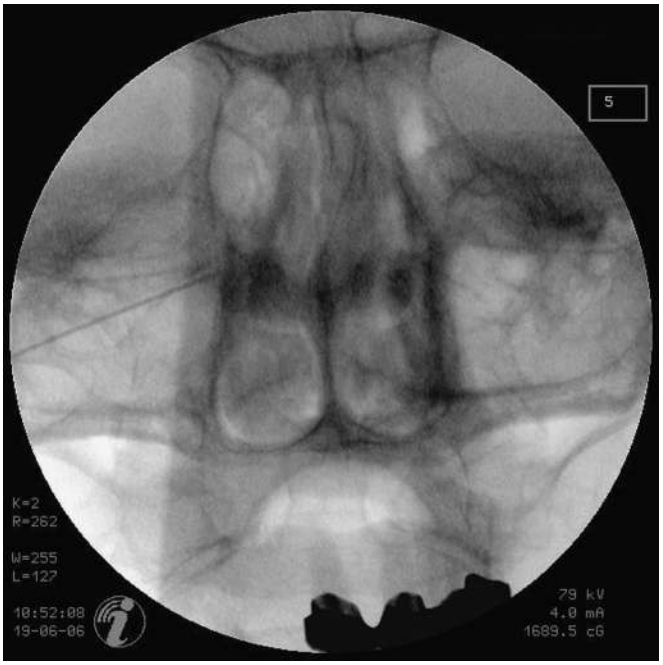
Procedure. The patient is placed in a supine position with the head immobilized. The pterygopalatine fossa is identified on the lateral fluoroscopic image, and a line overlying the fossa is drawn on the skin. The intersection of this line with the inferior edge of the zygomatic arch is the entry point. After anesthetizing the skin, a 10 cm RF cannula with a 5 mm active tip is inserted at this point and then carefully advanced under lateral fluoroscopic control in a superior and anterior direction to enter the pterygopalatine fossa (Fig. 66.5). As soon as the fossa is entered, the cannula contacts the maxillary nerve, and the patient reports paresthesia, 1–2 mL of 2% lidocaine is injected. The cannula is advanced further until the tip reaches the pterygopalatine fossa, which is located in the anterior superior corner of the fossa. The tip needs to pass the rim of the fossa to prevent damage to the maxillary nerve during the lesion.

The C-arm of the image intensifier is then placed in the anteroposterior (AP) position. The tip of the cannula should now be projected over the lateral wall of the nasopharynx (Fig. 66.6).

The stylet is removed and replaced with a thermocouple RF probe. The position of the electrode is verified by electrical stimulation at 50 Hz, and this usually results in paresthesia inside the nose at 0.2–1.0 V. Paresthesia occurring at the outside of the cheek or upper lip indicates stimulation of the maxillary nerve



• **Figure 66.5** Needle placement in the pterygopalatine fossa.



• **Figure 66.6** Anteroposterior view of needle placement in the pterygopalatine fossa.

and thus that the tip of the needle is too far lateral. If the patient reports paresthesia in the palate, the cannula is advanced a few millimeters. Treatment consists of three consecutive lesions performed at 70°C–80°C for 60 s.[64] In between these lesions the cannula is slowly advanced (1–3 mm).

Adverse Events and Complications. Total destruction of the pterygopalatine ganglion causes dryness of the eye, an "open nose" since the mucosa has less inclination to swell, and numbness of the soft palate. However, dryness of the eye is unusual after a thermal RF lesion. Numbness of the soft palate is usually temporary, with gradual recovery occurring over four to six weeks. Sometimes loss of taste can be permanent. No complications have been reported after PRF treatment of the pterygopalatine ganglion.

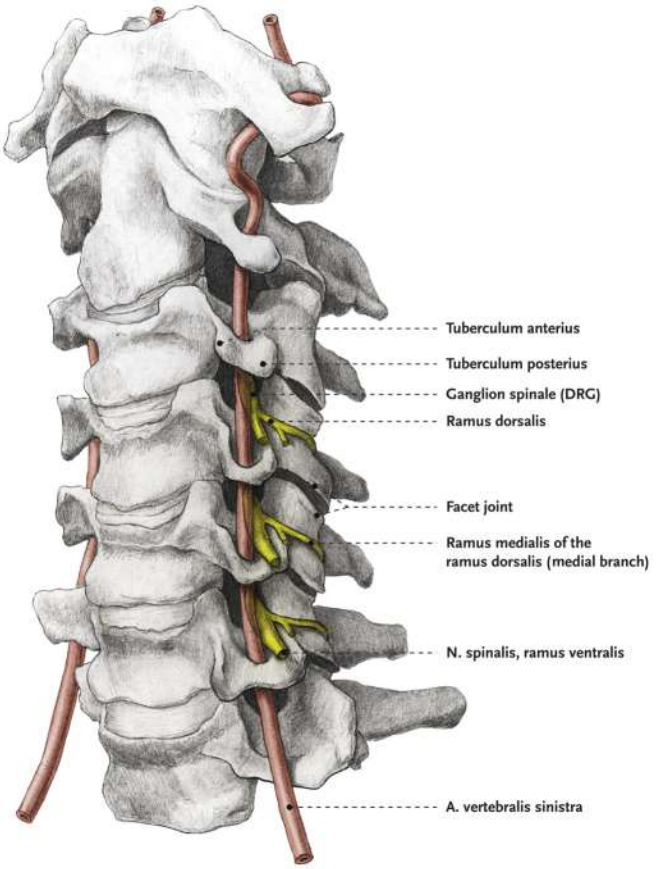
Radiofrequency Treatment Procedures on the Cervical Spine

Cervical Facet (Zygapophyseal) Joint Pain

Facet pain is discussed in more detail in Chapter 31.

The most common symptom of pain arising from the cervical facet joints is unilateral pain that does not radiate beyond the shoulder. Pain emanating from the cervical facet joints can be referred to as the occiput, the interscapular region, or the shoulder girdle regions, depending on which cervical facet joint is involved.[71–74] Pain from the higher cervical facet joints may be the origin of cervicogenic headache.[75] Physical examination of the cervical spine usually shows paravertebral tenderness and limitation of rotation and retroflexion.[76] Computed tomography and magnetic resonance imaging may reveal morphologic abnormalities of the facet joints. However, degenerative changes of the cervical spine are present in asymptomatic patients, thus supporting the lack of correlation between radiologic findings and pain.[77,78]

Indications for RF treatment of the medial branches that innervate the cervical facet joints are degenerative and posttraumatic neck pain (i.e. whiplash-associated disorders).[79–82] The anatomy of the cervical spine is illustrated (Fig. 66.7).[82,83] RF treatment of the cervical medial branches is aimed at reducing nociceptive signals



• **Figure 66.7** Anatomy of the cervical spine. *DRG*, Dorsal root ganglion. (Illustration courtesy of Rogier Trompert Medical Art. Available at: www.medical-art.eu.)

from the spinal facet joints and is usually performed at two or three segmental levels.

Evidence

Percutaneous RF treatment of cervical facet-mediated pain has been studied intensively. The data from original articles were summarized in systematic reviews.[84–87,88]

Following the GRADE systematics, there is a low quality of evidence that RF treatment of the medial branch reduces cervical facet joint pain.[51] Only one RCT has evaluated RF treatment of the ramus medialis (medial branch) of the ramus dorsalis in patients with whiplash-associated disorders.[79]

The effectiveness of RF treatment for degenerative neck pathology was shown in observational studies.[76,89,90] A retrospective chart analysis of the effect of repeated RF facet treatments illustrated that the mean duration of effect of the first intervention was 12.5 months. The procedure can be repeated when pain recurs, with similar success. Patients who respond positively to the first intervention received up to six additional interventions. After each RF intervention, more than 90% of the patients had satisfactory pain relief, and the duration of effect was between eight and 12 months.[91]

Van Suijlekom and coworkers evaluated the effect of RF lesioning of the medial branch of the dorsal ramus at the C3–6 levels for the treatment of cervicogenic headache.[92] In this study the posterolateral approach was used. They demonstrated that RF cervical facet treatment leads to a significant reduction in headache severity, number of days with headache, and analgesic intake in patients with cervicogenic headache diagnosed according to the criteria of Sjaastad and colleagues.[75] In a randomized, double-blind, sham-controlled study on RF treatment of facet joints C2–3 for the treatment of cervicogenic headache, 12 patients were included and monitored for 24 months. A slight improvement was noted in the RF group at three months, whereas no differences were seen during the remaining follow up period.[93] In contrast, Haspeslagh and associates[94] could not find evidence that RF treatment of the cervical facet joints, followed by cervical DRG when necessary, is better than steroid injection at the greater occipital nerve.

Two other observational studies with 104 patients,[95] and 130 patients[96] showed significant pain relief. In the first study, 74% and 61% of the patients attending two different practices had complete pain relief or at least 80% pain relief for at least six months. In this study, the duration of the effect was 17–20 months for the first RF treatment and 15 months for the repeat treatment.[95] The second study showed success (average pain relief of 88%) in 76% of the patients that lasted for 12 months.

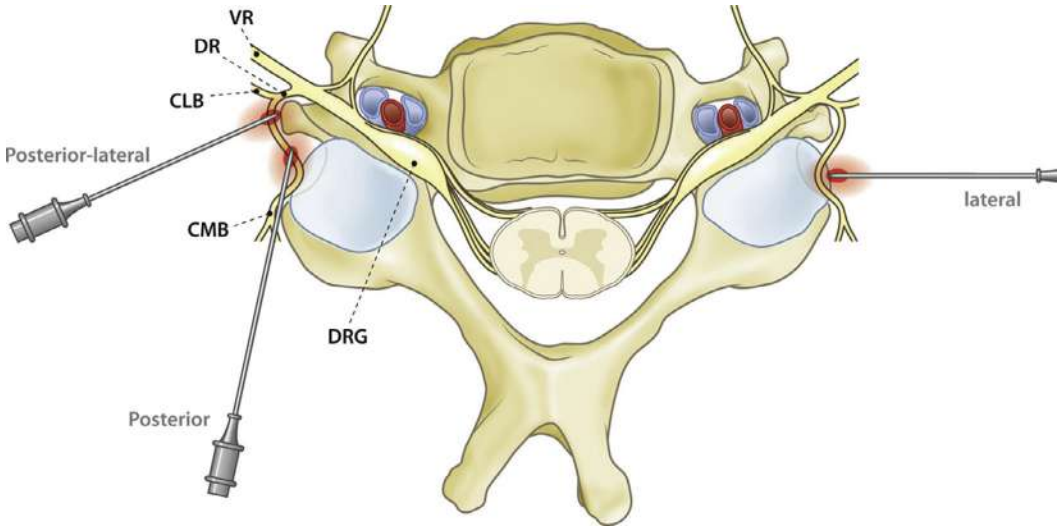
An additional exploratory study evaluated the therapeutic effect and its duration of RF treatment, using the single posterior-lateral approach in patients suffering from facet joint degeneration. Overall pain relief was reported in 55.4% at two-month follow up. At three-year follow up, 30% of the patients still reported pain reduction.[97]

Procedure

Several approaches can reach the medial branch of the dorsal ramus at the upper and middle cervical area.[98]

The technique that is most used in many observational studies is the posterior technique.[88,99]

The posterolateral technique**,** using oblique fluoroscopy, was first published in 1980 by Sluijter.[100] The patient is positioned in a supine position. The neuroforamen is visualized with an oblique X-ray projection. The target point for RF denervation of the cervical medial branch (CMB) is the base of the superior articular process, in oblique view posterior to the caudal part of the neuroforamen. The needle insertion point is estimated somewhat posterior and caudal to the target point. After insertion, the RF probe is advanced at an anterior angle to the frontal plane until bony contact is achieved. The angulation is necessary to get a more perpendicular position of the needle endpoint to the CMB. The target point is at the anterolateral side of the facet column close to the neuroforamen and the expected course of the CMB (Fig. 66.8). Then, with the X-ray projection in anteroposterior (AP) view, the RF probe is positioned in the concavity of the articular pillars of the cervical spine, taking care not to enter the neuroforamen. A safe distance between the needle tip and the cervical segmental nerve can be achieved in this way. Additionally, 50 Hz and 2 Hz stimulation are performed by a lesion generator to avoid a position



• **Figure 66.8** The three currently used techniques for radiofrequency denervation of the CMB: the posterolateral, the posterior, and the lateral approach. *VR*, Ventral ramus of the cervical segmental spinal nerve; *DR*, dorsal ramus of the cervical segmental spinal nerve; *CLB*, cervical lateral branch from the dorsal ramus; *CMB*, cervical medial branch from the dorsal ramus; *DRG*, dorsal root ganglion.

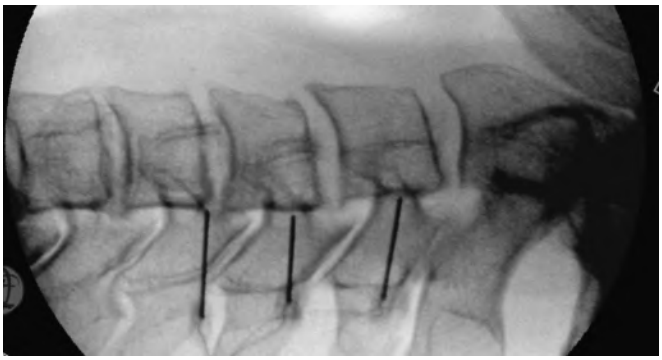
too close to the cervical segmental nerve. Then a single RF lesion is made at the described target point.

The posterior technique was first published in 1996 by Lord et al.[79] This technique is adopted by the Spine Intervention Society (SIS) and is part of SIS technique guidelines.[99] The patient is positioned in a prone position. The posterior technique is described as a two-stage procedure: first, in a lateral X-ray projection, a needle is positioned at the anterior side of the facet column, roughly at the same location as in the posterolateral technique. Then with the X-ray projection in anteroposterior (AP) view, an RF probe is advanced in a sagittal pass parallel to the expected course of the CMB (Fig. 66.8). Extensive and multiple lesions are made along the expected course of the CMB because there is a substantial inter-individual anatomical variation in the course of the CMB over the waist of the facet column.[101,102]

The lateral technique is first described as a technique for diagnostic blocks of the CMBs.[103,104] Later on, this technique was also described as a technique for RF treatment.[105–109] The patient can be positioned in a supine or lateral position. The X-ray beam is in a lateral position; thus this is a "coaxial" also called "tunnel view" technique. The target point of the needle is the midpoint of the rhomboid-shaped silhouette of the facet column (Fig. 66.8).

We developed a new approach of the posterolateral technique with a lateral projection. The target point is the same as in the technique as described by Sluijter. For this technique, the patient is also positioned supine on the operating table.[98]

The domelike structure between C1 and C2 should be aligned without any double contours to treat the upper cervical levels. Usually, the facet joint space of C3–4 is clearly visible, also without double contours. Adjustments of the C-arm are often necessary for the C4, C5, and C6 levels to align the facet joint spaces and the facetal column. In this position, the anterior and posterior tubercles of the neuroforamen can be seen projected over the vertebral body. The medial branch runs just above the posterior tubercle, midway between the facet joints. Needle entry points should be at the dorsal side of the facetal column in a virtual vertical line exactly between the facet joint spaces. Under fluoroscopic guidance, the needle electrode is carefully placed in a slightly anterior horizontal direction until contact is made with the facetal column (Fig. 66.9). The tip of the needle should be at or just above the posterior tubercle, midway or slightly rostral between the facet joint spaces. To confirm that the tip of the needle is close to the segmental nerve but not in the neuroforamen, the C-arm is placed in an approximately 30-degree oblique position in such a way that the projection of the contralateral pedicles is more or less anterior to the vertebral body (Fig. 66.10). This position is sometimes

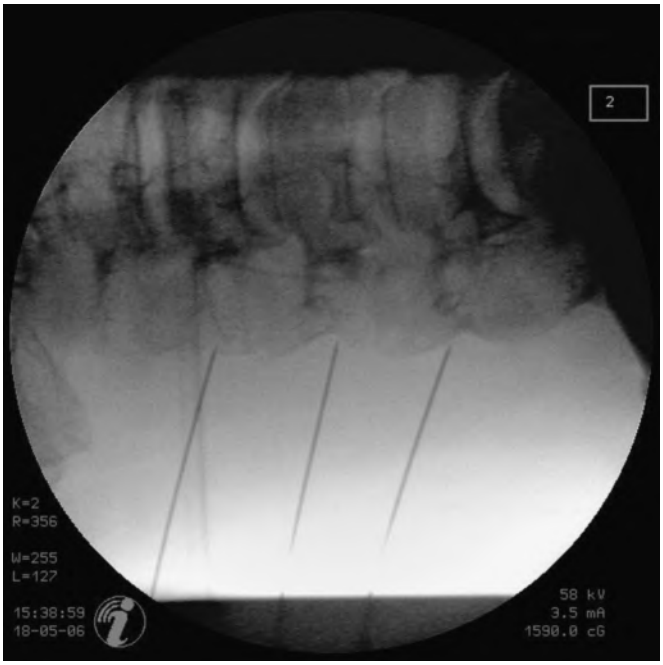


• **Figure 66.9** Fluoroscopic image of the position of the needle for a cervical medial branch procedure via a lateral approach.

• **Figure 66.10** Fluoroscopic image of the position of the needle for a cervical medial branch procedure.

preferred for treatment of the C6 and C7 levels because of over projection of the shoulders on the lateral view.

Positioning the C-arm in the AP direction should confirm the position of the tip of the needle adjacent to the concavity ("waist") of the articular pillars of the cervical spine at the corresponding level (Fig. 66.11). Electrical stimulation is performed to confirm the correct needle position when optimal anatomic localization of the needles is achieved. An electrical stimulation rate of 50 Hz should elicit a response (tingling sensation) in the neck at less than 0.5 V. Stimulation at 2 Hz is performed to confirm



• **Figure 66.11** Anteroposterior view of the cervical spine–needle position for a procedure on the medial branch.

accurate needle position. Contractions of the paraspinal muscles will be noticed. Muscle contractions in the arm indicate placement of the needle too close to the exiting nerve. In this case, the needle should be repositioned more posteriorly. Once proper positioning of the needle is confirmed, the medial branch of the dorsal ramus is anesthetized with 1–2 mL of local anesthetic solution (1% or 2% lidocaine). An 80°C RF thermal lesion is made for 60–90 s at each level.

Adverse Events and Complications

Complications are rare.[88] Nevertheless, one should be aware that the vertebral artery may be punctured if the needle is pushed too far anterior into the intervertebral foramen. The position of the tip of the needle should be verified with AP fluoroscopy to prevent intrathecal injection of the local anesthetic. In an observational study, the incidence of inadvertent intravascular penetration for medial branch blocks at a cervical level was reported to be 3.9%, comparable to the incidence at a lumbar level (3.7%).[110] Some patients experienced short-term vasovagal reactions. Intravascular uptake of local anesthetic and contrast solution was thought to be responsible for the false-negative diagnostic blocks. No systemic effects were reported.[110] Monitoring of the saturation level and availability of resuscitation equipment are essential.

Infections have been described, but the incidence is unknown and probably very low.[111,112] Other complications of facet joint interventions are related to needle placement and drug administration. They include dural puncture, spinal cord trauma,[113] spinal anesthesia, chemical meningitis, neural trauma, pneumothorax, facet capsule rupture, and hematoma formation.[87] After RF treatment, burning pain is regularly reported postoperatively. However, this pain disappears in one to three weeks.[94,114] There are no high quality incidence data on side effects and complications following cervical RF treatment of the ramus medialis (medial branch) of the ramus dorsalis.[88] At the lumbar level, the incidence of complications was lower than 1%.[82]

Radiofrequency Treatment of the Cervical DRG

Cervical Radicular Pain

Cervical radicular pain is a common pain syndrome, but it must be distinguished from cervical radiculopathy. Cervical radiculopathy implies an objective loss of sensory and/or motor function. In practice, both disorders may occur simultaneously. Radicular pain is a symptom that is caused by ectopic impulse formation. This may result from the same clinical entities such as narrowing the intervertebral foramen, intervertebral disc herniation, and radiculitis because of arthritis, infection, or inflammatory exudate. There is little published information on the natural history of cervical radicular pain. Bland estimated that 9% of all men and 12% of all women experience this pain at some time in their lives.[115] Later, in 1994, Radhakrishnan and associates published a population-based survey.[116] This epidemiologic survey found the annual incidence of cervical radiculopathy to be 83.2 per 100,000 population between 13 and 91 years of age. The most frequently involved levels are C7 in 45%–60% of the cases, level C6 is involved in 20%–25% of the cases, and levels C5 and C8 each represented approximately 10% of the cases.[31]

Cervical radicular pain is perceived in the upper limb as shooting or electric in quality. The distribution of the pain radiation pattern is indicative of the involved level.[117] This can be summarized as pain from C4 is restricted to the neck and suprascapular regions. Pain from C5 extends in the upper arm, and pain from C6 and C7 extends from the neck and shoulder into the forearm and hand.[118] Confirmation of the involved level can be obtained by diagnostic nerve blocks.[111,119–121]

Diagnosis of cervical radicular pain and radiculopathy requires complete history taking and clinical diagnosis using standardized methods of physical examination,[121,122] medical imaging, and electrophysiologic investigation.

The pathophysiologic mechanisms of cervical radicular pain are two-fold: (1) nucleus pulposus material leaking onto the nerve root and/or (2) compression of the nerve root by anatomic abnormalities. These pathogenic mechanisms induce two processes in the nerve: (1) an inflammatory reaction and (2) changes in ion-channel functioning.[122] In patients with persisting cervical radicular pain of a duration longer than three months despite conservative treatment, interventional pain management with radiofrequency can be considered.

Evidence for Radiofrequency Treatment Adjacent to the Cervical DRG

Following the GRADE system, there is moderate quality of evidence that RF of the cervical DRG reduces radicular pain.[51] Two RCTs report on the use of radiofrequency adjacent to the cervical DRG.[16,119] The first study[119] found radiofrequency treatment adjacent to the cervical spinal ganglion (DRG) to be superior to sham eight weeks after the intervention.

The second study compared RF with an electrode tip temperature of 40°C with RF at 67°C.[16] At six weeks and three months after treatment, there was a significant decrease in the visual analog scale pain score in both groups. There was no significant difference in outcome between the two groups.

Continuous thermal radiofrequency treatment uses neurodestructive electrode tip temperature, which results in nerve damage and potentially can cause deafferentation pain. This is the reason why continuous RF is less frequently used since the development of the less neurodestructive pulsed radiofrequency treatment.

Evidence for Pulsed Radiofrequency Treatment Adjacent to the Cervical DRG

Following the GRADE systems, there is moderate quality of evidence that PRF of the cervical DRG reduces radicular pain. A recent systematic review[123] found one RCT,[124] three before and after comparisons,[125–127] one case series,[128] on the use of PRF adjacent to the DRG for the treatment of cervical radicular pain. In a clinical audit 18 patients, with cervicogenic headache or cervicobrachialgia who failed conservative treatment underwent PRF treatment adjacent to the cervical DRG.[129] Seventy-two percent of the patients had a minimum reduction in pain of at least 50% at eight weeks. At one year, 33% of the patients rated the treatment outcome as good or very good. The RCT included 23 patients who were randomly assigned to PRF or sham intervention. The level to be treated was confirmed by means of diagnostic blocks.[124] At the three-month follow up, patients in the PRF group had significantly more pain reduction and a significantly better global perceived effect. The SF-36 domain vitality was significantly better in the PRF group. The need for pain medication was reduced in the PRF group at six-month follow up.[124] The systematic review concluded that there were positive efficacy findings in all the analyzed studies.[123]

A case series of 43 patients[125,127] suggested that more than 60% of patients benefited in terms of more than 50% pain relief or treatment success after six months with no serious adverse effects reported. This relief appears to be sustained at one year follow up

(12 of 21 patients). A meta-analysis of studies reporting the effect of PRF-DRG in patients with cervical radicular pain because of disc herniation, or cervical spinal stenosis included four studies: one RCT, two observational studies, and one retrospective study, showed a significant pain reduction at two weeks, one, three, and six-month follow up.[130] A recent retrospective study on 59 patients treated with PRF-CDRG for cervical radicular pain showed that 67% of the patients experienced >50% pain reduction. This effect lasted for 37 weeks.[131] In these studies, no motor or sensory complications were observed.

In summary, there is moderate evidence that PRF treatment of the DRG (PRF-DRG) on a cervical level is as effective as RF-DRG. However, PRF-DRG is safer and has fewer side effects. Therefore the authors suggest that cervical radicular pain be treated with PRF-DRG and not with RF-DRG.

Procedure

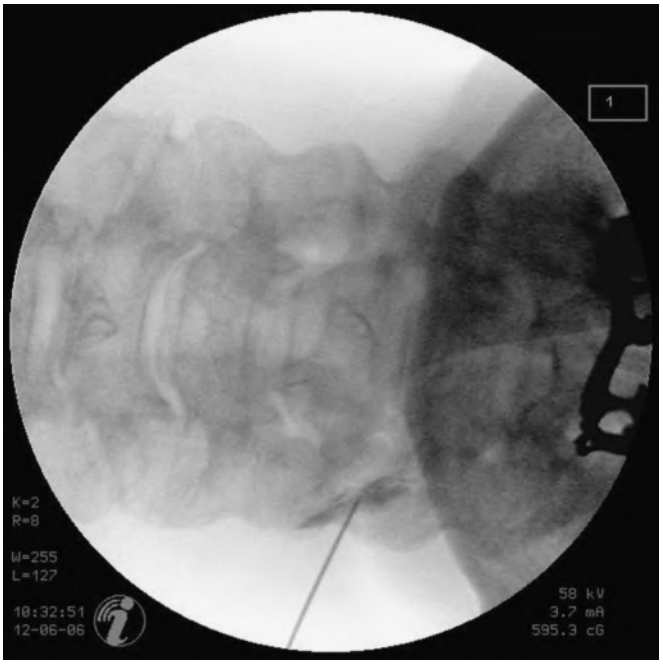
To perform a *diagnostic segmental nerve block,* a viewing technique is used in which the C-arm is positioned so that the x-rays are parallel to the axis of the intervertebral foramen. This axis points 25–35 degrees anteriorly and 10 degrees caudally. With the C-arm in this position, entry is determined by projecting a metal ruler over the caudal and posterior part of the foramen. A 50 mm, 22-gauge neurography needle is carefully introduced parallel to the beam of the x-rays. The direction of the x-rays is then changed to the AP position, and the cannula is introduced further until the tip is projecting just lateral to the facetal column. After the segmental nerve has been identified with 0.4 mL of iohexol contrast medium, 0.5 mL of 2% lidocaine is slowly infiltrated around the nerve. The resultant radiopaque mixture is closely observed during injection to avoid accidental overflow into the epidural space.[119]

For the RF procedure, the same viewing technique is used. The entry point is found by projecting the metal ruler over the caudal and posterior parts of the foramen. The cannula (SMK-C5 with a 2 mm exposed tip) is introduced parallel to the beam of the x-rays, and if necessary, the approach is corrected while still in the superficial layers until the cannula is projected on the screen as a single dot (Fig. 66.12). In practice, this dot should lie directly over the dorsal part of the intervertebral foramen at the transition between the middle and most caudal third. This dorsal position is chosen to avoid possible damage to the motor fibers of the segmental nerve and to the vertebral artery that runs anterior to the ventral part of the foramen. The direction of the x-rays is then changed to AP, and the cannula is further introduced until the tip is projected over the middle of the facetal column (Fig. 66.13).

The stylet is then replaced with the RF probe. After checking the impedance, electrical stimulation is started at a rate of 50 Hz. The patient should feel a tingling sensation between 0.4 and 0.65 V. The frequency is changed to 2 Hz, and the patient is observed for muscle contractions. These contractions should not occur below a voltage of 1.5 times the sensory threshold. Moreover, 0.5 mL of iohexol is injected to exclude accidental intradural positioning of the electrode, followed by 2 mL of 2% lidocaine. RF current is then passed through the electrode to increase the temperature of the tip to 67°C. This temperature is maintained for 60 s.

For the PRF procedure, the same technique is used. For the sensory stimulation, a sensation should be observed below 0.5 V. Since there are no reported complications, motor stimulation is unnecessary, nor is the use of contrast before the procedure.

• **Figure 66.12** Radiofrequency lesion adjacent to the dorsal root ganglion in a 20-degree oblique, 10-degree craniocaudal projection. The needle is positioned in the posterior aspect of the fossa at the junction of the middle and caudal third part. It is projected as a dot in tunnel vision.



• **Figure 66.13** Radiofrequency treatment of the dorsal root ganglion, anteroposterior view. The tip of the needle is projected over the facetal column.

Adverse Events and Complications

With conventional RF, a mild burning sensation (some deep neck soreness) in the treated dermatome is observed in 40%–60%, but it subsides spontaneously after one to three weeks.[132] Some sensory changes such as slight hypesthesia may occur but invariably disappear within three or four months.[15,16,119] With PRF-DRG, no sensory or motor complications were mentioned. A transient burning sensation may be felt.

Known complications of blockade of a cervical segmental nerve are epidural, intrathecal, or intravascular injection of local anesthetic. During this procedure, injectate can be placed in the adjacent venous plexus, in the vertebral artery, or even in the carotid artery. Because of the proximity of the higher cervical levels to the brain, there is a risk for local anesthetic CNS toxicity (seizure), although only a low volume of local anesthetic is used.[133]

Pulsed Radiofrequency Treatment of the Occipital Nerve

Occipital Neuralgia

The International Headache Society defines occipital neuralgia as paroxysmal shooting or stabbing pain in the dermatomes of the nervus occipitalis major or nervus occipitalis minor.[134] This definition was updated in 2013 to "unilateral or bilateral paroxysmal, shooting or stabbing pain in the posterior part of the scalp, in the distribution of the greater, lesser or third occipital nerves, sometimes accompanied by diminished sensation or dysesthesia in the affected area and commonly associated with tenderness over the involved nerve(s)."[135]

There are no epidemiologic data on occipital neuralgia. In 90% of the cases, the major occipital nerve is involved, compared to 10% involvement of the minor occipital nerve. In 8.7% of the cases, both occipital nerves are responsible for neuralgia.[136] Neuralgia is often caused by damage or irritation of the occipital nerves.

The course of the major occipital nerve is divided into three parts by two bends.[137] The major occipital nerve is formed by the dorsal ramus of the C2 nerve root. The first part runs between the origin of the nerve and the oblique capitis inferior muscle underneath which the nerve makes its first bend in a medial direction. The second part of the nerve runs cranially between the semispinalis capitis muscle on one side and the oblique capitis inferior, rectus capitis posterior, and the rectus capitis anterior muscles on the other side. When perforating the musculus semispinalis capitis muscle toward the surface, the nerve makes its second bend in a lateral direction. The third part of the nerve runs further laterally where the aponeurosis of the trapezius muscle is perforated, and the nerve begins its subcutaneous course. The major occipital nerve usually branches after perforating the aponeurosis.

Patients complain of a shooting or stabbing pain in the neck radiating over the cranium. Constant pain can persist between the paroxysms. The pain can be perceived in the retro-orbital area caused by the overlap of the C2 dorsal root and the nucleus trigeminus pars caudalis.[138] Vision impairment/ocular pain (67%), tinnitus (33%), dizziness (50%), nausea (50%), and congested nose (17%) can be present because of connections with cranial nerves VIII, IX, and X, and the cervical sympathicus.[139]

On clinical examination, hypo- or dysesthesia in the area of the nervus occipitalis major or minor and tenderness to pressure over the course of the nervus occipitalis major or minor can be observed. A positive Tinel's sign (pain upon percussion over the nerve) can be present.

Clinical presentation and a temporary improvement with a local anesthetic diagnostic block of the nervus occipitalis major and/or minor confirms the diagnosis.[134]

Evidence for Pulsed Radiofrequency Treatment of the Occipital Nerve

Following the GRADE system, there is very low evidence that PRF of the occipital nerves reduces occipital neuralgia.[51] In a prospective trial on 19 patients, 68.4%, 57.9%, and 52.6% reported an improvement of 50% or more one, two, and six months after PRF treatment of the occipital nerve, respectively. The mean visual analog score (VAS) score before treatment was 7.5 and declined to 3.5, 3.5, and 3.9 at one, two, and six months, respectively. There was a statistically significant improvement in the use of medication and quality of life parameters.[140,141]

In a case series of 10 patients with occipital neuralgia and a positive response to a greater occipital nerve (GON) and/or lesser occipital nerve (LON) block, fluoroscopy-guided GON and LON PRF were performed. The mean VAS score declined from 6.9 prediagnostic block to 1.2 and 0.8 post PRF and at the last follow up (mean 7.5 months), respectively. Eighty percent of the patients stopped the use of analgesics completely.[142]

A retrospective chart review included 102 patients with a primary diagnosis of ON who received PRF of the GON and the LON.[143] Fifty-one patients had a ≥50% pain reduction lasting for at least three months. Variables associated with a positive outcome included a traumatic inciting event (65.7% success rate; $P = 0.03$), lower diagnostic block volumes (odds ratio [OR]: 0.72; 95% confidence interval [CI]: 0.62–0.82), and multiple cycles of PRF (OR: 2.95; 95% CI: 1.77–4.92). Six "complications" were noted, five of which consisted of temporary worsening pain.

A randomized, double-blind, comparative-effectiveness study was published in 81 participants with ON or migraine with occipital nerve tenderness.[144] Forty-two participants were randomized to receive local anesthetic and saline, and three 120 second cycles of PRF per targeted nerve, and 39 were randomized to receive local anesthetic mixed with depot steroid and three rounds of sham PRF. Patients, treating physicians, and evaluators were blinded to interventions. The PRF group experienced a greater reduction in the primary outcome measure, average occipital pain at six weeks (mean change from baseline -2.74 +/- 2.49 vs. -1.38 +/- 2.0; $P < 0.001$), than the steroid group, which persisted through the six-month follow up. Comparable benefits favoring PRF were obtained for worst occipital pain through three months (mean change from baseline -1.93 +/- 3.20 vs. -0.54 +/- 2.64; $P = 0.043$), and average overall headache pain through six weeks (mean change from baseline -2.74 +/- 2.75 vs. -1.12 +/- 2.1; $P = 0.037$). Adverse events were similar between groups. No neurologic complications were reported.

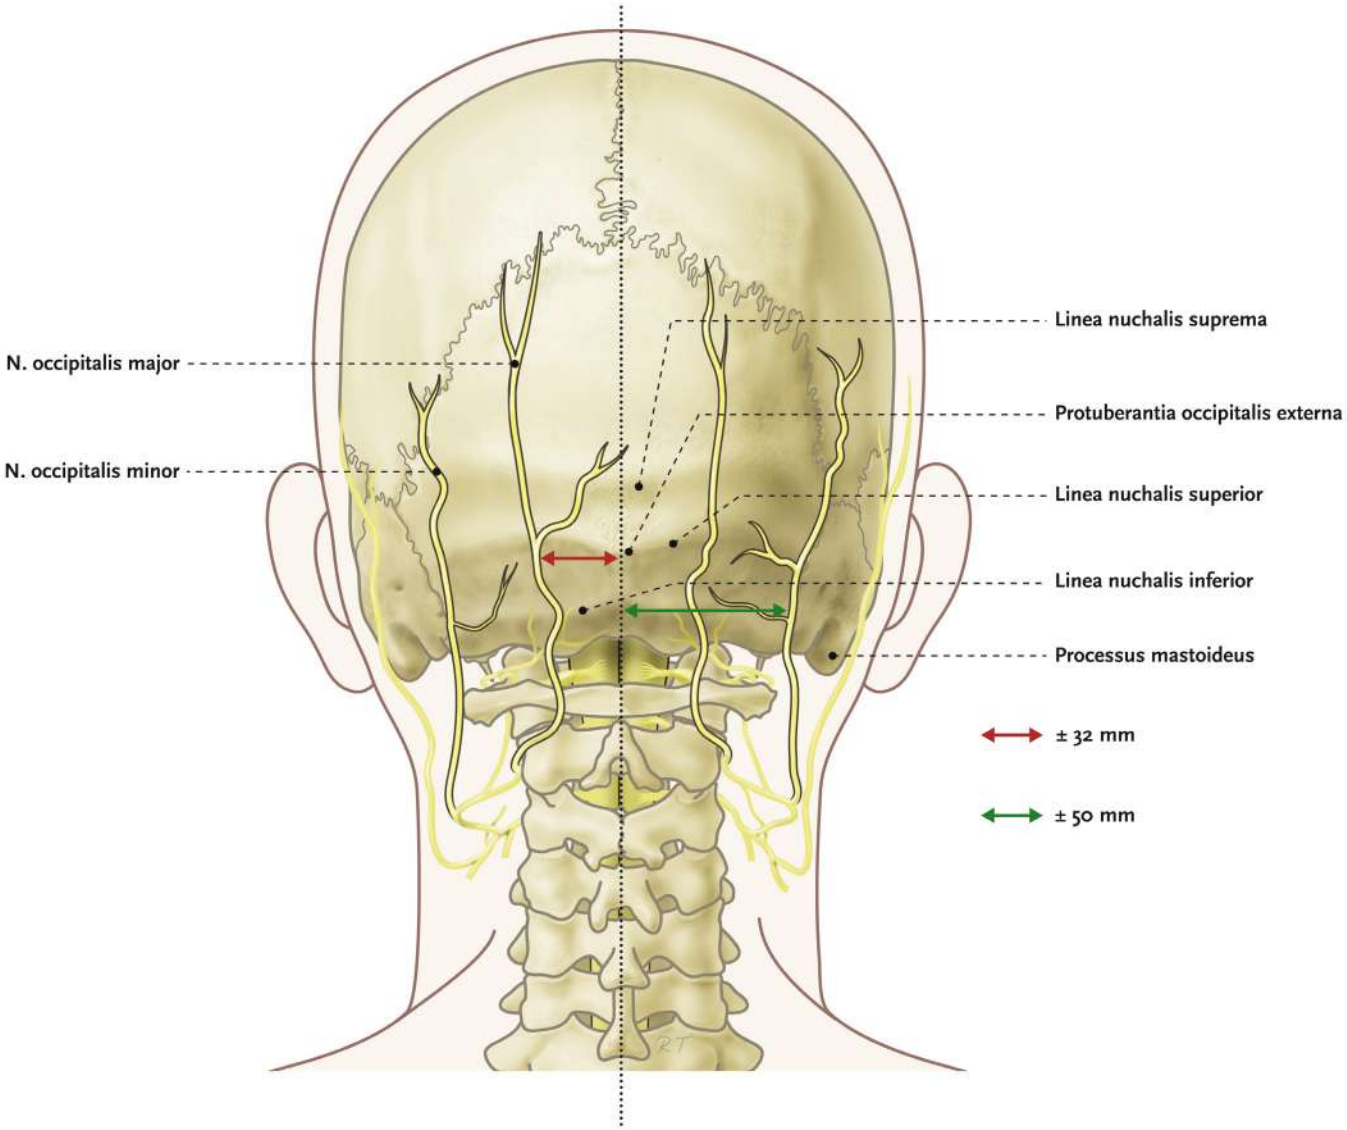
Technique for Pulsed Radiofrequency Treatment of the Occipital Nerve

The puncture site (22G needle, 5 cm, 1 cm active tip) is located according to the external landmarks described by Vital et al. (Fig. 66.14).[137] The thermocouple is introduced after perforation of the skin. The major and minor occipital nerves are located with a 50 Hz, 0.5 V current until the patient reports paresthesia in the dermatomes of the major and minor occipital nerve. Subsequently, a PRF treatment (45 V, 20 ms, 2 Hz) lasting 120 s with a maximum temperature of 42°C is performed twice.

Radiofrequency Treatment of the Lumbar DRG

Lumbosacral Radicular Pain

Several terms, including sciatica, ischia, nerve root entrapment, radicular pain, radiculopathy, and pain that goes down the leg, have been used to describe lumbosacral radicular pain. The latter and nerve root pain are more accurate and descriptive of the condition.[145,146]



In the general population older than 30 years old, up to 5% suffer from low back pain radiating into the leg,[147–149] making it probably the most commonly occurring form of neuropathic pain.[150–152] Acute lumbosacral radicular pain, caused by disc herniation and/or nerve root entrapment, improves considerably in the short term. About three-quarters of patients will recover after three months.[153–155] However, a high recurrence rate is reported.[156] Furthermore, when pain persists after this recovery period of three months, the prognosis of lumbosacral radicular pain is somewhat unfavorable, especially in the female population.[153,155,157–160] Patients suffering from lumbosacral radicular pain often experience a reduced functionality leading to an incapacity to work. A quarter of these patients are still out of work two years after onset.[161]

Lumbosacral radicular pain is characterized by radiating pain in one or more lumbar or sacral dermatomes; it may or may not be accompanied by paresthesia and/or symptoms of decreased function. The patient may experience the radiating pain as sharp, dull, piercing, throbbing, or burning. Pain caused by a herniated disc classically increases by sitting, coughing, or (excessive) stress on the lumbar discs and can be avoided by lying down or sometimes by walking.[147]

Conversely, pain from lumbar spinal canal stenosis typically increases walking and improves immediately upon bending forward.[162]

For clinical examination, the Lasègue/passive straight leg raising test was most often described and has a high sensitivity but low specificity. The crossed Lasègue test has good specificity but low sensitivity. Other neurologic signs such as paresis, sensory loss, or loss of reflexes are checked in a neurologic examination.[153,163] The suspected level is confirmed by imaging[164] and by one or more selective diagnostic blocks, using a minimal amount of local anesthetic.[165]

Procedure for Radiofrequency Treatment of the DRG

RF-DRG is aimed at creating a minimal lesion near the DRG for treating nerve root pain without causing neurologic deficits.[166] For this purpose, at the lumbar levels, a 10 cm electrode (22 gauge,

5 mm active tip) is placed in the dorsal cranial quadrant of the intervertebral foramen (lateral view) and introduced with its tip between a third and about halfway across the midfacetal column on the AP projection (Fig. 66.15).

Sensory and motor stimulation is applied at 50 and 2 Hz. The position of the electrode is adjusted if necessary to reach a sensory stimulation threshold of between 0.5 and 1.0 V. The motor stimulation threshold is required to be at least 1.5 times the sensory stimulation threshold. A final check of the electrode's position is made by injecting radiopaque contrast dye to visualize the nerve root and ganglion. Subsequently, a local anesthetic is injected through the cannula to achieve anesthesia. RF treatment is usually performed at 65°C–67°C for 90 s. At the sacral level, the position of the DRG is first visualized with a radiopaque contrast dye injected through a 22-gauge needle placed in the dorsal sacral foramen of the corresponding nerve root. Subsequently, a small hole is drilled with a Kirschner wire and a pneumatic drill through the overlying sacral bone to obtain access to the dorsal ganglion. The remainder of the procedure is identical to that at the lumbar level.

Note the spread of contrast medium.

Evidence for Radiofrequency Treatment of the DRG

Following the GRADE system, there is moderate evidence against the use of RF of the lumbar DRG.[51] In patients with radiating lower limb pain, one prospective[167] and several retrospective studies[10,168–171] reported beneficial effects of lumbosacral RF-DRG in 32%–76% of cases. In a retrospective study, 279 patients underwent RF-DRG because of chronic spinal pain radiating to the leg, and an initial success rate of approximately 60% was reported.[171] One high quality RCT to assess the efficacy of RF-DRG for lumbosacral radicular pain has been performed. In this study, lumbosacral RF-DRG failed to show an advantage over sham treatment with local anesthetics.[172] Since there is no clear evidence of the efficacy of continuous thermal RF-DRG treatment, the variable position of the lumbar DRG's and the potential to induce deafferentation pain, we prefer PRF-DRG.

Evidence for Pulsed Radiofrequency Treatment of the Lumbar DRG

Following the GRADE system, there is moderate evidence that PRF of the lumbar DRG reduces radicular pain.[51] The first RCT was a pilot study whose main aim was to consider the feasibility of assessing the efficacy of PRF-DRG compared to placebo.[173] However, this study was not powered for effectiveness.

An RCT (62 participants) compared the effect of three cycles of PRF treatment adjacent to the lumbar DRG (during the same session) with sham intervention in patients with MRI proven spinal canal stenosis. All participants also received a transforaminal epidural steroid injection after the PRF or sham procedure. Participants had ≥2-point pain reduction after a transforaminal epidural injection of local anesthetic and corticosteroid for a short duration (≤ six weeks). Patients in the PRF group showed a significantly greater improvement on a composite score for successful treatment during the three-month follow up than patients in the control group, but not on individual outcomes (mean difference pain reduction 0.331 (-0.252 to 0.914)), functional status, global perceived effect, and oral analgesic use.[174]

In another RCT (20 participants with lumbar radiculopathy) comparing pulsed radiofrequency (PRF) adjacent to the lumbar dorsal root ganglion (DRG) with transforaminal corticosteroid injections for patients with radicular pain, there were no differences in pain and functioning at two, four, eight, and 12 weeks.[175]

In another prospective RCT, 50 patients with lumbosacral radicular pain refractory to transforaminal epidural steroids received conventional monopolar or bipolar (two cannulae tips) PRF adjacent to the lumbar DRG. In the bipolar group, the pretreatment pain intensity (Numeric Rating Scale (NRS) 0–10) was 5.1±0.8. At one month, the mean NRS was 2.5±1.5, at two months, 2.6±1.6, and at three months, 2.6±1.7. In the monopolar PRF group, the mean NRS decreased from 4.6±0.8 pretreatment to 3.0±1.5 at one month, 3.0±1.5 at two months, and 3.0±1.5 at three months. Three months after treatment, 76% in the bipolar versus 48% in the monopolar PRF group reported successful pain relief (≥50% pain reduction).[176]

A prospective cohort study to evaluate the effect of PRF adjacent to the lumbar DRG on pain and quality of life included 65 patients with unilateral and monosegmental radiating pain. At six months follow up, the intention-to-treat analysis showed clinical success in 55.4% of the patients. The reduction in NRS and Oswestry Disability Index (ODI) was statistically significant compared to baseline. Moreover, the DN4 showed a significant improvement, indicating that the neuropathic component of the radicular pain is reduced after PRF treatment. The RAND-36 showed significant improvement in the physical component scale at three and six months.[177]

Procedure

The approach is identical to that described for RF-DRG. However, the threshold for sensory stimulation should be less than 0.5 V to reach the DRG maximally. Motor stimulation and the injection of dye are not necessary. If an adequate threshold is obtained, a pulsed current (routinely a 20 ms current and 480 ms without current) is applied for 4 min with an output of 45 V. During this procedure, the temperature at the tip of the electrode should not surpass 42°C.

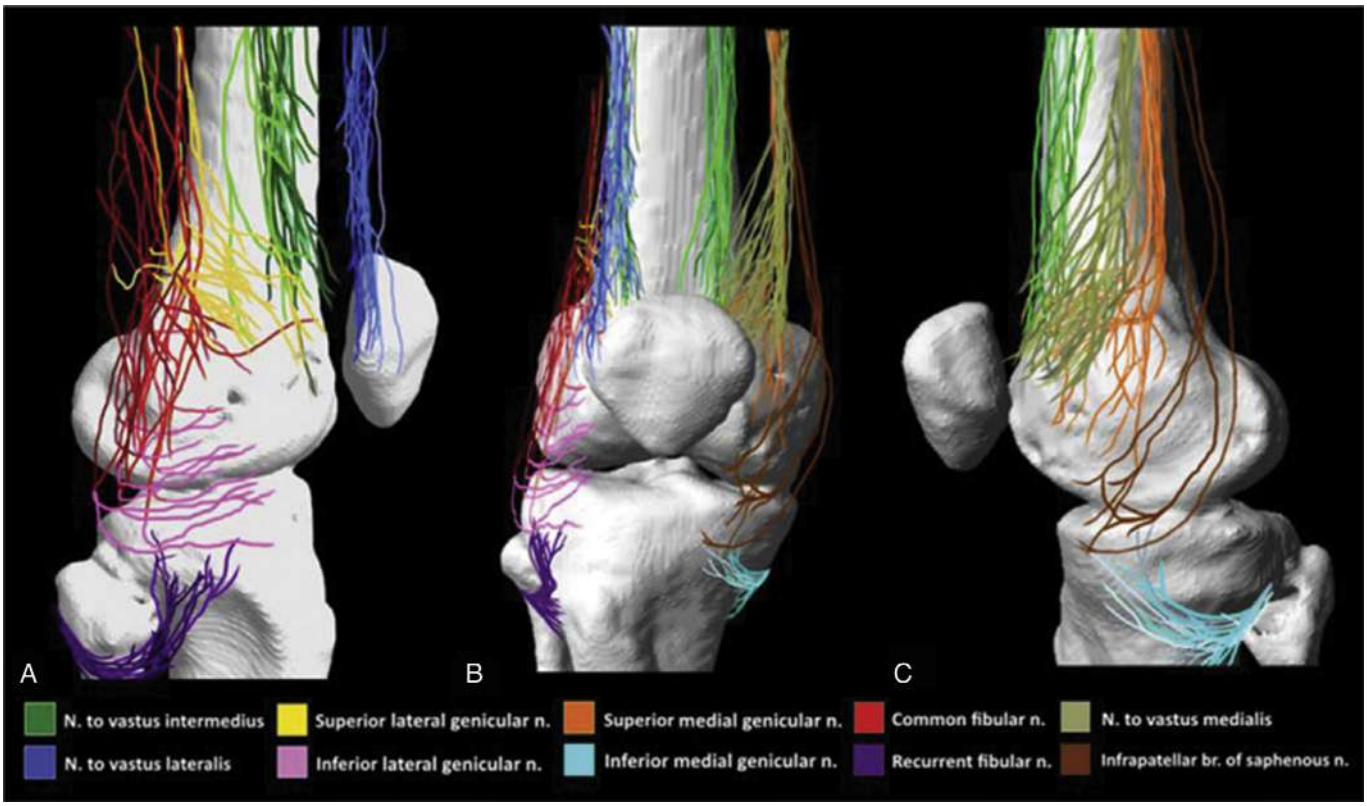
Radiofrequency Procedures on the Knee

Radiofrequency Treatment of the Genicular Nerves

Chronic Anterior Knee Pain

Chronic anterior knee pain is most frequently caused by osteoarthritis or because of a postoperative state. Knee osteoarthritis is a progressive degenerative process that affects joint cartilage and the subchondral bone. Approximately 10%–30% of all osteoarthritis patients suffer from disabling symptoms such as pain, stiffness, and loss of function, leading to psychological and sleeping disorders and a diminished quality of life.[178–181] When conservative treatment fails to treat the symptoms, a total knee arthroplasty can be performed.[182–185] Although not all patients are suitable candidates for a total knee arthroplasty procedure because of comorbidities or young age because of the limited lifetime of the prostheses used. In addition, the incidence of postoperative pain and functional limitation can mount up as high as 53%.[186–192] In those groups of patients, radiofrequency treatment of the genicular nerves can be an alternative treatment option. The sensory innervation of the anterior part of the knee is primarily accomplished by the genicular nerves. These are articular branches of the femoral, saphenous, obturator, common peroneal, tibial and sciatic nerves (Fig. 66.16). By targeting the superomedial, superolateral, and inferomedial genicular nerves, partial denervation of the anterior capsule of the knee can be achieved.[193–196]

Evidence. Radiofrequency treatment of the genicular nerves for pain because of *osteoarthritis* was first described by Choi and colleagues in 2011.[193] In this double-blind RCT, 38 elderly patients received a conventional RF treatment of 70°C for 90 s. They showed significant improvement in VAS, Oxford knee score, and global perceived effect at three months than placebo. Since this first report, multiple publications have investigated the effect of conventional and later pulsed and cooled RF treatment of the genicular nerves. In a recent systematic review and meta-analysis, which only included controlled trials, six studies were included, of which five studied a conventional and one a cooled radiofrequency treatment.[197] They concluded that a radiofrequency treatment showed significantly better short-term pain relief up to 24 weeks. The 50% pain relief rates at 12 and 24 weeks were also higher than the control group. The control group included sham operation, genicular nerve block, conventional analgesic therapy, and intraarticular knee injection. In terms of joint functional improvement, denervation therapy showed favorable outcomes at four and 12 weeks after treatment, but no significant difference was found at 24 weeks after the procedure between the groups. Overall, better results were reported in the radiofrequency treatment group with a relatively high grade of evidence. In another systematic review and meta-analysis on the effectiveness of RF treatment of the genicular



• **Figure 66.16** Frequency map of the innervation of the anterior knee joint. **A,** Lateral view. **B,** Anterior view. **C,** Medial view.

nerves, 12 RCTs were included.[198] They found that the VAS in the RF group were lower than those in the conservative treatment group up to three months (WMD -1.32, 95% CI -2.27 to -0.37, P < 0.01) after treatment, while there was no significant improvement in knee function. Furthermore, the authors concluded that radiofrequency ablation has better efficacy than pulsed radiofrequency treatment in reducing pain.[198] Recently, the results of a cooled RF treatment of the genicular nerves with a follow up to 24 months were published. They showed at least 50% pain reduction in 61% of the patients at 24 months.[199]

Studies on a radiofrequency treatment for *persistent post-surgery pain* (PPSP) after a total knee arthroplasty are less frequent. A large retrospective study showed no statistically significant difference between the outcomes after a conventional radiofrequency treatment in the group with PPSP and osteoarthritis.[200] Other observational studies also showed pain relief after (cooled) RF treatment.[201,202]

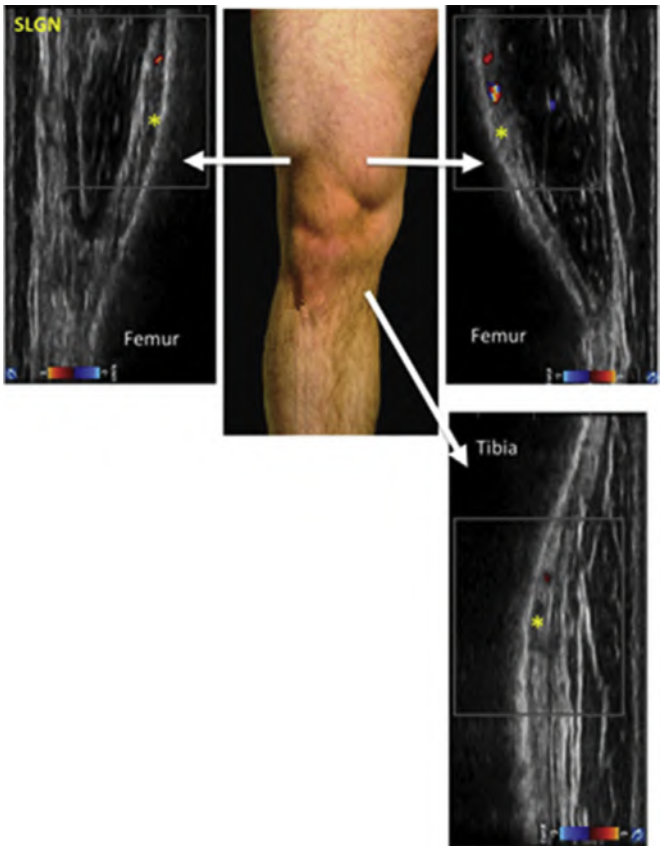
Procedure

The procedure was initially described under fluoroscopy and later on also with the use of ultrasound. Two RCTs compared fluoroscopy and ultrasound and found no differences in outcome.[203,204] Since there are no differences in outcome and ultrasound does not have radiation exposure and makes it possible to visualize soft tissue, ultrasound is the preferred imaging method to perform a radiofrequency treatment of the genicular nerves.

The patient is placed in a supine position with the index knee flexed 10–15° by placing a cushion in the popliteal fossa. The procedure is performed under sterile conditions. A diagnostic block can be performed, although there is a discussion on their utility since a recent study showed no prognostic value.[205] Using a high frequency linear ultrasound, the superomedial, superolateral, and inferomedial genicular nerves are targeted as described below. The inferolateral genicular nerve is not targeted because of its proximity to the common peroneal nerve with its motor branches (Fig. 66.17).[206]

Superomedial genicular nerve. The transducer is placed in a coronal orientation on the medial side of the proximal knee. After identifying the femoral medial epicondyle, the transducer is moved proximally and centered to the junction between the epiphysis and diaphysis of the femur and the vastus medialis superficial to it, just anterior to the adductor tubercle. The superomedial genicular artery may or may not be seen between the deep fascia of the muscle and the femur at this level. If the superomedial genicular artery is visualized just above the bony cortex, the target point is next to this artery. If the artery is not visualized, the junction between the epiphysis and diaphysis is the target point. The probe-to-target point distance is assessed with ultrasound. An out-of-plane entry point is marked perpendicular to the center of the probe at the assessed probe-to-target point distance. Consecutively, the transducer is turned 90° into the transverse plane at this point. The skin and soft tissue are anesthetized with 1 mL lidocaine 2% at the estimated entry point. The cannula is advanced using an anterior to posterior "in plane" approach in the transverse plane until contact is made with the bony cortex at the center of the femur.

Inferomedial genicular nerve. The transducer is placed in a coronal orientation on the medial side of the distal knee to visualize the junction of the tibial medial epiphysis and diaphysis, the



• **Figure 66.17** Ultrasound probe position and corresponding images for genicular radiofrequency treatment. Color Doppler shows the corresponding genicular arteries. Treatment sites are marked with *yellow asterisks*.

inferomedial genicular artery, and the medial collateral ligament. Suppose the inferomedial genicular artery is visualized just above the bony cortex beneath the medial collateral ligament at the midpoint between the tibial medial epicondyle and the tibial insertion of the medial collateral ligament. In that case, the target point is next to this artery. If the artery is not visualized, the junction between the epiphysis and diaphysis is the target point. The probe-to-target point distance is assessed with ultrasound. An out-of-plane entry point is marked perpendicular to the center of the probe at the assessed probe-to-target point distance. Consecutively, the transducer was turned 90° into the transverse plane at this point. The skin and soft tissue are anesthetized with 1 mL lidocaine 2% at the estimated entry point. The cannula is advanced using an anterior to posterior "in plane" approach in the transverse plane until contact is made with the bony cortex at the center of the tibia.

Superolateral genicular nerve. The transducer is placed in a coronal orientation on the lateral side of the proximal knee. After identifying the femoral lateral epicondyle, the transducer is moved proximally to visualize the junction between the epiphysis and diaphysis of the femur and the vastus lateralis superficial to it. The superolateral genicular artery may or may not be seen between the deep fascia of the muscle and the femur at this level. If the superolateral genicular artery is visualized just above the bony cortex, the target point is next to this artery. If the artery is not visualized, the junction between the epiphysis and diaphysis is the target point. The probe-to-target point distance is assessed with ultrasound. An out-of-plane entry point is marked perpendicular to the center of the probe at the assessed probe-to-target point distance. Consecutively, the transducer is turned 90° into the transverse plane at this point. The skin and soft tissue are anesthetized with 1 mL lidocaine 2% at the estimated entry point. The cannula is advanced using an anterior to posterior "in plane" approach in the transverse plane until contact is made with the bony cortex at the center of the femur.

RF procedure. An RF electrode is introduced in the cannula. Sensory stimulation (50 Hz) is applied and produces paresthesia at a threshold of less than 0.5 V. The absence of fasciculations below 1 V is observed after motor stimulation at 2 Hz, confirming sufficient distance to relevant motor branches.

If the needle tip is confirmed to be in the correct position, 1 mL of lidocaine 2% is injected before the start of RF treatment. Typical RF treatment settings are 70–80° for 90 s, for cooled RF 60° for 150 s, and PRF 45 V for 4–8 min.

Adverse Events and Complications. Side effects are rare, and this minimally invasive procedure is considered safe. There are only five case reports of complications. Two articles reported a bleeding complication. The first article reported a peri- and intraarticular hematoma in three patients, two of whom were on anticoagulants.[207] Another article reported a periarticular hematoma in a patient.[208] In all cases, cooled RF of the genicular nerves was used, and bleeding was probably because of damage to the genicular arteries. There is a case report of septic arthritis and an injury to the pes anserine tendon after the use of cooled RF.[209,210] In the patient with septic arthritis, a steroid was injected after the radiofrequency treatment to reduce the risk of post-procedure neuritis and could have played a role. Finally, a case of a third-degree burn wound after the use of conventional RF is also published.[211]

Conclusions

RF treatment of chronic pain syndromes has seen a remarkable evolution over the past decade. RF current can now be applied in a continuous and pulsed fashion and application of continuous RF through an internally cooled electrode. Continuous thermal RF application method generates heat lesions. With cooled RF, the internal cooling of the electrode tip prevents excessive tissue heating, thus allowing the application of higher energy at lower impendency without creating scar tissue. The electrical field generated by PRF induces changes in nerve cells. Besides studies on efficacy and safety, computer modeling and *in vitro* and animal experiments have begun to shed light on the potential mode of action of PRF.

Evidence from good-quality studies demonstrates that continuous RF, cooled RF, and PRF can be applied to treat some chronic pain syndromes effectively. When performed in well-selected patients, who often suffer pain refractory to conventional treatment, the degree of pain relief can be higher than with conventional treatment. Moreover, in contrast to drug studies, the follow up period is much longer, providing proof of its long-term efficacy. RF treatment can produce minor, immediate side effects that typically resolve spontaneously within a short period. Major neurologic complications are rare but have been reported with conventional heat lesioning, not with PRF. Because of the low neurodestructive potential, PRF is our choice for treatment involving the DRG. These encouraging results point to the urgent need for further studies on this promising minimal neurodestructive mode of treatment. In future studies, attempts should be made to assess a homogeneous patient population with specific pathology.

Key Points

- Radiofrequency (RF) treatment consists of the application of a high frequency current by a needle to specific anatomic structures. RF current heats the tissue surrounding the tip of the needle. In interventional pain procedures, these small heat lesions cause selective denervation.
- Cooled RF, by utilizing an internally cooled electrode, allows increasing the lesion size without damaging the surrounding tissue.
- Pulsed RF (PRF) uses a high frequency current during 20 ms followed by a silent period of 480 ms, thus allowing the generated heat to be washed out. The effect is attributed to the creation of electric fields. Indications are neuropathic pain syndromes. Other indications are subject to research.
- An accepted indication for RF treatment of the head is trigeminal neuralgia (RF of the Gasserian ganglion). Neurologic evaluation is mandatory to exclude red flags for treatment. The first step in treatment is medication. RF treatment of the pterygopalatine ganglion can be used for cluster headaches and some atypical facial syndromes. PRF was studied for the treatment of trigeminal neuralgia. A recent development using high voltage PRF seems to prolong the treatment effect.
- Indications for RF treatment of the medial branches of the cervical facet joints include degenerative and posttraumatic neck pain. RF treatment of the (higher) cervical facet joints for cervicogenic headache awaits further research. RF of the facet joint is usually performed at two or three segmental levels since there is overlap in the innervation of the facet joints.
- Radicular pain in the upper extremity is caused by nerve root irritation. The involved spinal level can be estimated by the dermatome where the pain radiates and can be confirmed by diagnostic nerve root blocks. PRF treatment of the DRG is safer and has fewer side effects than RF treatment does.
- Lumbosacral radicular pain is probably the most frequent neuropathic pain. There is no clear evidence of the efficacy of continuous thermal RF treatment of the DRG and could potentially create a deafferentation pain. PRF treatment of the DRG is therefore preferred.
- Chronic knee pain because of osteoarthritis or persistent pain after knee arthroplasty can be treated with RF of the genicular nerves

Pain Interventions for the Knee, Hip, and Shoulder

CHRISTINE L. HUNT, DAVID A. PROVENZANO, KAILASH CHANDWANI

Introduction

Targeted treatment of peripheral joint pain because of musculoskeletal disorders involves the utilization of intraarticular (IA) injections as well as ablative procedures. IA joint and bursa injections are used to treat pain in the joint and surrounding soft tissue structures. Radiofrequency ablation (RFA) creates a controlled lesion targeting sensory nerves associated with the large peripheral joints, including the hip, knee, and shoulder. Musculoskeletal system disorders, including osteoarthritis, are some of the most common medical conditions for which patients seek care. Musculoskeletal diseases are associated with high levels of disability, and significant economic costs.[1–3] Osteoarthritis is a non-inflammatory rheumatologic condition and the most prevalent form of arthritis. Osteoarthritis affects approximately 15% of the United States population and is the leading cause of lower limb disability among older adults.[4] The prevalence of osteoarthritis in the United States increased by 23% from 1990–2017, and the prevalence and incidence rates of osteoarthritis in the United States are among the highest in the world.[5]

Hollander first introduced IA corticosteroid injection for the treatment of rheumatoid arthritis (RA) in the 1950s.[6–8] The first clinical trial for IA joint injections for osteoarthritis was performed in 1958.[9] Currently, joint injections continue to be used extensively in a multimodal treatment platform for musculoskeletal conditions. The updated American College of Rheumatology (ACR) guidelines for the medical management of osteoarthritis strongly recommend IA injections and exercise and self-management programs to improve pain and function.[10]

Radiofrequency ablation for the management of osteoarthritic pain has evolved considerably over the last 20 years, and its use has expanded from the axial spine to peripheral joints. Thermal RFA has been well investigated and includes traditional monopolar and bipolar cannulae setups and internally cooled electrodes. Internally cooled electrodes create larger lesions with a significant portion of the lesioning occurring distal to the tip (i.e. approximately 40%), both of which are attractive for ablation of peripheral joint targets. Over the last 10 years, more research has been published demonstrating the effective employment of RFA for the management of painful osteoarthritis of the knee, hip, and shoulder, especially in individuals that have not responded to injectable corticosteroid therapy or viscosupplementation.[11]

This chapter provides an updated review of IA joint injections and RFA techniques targeting peripheral joints. Six major areas are covered: 1) pharmacology of common injectable agents, 2) indications for treatment, 3) image guided injection techniques, 4) IA injection-associated adverse effects and complications, 5) technique of RFA for treatment of peripheral joint pain, and 6) safety and effectiveness of RFA for peripheral joint pain. The three major joints addressed are the shoulder, hip, and knee. Assessments of the accuracy and therapeutic efficacy of each technique are provided.

Pharmacology of Agents Utilized for Joint Injections

IA needle placement is routinely used to deliver therapeutic agents to reduce pain and improve function. The three agents routinely employed for IA injections are local anesthetics, corticosteroids, and viscosupplements.

Local Anesthetics

Indications and Mechanism of Action

Local anesthetics are often utilized in combination with corticosteroids for IA and extra-articular injections. The rationale for utilizing LAs includes providing pain relief for the needle insertion itself and diagnostic purposes, as well as diluting and distributing the steroid preparation within the joint.

Local anesthetics act by reversibly binding to sodium channels on neuronal cell membranes, thereby blocking nerve conduction.[12] Local anesthetics also have transient anti-inflammatory effects and inhibit several leukocyte functions.[13]

Local anesthetics commonly employed for joint injections include the short-acting LA lidocaine and the long-acting LAs bupivacaine and ropivacaine.

Adverse Effects and Complications Associated With Local Anesthetic Injection

Local anesthetics are associated with local and systemic side effects. Local effects of LAs include myotoxicity and chondrotoxicity. Myotoxicity can occur from LA administration in or around muscle tissue, although it is usually not clinically relevant and muscle regeneration occurs.[14] Bupivacaine is more myotoxic than lidocaine and ropivacaine.[15] Local anesthetics produce myonecrosis through the lytic degeneration of the sarcoplasmic reticulum and mitochondria. The addition of corticosteroids to LA injection amplifies the muscle damage and prolongs the recovery phase.[16]

Myonecrosis rarely presents any clinically discernible manifestations in the course of routine use of local anesthetics for IA joint injections.

Local anesthetics are also chondrotoxic.[17–22] Most reported cases of chondrolysis occurred after the use of continuous IA local anesthetic infusions to manage postoperative pain rather than single IA injections.[21] *In vitro* studies have demonstrated that LAs cause mitochondrial dysfunction and apoptosis in human chondrocytes.[14] Chondrotoxic effects are influenced by the LA type and concentration. Grishko et al.[18] demonstrated that 2% lidocaine caused massive necrosis of cultured chondrocytes after 24 hours of exposure, whereas 1% lidocaine caused a detectable but insignificant decrease in cell viability. Therefore clinically, the use of lower concentrations of local anesthetic may be advantageous. For longer acting LAs, *in vitro* studies indicate that 0.5% ropivacaine is significantly less chondrotoxic to cultured human articular cartilage than 0.5% bupivacaine.[19] Similar to myotoxicity, combining LA with corticosteroids amplifies chondrotoxicity.[23] Although the molecular mechanisms of LA chondrotoxicity are still incompletely elucidated, LAs are thought to lead to mitochondrial dysfunction by influencing sodium, calcium, and potassium channels, ultimately resulting in cell necrosis or cell apoptosis in a time- and dose-dependent manner.[22]

When combining LA with corticosteroids, flocculation—aggregation of the particles of steroid—may occur.[24] Indeed, dilution with either saline or LA may influence the size of corticosteroid particles.[25] Betamethasone sodium phosphate/betamethasone acetate (Celestone Soluspan) should not be mixed with LAs that contain the excipients methylparaben, propylparaben, or phenol because of an increased risk of flocculation.[24] Flocculation leads to larger particles that may clog smaller bore needles, preventing injection. The effect of flocculation of the injected steroid on their therapeutic effect is unclear. Theoretically, the change in the size of the microaggregates of steroids could significantly alter the bioavailability of the steroid over time and the distribution within the joint after injection, altering their therapeutic effect.

Systemic effects of LAs include allergic reactions, central nervous system, and cardiac toxicity.[26] When appropriate steps are taken to avoid intravascular injection, including frequent aspiration and using small volumes for musculoskeletal injections, the incidence of these occurrences are low. Allergic reactions are more common with amino-ester LAs secondary to the production of metabolites related to para-aminobenzoic acid. Allergic reactions may also be because of the preservatives contained within the carrier solution (e.g. methylparaben). Cross-sensitivity does not exist between LA structural classes.

Corticosteroids

Indications and Mechanism of Action

Corticosteroids are often used for pain associated with symptomatic arthritis and soft tissue conditions, e.g. tendinitis, bursitis, and tenosynovitis. Numerous guidelines with a specific focus on osteoarthritis of the knee recommend IA corticosteroid injection for short-term pain relief.[27–30] Intraarticular steroid injections should be part of a multimodal treatment plan that includes aerobic and muscle-strengthening programs. Contraindications to IA injection are shown in Table 67.1.

The exact mechanism of action of corticosteroids in reducing arthritic joint pain has not been completely defined. Corticosteroids placed in the joint exert both local and systemic effects.[24,31,32]

TABLE 67.1 Absolute and Relative Contraindications for Intraarticular Joint Injections With Corticosteroids or Viscosupplementation

Absolute Contraindications
Overlying skin infection or recent procedure violating the epidermal layer (i.e. unhealed tattoo)
Fracture site
Severely compromised immune status
Suspected bacteremia
Suspected infectious arthritis
Hypersensitivity to previous viscosupplementation
Relative Contraindications
Coagulopathy
Hypersensitivity to avian products (proteins, feather, and egg products)[a]
Joint prosthesis
Poorly controlled diabetes mellitus
Previous lack of efficacy

[a]Consider using non-avian viscosupplementation products.

In individuals with RA, changes in the non-injected knee thermographic index, a quantitative measure of radiated energy from a defined area of the joint surface, have been demonstrated after IA prednisolone and triamcinolone hexacetonide (TH) injection into the symptomatic knee.[32,33] Intraarticular placement of methylprednisolone acetate (MPA), 40 or 80 mg, resulted in detectable systemic serum levels with peak levels occurring between 2 and 12 hours after injection. Additionally, endogenous serum cortisol levels were suppressed for up to one week after injection.[34] The systemic effects are further confirmed by the reduction of systemic inflammatory marker levels, including erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP).[24]

Corticosteroids have significant anti-inflammatory and immune effects and are active at the cellular level by combining with receptors to alter the rate of messenger ribonucleic acid synthesis and specific protein production. Specifically, corticosteroids result in increased synthesis of annexin-1 (lipocortin 1). Annexin-1 has phospholipase A_2-inhibitory activity that reduces the production of multiple inflammatory mediators, including eicosanoids, lysosomal enzymes, interleukin-1, leukotrienes, and prostaglandins.[35–37] The clinical response to IA steroids is accompanied by histologic improvement and decreased expression of genes involved in articular cartilage destruction.[38] Additionally, corticosteroids reduce microvascular permeability and synovial perfusion and increase synovial fluid viscosity.[39]

Corticosteroids seem to exert greater therapeutic effects with IA injection versus systemic or intramuscular (IM) administration. Injection of corticosteroid into multiple joints in RA patients resulted in greater improvement in ACR Criteria, patient disease activity, number of tender points, and reduced systemic side effects compared to equivalent IM dosing.[40] There is moderate evidence to support the effectiveness of IA steroid injections into the knee, with studies suggesting efficacy up to three months after injection.[41]

Corticosteroid Selection (Structure and Function)

The first steroid used for IA injection was hydrocortisone.[7,8] Pharmacologic developments have resulted in the advancement of steroid preparations over the past 50 years. However, substantial variation still exists for agent selection. There remains a paucity of randomized controlled trials (RCTs) comparing the efficacy of different corticosteroids for osteoarthritis. Thus evidence-based recommendations to guide steroid selection cannot be made. In 2014, a survey of ACR members indicated that agent selection for IA injections was usually determined empirically, and no consistent pattern was reported in terms of the type of corticosteroid based on anatomic site. The three most commonly utilized agents were MPA (used by 45% of respondents), triamcinolone acetonide (TA; 26.1%), and TH (22.1%).[42]

Table 67.2 lists commonly utilized corticosteroids that are FDA-certified for IA injection. TA extended release formulation is FDA-approved only for use in the knee joint and has not been studied in other peripheral joints. Approved for commercial use in the United States in 2017, it is supplied as a crystalline powder that is mixed at point-of-care with the manufacturer-supplied diluent to deliver 32 mg of TA extended release in 5 mL of solution that is equivalent to 40 mg of immediate-release TA. The extended release formulation utilizes poly (lactic-co-glycolic acid; PLGA) microspheres that allows for the slow release of TA. This formulation allows for the prolonged presence of steroids in the joint.[43] The only other corticosteroid approved for IA injection is dexamethasone. Dexamethasone, a highly water soluble, nonparticulate steroid preparation, exerts primarily systemic effects even after IA injection and is not routinely utilized for IA injections.[24,25] Ultimately, the selection of a depot corticosteroid can be based on cost and multiple pharmacologic properties, including solubility, crystal, and molecular structure.

Corticosteroid solubility may influence the duration of action, although published studies are conflicting. TH is the most insoluble injectable corticosteroid. Some IA injection studies have demonstrated a prolonged duration of activity with TH compared to other corticosteroids with higher solubility. Derendorf et al.[44] demonstrated that TH was associated with lower levels of systemic absorption and higher synovial levels than similar IA administration of TA. Comparison of TH and MPA for knee osteoarthritis did not support steroid solubility as the only factor influencing drug duration of action and therapeutic efficacy.[45] After three weeks, TH was more effective, but only MPA resulted in continued improvement in pain and disability scores at eight weeks. Another study comparing TH and MPA for RA treatment demonstrated a longer therapeutic effect with TH.[46] Thus available data are conflicting.

There is limited evidence to guide corticosteroid selection based on the peripheral joint target. MPA and TA seem to have similar short and intermediate term effectiveness for improving pain and function in peripheral joint targets. Most studies do not show greater pain improvement with a higher dose of steroids.[47]

The adverse effect profile of a corticosteroid should also be considered. Methylprednisolone acetate may be utilized for both joint and soft tissue injections, whereas TH is not recommended for soft tissue injections because of the higher risk of calcification, necrosis, and atrophy of soft tissues.[12,48,49]

Corticosteroid Dosing and Post-injection Protocols

Corticosteroid dosing ranges for various joints are listed in Table 67.2. Evidence-based recommendations for dosing and the maximum injection frequency do not exist. Cumulative doses of epidural steroid injections greater than 200 mg methylprednisolone equivalents annually have been shown to be associated

TABLE 67.2 Common Corticosteroid Preparations for Intraarticular and Periarticular Injections[19,28,30,33,40]

Preparation	Administration	Equivalent Dosage (mg)[a]	Anti-inflammatory Potency[b]	Solubility (%wt/vol)	Fluorinated	Dose Based on Joint Size
Betamethasone sodium phosphate/ betamethasone acetate (BSP/BA)	3 mg BSP/+ 3 mg BA per 1 mL	0.75	25	[c]Not specified	Yes	Large: 1–2 mL Medium: 0.5–1.0 mL Small: 0.25–0.5 mL
Methylprednisolone acetate (MPA)	20, 40, 80 mg/mL	4	5	0.001	No	Large: 20–80 mg Medium: 10–40 mg Small: 4–10 mg
Triamcinolone acetonide (TA)	10, 40 mg/mL	4	5	0.004	Yes	Large: 5–15 mg Small: 2.5–5 mg
Triamcinolone hexacetonide (TH)	5, 20 mg/mL	4	5	0.0002	Yes	Large: 10–20 mg Small: 2–6 mg
Triamcinolone acetonide (TA) extended release	32 mg powder for reconstitution	4	5	Insoluble[d]	Yes	Large: 32 mg[e]

[a]Equivalent to 5 mg prednisone. For TA and TH, the specific dosing for medium-sized joints was not mentioned.

[b]Relative potencies based on equivalent milligram doses with hydrocortisone being the relative baseline with a potency of one.

[c]The betamethasone preparation consists of the highly soluble ester BSP, which is devoid of particles and the less soluble BA.

[d]Per FDA labeling, the crystalline powder form of extended release TA is practically insoluble in water and very soluble in alcohol.

[e]The extended version of TA has been FDA-approved for use in the knee only and not in any other joint. The long-term safety and efficacy of repeated injections have not been studied.

with compromised bone mineral density,[50] and practitioners should be aware of the total steroid exposure a patient receives over time from all injection sources. Standard recommendations for weight bearing joints include a maximum of three to four injections per year, typically with three to four months between injections.[39,48] Conflicting evidence exists regarding the long-term safety of repeated IA corticosteroid injections. Long-term corticosteroid safety was studied by Raynauld et al.[51] in a randomized, double-blind placebo-controlled trial that compared IA knee injections of TA or saline every three months for up to two years. No detrimental effects or joint space destruction were observed on radiographs. Balch et al.[52] found no radiographic evidence of corticosteroid-induced joint destruction after long-term repeated IA injections (from four to 15 years) on knee joints affected by RA and osteoarthritis. However, a recent RCT examining IA corticosteroid injection treatment demonstrated significantly greater cartilage volume loss with no significant difference in pain scores with triamcinolone compared to saline when administered every three months over a two-year period.[53] Moreover, 80 mg of TA is not superior to 40 mg for IA knee injection in terms of pain relief or functional improvement.[54]

Following IA corticosteroid injection, patients are often advised to avoid overusing the joint for two to three days post-injection.[55] Studies investigating potential benefits of rest following corticosteroid injections have reported conflicting results.[24] Chakravarty et al.[56] demonstrated additional improvement in individuals that rested for 24 hours after IA injection, while Chatham et al.[57] found no benefit in individuals that rested for 48 hours.

If an individual is going to undergo a joint replacement surgery in the near future, caution should be exercised in performing IA injections close to the surgical date (typically within three months).[58] Retrospective comparative studies demonstrated an increased risk for deep infection in individuals that received IA corticosteroid injections shortly before the surgical replacement procedure.[59–61] However, Kokubun et al.[62] did not observe increased complications or infections IA injections within 90 days prior to total knee replacement. A meta-analysis in 2014 showed no clear association between IA injections performed prior to arthroplasty and the development of subsequent infection following joint replacement.[63] However, this study was not limited to injections performed within 90 days of surgery and thus speaks more to the apparent safety of injections performed at any time prior to arthroplasty. Patients should be counseled on the risks of periprosthetic infections when considering the use of IA injections as temporizing pain reduction techniques prior to joint replacement surgery.[64]

Adverse Effects and Complications Associated With Corticosteroid Injection

The adverse effects and complications of corticosteroid injections can be divided into local and systemic effects. Local adverse effects include tissue (skin or fat) atrophy, Nicolau's syndrome, tendon rupture, cartilage damage, post-injection flare, hemarthrosis, joint destruction, avascular necrosis, and septic arthritis.[12,48,65,66] Local tissue atrophy is one of the most common local adverse effects occurring in 1%–8% of cases and is often associated with superficial injection, inaccurate placement, and less soluble agents, e.g. triamcinolone compounds. Skin atrophy typically develops between one and four months after injection.[39,65] Methylprednisolone acetate is less frequently associated with soft tissue atrophy. Another common adverse effect is post-injection flare in pain, with a prevalence of 2%–25%. Post-injection flare typically presents within a few hours of injection and resolves within one to three days.[48]

Concern also exists for corticosteroid-specific effects on cartilage, tendon, and bone. Current data on corticosteroid effects on cartilage are conflicting. Animal studies have been inconsistent, with some demonstrating cartilage destruction while others revealing a cartilage-protective effect during acute inflammatory events.[67-73] Clinical studies suggest that cartilage loss may occur more frequently with repeated injections in large numbers.[12,53] Avascular necrosis has also been reported after joint injections, with the hip being the most commonly affected joint. This complication typically occurs after multiple joint injections within a short period and is seen more often in individuals who are concurrently taking oral steroids.[65] Tendon disruption has also occurred following corticosteroid injection, and care should be taken to avoid direct injection within tendons.[65,74]

Hemarthrosis and septic arthritis are two infrequent complications that carry significant morbidity. No specific guidelines exist for the performance of IA steroid injections in individuals on anticoagulants, and surveys have demonstrated substantial practice variation.[75] A small study demonstrated a low risk of hemorrhage in individuals taking warfarin sodium that received IA injections.[76] Septic arthritis has a reported incidence ranging from one in 3,000 to one in 50,000.[24,77,78] To reduce the risk of this adverse event, it is important to understand contraindications to injection (Table 67.1) and utilize a stringent aseptic technique. When performing a joint injection, if synovial fluid appears abnormal, the aspirated fluid should be sent for a complete white blood cell count (WBC) count, including differential, crystal analysis, Gram stain, and culture. Steroids should not be placed until the synovial fluid analysis (Table 67.3) is reviewed and interpreted. Septic arthritis is a medical emergency

TABLE 67.3 Synovial Fluid Analysis[231–233]

Diagnosis	Color	Clarity	WBC count per mm^3	% Neutrophils	Gram stain
Normal	Clear	Transparent	<200	<25	Negative
Non-inflammatory	Straw	Translucent	200–2000	<25	Negative
Inflammatory (Crystalline)	Yellow	Cloudy	2000–100,000	>50	Negative
Septic arthritis	Yellow	Cloudy	>25,000–50,000	>75	Variable
Pseudosepsis	NA	NA	5000–80,000[a]	NA	Negative

[a]Unlike septic arthritis, aspirate from joints with suspected pseudosepsis may contain an elevated eosinophil count suggestive of an immune-mediated inflammatory reaction.[82]

NA, Not available.

and can result in cartilage destruction, septicemia, and death within a few days if untreated. When septic arthritis is suspected, orthopedic surgery and infectious disease specialists should be consulted immediately. Arthrocentesis and synovial fluid analysis (Table 67.3) are mandatory for diagnosis and to guide treatment. Blood tests including a WBC, ESR, and CRP are neither sensitive nor specific in diagnosing or excluding septic arthritis.[79] Broad-spectrum antibiotics are initially started after obtaining the synovial fluid, and antibiotic selection is further guided by culture and sensitivity results. Septic arthritis has also been reported following viscosupplementation injections.[80]

Systemic adverse effects of IA corticosteroids include endocrine, metabolic, and vascular effects.[81] The most common and predictable endocrine effect is the rapid suppression of endogenous cortisol production. Maximal suppression of serum cortisol levels occurs 24–48 hours after IA injection. Adrenocorticotropic hormone (ACTH) levels typically return to normal between one and four weeks, indicating recovery of normal endogenous steroid production.[34,81,82] Metabolic effects include elevation of blood glucose levels in diabetic patients.[83] In people with diabetes with appropriate glucose control, acute hyperglycemia may persist for two to three days with peak glucose levels reaching 300 mg/dL.[81,84] Facial flushing is an unpleasant adverse effect seen in 15%–40% of patients.[12] The effect occurs, on average, 19 hours after injection and is self-limiting, lasting approximately 36 hours. Triamcinolone administration is associated with a higher rate of facial flushing.[81]

Viscosupplementation

Indications and Mechanism of Action

Viscosupplementation refers to IA administration of synthetic hyaluronic acid (HA). Intraarticular HA administration (IAHA) was initially recommended by numerous specialty guidelines, including the ACR, Osteoarthritis Research Society International (OARSI), and European League Against Rheumatism (EULAR), as a treatment option for the management of knee osteoarthritis.[27,85,86] Expert consensus supported the use of IAHA as an effective treatment in mild to moderate knee OA and is a well tolerated treatment in the knee and other joints.[87] However, the 2019 ACR and Arthritis Foundation Guideline for the management of osteoarthritis of the hand, hip, and knee continued to strongly recommend the utilization of intraarticular glucocorticoid injections but changed their position on intraarticular HA injections. The 2019 recommendations conditionally recommended against the use of intraarticular HA injections in individuals with osteoarthritis of the knee and strongly recommended against its use in patients with hip osteoarthritis.[10] The guidelines concluded that the initial recommendation for IA HA injections did not consider the risk of bias of individual primary studies. The studies that demonstrated benefit were often restricted to studies with a higher risk of bias. When meta-analyses were limited to trials with a low risk of bias, the effect size of HA injections compared to saline was not statistically significant. Therefore careful risk-benefit assessment and patient and physician informed decision making is required before performing IA viscosupplementation for the knee

IA HA administration is approved by the United States Food and Drug Administration (FDA) only for knee osteoarthritis. Off-label application of IAHA has been reported for the shoulder, hip, and ankle. Selection criteria include failure of standard noninvasive treatment programs with clinical and radiologic signs of knee osteoarthritis.[27,88] Osteoarthritis severity may be an important predictor in determining the magnitude of clinical response to IAHA injection. In general, IAHA seems most beneficial in individuals with early osteoarthritis and radiographic evidence of joint space preservation.[89–91] Contraindications to IAHA injection are shown in Table 67.1.

Although the exact mechanism of action is unknown, the treatment goal is to restore the viscoelastic properties of synovial fluid.[92] Observed treatment benefits are not entirely explained by IA residence time, which is considerably shorter than the duration of clinical benefit. Several *in vitro* and pre-clinical studies have proposed additional mechanisms of action for IAHA, including inhibition of inflammation and cartilage degradation, reduction of pain mediators, and induction of *in vivo* HA synthesis.[93,94] HA has been best studied in the knee; some studies show that it may provide longer lasting improvement in pain and function than intra-articular steroid (IAS).[95]

Viscosupplementation Agent Selection (Structure and Function)

HA is a glycosaminoglycan synthesized by synoviocytes, fibroblasts, and chondrocytes that confers viscous and elastic properties to the joint.[96] Viscosupplementation formulations differ in their origin, production method, molecular weight, treatment schedule, and physicochemical properties.[94] At least 12 HA preparations are approved for knee osteoarthritis in the United States, initially offered as a series of injections with the first single injection option introduced in 2009.[96] Formulations are classified as cross-linked or non-cross-linked and are further defined by chemical modifications and production method (avian- versus non-avian-derived products). Non-avian products are produced by bacterial fermentation. All available avian preparations are derived from rooster combs and are purified natural products. The avian sourced hylan G-F 20, Gel-One®, and non-avian sourced Monovisc®, Durolane® are chemically modified (cross-linked HA) to increase the molecular weight to replicate the properties of native synovial fluid more closely and to lengthen IA residence half-life.[92,97] No conclusive evidence exists that differences in viscosupplement physical properties translate into superior clinical efficacy.[98]

Dosing and Post-injection Protocols

The recommended dosing regimens for specific viscosupplementation products are based on the physical properties and the manufacturers' prescribing recommendations. Currently, there is insufficient evidence to guide the appropriate injection frequency and dosing intervals. Common recommendations are either for a single injection or a total of two to five weekly injections based on the selected product (Table 67.4), but these are solely based on the manufacturer's recommendations that arose from the pre-marketing registry trials for each product.[99] Evidence-based recommendations do not exist for interval timing for repeating treatment, although repeated courses of IAHA are generally safe and well tolerated, with injections or series spaced at least six months apart demonstrating effectiveness in several RCTs.[100] Insurance providers typically require a minimum of 6 months between repeated treatment courses. Pre-injection synovial fluid aspiration and avoidance of excessive weight bearing activities for 48–72 hours post-injection may yield better outcomes.[89,91,101]

Adverse Effects and Complications Associated With Viscosupplementation Injection

In general, viscosupplementation is well tolerated with more local reactions but fewer systemic side effects than other medical interventions for managing knee osteoarthritis.[102] Frequently reported

TABLE 67.4 Commonly Used Hyaluronic Acid Preparations for IA Viscosupplementation

Product Structure	Product Name	Origin	Molecular Weight (kDa)	Injection Interval	Dosing Volume	Recommended Dosing Regimen[a]
Cross-linked	Synvisc®	Sodium Hyaluronate	6000	One week	2 mL	3
	Synvisc-One®	Sodium Hyaluronate	6000	N/A	6 mL	Once

kDa, Kilodalton; *N/A*, not applicable

local adverse effects include injection site pain, short term erythema, and joint effusion development. These effects are typically mild and resolve within 24–48 hours.

Other infrequent local adverse effects include pseudosepsis and pseudogout.[103] Pseudosepsis, a severe acute inflammatory reaction, is considered an extreme local adverse reaction. It is characterized by a large effusion, severe pain, and cellular infiltration occurring within 24–72 hours after the injection. Pseudosepsis often requires clinical intervention such as arthrocentesis, IA corticosteroids, and systemic analgesics.[104] Pseudosepsis may be misdiagnosed as septic arthritis.[104] The proposed mechanisms of pseudosepsis include an immune reaction to cross-linked products. Inappropriate injectate placement has also been suggested as a causative factor in pseudosepsis.[89,105] When pseudosepsis is suspected, other clinical conditions such as septic arthritis must be ruled out.

Pseudogout is a type of crystal-induced arthropathy characterized by calcium pyrophosphate crystal deposition. Individuals with pseudogout present with acute pain, joint swelling, and decreased function. The pathophysiology leading to pseudogout after IAHA is not clearly understood. Pseudogout occurs more frequently in patients with preexisting chondrocalcinosis. Therefore IAHA should be used with caution in these individuals.[106,107] Pseudogout may also be mislabeled as pseudosepsis. Synovial fluid analysis is helpful in making the correct diagnosis (Table 67.3).

Joint Injection Techniques

Three injection techniques (palpation, ultrasound guided, and fluoroscopy guided) may be used for the placement of drugs into the IA space. The use of ultrasound improves both accuracy and short term outcomes in pain and function compared to palpation guidance with IA injections.[108] Palpation guided IA injections are associated with inappropriate needle placement rates as high as 50%–60%.[109,110] Fluoroscopy and ultrasound guided methods have evolved to increase injection accuracy. Although both techniques allow for needle visualization, ultrasound guidance has advantages. Benefits of ultrasound guided injection include dynamic real-time multiplanar imaging of relevant anatomic structures, direct visualization of injected therapeutic agents, and the absence of ionizing radiation.

Improved injection accuracy with visually guided techniques ensures correct IA compound placement and may significantly

influence clinical outcomes. The benefit of accurate IA placement was demonstrated in a randomized control trial evaluating clinical outcomes in individuals who received either anatomic palpation guided or ultrasound guided IA joint injections.[110] A total of 148 joint injection procedures were studied, with 95% of injections occurring in large joints (knee, hip, shoulder, elbow, wrist, and ankle). The remaining 5% of the injections occurred in small joints (interphalangeal or metacarpophalangeal joints). IA knee injections represented the largest category at 42%. Sonographic needle guidance was found to be statistically superior in multiple areas. Compared to palpation guided injections, ultrasound guided injections resulted in a 43% reduction in procedural pain, a 58.5% reduction in absolute pain scores at two weeks, a 26% increase in responder rate, and a 62% reduction in the non-responder rate. Sonographic needle placement also improved detection of joint effusion by 200% and increased aspirated fluid volume by 337%. The authors concluded that sonographic guidance for IA injections is associated with significant short-term clinical advantages.

This section will describe the injection techniques for the three major joints: shoulder, hip, and knee. Emphasis will be placed on the image guided techniques. The efficacy for IA and viscosupplementation will also be discussed. Strict aseptic technique should be utilized for all injections.

Shoulder

Anatomy

The shoulder is a complex anatomic structure allowing multidirectional movement. The shoulder girdle refers to several articulations associated with important muscle groups that provide a wide range of shoulder movement. Three important shoulder joints are the glenohumeral, acromioclavicular, and sternoclavicular. The glenohumeral joint is a ball and socket joint that allows abduction, adduction, flexion, extension, rotation, and circumduction. The acromioclavicular joint is situated superficially between the lateral end of the clavicle and the acromion process of the scapula. The rotator cuff muscles include the supraspinatus, infraspinatus, teres minor, and subscapularis. The subacromial bursa is positioned within the subacromial space between the overlying deltoid muscle and the underlying supraspinatus tendon and provides rotator cuff lubrication.

Injection techniques for the shoulder including palpation (anatomic landmarks) and image guided (ultrasound and fluoroscopy) approaches. We will focus the discussion on image guided techniques for the three major anatomic locations for shoulder injections: 1) subacromial/subdeltoid bursa, 2) glenohumeral joint, and 3) acromioclavicular (AC) joint. Shoulder injection using only anatomical landmarks may be inaccurate,[111–115] which may adversely affect short-term clinical outcomes.[116,117]

Subacromial/Subdeltoid Bursa Injections

Indications and Musculoskeletal Pathophysiology

Subacromial injections are used to treat various shoulder conditions, including rotator cuff pathology, subacromial bursitis, and subacromial impingement.[118,119] Impingement refers to the narrowing of space available for the rotator cuff resulting in compression of rotator cuff tendons against the undersurface of the coracoacromial arch.[120] Rotator cuff impingement may result in the development of bursitis, subacromial inflammation, secondary tendinitis, and degenerative tears.[121]

Clinical outcomes following subacromial injections have been linked to the accuracy of injection, the severity of imaging findings, and the duration of symptoms.[116,117,122] Specifically, an MRI finding of isolated bursitis without rotator cuff tear, younger age, and shorter duration of symptoms (less than one year) are associated with better post-injection clinical outcomes.[122] Outcomes are typically better when injection therapy is combined with an appropriate home exercise program.[123]

Palpation Guided Anatomic Injection Technique

Commonly utilized portals for palpation guided subacromial injections include the posterior lateral and anterior-lateral approaches.[111,121,124,125] In the posterior approach, the needle is inserted 1–2 cm inferior to the posterior lateral aspect of the acromion process. The needle is directed anteriorly and cephalad. In the anterior approach, the needle is inserted approximately 1 cm inferior to the anterior/inferior aspect of the acromion process. The needle is directed posteriorly and cephalad. The posterolateral approach is preferred because of the existence of a larger subacromial space, although no definitive evidence exists to support the superiority of any single approach.[125]

Fluoroscopy Guided Injection Technique

Limited information exists detailing subacromial joint injections performed under fluoroscopic guidance. The utilization of fluoroscopy with radiographic contrast IA injection has been employed as a confirmatory adjunct to palpation guided injections to ensure appropriate needle and injectate placement.[124,126]

Ultrasound Guided Injection Technique

The patient sits in the upright position with the shoulder extended, elbow flexed, and palm of the hand placed over the ipsilateral back pocket (modified Crass position).[119,127] Initially, the IA portion of the biceps tendon is identified over the anterior shoulder with a high frequency linear-array ultrasound probe. The probe is oriented in the coronal plane and is moved superiorly and posteriorly until it is aligned with the supraspinatus tendon longitudinal axis. The supraspinatus tendon in this position has a typical beak-shaped appearance.[127] The subacromial-subdeltoid bursa is visualized as a thin hypoechoic band outlined by highly reflective lines corresponding to peribursal fat between the deltoid muscle and supraspinatus tendon (Fig. 67.1).[119,128] Other structures visualized include the acromion process at the medial end and the greater tuberosity at the lateral end of the scan plane. The lateral end of the transducer is marked for the skin entry. A procedure needle is advanced with an in-plane technique into the subacromial-subdeltoid bursa. After confirming the needle position within the bursa, the desired medication is injected slowly while noting the expansion of the bursa.[129] Injection without bursa distention suggests intramuscular or intratendinous needle insertion and requires needle tip repositioning. The technique can also be performed with the patient in the lateral recumbent position on the contralateral shoulder with the targeted extremity extended and relaxed along the torso, and target approached using an in-plane technique using the same landmarks as described above.[130]

When directly comparing visually guided techniques to palpation guided techniques, Naredo et al.[117] demonstrated improved technique accuracy and outcomes (functional shoulder assessment) with ultrasound guided injection versus palpation guided injection. Palpation guided injection resulted in a 30% accuracy rate when validated with ultrasound confirmation of injectate placement. Image guided injections are shown to be more accurate

than palpation guided injections.[131] When examining individual studies for palpation guided anatomic injection techniques, clinical and cadaveric studies have reported variable accuracy rates in the range of 29%–91%.[111,116,124,126,132,133] Improved injection accuracy resulting from ultrasound guidance[117] or fluoroscopic confirmation[116] may positively affect short-term clinical outcomes.

Mathews et al.[134] questioned the reliability of fluoroscopy guided injections in a cadaveric study. Approximately 7% of injections considered to be accurately placed under fluoroscopic guidance were found to be placed inaccurately on subsequent cadaveric dissection. Because of the complex soft tissue anatomic structures of the shoulder joint, fluoroscopic guidance may not guarantee accurate needle placement in the subacromial space. Better visualization of soft tissues using ultrasound guidance potentially favors this method for subacromial joint injections and diagnostic shoulder imaging.[117,121,127]

Glenohumeral Joint Injections

Indications and Musculoskeletal Pathology

Glenohumeral joint injections are used as a non-operative management technique for painful glenohumeral arthrosis or adhesive capsulitis (frozen shoulder).[118]

Fluoroscopy Guided Injection Technique

The patient is placed in the lateral decubitus position with the head resting on the non-targeted arm with the targeted shoulder in the non-dependent position. A bolster is placed in front of the patient, and then the patient rotates onto the bolster with the targeted arm internally rotated until the glenohumeral joint space is aligned under the fluoroscopic anterior-posterior view (Fig. 67.2).[135] The skin entry site is marked over the inferomedial quadrant of the humeral head.[136] A 22-gauge needle is advanced with a coaxial fluoroscopy guided technique to the humeral head. After negative aspiration, radiographic contrast is injected to confirm IA needle placement. Although the posterior approach is commonly used, additional fluoroscopic techniques have been described utilizing the anterior[137] and rotator cuff interval approaches.[138]

Ultrasound Guided Injection Technique

The patient is placed in either the semi-prone position resting on the contralateral shoulder or in an upright sitting position with the ipsilateral arm placed on the contralateral shoulder to open up the glenohumeral joint space.[112] A high frequency linear-array probe facilitates visualization of superficial structures, including the infraspinatus muscle, glenoid cavity, glenohumeral joint, and associated labrum. Many patients may require the use of a curvilinear probe depending on body habitus. The probe is positioned over the infraspinatus fossa inferior and parallel to the scapular spine. The field of view is adjusted to encompass the posterior glenoid rim and the glenohumeral junction (Fig. 67.3). The posterior glenoid labrum appears as a triangular structure. The lateral end of the transducer is marked for the skin entry. A 22-gauge needle is advanced with an in-plane approach into the joint deep to the infraspinatus tendon, between the posterior glenoid labrum and the hypoechoic humeral articular cartilage.[139] Resistance at the time of injection suggests a needle tip position within articular cartilage or labrum and necessitates needle repositioning. Alternative techniques include the anterior[140] and rotator cuff interval approaches.[141] There is no statistically significant difference in terms of the accuracy of GH joint injection between fluoroscopic and ultrasound guidance, and sparing the patient radiation exposure may be a consideration when selecting guidance modality.[142]

When directly comparing ultrasound guided techniques to palpation guided techniques, Cunnington et al.[143] demonstrated that junior trainees with basic ultrasound skills achieved higher IA injection accuracy rates using ultrasound guided (63%) than using palpation guided (40%) approach. No studies exist that directly compare fluoroscopy versus palpation guided glenohumeral injection techniques. In one review, image guidance (fluoroscopy, ultrasound, and MRI) had an average accuracy rate of 95%

compared to an average accuracy rate of 79% with palpation guidance.[131] When examining individual studies for palpation guided anatomic injection techniques, clinical and cadaveric studies have reported variable glenohumeral injection accuracy rates in the range of 27%–100%.[116,133,144–146]

Improved glenohumeral injection accuracy resulting from ultrasound guidance[143,147] or fluoroscopic confirmation[116,143] significantly enhances the short-term clinical outcome. Sibbitt et al.[110] demonstrated in a study involving multi-joint interventions that ultrasound guidance significantly improves clinical outcomes. When directly comparing ultrasound guidance with fluoroscopic guidance, Rutten et al.[112] demonstrated that ultrasound guidance improved procedural outcomes. Ultrasound guidance resulted in a first pass accuracy rate of 94% compared to 72% obtained with fluoroscopic guidance, and also comparatively reduced procedural time and patient discomfort levels.

Acromioclavicular Joint Injection

Indications and Musculoskeletal Pathology

Acromioclavicular (AC) joint injections are employed for diagnostic and therapeutic purposes for painful AC joint arthritis.[118,148]

Fluoroscopy Guided Injection Technique

Few reports exist describing fluoroscopically guided AC joint injections. With the patient in the supine position, a 25-gauge needle is advanced into the AC joint using either an anterior or superior approach. Less than 0.5 mL of radiographic contrast is utilized to confirm IA placement.[149,150]

Ultrasound Guided Injection Technique

Ultrasound guidance has been associated with greater improvement in pain and function than palpation guided approaches to AC joint injection.[151] The accuracy rate of intraarticular AC joint injection using palpation guidance has been shown to be only 36.5%.[152] Both in-plane[153] and out-of-plane[119,129,154] ultrasound guided techniques have been described. However, the out-of-plane technique is preferred because of this joint's small size and superficial location. The patient is positioned in the sitting position, and a high frequency linear-array probe is placed in an anatomical coronal plane over the superficially located AC joint (Fig. 67.4). The acromion process, clavicle, joint capsule, and wedge-shaped fibrocartilaginous disk are visualized. A 25-gauge needle is advanced using an out-of-plane technique. Because of the shallow AC joint depth, needle insertion must be carefully controlled to avoid misplacement into the subacromial space.[119,148]

Because of the small size and variable morphology of the AC joint, intraarticular needle placement without image guidance is often difficult and inaccurate.[132,155] In a direct comparison cadaveric study, ultrasound guided AC injections using the in-plane technique demonstrated a 100% accuracy rate compared with the 40% accuracy rate for palpation guided injections.[153] For anatomically guided palpation techniques, clinical and cadaveric studies have reported variable accuracy rates in the range of 40%–66% when confirmation of needle or injectate placement was validated with fluoroscopy or cadaveric dissection.[132,155,156] Sabeti-Aschraf et al.[154] observed similar clinical outcomes following palpation guided and ultrasound guided AC injections when performed by experienced physicians.

Efficacy of Shoulder Injections

Efficacy of Subacromial/Subdeltoid Bursa Injections

Evidence for the efficacy of subacromial/subdeltoid bursa injections is conflicting. This incongruity may correlate with the lack of selection of specific shoulder diagnoses in some study populations or inaccurate injectate placement.[117,122,157] Predictors of success following subacromial injections have been investigated. MRI findings consistent with low-grade impingement and bursitis without evidence of a rotator cuff tear are positive predictors of injection response.[122] The use of image guidance may improve the effectiveness of subacromial/subdeltoid bursa injections in terms of pain, function, and range of motion.[158]

Efficacy of Glenohumeral Joint Injections

The majority of available evidence for therapeutic glenohumeral joint injection relates to adhesive capsulitis.[157] Multiple systematic reviews have demonstrated that IA corticosteroid injection for the treatment of adhesive capsulitis may result in improvement in function and range of motion, particularly when performed in conjunction with physical therapy and exercise,[159–161] with the most recent systematic review suggesting that improvements in range of motion may be sustained for a longer period (24 weeks) than pain relief (eight weeks). IA GH joint injection is considered

to be as effective as physical therapy for the treatment of adhesive capsulitis with neither demonstrating clear superiority across nine RCTs and certainly a reasonable approach would be to incorporate both into a comprehensive nonsurgical management program.[162] IA GH joint injections may also be considered for standard conservative treatment of painful GH joint arthritis alongside oral pain medication and physical therapy.[163] They are often considered in patients with significant pain and functional limitation prior to shoulder replacement surgery.[164]

Efficacy of Acromioclavicular Joint Injections

To date, no RCTs have been published evaluating the long-term effectiveness of AC joint injections. A limited number of studies, including one RCT with a three-week follow up, reported short term improvement with IA injection in terms of AC joint pain.[165–167] A single prospective study involving 20 patients (25 shoulders) with primary AC joint arthritis with five-year follow up demonstrated significant, sustained pain improvement at 12 months that diminished by five years but was still improved compared to baseline.[168] AC joint injections may provide significant pain relief in patients with chronic AC joint pain who fail to respond to comprehensive conservative management, including pain medications, physical therapy, and activity modification.[169]

Hip

Anatomy

The hip joint is a ball and socket type of synovial joint situated deeply within the pelvis. Hip joint stability is attributed to the articulation of the convex femoral head (ball) into the concave acetabulum (socket), with additional reinforcement arising from the articular capsule and surrounding muscles and ligaments. The fibrous articular capsule extends from the acetabular rim across the joint to the base of the femoral neck.[170] This capsular anatomy allows for accurate IA injectate placement into the capsule at the femoral head/neck junction without going directly into the joint space. The femoral neurovascular bundle lies medially to the hip joint in the femoral triangle.

Indications and Musculoskeletal Pathology

Intraarticular injections may be used to diagnose and treat the symptoms of inflammatory and non-inflammatory arthritis of the hip joint. Osteoarthritis is a significant cause of hip pain and disability. Intraarticular hip injections are used as a non-operative treatment for hip osteoarthritis. Intraarticular hip injections are also utilized for diagnostic purposes to determine and distinguish IA hip pathology from extra-articular sources of pain.[171] Clinical predictors of a successful response include the presence of joint effusion[172] and lack of an atrophic radiologic pattern.[173] The radiographic severity of hip arthritis does not predict pain relief outcome for therapeutic IA hip injection.

Palpation Guided Anatomic Injection Technique

Multiple hip joint injection techniques are described in the literature, including palpation (anatomic landmarks) and image (fluoroscopy and ultrasound) guided techniques. Palpation guided injections include both anterior and lateral approaches. Intraarticular hip injections using anatomic landmarks are often inaccurate because of the joint's deep location.[174,175] Here, we will focus on descriptions of image guided techniques, which are associated with improved injection accuracy.[176–178]

Fluoroscopy Guided Intraarticular Hip Joint Injection Techniques

Anterior Approach

The patient is placed in the supine position on the fluoroscopy table. First, the femoral artery is identified with palpation along the inguinal crease.[179] With fluoroscopy under an anterior-posterior view, the lateral aspect of the femoral head/neck junction is identified.[149] A needle is then directed coaxially under fluoroscopic guidance to the lateral femoral head/neck junction while avoiding the previously marked femoral artery. After reaching the lateral aspect of the femoral head/neck junction, the needle is slightly withdrawn. Following negative aspiration, a radiographic contrast agent is injected to confirm the intracapsular needle placement. Corticosteroids, often with local anesthetics, are then injected (Table 67.2).

Lateral Approach

The patient is placed in the lateral decubitus position on the fluoroscopy table with the targeted hip in the non-dependent position. The skin entry point is identified immediately proximal to the greater trochanter. The center of the hip joint often corresponds to the midplane between the anterior and posterior aspects of the thigh.[180] In the anterior-posterior view, the needle is advanced to the lateral aspect of the femoral head/neck junction (Fig. 67.5). Care is taken to avoid an anterior or posterior needle trajectory to

• **Figure 67.5** Fluoroscopy guided lateral approach hip joint injection. An anteroposterior fluoroscopy guided view is used to position the needle for a lateral approach hip joint injection. The needle tip is positioned at the lateral femoral head/neck junction. Injection of radiographic contrast medium confirms accurate intracapsular needle placement. The *arrows* point to the needle. *Asterisk (*)* outlines the intracapsular radiographic contrast agent spread. (Please see text for a detailed description of patient positioning.)

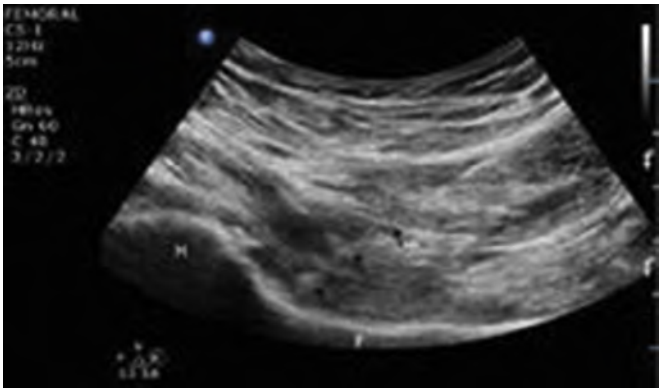
the femoral head/neck junction. On the fluoroscopy image, if the needle has passed the femoral head/neck junction without contacting bone, the needle must be repositioned to ensure intracapsular injection. Corticosteroids are then administered, often with local anesthetics (Table 67.2). Proposed advantages of the lateral approach include a skin entry distant from the femoral neurovascular bundle and visualization of the needle throughout placement.[179]

Ultrasound Guided Intra-articular Hip Injection Techniques

The patient is placed in the supine position on the procedure table. Typically, a low frequency curvilinear probe is employed to allow for adequate penetration and a larger field of view.[181] The femoral neurovascular bundle is identified in the short axis view. Then, the probe is moved laterally and oriented to align it parallel to the long axis of the femoral neck. In the anterior-oblique-sagittal (anterior-longitudinal) view, the femoral neck, femoral head, acetabular rim, and anterior synovial recess should be visualized.[178,181,182] The anterior synovial recess at the femoral head/neck junction is the target location. In this view, the femoral neurovascular bundle is located 20–30 mm medial to the desired needle trajectory.[182] Power or color Doppler is utilized to identify any overlying vascular structures such as the ascending branch of the lateral femoral circumflex artery.[183] The ultrasound view is adjusted to provide a needle trajectory that is clear of any vascular structures. A 22-gauge needle is advanced with an in-plane approach into the anterior synovial recess (Fig. 67.6). After confirming the needle position within the synovial recess, the medication is injected slowly while noting the expansion of the anterior hip capsule.

Efficacy of Intra-articular Hip Injections

Limited data exist that evaluate the efficacy of IA hip injections for osteoarthritis. Efficacy data for IA knee injections cannot be extrapolated to the IA hip injections because of differences in anatomical and functional characteristics. Three prospective randomized controlled studies suggest short-term efficacy for pain relief and functional outcome with visually guided (ultrasound or fluoroscopy) administration of corticosteroids.[172,184,185]



• **Figure 67.6** Ultrasound guided intraarticular hip injection. The *arrows* indicate the needle tip accurately placed within the synovial recess at the femoral head/neck junction. *F,* Femoral shaft; *H,* femoral head. (Please see text for a detailed description of patient and ultrasound probe positioning.)

Accuracy and Efficacy for Injection Technique Comparisons

Although multiple studies have recommended image guidance to improve accuracy, no studies have directly compared image guided versus palpation guided techniques.[173,174,176–178] Conventional palpation guided IA injections may result in inaccurate needle placement. The femoral neurovascular bundle is the primary anatomic structure at risk of injury.[174,186] Accuracy rates of 60%–80% for IA injectate placement have been documented with palpation guided techniques.[174–176,187]

Ultrasound guided IA hip injections have demonstrated accuracy rates of 97%–100%, which are comparable to the accuracy rates associated with CT or fluoroscopy guided injections.[178,187] Given the paucity of clinical outcome studies, no conclusive relationship can be established between improved accuracy rates and clinical and functional outcomes. Further evaluation is warranted regarding the safety and efficacy of IA hip injections, with direct comparison necessary between fluoroscopy and ultrasound guided techniques.

Knee

Anatomy

The knee joint is a synovial joint composed of three bones: the patella, femur, and tibia. The four major ligaments providing stability to the knee are the anterior cruciate, posterior cruciate, medial collateral, and lateral collateral.[188,189]

The medial and lateral menisci are fibrocartilaginous structures that provide stability, lubrication, and nutrition to the joint space. Meniscal tears occur three times more frequently in the medial meniscus. Knee flexion and extension are the main motion planes. The knee is divided into three major compartments: medial, lateral, and patellofemoral. Knee arthritis typically occurs in two or more compartments.[189,190]

The articular (sensory) branches innervating the anterior knee joint capsule are the targets of radiofrequency ablation lesions. A recent detailed cadaveric study described the highly variant anatomy of the genicular nerve branches that are targeted by needle placement under fluoroscopic guidance at key bony anatomic landmarks.[191] The superolateral quadrant is innervated by the nerve to the vastus lateralis, nerve to the vastus intermedius, the superior lateral genicular, and common fibular nerves. The inferolateral quadrant is innervated by the inferior lateral genicular and recurrent fibular nerves. The superomedial quadrant is innervated by the nerve to the vastus medialis, nerve to the vastus intermedius, and superior medial genicular nerve. The inferomedial quadrant is innervated by the infrapatellar branch of the saphenous nerve. The inferolateral quadrant is not a lesion target because of the location of the common peroneal nerve and one of its divisions (i.e. recurrent fibular nerve), the coagulation of which result in motor nerve injury.

Indications and Musculoskeletal Pathology

IA knee injections with either corticosteroids or viscosupplements are part of the non-operative management of knee osteoarthritis. In 1997 viscosupplementation was approved in the United States to treat knee osteoarthritis. For knee osteoarthritis, patients with evidence of severe damage or degeneration on x-ray or MRI may be less likely to respond to IA injection with corticosteroid than

those with mild structural damage.[192] Other factors negatively associated with the likelihood of improvement in pain and function to IA knee injection include more restricted range of motion, local knee tenderness, and older age.[193,194–197]

Injection Techniques

Palpation Guided Anatomic Knee Injection Techniques

Commonly utilized knee portals for IA injections include superior anteromedial, superior anterolateral, inferior anteromedial, inferior anterolateral, and lateral and medial midpatellar approaches. Multiple studies have examined different injection techniques in specific populations. In individuals without knee effusions, confirmation of appropriate needle placement can be difficult when using a palpation guided technique. Jackson et al.[198] demonstrated that the lateral midpatellar approach resulted in a higher accuracy rate (93%) in comparison with both the anteromedial (75% accuracy) and anterolateral (71% accuracy) approaches. The anteromedial and anterolateral injections were performed inferior to the patella, with the affected leg over the side of the examination table and the knee flexed to approximately 90°.

A cadaveric study compared four different IA injection sites (anteromedial, anterolateral, lateral midpatellar, and medial midpatellar).[199] The midpatellar approaches were performed with the knee extended on an examination table. The anteromedial and anterolateral injections were performed inferior to the patella with the leg over the side of the examination table and the knee flexed to approximately 90°. The accuracy rate was highest for the anterolateral approach (85%) and lowest for the medial midpatellar approach (56%).

Wind and Smolinski[200] examined injection portals superior to the patella (superolateral and superomedial) for low-volume (2–3 mL) injections, consistent with viscosupplementation treatment. Injections were performed with the knee extended. In this study, the lateral joint line injection was unreliable and resulted in IA placement less than 50% of the time.

Fluoroscopy Guided Knee Injection Techniques

Techniques have been described for fluoroscopic needle advancement, and fluoroscopic confirmation of appropriate injectate location following palpation guided IA injection.[149,201] The fluoroscopy guided injection technique can be performed above (Fig. 67.7), below, or at the level of the patella. When the injection is performed at the patellofemoral joint with either a medial or lateral approach, the patella is manually displaced away from the needle, and the needle is advanced into the joint.[149] In individuals with severe patellofemoral joint arthritis, access into the joint may be difficult with this technique.

Anterior approaches have also been described.[202,203] Moser et al.[203] assessed the infrapatellar anterolateral and anterior paramedian needle insertion approaches for technical success and patient tolerance levels during knee arthrography. For the anterior paramedian approach, the knee is flexed to 60°, and the needle is introduced just lateral to the inferior patellar ligament and directed cephalad and medial toward the femoral notch. For the anterolateral approach, the knee is flexed to 90°, and the joint space is located. The needle is placed at the joint line and directed posteriorly and slightly medial toward the lateral femoral articular condyle.

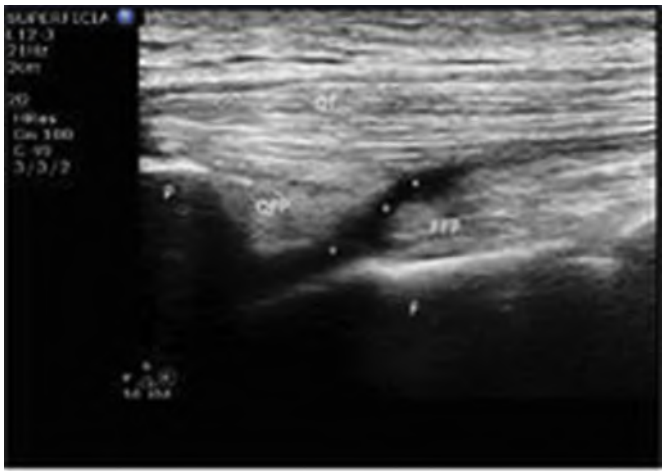
For the fluoroscopy guided techniques, radiographic contrast agent may be injected to confirm appropriate needle placement. If radiographic contrast cannot be utilized, IA placement has also been verified by mini-air arthrography.[201] For the superior patellar approach, mini-air arthrography can confirm IA placement when a sharply defined shadow of air is found in the suprapatellar pouch after 0.5–5 mL of air is injected.[201,204] Extra-articular placement is suggested when the air is found diffusely in the surrounding tissues. Although air arthrography has been suggested as a safe procedure, the Doppler function for ultrasound or a negative aspiration for fluoroscopy guided injections should be utilized prior to injecting air to prevent an intravascular injection and the possible development of an air embolism.

• **Figure 67.7** Fluoroscopy guided lateral approach for suprapatellar intraarticular knee injection. Accurate needle tip placement in the suprapatellar synovial recess is confirmed by appropriate localization of injected radiographic contrast medium. (Please see text for a detailed description of patient positioning.)

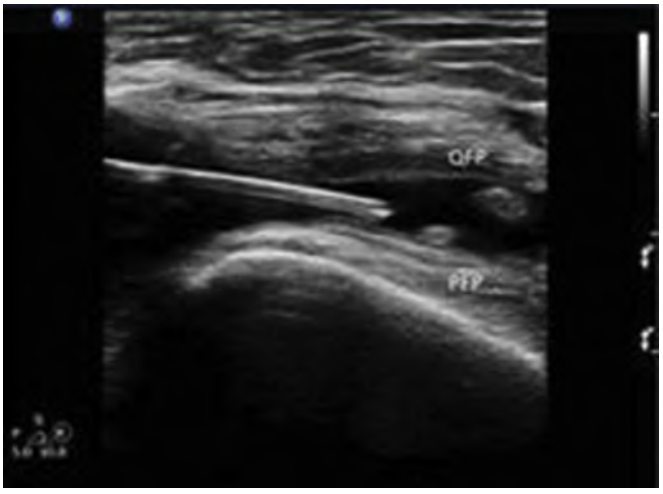
Ultrasound Guided Injection Techniques

Ultrasound guided approaches include the midpatellar lateral,[204] the midpatellar medial,[205] and the suprapatellar synovial recess[206] approaches. With both the medial and lateral midpatellar approaches, the patella prevents direct visualization of the needle and injectate in the IA space. Therefore the preferred technique is the suprapatellar synovial recess approach. This approach also minimizes the risk to soft tissue structures and the articular cartilage.[206] One disadvantage of this approach is that the suprapatellar synovial recess can be difficult to visualize in individuals without knee effusions.

For the suprapatellar approach, the patient is in the sitting or supine position with the knee flexed approximately 20–30°.[207] The knee should be supported with a pillow or rolled towel to allow relaxation of the quadriceps tendon. A high frequency linear-array probe is utilized. First, the knee is scanned with the transducer parallel to the longitudinal axis of the quadriceps tendon (Fig. 67.8). Then the skin and subcutaneous tissues, quadriceps tendon, patella, quadriceps fat pad, prefemoral fat pad, femur, and suprapatellar synovial recess are identified. The suprapatellar synovial recess is located between the prefemoral and quadriceps fat pads, and it communicates directly



• **Figure 67.8** Long axis view of the suprapatellar synovial recess. *P* indicates patella; *F,* femur; *PFP*, prefemoral fat pad; *QFP*, quadriceps fat pad; *QT,* quadriceps tendon. *Asterisk (*)* indicates the outline of the suprapatellar synovial recess communicating with the intra-articular joint space. (Please see text for a detailed description of patient and ultrasound probe positioning.)



• **Figure 67.9** Short axis (transverse) view of the suprapatellar synovial recess. The needle was accurately placed in the suprapatellar synovial recess between the prefemoral fat pad *(PFP)* and quadriceps fat pad *(QFP)*. (Please see text for a detailed description of patient and ultrasound probe positioning.)

with the knee joint. Transducer pressure must be minimized to prevent compression of the synovial recess. In some individuals, a significant effusion will be visualized in the synovial recess. Next, the transducer is rotated 90° to the axial (transverse) plane for the short axis view (Fig. 67.9), and the same structures are identified. The needle is advanced in the short axis view with an in-plane technique from lateral to medial into the suprapatellar synovial recess. Synovial fluid should be aspirated if there is a significant effusion. Then the injectate is placed into the joint under direct ultrasound visualization. The Doppler function can also be utilized to enhance the visualization of the injected fluid.

The suprapatellar synovial recess injection may also be performed with the ultrasound transducer along the longitudinal axis.[206] With this technique, the superior margin of the patella is the inferior landmark of the suprapatellar synovial recess. The transducer is moved laterally to avoid insertion into the quadriceps tendon. The cephalad end of the transducer is positioned more laterally than the caudal end. The needle is advanced in-plane in the long axis. This approach may be advantageous when it is difficult to view the suprapatellar synovial recess in the short axis (transverse) plane.

In a direct comparison of visually guided techniques to palpation guided techniques for knee IA injections, numerous studies have demonstrated greater accuracy with image guided methods.[110,205–208] For the suprapatellar approach, ultrasound guided IA injection resulted in greater accuracy rates (96%–100%) than palpation guided injections (55%–84% accuracy).[206,207] For the medial patellar portal, injection accuracy increased from 77% for blind injections to 96% for ultrasound guided injections.[205] Improvement in accuracy from ultrasound needle guidance positively and significantly influences clinical outcomes and cost effectiveness.[110,208] Improvement in outcomes using ultrasound guidance for arthrocentesis of the effusive knee included a 48% reduction in procedural pain and a 183% increase in aspirated synovial fluid volumes.[209] Short-term pain outcomes were also improved at two weeks post-injection. Although fluoroscopic guidance assists with needle placement, data have not yet been presented that demonstrates improvements in clinical or functional outcomes.

Efficacy and Safety of Intra-articular Knee Injections

A systematic review of 28 trials included comparisons of corticosteroids to placebo, viscosupplementation (hyaluronan and hylan derivatives), and joint lavage.[210] Injected corticosteroids were found to be superior to placebo in terms of pain relief at one week with a number-needed-to-treat of three. Increased pain reduction by injection versus placebo lasted up to three weeks. From four to 24 weeks, there was a lack of evidence to support prolonged therapeutic efficacy. Functional outcomes were difficult to evaluate, secondary to a lack of data. Corticosteroid injection and viscosupplementation benefits were similar between one and four weeks post-injection. From weeks five to 13, viscosupplementation was assessed as superior, with improvements maintained in functional and pain outcomes.

A systematic review of viscosupplementation for the treatment of osteoarthritis evaluated 76 trials.[102] Compared to a placebo, viscosupplementation was found to be superior. From five to 13 weeks post-injection, viscosupplementation improved pain relief from baseline by 28%–54% and enhanced function by 9%–32%. Although slower in onset, viscosupplementation appears to have a more prolonged therapeutic effect than IA corticosteroids.[211] Comparisons between different formulations of viscosupplementation could not be made secondary to differences in study designs and outcome measures.[102,194,212]

Radiofrequency Ablation

Conventional and internally cooled radiofrequency ablation (RFA) techniques induce a controlled, thermal coagulative necrosis at a specific lesion site using defined selected parameters, including tip size and time and temperature settings. These techniques are best described for the knee joint among large peripheral joints but are also employed for the hip and shoulder. RFA techniques have emerged as safe, effective, and economical alternatives to IA corticosteroid injections for painful osteoarthritis of the knee and are a viable option prior to joint replacement surgery in patients who are not surgical candidates.

Radiofrequency Ablation of the Knee Joint

Radiofrequency ablation of the genicular nerve involves thermal coagulation at three to four target areas, including the lateral superior, medial superior, and medial inferior genicular nerve branches and the middle branch from the vastus intermedius. Both fluoroscopy and ultrasound can be used to identify relevant landmarks needed to target these areas.[191,194,213] Prior to performing RFA, diagnostic blocks are often used to help identify patients that may improve with treatment. Although research is mixed regarding the prognostic capabilities of diagnostic genicular nerve blocks, further research is needed to determine the role of these injections. A recent prospective RCT evaluating the utility of genicular nerve blocks to predict the outcomes of genicular nerve RFA comparing the use of diagnostic blocks with a selection threshold of ≥50% pain relief to a no block group did not demonstrate increased treatment success using diagnostics blocks.[214] A recent multicenter RCT comparing the efficacy of internally cooled electrode radiofrequency ablation to IAS for knee pain because of OA found more favorable outcomes in terms of pain reduction, improved physical function, and reduction in nonopioid medication use in the RFA group.[196] In addition to possibly longer lasting therapeutic effect than IAS and sparing of steroid administration, RFA has the advantage of remaining a viable treatment option after joint replacement surgery, although robust evidence to support its use in the post-surgical population is lacking. A recent systematic review and meta-analysis of RFA of the genicular nerves for nonsurgical treatment of knee pain favored RFA treatment in all seven included RCTs, with no studies reporting serious adverse events related to the procedure.[215] RFA was shown to be superior to sham treatment, IA corticosteroid, and viscosupplementation among five high-quality RCTs and two moderate quality RCTs.

Although only three to four nerves are targeted in the traditional RFA technique, anatomic dissections demonstrate that over 10 nerves or branches provide innervation to the knee joint.[191] Future anatomic and clinical studies are needed to guide physicians in determining which nerves require lesioning for optimal clinical outcomes.

Fluoroscopy Guided Technique

The thermal radiofrequency ablation technique is the most common approach utilized. Three to four sites are the targets of the anesthetic blocks and cooled radiofrequency ablation lesions.[216] From an anterior-posterior (AP) view of the knee, these include periosteum at the junction of the shaft of the femur with the medial and lateral epicondyles (superomedial and superolateral genicular nerve branches) and the junction of the shaft of the tibia with the medial epicondyle (inferomedial genicular nerve branch), with the option of a fourth lesion target approximately 3 cm above the patella targeting the nerve from the vastus intermedius. The inferolateral genicular nerve branch is not targeted in order to avoid damage to the common peroneal nerve. The needles or introducer are advanced along the periosteum to 40%–60% the depth of the femur or the tibia in a lateral view for the genicular nerve branches, and the suprapatellar location is advanced to the periosteum, either through quadriceps tendon or using a lateral approach to pass underneath tendon and along periosteum. It is important to perform motor stimulation testing prior to proceeding with RFA for the ablation technique, stimulating each nerve branch at 2 Hz up to 2 volts and confirming no motor response. Each ablation site is then anesthetized for an appropriate period, and then ablation is performed.

Ultrasound Guided Technique

Genicular nerve block and RFA can be performed using ultrasound guidance, although this guidance modality is not demonstrated to be superior to fluoroscopic guidance in terms of safety or efficacy.[217] One advantage of using ultrasound guidance is the ability to directly visualize vascular structures in the vicinity of targeted nerves, avoiding the need to rely exclusively on periosteal landmarks for approximate locations of the nerves. The efficiency of the ultrasound guided technique is highly operator dependent.

Safety and Effectiveness of Radiofrequency Ablation of the Knee Joint

Genicular nerve RFA has been found to be generally safe and efficacious for at least three months.[212] However, case reports exist demonstrating injuries to vascular structures that can lead to the creation of abnormal vascular structures, hemarthrosis, and osteonecrosis.[194] Thirty-three studies including 13 RCTs examining the effectiveness and safety of RFA found that knee ablation techniques improved pain and function in subjects with knee pain because of osteoarthritis through follow up ranging from three to 12 months.[218] Thirteen of the studies examined pulsed radiofrequency using various parameters with respect to voltage (40–50 V), frequency (2–5 Hz), temperature (38.9°C–42°C), pulse width (5–20 ms) and duration (4–15 minutes). Five studies examined RFA with internally cooled electrodes, and 16 studies investigated conventional RFA using varied parameters in terms of temperature (60°C–80°C) and duration (60–120 seconds). Twenty-nine of the 33 studies reported adverse events (AEs), with nine of those studies reporting minor AEs including knee swelling, temporary periosteal pain during the procedure with cannula placement, hemarthrosis, subcutaneous bleeding at the needle insertion site, and hypoesthesia. There were no serious procedure related AEs reported, including infection, hemorrhage, motor damage, or thermal injury.

Although rare, the most concerning theoretical adverse effects of RFA of the knee joint include vascular injury, motor injury, and thermal injury to the skin. Arteries lying in close proximity to genicular nerve targets are at risk for injury from radiofrequency ablation of the genicular nerves, and although vascular injuries as a consequence of RFA are rare,[219] they are well described in the surgical literature.[194] Particular attention should be paid to the inferomedial genicular nerve branch target site, which involves a thinner dermal layer in many patients, and with which thermal injury to the skin has been reported using the conventional RFA technique.[220]

Genicular nerve RFA or RFA of the knee joint is an attractive alternative to traditional knee IA injection for several reasons, including sparing patients corticosteroid exposure and potentially longer lasting benefit following treatment. An RCT comparing cooled RFA to IA corticosteroid injection of the knee found superior results at six months in terms of 1) numeric rating scale (responders 50% or greater, 74.1%–16.2%, $P < 0.0001$), 2) improvements in the mean Oxford Knee Score (35.7 ± 8.8 to 22.4 ± 8.5, $P < 0.0001$), and 3) Global Perceived Effect (91.4%–23.9%, $P < 0.0001$).[196] There were no procedure related AEs. When selecting patients, an 80% or greater response to diagnostic anesthetic nerve blocks and duration of pain less than five years is associated with higher treatment success.[221] Radiofrequency ablation is also demonstrated to be a highly cost effective treatment for knee pain because of osteoarthritis.[222]

Radiofrequency Ablation of the Hip Joint

Although not as well described as RFA techniques targeting the genicular nerves, RFA may also be employed to relieve chronic hip pain because of osteoarthritis. The anterior hip capsule is the target

of RFA techniques of the hip joint, including a branch from the femoral nerve, the obturator nerve, and the accessory obturator nerve.[223]

Fluoroscopy Guided Technique

The patient is placed in a prone position and using either palpation or ultrasound guidance, the femoral artery is carefully marked with an indelible ink marker, taking care to be well lateral of this structure on needle entry. Moving from an AP pelvis view directly laterally, the femoroacetabular joint is visualized classically with the incisura in view. The articular branch of the femoral nerve is targeted at the 12 o'clock position on the superior acetabulum, with either the diagnostic nerve block needle or introducer needle against the periosteum at the lesion target site. For the articular branch of the obturator nerve, the needle is advanced typically from a position over the inferior ischium to advance the needle sagittal and deep to neurovascular structures to the bony ischium just lateral to the incisura. For the accessory branch of the obturator nerve, a second lesion is performed by advancing the needle approximately 1 cm cephalad. Care must be taken to advance along the periosteum without causing excessive pain, particularly as the introducer is advanced. Up to 1 cc of anesthetic is then injected for the diagnostic block. Motor stimulation is conducted prior to RFA lesioning.

Safety and Effectiveness of Radiofrequency Ablation of the Hip Joint

There is a far less robust body of literature including anatomic studies to guide clinicians in considering this option for chronic hip pain. However, a systematic review summarizing 14 studies investigating RFA procedures of the hip joint found a high success rate following treatment up to 36 months following the procedure. However, none of the studies were RCTs.[224] Similarly, there is little data to guide estimates of rates of AEs but reported AEs following hip RFA include hypoesthesia and hematoma, particularly at the target for the accessory obturator nerve, illustrating the importance of using caution and carefully identifying the femoral artery prior to needle entry.

Radiofrequency Ablation of the Shoulder Joint

RFA of the glenohumeral joint is a newer procedure relative to those targeting the knee and hip and the least well described in terms of safety and efficacy. Patient selection involves patients with intractable pain of the shoulder joint, acromioclavicular joint, rotator cuff, or adhesive capsulitis who are not candidates for surgery or who wish to employ conservative management for as long as possible. Nerve targets include the articular branches of the suprascapular nerve and axillary nerve posteriorly and the lateral pectoral nerve anteriorly.[225]

Fluoroscopy Guided Technique

The patient is placed in the prone position, and the arm is gently internally or externally rotated to optimally expose the greater tuberosity of the humeral head. For the articular branches of the suprascapular nerve, the C-arm is obliqued ipsilaterally, approximately 30–45° with a 15 degree caudal tilt. The articular branches of the suprascapular nerve targets lie on the posterior osseous rim of the glenoid fossa lateral to the spinoglenoid notch and inferior to the spine of the scapula. For the articular branches of the axillary nerve, the same fluoroscopic view was utilized. The posterior lateral humeral head and greater tubercle are located. The radiofrequency cannula is directed under fluoroscopic guidance to the posterior and inferior aspects of the greater tubercle just above the metaphyseal-diaphyseal junction. For the articular branches of the lateral pectoral nerve, the patient is repositioned to the supine position. For the lateral pectoral nerve, the C-arm is obliqued ipsilaterally, approximately 15° with a cranial tilt. The target is the center of the coracoid process.

Safety and Effectiveness of Radiofrequency Ablation of the Shoulder

There is a paucity of literature establishing knowledge with respect to the effectiveness and safety of the RFA technique for pain related to the shoulder joint, AC joint, and rotator cuff. A recent systematic review including 18 studies (six of which were RCTs) investigated the use of RFA for the management of chronic shoulder pain. Sixteen studies investigated pulsed RFA and two conventional RFA.[226] The study methodologies were so varied, including employing RFA techniques in combination with other treatments such as physical therapy or corticosteroid injection, and the RFA techniques themselves varied in terms of lesion parameters such that no definitive conclusions could be drawn regarding the efficacy of these techniques for the shoulder. Nevertheless, all studies reported positive results with RFA with few side effects, including several patients reporting transient tingling at the needle puncture site resolving within 1 hour and a single patient developing hematoma at the puncture site. The surgical literature describes thermal injuries to the skin occurring during arthroscopic acromioplasty,[227] and thermal injury should always be considered a risk with any percutaneous RFA procedure. Pulsed RFA targeting the axillary nerve[228] and suprascapular nerve[229,230] individually for shoulder pain syndromes is fairly well described, with poor quality of evidence supporting long-term efficacy but very reassuring safety profiles.

Conclusion

Joint injections are an important part of non-operative multimodal treatment for painful musculoskeletal conditions. Ultrasound and fluoroscopy guided IA injections assist in improving the accuracy of needle placement. Ultrasound is particularly helpful for interventional musculoskeletal procedures, offering advantages for specific procedures because of its ability to visualize periarticular soft tissues and provide real-time needle tracking without using ionizing radiation. The improvement in the accuracy of needle placement with ultrasound guidance for some joints is associated with significant clinical outcome benefits compared with palpation guided techniques. Future comparative studies are needed to develop guidelines for selecting the most appropriate IA corticosteroid and viscosupplementation agents and selecting the best methods to deliver these agents. Particular attention must be paid to the efficacy and adverse effects associated with the treatment of each joint and underlying musculoskeletal condition. Furthermore, optimal protocols for the timing of injection, post-procedure activity, and specific dosing regimens need to be defined. For some joint injections, larger scale studies are needed to directly compare the safety and efficacy of ultrasound guided IA techniques with traditional landmark-based and fluoroscopy guided techniques. As image guidance becomes more widely available and commonly utilized, palpation guided techniques for IA injections are used less and less.

Radiofrequency ablation is a newer therapy that is a safe and effective alternative to IA corticosteroid injections targeting knee, hip, and shoulder pain because of osteoarthritis. To date, the most comprehensive research exists for the knee joint. Additional research is needed to support the long term efficacy and safety of RFA for shoulder and hip pain.

Safe and effective performance of the procedures described in this chapter are critical to the development of an interventional practice, offering percutaneous therapies for the treatment of chronic peripheral joint pain because of osteoarthritis, including detailed knowledge of the relevant anatomy and potential risks to the patient from any procedure.

Key Points

- Musculoskeletal diseases, including symptomatic arthritis and soft tissue conditions, are associated with high levels of disability and significant economic costs. Osteoarthritis is the most prevalent form of arthritis.
- When joint injections are used, they should be incorporated into a multimodal treatment plan.
- Agents utilized for joint injections include corticosteroids, local anesthetics, and viscosupplements.
- Multiple corticosteroid and viscosupplementation formulations exist with differing pharmacologic properties.
- Viscosupplementation may have a more prolonged analgesic effect than IA corticosteroids but is no longer supported by the ACR guidelines for pain in joint arthritis.
- It is important to understand the adverse effects and complications associated with each injectate class. Appropriate management strategies should be employed when these events occur.
- Joint injections may be performed either with palpation, ultrasound guidance, or fluoroscopic guidance.
- Image guided techniques (ultrasound and fluoroscopy) have been shown to improve the accuracy of needle placement.
- Ultrasound offers advantages for specific procedures because it can visualize periarticular soft tissues and provide real-time needle tracking without ionizing radiation.
- Appropriate IA placement with ultrasound has been shown to positively influence clinical and economic outcomes.
- Radiofrequency ablation has emerged as a safe and effective alternative to corticosteroid injections for the management of chronic peripheral joint pain.
- RFA of the knee has the most robust evidence supporting its safety and effectiveness and may be considered in patients with or without prior knee surgery.
- RFA of the hip should involve a careful assessment of neurovascular structures, including consideration of using ultrasound guidance to identify the femoral artery.
- RFA of the shoulder is a newer technique with still evolving evidence regarding its safety and effectiveness.

Myofascial Injections and Fascial Plane Blocks for Perioperative and Chronic Pain Management

ARIANA M. NELSON, CARLOS E. GUERRERO, ANDREA L. CHADWICK

Overview and Pathophysiology of Myofascial Pain Syndromes

Myofascial pain is a common source of pain in the neck, low back, and other areas of the body. The term "myofascial pain" encompasses many different painful conditions, including muscle strain, myofascial trigger points (TrPs). It also includes specific myofascial pain syndromes, including piriformis syndrome, iliopsoas-related pain, and pain related to compression of the brachial plexus by the scalene muscles (neurogenic thoracic outlet syndrome). Skeletal muscle consists of muscle fibers under somatic nervous control. Each nerve root innervates a muscle or group of muscles known as a myotome. The muscle belly of skeletal muscles is connected by tendons to the bone. TrPs occur in the body of the muscle, most often located in the center of the muscle.

While much remains to be discovered about the pathophysiology of myofascial pain, several theories have been advanced in recent years. Underlying biomechanical and postural factors may interact with neurologic factors, psychological elements including depression and anxiety, and hormonal and nutritional imbalances. These factors (in total or in part) may create peripheral sensitization, autonomic dysregulation, and ultimately, central spinal cord sensitization, which can amplify the symptoms experienced by patients with myofascial pain. Vasoactive mediators, pro-nociceptive neurotransmitters, and inflammatory mediators including bradykinin, norepinephrine, serotonin, calcitonin gene-related peptide, substance P, tumor necrosis factor-α, and interleukin 1-B have been identified in the hypersensitive loci of TrPs.[1–3] These substances are pro-nociceptive and sensitize peripheral nociceptors. They are responsible for the sensory experience of myofascial pain, including referred pain and the local twitch response.

The motor phenomena seen in myofascial pain have been hypothesized to be caused by excessive acetylcholine (ACh) leakage, which creates dysfunctional endplates responsible for taut muscle band formation. Excessive ACh release leads to sustained muscle contraction by increased depolarization of the postjunctional endplate. Evidence of maximal sarcomere shortening in TrPs has been found in animal and human subjects.[4] A positive feedback cycle may be created by the interaction of increased ACh release, sarcomere shortening, and the release of sensitizing substances. The hypothalamus-pituitary-adrenocortical and sympathetic-adrenal-medullary system responses to experimentally induced stress in patients with myofascial pain revealed that plasma concentrations of cortisol, epinephrine, and norepinephrine were found to be significantly elevated in myofascial pain patients than in healthy controls.[5]

The taut muscle band present in myofascial pain syndrome has a higher resting tension and contains hypercontracted muscle fibers. Chronicity of this hypercontraction can increase local energy consumption and may cause areas of tissue hypoperfusion and ischemia. Vasoactive mediators are released in the setting of muscle ischemia, leading to increased ACh release, exacerbation of local ischemia, and sensitization of peripheral nociceptors, thereby causing pain. Vasoactive mediators such as those released in the taut bands of MP have been known to sensitize peripheral nociceptive nerve fibers such as those found in skeletal muscle. Nociceptors spontaneously discharge with a lower threshold to painful stimulation and exhibit discharge to non-painful stimuli in a sensitized state.[6] Over time, this heightened abnormal peripheral sensory input creates a state of central neuronal sensitization.[7]

The clinical manifestation of abnormal electrical activity in the TrP is called a local twitch response (LTR) and is believed to be mediated by a segmental spinal reflex.[8] LTR is elicited by deep palpation or needling of the TrP and leads to a brisk muscle contraction in the taut band. The location of the LTR is called the "sensory locus," which has been correlated histologically with sensory nerve receptors.[9] The "active locus" is the site where spontaneous electrical activity is recorded, the waveforms of which correspond to published reports of motor endplate noise. According to this model, the sensory locus and the active locus act as the nociceptor and the motor endplate and are distributed throughout muscle. Where these align and are highly concentrated, we observe myofascial TrPs. Abnormal spontaneous electrical activity is present at the site of TrPs, with excessive ACh release creating endplate noise seen on electrophysiologic studies at the neuromuscular junction.[10] Spontaneous electrical activity occurs in TrPs more frequently than in normal tissue and displays aberrant patterns in TrPs. Therefore this spontaneous electrical activity is distinct from normal endplate potentials. This abnormal electrical activity detected in TrPs is thought to be directly connected to excessive ACh release.

Clinical Presentation and Diagnosis of Myofascial Pain Syndromes

A careful history and physical exam remain the keystone of diagnosis. The most common presentation of myofascial pain syndrome includes the following diagnostic criteria: regional body pain and stiffness, limited range of motion of the affected muscle, twitch response produced from a taut band, referred pain from a TrP to a zone of reference, and resolution of the symptoms with local anesthesia applied to the TrP.[11] As discussed previously, TrPs are localized painful areas of skeletal muscle containing taut bands that can be exquisitely sensitive to digital pressure. TrPs may be active or latent. Active TrPs are present in patients with painful regional conditions. Latent TrPs are asymptomatic but may be revealed by deep palpation on physical examination. Latent TrPs have been found in the shoulder girdle muscles of 45%–55% of healthy young adults.[12] myofascial pain may occur after an injury, with chronic strain from repetitive microtrauma, or without any clear precipitating event. Aberrant body mechanics or postural abnormality may initiate or further maintain the problem. The quality of pain tends to be a deep "aching" of variable intensity, and the pain is confined to a specific anatomic region. Characteristic referred pain patterns are associated with specific muscles, although these referral patterns are often unreliable.[13] The muscles commonly involved are the trapezius, splenii, cervical and lumbar paraspinal, and quadratus lumborum.

It is essential to have hands on formal training in the physical examination of myofascial pain and TrPs to achieve a reliable result.[14] Musculoskeletal examination should be performed with the objective of identifying potential orthopedic or neurologic dysfunction that could have a role in generating secondary myofascial pain and dysfunction. Although there are no universally accepted diagnostic criteria for myofascial pain, physical findings may help establish a diagnosis. A distinct pattern of TrP findings may reveal itself in myofascial pain syndrome after a given insult.[15] These painful TrPs limit the full range of passive motion in the afflicted muscle group. While these findings have been suggested as diagnostic criteria,[16–18] investigators have found it problematic to demonstrate consistent agreement in the presence or absence of TrPs among examiners in blinded studies with control groups.[19–21] Discrepancies in diagnosis may be attributed in part to a lack of a standardized examination technique and variability in the interpretation of examination findings. Variations in muscle anatomy, physical conditioning, and deconditioning can pose obstacles to proper diagnosis as well. The most reproducible diagnostic findings on physical examination include identification of a TrP in an affected muscle, referral of pain to a zone of reference, and reproduction of the patient's regular pain on physical exam.

Differential diagnosis of myofascial pain should include (1) musculoskeletal and neuropathic disorders such as arthritis, degenerative disk disease, radiculopathy, bursitis, and tendonitis; (2) autoimmune or infectious etiologies; (3) metabolic and endocrine dysfunction including hypothyroidism; (4) psychiatric disorders including depression and anxiety; and (5) fibromyalgia or diffuse amplified musculoskeletal pain.

Imaging studies have only recently demonstrated anatomic changes associated with trigger points. Ultrasound examination combined with Doppler blood flow has been reported to allow visualization of trigger points, and ultrasound imaging can help direct muscle injection techniques (see later). Recently developed techniques using magnetic resonance and ultrasound elastography purport to reveal changes in intramuscular signal consistent with trigger points, but this technology has not yet been validated.[22,23]

Treatment of Trigger Points

Treatment of trigger points commonly includes physical therapy (manual release techniques, stretching and strengthening, conditioning, therapeutic modalities), trigger point injections (TPIs), dry needling and acupuncture, and transcutaneous electrical nerve stimulation.[24] A broad range of treatment modalities have been reported, but weak research methodology continues to limit interpretation of the results. Regarding medications, tizanidine, but not cyclobenzaprine, was noted to be efficacious for acute skeletal muscle spasms.[24] Diazepam, amitriptyline, and lidocaine patch were found to be effective, but literature support for the use of anti-convulsants in treating myofascial pain syndrome is limited. Although clonazepam appears to be effective, its use is limited by the side effects of depression, liver dysfunction, and difficulty weaning the patient from this drug. Nonsteroidal anti-inflammatory drugs (NSAIDs), specifically ibuprofen, appear to be effective when given with other agents, but not as monotherapy.[24]

TPI is a widely used invasive therapy wherein a needle is guided directly into a TrP that has been previously identified on physical examination. TPI is best utilized in a series of injections and as part of a comprehensive treatment plan that includes guided, structured physical therapy. This strategy can be particularly beneficial when TPI is initially employed to reduce pain in patients otherwise intolerant of physical therapy or stretching, allowing the physical modalities to be more effective.[25] The following conditions are contraindications to TPI: (1) infection, systemic or localized; (2) coagulopathy; (3) distorted or complicated anatomy; and (4) patient refusal.

Saline, corticosteroids, various local anesthetics including lidocaine and bupivacaine, botulinum toxin serotype A (BoNT-A), and dry needling have all been used and studied. Stimulation of the LTR in direct needling of the TrP is valuable in achieving immediate effect.[26] There is good evidence to suggest that there is no advantage of one injection therapy over another or of any drug injectate over dry needling.[27] In a systemic review of 23 RCTs, Cummings and White concluded that any effect derived from TPI is likely derived from the needle itself rather than any specific substance injected, as there was no difference in the therapeutic benefit of "wet" needling versus "dry" needling.[27] Their review also suggested that pain reduction with saline TPI is equal to pain reduction with local anesthetic TPI, both significant. Although adding corticosteroid preparation to local anesthetic is common, it has not been reliably shown to reduce pain more than TPI with local anesthetic alone. Despite the widespread practice of TPI for MP, there is no consensus regarding the number of injection points, frequency of administration, and volume or type of injectate. Controlled studies are needed to evaluate the comparative efficacy of TPIs and their potential benefits in long term pain reduction if any.

Botulinum toxin serotype A (BoNT-A) produces sustained and prolonged relaxation of muscles by inhibiting the release of ACh at the motor endplate and is itself an analgesic inhibiting central sensitization.[28] Commercially prepared BoNT-A is expensive and should be employed with care by a well-trained physician. Although this therapy is promising, the results of RCTs have been mixed, and multiple systematic reviews have concluded that the current clinical evidence to support the use of BoNT in the treatment of MPS is inconclusive. Ferrante et al. found no statistically significant improvement compared to placebo with BoNT-A injection when injected directly into painful TrPs for cervicothoracic MP.[29] They concluded that although it is intuitive for the clinician to consider therapeutic injection of BoNT-A as a treatment for MP

(given its *a priori* similarity to TPI), peculiarities inherent to the use of toxin instead of dry needling or local anesthetic must be accounted for (i.e. toxin spread through fascial planes), including the effects of dosing of toxin, volume of injectate, muscles chosen to inject, postural relations and abnormalities, and injection technique. Harden et al. were able to identify a short term (12-week) reduction in MP of chronic tension-type headache with BoNT-A injection compared to placebo.[30] Graboski et al. found no significant difference in BoNT-A versus 0.5% bupivacaine injected into TPs of patients with MPS, though both were effective in reducing pain below the baseline level.[31] Venancio et al. studied 45 MP patients assigned randomly to one of three groups: dry needling, 0.25% lidocaine TPI, and BoNT-A TPI, and assessed over a 12-week period.[32] While all three groups showed favorable response to treatment, the BoNT-A group demonstrated less use of rescue medication and less post-injection local sensitivity.[32] In another study, Nicol et al. reported that BoNT-A injected directly into painful muscle groups using a "follow the pain" and pattern injection technique instead of trigger points led to reduced average numerical pain scores, reduced number of headaches per week, and improvement in general activity and sleep quality of life measures.[33] Similar positive findings were seen in the studies by Benecke et al.[34] and Miller et al.,[35] wherein patients with cervical myofascial pain received BoNT-A using a fixed-location injection technique.

Trigger Point Injection Technique and Follow Up

After informed consent, the muscle is palpated, and the trigger points are identified and marked. The area is prepared in a sterile fashion, and a 25- to 27-gauge, 1.5 inch needle is inserted into the trigger point. A local twitch may be elicited at this time, or the patient verbally identifies the painful area. After negative aspiration, 0.25% bupivacaine, 0.2% ropivacaine, or 1% lidocaine is injected with or without steroid, either dexamethasone (4 mg in a 30 mL bottle of local anesthetic) or a low dose of particulate steroid (e.g. 20–40 mg of methylprednisolone or triamcinolone diluted in the local anesthetic solution).

Possible complications include bleeding, hematoma, nerve block, and infection. The patient should be monitored closely for bleeding, development of neurologic symptoms (numbness or weakness, urinary or bowel incontinence), or signs of infection. Depending on the location of the injection, the patient should be instructed on the signs and symptoms of pneumothorax (from neck, shoulder, thoracic, and anterior chest wall injections) or local nerve blockade (for example, inadvertent median nerve block with injection of the flexor carpi ulnaris).

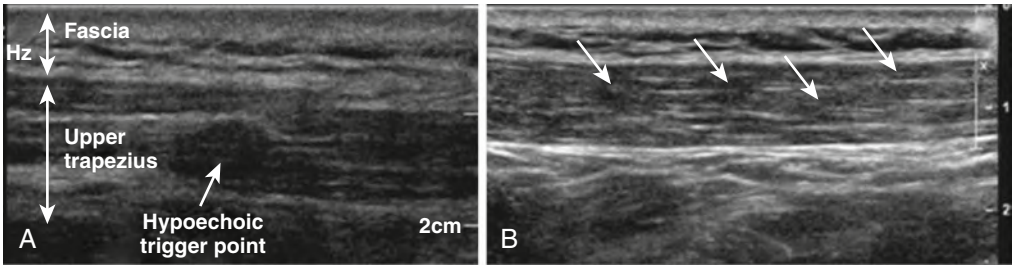
The success of the procedure is dependent on the diagnosis and localization of the trigger point. Patients with widespread chronic pain or psychological disorders are less likely to respond to TPI only. Patients with focal muscle pain and the characteristics of myofascial pain can achieve significant relief for days to months with a well-performed TPI. The success of TPI is often dependent on subsequent stretching and strengthening and neuromuscular education of the muscle.[1] The most effective treatment of myofascial pain syndrome is often a multi-disciplinary approach tailored to the individual needs of the patient that incorporates TPI with physical therapy and medication, as noted earlier. Practitioners are counseled to provide appropriate follow up after TPI and encourage patients to address other factors that perpetuate chronic pain (coping, employment, decreased social activity).[36,37]

Ultrasound Guided Trigger Point Injection Techniques

Ultrasound guidance provides several theoretical advantages over blind needle insertion. As stated, it allows visualization of the trigger point (Fig. 68.1). The practitioner is ensured that the needle is penetrating muscle tissue, which may be of use in patients with considerable adipose tissue, and can avoid local anatomic structures that are sensitive to needle penetration or local anesthetic infiltration (i.e. neurovascular structures or viscera).[38] Ultrasound imaging also allows visualization of the muscle twitch response with needle penetration, especially in muscles that are deep or small.[39] An additional use of the ultrasound is to confirm local anesthetic infiltration between fascial planes.[40] It also aids in blocking the spinal accessory nerve for diagnosis of trapezius muscle-related myofascial pain.[41]

Piriformis Injections

Piriformis syndrome is described in detail in Chapter 30 of this text but generally consists of pain in the buttock with or without radiation in the distribution of the ipsilateral sciatic nerve. It is considered the principal pain generator in approximately 8% of patients presenting with the buttock as the origin of pain. The syndrome can be a consequence of an abnormal relationship between the sciatic nerve and the piriformis muscle that results in irritation of the sciatic nerve. A hypertrophic muscle, infection, or invasion of the muscle by a tumor can cause pressure or irritation on the nerve.[42,43] In 78%–84% of the population, the sciatic nerve passes in front of the muscle. In 12%–21% of individuals, the divided nerve passes through or posterior to the piriformis and is exposed to muscle contractions, which trigger sciatic symptoms.[42] Piriformis syndrome is a diagnosis of exclusion since there are no

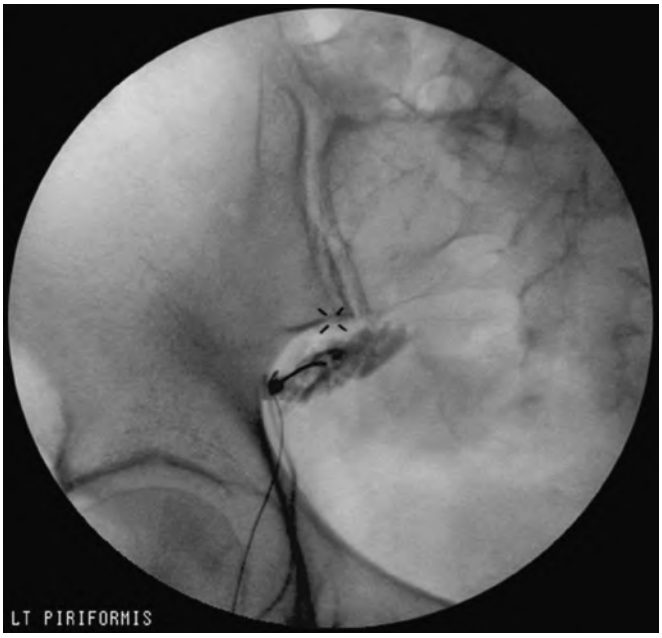


• **Figure 68.1** Gray-scale imaging of trigger points in the upper trapezius muscle. **A,** An isolated trigger point appears as a well-defined focal hypoechoic nodule. **B,** A series of four hypoechoic trigger points in the upper trapezius. (From Sikdar S, Shah JP, Gebreab T, et al. Novel applications of ultrasound technology to visualize and characterize myofascial trigger points and surrounding soft tissue. *Arch Phys Med Rehabil*. 2009;90:1829-1838, with permission.)

standardized diagnostic criteria for it. The syndrome should be considered in patients with buttock pain, tenderness to palpation over the piriformis muscle, and a positive response to provocative maneuvers, including:

1. Pace's sign: pain and weakness with seated abduction of the hip against resistance.
2. Lasègue's sign (also known as the straight-leg raise test): pain with unresisted flexion, adduction, and internal rotation of the flexed hip.
3. Freiberg's sign: pain with forced (i.e. against resistance) internal rotation of the extended hip.[42]

The piriformis muscle is usually injected under imaging guidance because of its small size compared to the gluteus muscles, its proximity to neurovascular structures, and its deep location. Studies have universally shown that the injections of local anesthetics and steroids can significantly reduce pain from piriformis syndrome, which holds true for the most common imaging techniques: fluoroscopic,[44,45] ultrasound guided,[46–48] and computed tomography (CT)-guided.[49] Other imaging guidance techniques include nerve stimulators and electromyography,[50] which were used more often prior to the increased availability of fluoroscopy and consistently improving the image quality of ultrasound.[51] Contraindications are the same as those noted in the section on TPI.[52]



• **Figure 68.2** Fluoroscopic image guided piriformis muscle injection.

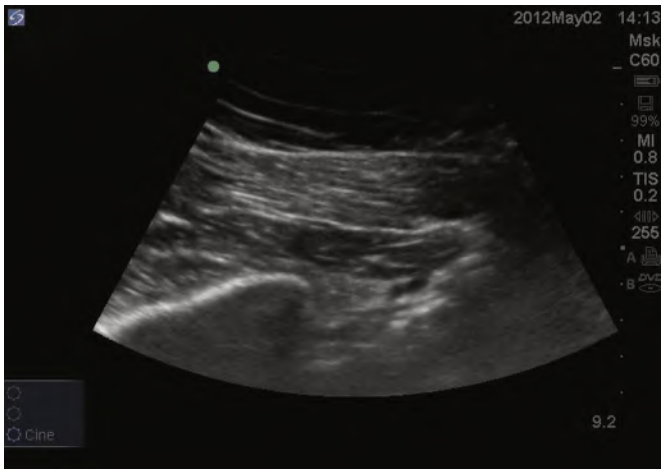
Combined Fluoroscopic Nerve Stimulator Guided Technique

The patient is placed prone on a fluoroscopy table, and the inferior margin of the sacroiliac joint is imaged and marked. The needle insertion site is 1–2 cm caudal and 1–2 cm lateral to the inferior margin of the sacroiliac joint. After sterile preparation and infiltration of local anesthetic, a 7–10 cm insulated needle is inserted and advanced with the nerve stimulator turned on (1 mA, 2 Hz, 0.1 ms) until an evoked motor response of the sciatic nerve is achieved (dorsiflexion, plantar flexion, eversion, inversion) at 0.4–0.6 mA. The needle is then withdrawn slightly until the sciatic stimulation disappears to avoid intraneural injection. Steroid (40 mg of either methylprednisolone or triamcinolone) plus 5 mL of saline is injected around the sciatic nerve—this is helpful, especially in patients with signs of sciatic nerve irritation. The needle is then pulled back 1 cm into the belly of the piriformis muscle, and 1–2 mL of contrast agent is injected. The contrast agent should outline the piriformis muscle belly with no sign of spillage (Fig. 68.2). After the characteristic spread of dye is achieved—outline of the piriformis muscle with clean margins—the local anesthetic solution with steroid is administered.

Ultrasound Guided Piriformis Muscle Injection Technique

The ultrasound guided technique permits a direct view of the piriformis muscle and allows examination of the anatomic variation in the relationship between the piriformis and the sciatic nerve. The patient is placed in the prone position with the ultrasound machine on the side opposite the operator. A curved, low-frequency ultrasound probe (2–6 MHz) is used to scan a wider and deeper area. The ultrasound machine should have Doppler to identify the inferior gluteal artery medial to the sciatic nerve and anterior to the piriformis. A 20- to 22-gauge, 10–12 cm long needle is recommended.

One technique involves positioning the transducer in the short axis (transverse) over the sacroiliac joint, where medially the sacrum will be visible, and laterally the ilium/gluteus maximus muscle complex will be observed.[47] While keeping the sacroiliac joint in the center of the screen, the transducer is moved caudally until the lateral view of the ilium is lost, which indicates that the transducer is over the greater sciatic notch. In this position, the operator will see the hyperechoic lateral portion of the sacrum medially. In the center of the image, the following are visualized: skin and fat in the near field and then the gluteus maximus muscle. Deeper to the gluteus maximus and originating from the anterior and lateral sacral edge is the piriformis muscle with its typical longitudinal fibers (Fig. 68.3). By moving the transducer slightly lower and mildly rotating the left gluteal area clockwise (counterclockwise on the right side), the sciatic nerve becomes visible deeper in the medial aspect of the piriformis. The ischium initially appears as a curved hyperechoic line (posterior acetabulum); more caudally, it becomes a flat line deeper to the piriformis. Another way to find the piriformis is to place the transducer over the line between the greater trochanter



• **Figure 68.3** Ultrasound anatomy of the piriformis muscle.

and ischial tuberosity. Once the sciatic nerve is identified, it is followed cephalad until the piriformis and gluteus maximus muscles are visualized overlying the sciatic nerve.

To confirm the view of the piriformis muscle, flex the patient's knee 90 degrees and rotate the hip internally and externally. During this maneuver, the piriformis will slide over the ischium while the position of the gluteus maximus remains stable. While observing the sciatic notch, it is useful to identify the ischial spine and differentiate other muscles close to the piriformis that insert in the area (i.e. the gemelli and obturator muscles).

The piriformis runs in a nearly axial plane between the sacrum and the femur. A lateral-to-medial, in-plane approach is ideal to maximize visualization of the needle; the needle enters the skin 3–4 cm lateral to the lateral edge of the transducer. The needle should cross the skin and fat in a lateral-to-medial, posterior-to-anterior direction and enter the gluteus maximus and then the piriformis in its medial half. Hydrodissection with normal saline (or a nonelectrolyte solution such as 5% dextrose if using stimulation) may help confirm the position of the tip of the needle before administering injectate. After injecting the piriformis muscle, to decrease sciatic nerve irritation, the needle can be advanced and positioned between the piriformis and the sciatic nerve to deposit injectate in that plane.

Injectate for Piriformis Target

Steroid

The most common combination for piriformis injectate is a corticosteroid (CS) plus local anesthetic (LA), often 5 mL of 0.25% bupivacaine plus 40 mg of methylprednisolone or triamcinolone. A retrospective study noted that 76% of patients treated with physical therapy and CS/LA injection had greater than 50% improvement at an average 10.5 month follow up.[53] A prospective study noted that patients had improved outcomes with CS/LA injection for a full year after treatment than with medication and physical therapy alone.[49]

Local Anesthetic

Although steroid injection is common, a 2015 randomized controlled trial (RCT) reported no difference in CS plus LA injection to the piriformis than LA alone. That said, both injection groups were clinically effective in treating pain.[54] It is not uncommon for weakness or numbness to develop in the distribution of the sciatic nerve for the expected duration of the LA.

Botulinum Toxin

Botulinum toxin is an increasingly common injection when the duration of effect from LA and CS injections is insufficient. A typical dose would be 100 mouse units in a 2 mL volume.[55] Due to its paralytic effect on the muscle, it causes atrophy and fatty degeneration of the muscle over time, as evidenced by magnetic resonance imaging (MRI).[56] This reduction in muscular volume would decrease pressure on the sciatic nerve and is the mechanism of analgesia,[51,53,57–63] but is a more profoundly effective treatment when combined with physical therapy.[53,58,61] Several uncontrolled studies have evaluated the use of botulinum toxin, often in combination with physical therapy, and reported high rates of success that lasted for months (Table 68.1).[55,57–62,64–67] A controlled study demonstrated the superiority of botulinum toxin over placebo injection for ten weeks.[60] Other controlled studies have reported that the efficacy of botulinum toxin is superior to that of local anesthetic/steroid or normal saline injections for the treatment of piriformis syndrome.[46,61,68]

Clonidine

When comparing clonidine versus normal saline as an additive to bupivacaine, a prospective study found a significantly lower pain score at six months in the clonidine group.[69]

Results of Treatment

Injection of the piriformis may improve pain related outcomes for several months. However, the published studies are limited by poor study methodology and reporting, inconsistent outcome selection, small sample sizes, heterogeneous patient populations, and the absence of standardized diagnostic criteria. The combination of a sciatic nerve conduction study with the flexion, abduction, internal rotation test may predict those who will respond to physical therapy.[53] More research into this topic comparing different treatment combinations would be welcome, but at present, it does appear that injection into the piriformis is an effective treatment modality for a patient that has failed conservative therapy.

Iliopsoas Injection

Pain emanating from the iliopsoas muscle is relatively uncommon but can be a source of inguinal, hip, or even low back pain. Patients typically have unilateral low back or anterior hip pain, although the pain can be referred to the thigh or inguinal area. Patients can vary widely, from young and active athletes, particularly those who participate in hockey, soccer, and dance, to older and more sedentary individuals who spend most of their time sitting, such as office workers and drivers. Myofascial pain arising from the iliopsoas muscle itself is distinct from that caused by iliopsoas bursitis or tendonitis (*coxa saltans* or "snapping hip syndrome"), although these causes are frequently included in the differential diagnosis. In addition, other causes such as lumbar spinal stenosis, iliotibial band syndrome, osteoarthritis or joint infection, inguinal hernia, and nerve entrapment syndromes should be considered.[70]

On physical examination, an antalgic gait because of a shortened stride on the affected side may be noted as the patient enters the examination room. The patient may also have pain or weakness when squatting to sit or when transitioning from a seated position to standing. The psoas muscle can be palpated deep in the abdomen, medial to the anterior superior iliac spine when the ipsilateral hip is flexed. Pain on palpation while flexing the hip against resistance is an excellent tool for diagnosing psoas major myopathy but may be uncomfortable for the patient. Provocative tests are not specific for the iliopsoas muscle but can aid in the diagnosis via active and passive extension of a painful muscle.[71]

- Thomas's test—The patient is supine and unable to extend the affected hip completely with the contralateral hip fully flexed; this is because of tightened hip flexors.
- Yeoman's test—The patient is prone and experiences pain with passive extension of the affected hip, typically a sacroiliac joint test but can cause anterior hip pain with passive iliopsoas extension.
- Gaenslen's test—The patient is supine and feels pain with extension of the affected hip (leg hanging off the examination table) while the contralateral hip is flexed (knee held to the chest), typically a sacroiliac joint test but can cause anterior hip pain with passive iliopsoas extension.
- FABER test—The patient is supine and experiences pain with *f*lexion, *ab*duction, and *e*xternal *r*otation of the affected hip.
- Snapping hip test—"Snapping" or "clicking" is heard when the hip is rotated from flexion and abduction to extension and adduction—this rules out *coxa saltans.*

TABLE 68.1 Results of Studies on Botulinum Toxin Injections for Piriformis, Iliopsoas, and Scalene Muscle Injections

Study	Muscle Injected	Type of Study	Groups Compared	Results
Porta[55]	Piriformis	Randomized, controlled	Botox A (100 units) vs. steroid	Pain scores were significantly lower in the Botox group 60 days after injection
Lang[57]	Piriformis	Open label	Botox B (5000 units)	Significant reduction in buttock and hip pain up to 16 weeks
Fishman et al.[61]	Piriformis	Prospective, dose ranging	Botox B (5000 7500, 10,000, 12,500 units)*	12,500 units superior to 10,000 units 12 weeks after injection
Yoon et al.[59]	Piriformis	Prospective, open label	Botox A (150 units) vs. lidocaine/dexamethasone (5 mg)	Improvement in SF-36 subscales (pain, physical and social functioning, vitality, general health) at four weeks
Childers et al.[60]	Piriformis	Double-blind, crossover	Botox A (100 units) vs. vehicle	Results better with Botox injection
Porta[55]	Iliopsoas	Randomized, controlled	Botox A (150 units) vs. steroid	Pain scores were significantly lower in the Botox group 60 days after injection
De Andrés et al.[64]	Iliopsoas	Randomized, controlled	Botox A (50 units) vs. 0.25% bupivacaine or NaCl (injected into the contralateral side)	No improvement with either treatment; no difference between groups; trend toward a decrease in pain scores with Botox
Jordan et al.[65]	Scalene	Prospective, open label	Botox (12–15 units per muscle)	64% of patients had >50% pain reduction for at least one month
Jordan et al.[66]	Scalene	Retrospective	Botox A (12–15 units per anterior/middle scalene); fluoroscopy/EMG guidance compared to ultrasound/EMG guidance	Results comparable: 91% good results with ultrasound and 81% with fluoroscopy
Christo et al.[67]	Scalene	Prospective	Botox (20 units) into the scalene muscle	Significant relief of pain for three months

Note: For botulinum toxin injection of myofascial trigger points, the preponderance of studies showed a lack of efficacy.

EMG, Electromyographic; *SF-36*, 36-Item Short-Form Medical Survey.

*The Botox injection was combined with physical therapy.

Relevant Anatomy

The psoas major muscle is located in the retroperitoneal space and consists of a deep layer that originates from the transverse processes of L1–5 and a superficial layer that originates from the lateral portions of T12–L4. The lumbar plexus is located between these two layers of muscle. The psoas major also has fibrous attachments to all the lumbar disks except L5–S1. According to their position, the attachments are categorized as either "anterior" or "posterior." The attachments located on the vertebral bodies and intervertebral disks are referred to as anterior fascicles, whereas those located on the transverse processes are known as the posterior fascicles.[72]

The psoas joins the iliacus muscle, which arises from the ilium, to form the iliopsoas muscle within the iliac fascia. This muscle then runs anterolaterally through the iliopubic (iliopectineal) eminence and the muscular lacuna beneath the inguinal ligament, next forms a tendon that sits anterior to the hip joint and finally inserts onto the lesser trochanter of the femur.[73] The psoas muscles are usually asymmetric in size, with the right side larger than the left. Innervation of the psoas muscle is achieved via the lumbar plexus from the ventral rami of L1–3, whereas the iliacus muscle is innervated by the femoral nerve from the ventral rami of L1–4.

Occasionally, a psoas minor muscle is present and arises from T12–L1. It follows the medial border of the psoas major and inserts into the iliopectineal eminence of the innominate bone and the iliac fascia at the pelvic brim. The psoas minor is absent in 40% of adults and can therefore be mistaken for lymphadenopathy on imaging studies. This muscle is considered a weak flexor of the spine and is innervated by the ventral rami of L1.[74]

Although it is widely accepted that the iliopsoas muscle aids in flexion and external rotation of the hip, there is controversy surrounding the muscle's other functions.[75] Other electromyographic studies have demonstrated varying degrees of activation of the iliopsoas muscle during hip rotation, adduction, and abduction, as well as during lumbar spine stabilization, flexion, and lateral flexion. As a result of these investigations, the iliopsoas muscle is thought to be "dynamically active" in that it adjusts its function according to spinal position and loading.[76]

To reduce friction between the bone and muscle, a large synovial-lined bursa with only a trace amount of fluid is located at the level of the iliopubic eminence. The bursa itself is relatively undetectable on many imaging modalities and requires MRI to

visualize it adequately. Additionally, the bursa communicates with the hip joint in a small percentage of adults, although the incidence rises dramatically in the setting of trauma or inflammation.[70]

Imaging

Iliopsoas syndrome can be confirmed via the history and physical examination alone, without the aid of special imaging. However, diagnostic imaging may be required because of the uncommon nature of the syndrome, and the diagnosis is frequently based on incidental findings. Multiple imaging modalities, including ultrasonography, CT, and MRI, can be useful in providing rapid and accurate information. CT can be used to outline the extent of affected tissue and may provide a diagnosis, such as infection or tumor. MRI can be used selectively in cases in which spinal canal or vertebral involvement is suspected.[74]

Ultrasonography has evolved to become a very useful modality for both the diagnosis and treatment of iliopsoas-associated disorders. Specifically, ultrasound can quickly identify abnormal motion of the tendon or assess for the presence of fluid in the muscle (e.g. abscess, hematoma). Other advantages to using ultrasound include the ability to scan the hip for assessment of symmetry and to direct injections into the muscle, tendon, or bursa.[77–79]

Technique

Basic Considerations

The same concerns that apply to any myofascial injection apply to iliopsoas injections as well. Care must be taken to ensure that the muscle is free of tumor, abscess, or hematoma before proceeding with an injection.

Fluoroscopic Technique

The patient lies prone with pillows placed beneath the abdomen to correct the lumbar lordosis. The L4 transverse process is visualized on anteroposterior fluoroscopy. After LA infiltration, a 3 inch, 22-gauge (spinal) needle is advanced until it touches the transverse process. For psoas muscle injection, the tip of the needle touches the superior aspect of the middle or the lateral third of the transverse process and is advanced 1 cm beyond the transverse process. Contrast agent is injected, and the muscle striation pattern is noted (Fig. 68.4). A lateral view is obtained and injectate administered. To inject the adjoining quadratus lumborum muscle, the needle touches the lateral tip of the transverse process and is advanced 1 cm. The same procedure as for the psoas muscle is then performed.

Ultrasound Guided Technique

Single-shot procedures, as well as catheter placement, can be accomplished safely with ultrasound guidance.[78,79] Two ultrasound guided techniques are described below.

Lateral Approach

The lateral approach is a technique modified from the one proposed by Kirchmair and colleagues.[80] This technique is recommended in patients with a body mass index lower than 35 since the ultrasound view will be impaired by a thick abdominal wall. The patient is placed in the lateral decubitus position with a mild anterior tilt. A low-frequency (2–6 MHz) curved probe is recommended. The transducer is initially placed lateral to the spine in a cross-sectional view, just above the iliac crest, to identify the transverse process and spinous process. The proceduralist then scans laterally around the waist of the patient with the probe perpendicular to the skin over the posterior axillary line, maintaining the transverse process in view. The following structures should be identified: skin, fat, lateral portion of the erector spinae muscle, quadratus lumborum, part of the external and internal oblique muscles, and the transverse process of L4. At this level, it is unlikely that the kidney will be in view unless the patient takes a very deep breath. The transducer is then moved laterally to obtain a full lateral view of the spine and paravertebral structures. The hyperechoic lateral portion of the vertebral body is seen as a thick line curving deeply in the anterior part; lateral to it is the cross-sectional cut of the psoas muscle between the lateral portion of the vertebral body and anterior to the transverse process (Fig. 68.5). Gentle, slow scanning of the psoas muscle while viewing the medial-posterior area will show the nerve root entering the muscle along with a segmental artery. In-plane needle access is recommended, with the entry point in the skin located about 4 cm medial to the medial/posterior end of the transducer. A 12–15 cm long, 20-gauge needle is used for single-shot injections, whereas a long epidural needle is required to insert a catheter into the muscle. The needle is advanced toward the junction between

• **Figure 68.4** Fluoroscopically guided iliopsoas muscle injection.

• **Figure 68.5** Ultrasound guided iliopsoas muscle injection.

the posterior and middle third of the muscle (in the anteroposterior plane) (see Fig. 68.5). If a catheter is planned, it should be advanced 2–3 cm beyond the tip of the needle under direct vision, with the bevel of the needle facing cephalad along the fibers of the muscle.

Posterior Approach

The patient is prone with a pillow under the abdomen to obtain a flat, more superficial spine position. In this approach, the same curved transducer probe is initially positioned longitudinally over the spinous process at the level of L3–4. The spinous processes are identified, and the transducer is moved laterally to show the laminae, masses of the facet joints, and finally, the transverse processes of L2–4, which appear like a trident on the ultrasound monitor.[81] Careful observation while the patient flexes the ipsilateral thigh against the table will demonstrate the fibers of the psoas muscle in between the transverse processes. The needle is oriented such that it crosses in between the transverse processes of L3 and L4 about 1.5 cm deeper than the distance measured from the probe to the posterior surface of the transverse process. When injecting in this location, no injectate should be observed superficially to the transverse processes. The catheter, if required, can be advanced similarly to the lateral ultrasound guided approach.

The patient should be monitored for signs of intravascular injection (the aorta or vena cava when the needle is too anterior), unilateral lower extremity weakness from lumbar plexus blockade, or bilateral lower extremity weakness as a result of epidural or subarachnoid injection (the needle is too medial or larger volumes are injected).

Results of Treatment

Stretching in combination with dry needling was reported to be very effective in a case series.[71] Standard physical therapy interventions such as stretching, strengthening, and improving neuromuscular control with the assistance of appropriate physical modalities (such as heat and therapeutic ultrasound) are also effective in the treatment of iliopsoas syndrome and associated musculotendinous disorders.[82]

Steroid and Local Anesthetic Injections

Iliopsoas injections are generally beneficial with judicious patient selection. A 2019 prospective study demonstrated that in patients with iliopsoas tendinopathy, the outcomes of injection were positive regardless of co-existing intra-articular hip abnormalities.[83] Similarly, if the iliopsoas tendon is painful, the patient will benefit from bursal injection even if the physical exam does not demonstrate snapping hip or tendinopathy.[84] A 2020 retrospective study showed that injection improved joint function and improved lower back and groin pain.[85] An example of typical injected medications would be 6–8 mL of LA (0.25% bupivacaine) and steroid (40 mg methylprednisolone or triamcinolone).

Botulinum Toxin Injection

One controlled study reported the superiority of botulinum toxin injection (150 units in a 3 mL volume) over steroid and LA.[46] This was similar to the 2000 study by Porta that showed benefit from botulinum toxin.[55] This is in contrast to another controlled study using a side to side comparison in the same individuals who did not benefit from botulinum toxin injection over LA or saline injection (Table 68.1).[64]

Truncal Blocks

Introduction

Surgeries of the thoracic wall are exceedingly common and are an underrecognized source of chronic postsurgical pain from incisional disruption of nerve fibers. Thorascopic or open thoracic surgeries are common culprits for postsurgical pain,[86] as are neoplastic or cosmetic breast surgeries.[87] In this section of the chapter, we will discuss the various regional techniques developed to provide postoperative analgesia for breast surgery but are now widely used to treat pain following thoracic surgeries or the acute pain of rib fractures. In contrast to peripheral nerve blocks, fascial plane blocks provide analgesia via the spread of LA along fascial planes or by diffusion through muscle tissue. Although the affected area is not as circumscribed or consistent as in neuraxial or targeted nerve block techniques, fascial plane blocks are particularly well-suited for providing analgesia to broad areas of the thorax.[86] By reducing the acute pain burden of surgical or traumatic insults, we reduce the likelihood of resultant chronic pain from these surgeries.[88]

Quadratus Lumborum Block

Quadratus lumborum block (QL) is not commonly a target for the treatment of chronic back pain but instead is an option for regional anesthetic management of the perioperative patient. It was first described in 2007,[89] and can be performed by one of three approaches. The QL has been shown to reduce pain in abdominal surgery,[90] renal surgeries,[91,92] laparoscopic hepatectomy,[93] and Cesarean delivery.[91,94–96] It has been shown to be superior to intravenous (IV) morphine for C-section,[97] and is comparable to epidural analgesia in laparoscopic nephrectomy.[98] Some RCTs have shown inferiority compared to spinal morphine,[99–101] and it does not necessarily provide superior analgesia to other regional techniques.[90,91,102] There are three approaches to the QL block, and the target of each varies.[103]

Lateral block (QL1): The needle is advanced to the transversus abdominis aponeurosis (between transversus abdominis and transversalis fascia), after which LA is injected at the lateral border of QL muscle. Injectate tends to spread to the transversus abdominis plane (TAP) and subcutaneous tissue anteriorly.[103]

Posterior QL block (QL2): LA is injected along the posterior surface of the QL muscle at the border between QL and erector spinae muscle. Injectate then spreads to the TAP and posteriorly along the middle thoracolumbar fascia intertransverse area.[103,104]

Anterior QL block (Transmuscular QLB or transverse oblique paramedian [TOP] QL3): LA is injected anterior to the QL muscle, in the tissue plane between the QL and psoas muscle. Injectate consistently spreads to the anterior aspect of the QL muscle and will occasionally spread interfascially to the lumbar nerve branches or thoracic paravertebral space.[104] Several approaches to this block variation have been described, including the transverse oblique approach and the paramedian sagittal oblique or subcostal approach.[103–106] This approach is not a one-size-fits-all technique, as an RCT showed that the transmuscular QL block did not reduce opioid consumption after laparoscopic hysterectomy.[107] However, this approach did improve analgesia after laparoscopic nephrectomy,[108] and provided comparable analgesia as combined ilioinguinal and iliohypogastric nerve block when used in the regional anesthetic management of inguinal herniorraphy.[109]

Pecs I Block

An ultrasound guided fascial plane block, the PEC I block, targets the medial and lateral pectoral nerves. These nerves lie in the fascial plane between the pectoralis major and minor muscles, and proper execution will anesthetize the pectoralis muscle (Fig. 68.6). The PECS I block as an isolated block has fallen out of favor, especially after a 2020 RCT demonstrated that it did not provide better pain relief than a placebo.[110]

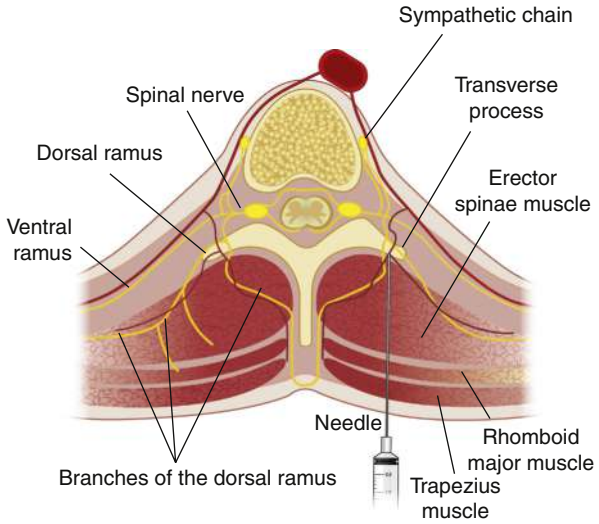
Pec II Block

The Pecs II block includes the Pecs I block but adds another injection laterally at the fascial plane that separates the pectoralis minor and the serratus anterior (Fig. 68.6). This extension of block surface area targets the upper intercostal nerves. Compared to the PECS I block, the PECS II has been shown to provide markedly superior analgesia.[111–114] The PECS II also provides improved pain relief compared to paravertebral block in terms of reduced opioid use, reduced pain score,[115] and improved duration of analgesia.[116] Similarly, it is superior to erector spinae plane block in reducing pain scores and opioid use postoperatively,[117] which was also shown in a 2020 meta-analysis.[118] Lastly, if an interscalene targeted nerve block is added to the PEC II block, this combination is superior to interscalene block alone.[119]

Erector Spinae Plane Block

The group of muscles that comprises the spine-stabilizing erector spinae group are the longissimus, iliocostalis, and spinalis muscles. These originate from the spinous and transverse processes and extend laterally to insertion points that are variable based on the craniocaudal level of the spine (Fig. 68.7). Forero et al.[120]

Efficacy of pectoral nerve block type II for breast-conserving surgery and sentinel lymph node biopsy: a prospective randomized controlled study. *Pain Res Manage.* 2018:4315931.



• **Figure 68.7** Anatomic rendering of needle placement for erector spinae block. Shim J-G, Ryu K-H, Kim PO, et al. Evaluation of ultrasound-guided erector spinae plane block for postoperative management of video-assisted thoracoscopic surgery: a prospective, randomized, controlled clinical trial. *J Thor Dis.* 2020;12(8):4174–4182.

introduced the erector spinae plane block (ESPB) in 2016 as an attractive option for analgesia because although it is not as effective as epidural analgesia,[121] it is less invasive and does not require cessation of anticoagulation like the paravertebral block or neuraxial techniques. ESPB does not access the neuraxial space, but the precise nerve targets through which the LA generates analgesia are still a source of divisive discourse. Potential mechanisms include 1) LA spread via the fascial plane to the posterior rami of the spinal nerves,[122] or 2) anterior spread to the paravertebral space with spread to the sympathetic chain. Involvement of the sympathetic chain is controversial, with some cadaveric data showing dye spread superiorly, inferiorly, and laterally only with no spread anteriorly to the paravertebral space.[123] Another cadaveric study showed that 10 mL volume of injectate did not spread to the paravertebral space, while a 30 mL volume did spread minimally to this space on one occasion.[124] However, clinical reports suggest that ESPB anesthetizes sympathetic fibers.[125,126] Therefore the balance of data is still inconclusive.

Although the mechanism of action still eludes clinicians, ESPB has become popular and well-studied in terms of clinical effects. The ESPB has now been described for use at multiple levels up and down the cervical and thoracic spine,[127–132] and can provide analgesia for thyroid surgery,[133] video-assisted thorascopic surgery (VATS),[134] mastectomy,[118,135] total abdominal hysterectomy (TAH),[136] pediatric splenectomy,[137] rib fractures,[138,139] and for chronic thoracic pain.[140]

As mentioned above, ESPB is not considered superior to the Pec II block for breast surgery, but it provides similar analgesia and side effect profile to the serratus anterior plane block (SAPB)[141] and to the thoracic paravertebral block (TPVB).[118] It is also superior to tumescent local anesthesia that is occasionally used in breast reduction surgeries.[142] As for thoracic surgery, ESPB is more effective than SAPB in analgesia,[143,144] quality of recovery at 24 h, and morbidity scores.[144] It was also equivalent to TPVB after VATS surgery.[134]

These clinical trials stand in contrast to two recent volunteer studies showing that the sensory area covered by the ESPB is the posterior thorax only and would be unlikely to improve analgesia in thoracic surgeries.[122,145] Most cadaveric and volunteer studies support that ESPB analgesia is achieved via the dorsal branches of spinal nerves. However, clinical studies in surgical patients suggest the mechanism is spread to the paravertebral space and potentially the sympathetic chain. Given a recent meta-analysis showing that ESPB confers statistically significant but brief and clinically inconsequential relief to breast surgery patients, patient selection is paramount when opting for this procedure.[146]

Serratus Anterior Plane Block

The SAPB is a further modification of the Pecs I & II blocks that targets the lateral cutaneous branches of the intercostal nerves in the fascial plane between the serratus anterior and latissimus dorsi (Figs. 68.8–68.10).[147] This block significantly improves postoperative analgesia in mastectomy patients compared to Pecs II block,[148,149] and ESPB[141] in some studies. However, other studies showed that in mastectomy, the SAPB is similar in results to the ESPB,[141,150] but both increased time to first required dose of IV morphine postoperatively and decreased nausea and vomiting.[150] Lastly, the SAPB has been effectively used for post-thoracotomy pain[151] and rib fracture pain.[152]

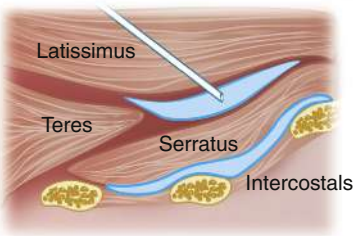
Scalene Muscle Injections for Neurogenic Thoracic Outlet Syndrome

Overview of Thoracic Outlet Syndrome

Thoracic outlet syndrome (TOS) remains a challenging, controversial, and frequently misdiagnosed neurovascular upper limb disorder.[153] TOS is a complex pathologic condition that presents with sensory and motor symptoms that may affect the neck, upper chest, shoulder, arm, and hand.[154] The incidence of TOS varies widely from three to 80 cases per 1000 people, and it exists in three different forms: neurogenic, venous, and arterial.[155] The most common type, neurogenic, accounts for 95% of all cases and is mostly seen in the third and fourth decades of life (Fig. 68.11).[155]

The thoracic inlet, also known as the superior thoracic outlet, refers to the opening at the top of the thoracic cavity. It is essentially a hole surrounded by a bony ring, through which several vital structures pass. TOS is caused by compression of the neurovascular structures passing through the superior thoracic outlet. It results from neck trauma (whiplash-induced injuries often from car accidents), repetitive stress injury, anatomic abnormalities (e.g. cervical ribs, elongated transverse process), muscle anomalies (presence of the scalene minimus muscle, sickle-shaped middle scalene), or a combination of these.[155] A small percentage of TOS cases are acquired through tumor metastases, osteomyelitis, or other uncommon sources.[156] Even though its cause is multifactorial, neurovascular compression at the interscalene triangle, costoclavicular, and retropectoralis minor spaces play an important role.[154] The cause of neurogenic TOS may be unknown in 12% of cases and related to a cervical or anomalous first rib in 2%. A cervical rib is an extra rib that arises from the seventh cervical vertebra. Their presence is a congenital abnormality. It is hypothesized that posttraumatic intrascalene muscle hemorrhage leads to scarring and spasm that cause pressure on the braquial plexus.[157]

Given that the estimated prevalence of the cervical rib in the general population is 0.5%–2%, and of neurogenic TOS is 1 per million; statistically, the presence of a cervical rib *per se* does not constitute a diagnosis for neurogenic TOS.[158] Cervical ribs occur in less than 1% of the general population.[158,159] Fifty percent are bilateral,[154] and 70% occur in females.[158] These have been reported in 5%–9% of patients with TOS.[159] Most cervical ribs are asymptomatic but can produce the neurogenic form of TOS more frequently than the vascular form.[155]



• **Figure 68.8** Anatomic location of the serratus anterior plane and needle placement for SAPB. Khalil AE, Abdallah NM, Bashandy GM, Kaddah TA. Ultrasound-guided serratus anterior plane block versus thoracic epidural analgesia for thoracotomy pain. *J Cardiothorac Vasc Anesth.* 2017;31(1):152-158.

Clinical Presentation and Diagnosis of TOS

The diagnosis of neurogenic TOS (NTOS) is challenging since most patients present with subjective complaints of positional or exertional arm pain, fatigue, and paresthesia affecting the fourth and fifth finger predominantly.[157] Patients often have unilateral paresthesia, usually in the ulnar nerve distribution, weakness of the upper extremity, and variable other symptoms such as headache and cold intolerance. The diagnosis is difficult to make because of a lack of specific diagnostic criteria, the relative insensitivity of imaging modalities and other diagnostic testing, and a long list of differential diagnoses.[160]

Patients may present with symptoms of upper plexus compression (C5–C7), like pain on the ipsilateral aspect of the neck or mastoid area or even occipital headaches.[154,155] Symptoms are usually aggravated by continuous elevation of the arm.[155] Other symptoms are discoloration and cold intolerance of fingers in cases involving sympathetic fibers; and, less commonly, weakness of the upper extremity.[155] In patients with NTOS, clinical examination may reveal tenderness over the scalene and trapezius muscles, a positive Tinel sign over the brachial plexus, and a positive response to provocative maneuvers. Electromyography and nerve conduction velocity studies are helpful to exclude other causes of symptoms; however, this can be limited by low sensitivity in mild cases and false negative results.[157]

Paget-Schroetter syndrome, also referred to as "effort thrombosis," refers to primary thrombosis of the subclavian vein at the costoclavicular junction and is a form of venous TOS.[159] Clinical presentation is classic, with the patient complaining of a blue, swollen, heavy, painful arm. Patients typically present with sudden onset of an aching discomfort with a feeling of heaviness, swelling, and frequently a reddish-blue discoloration of the affected upper extremity.[159] Arterial TOS is associated with hand ischemia caused by either external compression of the subclavian artery or from emboli arising from a subclavian artery aneurysm. The symptoms of arterial TOS include digital ischemia, claudication, pallor, coldness, paresthesia, and pain in the hand but seldom in the shoulder or neck.[155]

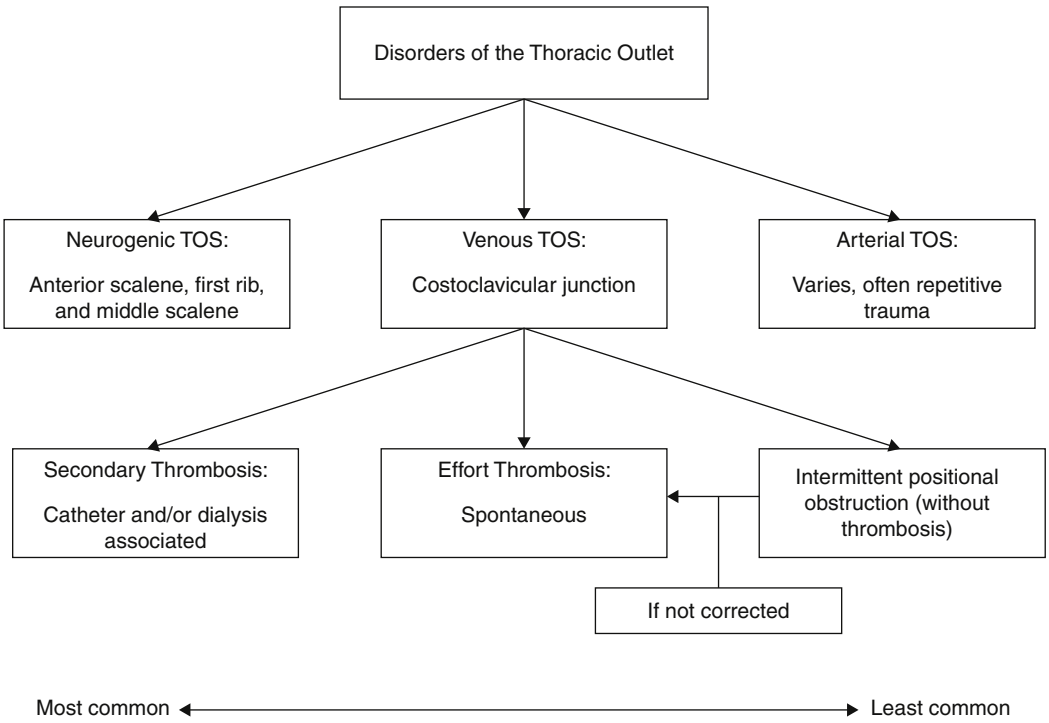
The treatment options for TOS may be conservative, such as stretching, massage, compression, injections on the scalene muscles with lidocaine, ropivacaine, bupivacaine, and botulinum toxin.[158] Despite being the main treatment option, surgical intervention for NTOS remains controversial.[154] Scalene muscle injections have been used to confirm the diagnosis of NTOS and predict the response of patients to surgery.[161] LA injections into the anterior scalene muscle alone or both the anterior and middle scalene muscles can relieve TOS. The injection relaxes the muscle or muscles elevating the first rib and mimics the effects of first rib resection or scalenectomy. Relief with this technique correlates well with successful physical therapy and surgical treatment.[157] Successful treatment of TOS with scalene muscle injection has been shown to be independent of any brachial plexus blockade.[162] However, to be predictive, the injection should avoid anesthesia of the brachial plexus and sympathetic chain, and the patient should be both medically and psychologically stable.[155] Different methods have been used to guide the scalene injection, including the use of anatomic landmarks, electromyography (EMG), ultrasonography, combinations of EMG and sonography, EMG and fluoroscopy, and most recently CT.[155]

Injections of medications such as local anesthetics or botulinum toxin (BTX) into muscles adjacent to brachial plexus, such as anterior scalene (AS) and pectoralis minor (PM), can help evaluate cases of suspected NTOS and provide temporary symptom relief.[154] Botulinum toxin type A (BTX-A) injection into the middle interscalene muscle or pectoralis muscle planes[153] is gaining popularity because it provides significant symptomatic relief and helps predict future surgical decompression success.[154] Recent evidence suggests anesthetic injections into the AS may predict surgical outcome in patients older than 40 years.[154]



• **Figure 68.11** Basic classification of thoracic outlet syndrome (TOS). Illig KA, Doyle AJ. A comprehensive review of paget-schroetter syndrome. *J Vasc Surg.* 2010;51(6):1538-1547.

Relevant Anatomy

The scalene musculature consists of three muscles located on the lateral aspect of the neck (Fig. 68.12). They have variable origin and insertion sites along the neck and frequently fused fascicles between the individual muscles. A fourth muscle is occasionally present, the scalene minimus. The AS arises from the anterior tubercles of the transverse processes of the C3–6 vertebral bodies and inserts onto the scalene tubercle of the first rib proximally and anterior to the subclavian artery. The middle scalene stems from the posterior tubercles of C2–7 and inserts onto the first rib posterolateral to the AS and posterior to the subclavian artery. The anterior and middle scalene muscles contain the brachial plexus between them. The posterior scalene originates from the posterior tubercles of C4–6 and inserts posterolateral to both the anterior and middle scalenes on the posterior border of the second rib. All the scalene muscles have multiple variations in their points of origin and insertion.[163]

The scalene muscles are cervical spine flexors. Cervical spine flexion results when the scalene muscles contract bilaterally, and lateral spine flexion results when the muscles contract unilaterally. Additionally, the scalenes serve as accessory muscles of respiration when the cervical spine is stabilized, with the anterior and middle scalenes helping to elevate the first rib and the posterior scalene elevating the second rib during deep inspiration. This group of muscles also rotates the spine ipsilaterally and reaches maximal stretch with contralateral rotation.[164,165] The scalene muscles are included in the posterior triangle of the neck, which is bordered by the trapezius posteriorly, the sternocleidomastoid anteriorly, and the clavicle inferiorly. Its apex is formed by the junction of the sternocleidomastoid and trapezius at the level of the occipital bone. Also within these demarcations are the brachial plexus (from roots to divisions), cervical sympathetic ganglia, spinal accessory nerve, phrenic nerve, subclavian artery, transverse cervical artery, and lymph nodes.

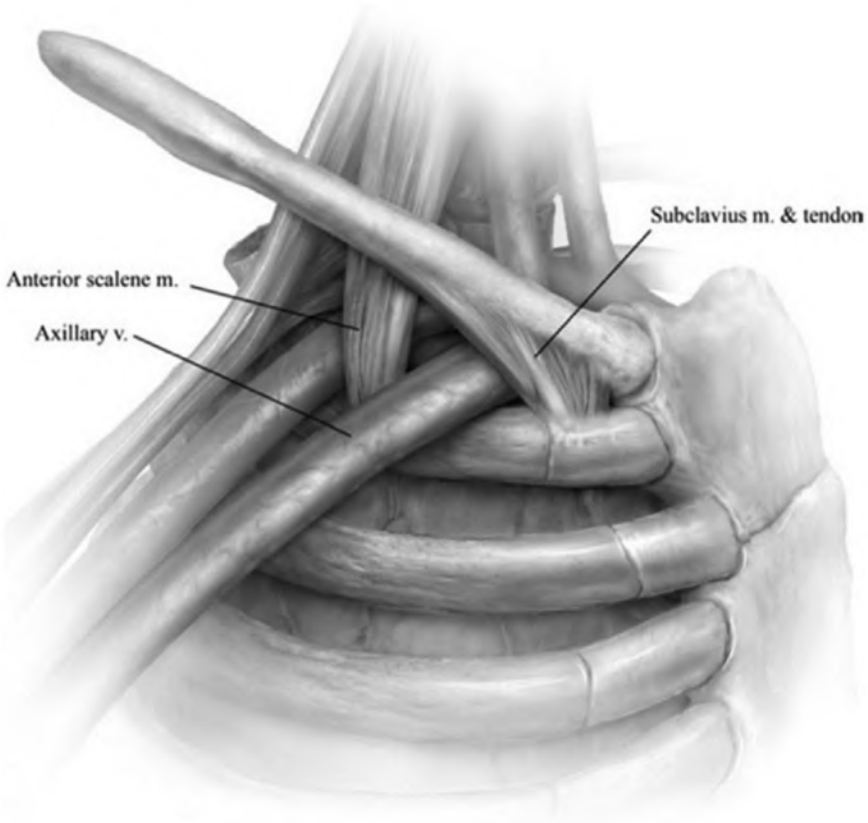
It should be noted that the interscalene groove, where the roots of the brachial plexus are located, is a potential groove. The anterior sheath of the interscalene groove is actually the posterior fascial sheath of the AS muscle, and the posterior sheath of the groove is the anterior fascial sheath of the middle scalene muscle.[162]

Imaging

Imaging modalities, including MRI, usually fail to reveal any abnormalities causing TOS. However, there are reasons to obtain imaging before performing any procedure in the posterior triangle of the neck. Such reasons include confirmation of muscle anomalies (presence of the scalene minimus muscle) and bone abnormalities (cervical rib, elongated transverse process), evaluation of the surrounding soft tissue for evidence of other injuries (e.g. rotator cuff tear), and identification of the presence of tumor, osteomyelitis, or other uncommon causes.

Injection Technique

Several techniques have been described to guide needle placement in the AS muscle, including the use of anatomic landmarks, and EMG alone or combined with ultrasonography, or image guided with ultrasonography, fluoroscopy,[157] or CT. With no imaging guidance, there is a high possibility of a false-positive result because of accidental brachial plexus anesthesia (10% of cases) or a false-negative result because of inaccurate targeting of the scalene muscles or inadvertent puncture of important vascular structures.[155] Contraindications to and concerns with scalene muscle injections are the same as those noted for trigger point



• **Figure 68.12** Basic anatomy of the thoracic outlet. Illig KA, Doyle AJ. A comprehensive review of paget-schroetter syndrome. *J Vasc Surg*. 2010;51(6):1538-1547.

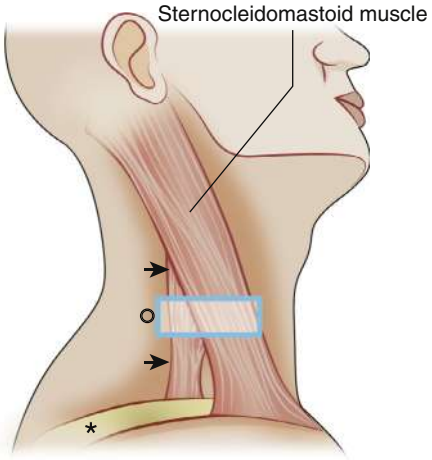
and piriformis injections. The ultrasound guided technique is preferred for safety reasons since the thyroid, esophagus, carotid, jugular vein, and brachial plexus are visualized, and hence this technique will be described.

Ultrasound Guided Technique

The patient is supine, and the area is prepared in a sterile fashion. Ultrasonography is used to visualize the anterior and middle scalene muscles through one of two approaches. The probe is placed at the level of the cricoid cartilage/C6 vertebra and moved laterally from the trachea, carotid artery, and internal jugular vein (compressible) to identify the two scalene muscles with the brachial plexus (hypoechoic nerve roots) between them. Alternatively, the ultrasound probe can be placed in the inferior (just above the clavicle) and lateral (lateral to the sternocleidomastoid) aspect of the neck. After identification of the subclavian artery and brachial plexus, the plexus is traced cephalad to the level of C7, in between the anterior and middle scalene muscles. After skin infiltration, a 1.5 cm, 21- or 22-gauge needle is advanced out of plane into the belly of the muscle away from the brachial plexus. The out of plane approach is preferable to avoid injection of LA into the brachial plexus.[162]

The AS muscle can be scanned along its craniocaudal extension and best visualized on images through its lower half. A lateral-to-medial needle approach is the preferred method to decrease the likelihood of vascular injury (Fig. 68.13).[157]

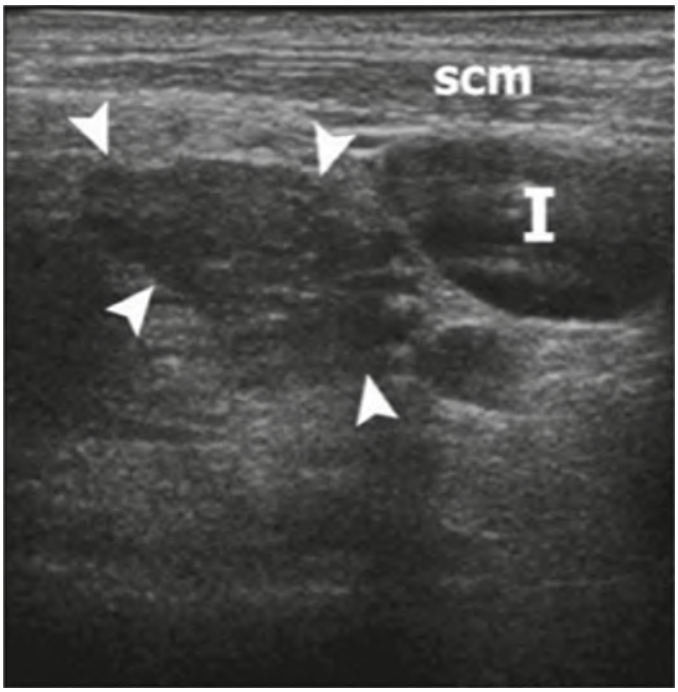
Approximately 1 mL of lidocaine 1% is injected subcutaneously at the previously marked site. A syringe containing 2 mL of bupivacaine 0.5% is connected to a 25-gauge 1.5 inch. Once



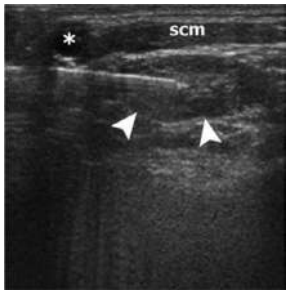
• **Figure 68.13** Approach for ultrasound guided injection of the anterior scalene muscle. Torriani M, Gupta R, Donahue DM. Sonographically guided anesthetic injection of anterior scalene muscle for investigation of neurogenic thoracic outlet syndrome. *Skelet Radiol*. 2009;38(11):1083–1087.

the needle tip is seen within the belly of the AS muscle, bupivacaine is slowly injected under real-time monitoring (Figs. 68.14 and 68.15).[157] Although some authors inject both the anterior and middle scalene muscles, others inject only the AS muscle.[162]

Relief of symptoms can occur within 15–30 min and may last for days or weeks. The brachial plexus may be blocked, with resultant numbness of the upper extremity, since it is not uncommon



• **Figure 68.14** Transverse ultrasound anatomy for anterior scalene muscle injection. Torriani M, Gupta R, Donahue DM. Sonographically guided anesthetic injection of anterior scalene muscle for investigation of neurogenic thoracic outlet syndrome. *Skelet Radiol*. 2009;38(11):1083–1087.



• **Figure 68.15** Ultrasound guided needle placement for anterior scalene muscle injection. Torriani M, Gupta R, Donahue DM. Sonographically guided anesthetic injection of anterior scalene muscle for investigation of neurogenic thoracic outlet syndrome. *Skelet Radiol*. 2009;38(11):1083–1087.

for the roots of the brachial plexus to pass through the middle scalene muscle. The injected LA may spill through the fascia of the scalene muscles. If this happens, the patient should be discharged with an arm sling. Note that relief is not dependent on blockade of the brachial plexus. A series of injections can be performed two to three weeks apart if the relief is prolonged. Even though the usual duration of relief is days to a week, it may last up to four weeks when a series of injections are performed.[156] If relief lasts only for hours or a few days, either injection of botulinum toxin or resection of the anterior or middle scalene (or both) can be performed. Published doses of botulinum toxin are 12–15 units of botulinum toxin A per muscle. Regarding the results of surgery, a retrospective two-year functional outcome study showed good and fair results in 49% and 35% of patients, respectively.[166] A good response to injection of LA into the scalene muscles correlates with a good outcome after scalenotomy, and first rib resection.[162,167] Relief of pain from scalene muscle injections in patients with TOS is not related to blockade of the brachial plexus.[162]

Rached et al. published a randomized, placebo-controlled, double-blind clinical trial with a parallel group. They concluded that the injection of 0.375% ropivacaine in doses of 2.5 mL in each belly of the anterior and middle scalene muscles, guided by ultrasound, in the treatment of disputed neurogenic TOS, assists in the improvement of function (primary outcome) evaluated for 12 weeks by the disabilities of the arm, shoulder, and hand - DASH scale.[158]

Mashayekh et al. performed CT guided scalene injections, which produced accurate results compared to other techniques of image guided scalene injection.[155] CT guided LA or botulinum toxin injection of the scalene muscle is a novel technique, and they evaluated the outcomes and complications of this procedure in a large group of patients. In this study, 68/83 (82%) of the anesthetic injections into the ASM alone or anterior scalene muscle (ASM)/middle scalene muscle (MSM) together resulted in a positive scalene block, which was higher than that in studies using needle guidance by sonography (11/29, 38%), 11 EMG and fluoroscopy (4/22, 18%), 20 or EMG alone (93/122, 72%) under CT guidance, highlighting that scalene injection is a safe procedure.[155]

Donahue et al. demonstrated a favorable response to sonographically guided BTX injections is associated with favorable surgical outcomes at two years follow up and has a high positive predictive value, suggesting they may help predict surgical outcomes.[154] They used a free-hand technique, with AS being injected lateral-to-medial and PM injected via an oblique approach. BTX type A was reconstituted in 2 mL of preservative-free saline with a fixed dose for all patients: 18 U for AS and 23 U for PM.

Sonographically guided injection of anesthetic into the AS muscle is safe and well tolerated. Sonography allowed precise depiction of AS muscle and intramuscular needle placement. Unintended brachial plexus blocks may occur in up to a third of the procedures.[157] Scalene injection confirms the clinical diagnosis of TOS in patients presenting with typical patterns of pain and paresthesia and helps to identify the relative contribution of TOS when symptoms overlap with another disease. An earlier return to everyday life and work in patients with TOS is possible by combining scalene injection with conservative treatments such as medication.

Summary

Myofascial pain and myofascial pain syndromes are among some of the most common acute and chronic pain conditions. The pathophysiology of myofascial pain includes biomechanical and postural factors that likely interact with neurologic factors, psychological elements including depression and anxiety, and hormonal and nutritional imbalances. These factors (in total or in part) may create peripheral sensitization, autonomic dysregulation, and ultimately, central spinal cord sensitization, which can amplify the symptoms experienced by patients with myofascial pain. Many interventional procedures can be performed in acute and chronic pain settings to address myofascial pain syndromes. Injections can be achieved with or without imaging guidance, such as fluoroscopy and ultrasonography. However, the use of imaging in years past has been recommended to improve patient outcomes and safety. Injections can be performed utilizing no injectate (dry needling) or involve the administration of LAs, botulinum toxin, or corticosteroids. A proper history and physical examination of the patient and imaging studies may help identify the correct myofascial pain syndrome and aid in developing an appropriate treatment strategy for these very common conditions.

Key Points

- A trigger point is the hallmark of myofascial pain syndromes, which may be treated with physical therapy and injections.
- The growing accessibility of ultrasound has improved available options for anesthesia and analgesia to the thoracic region and the piriformis, iliopsoas, and scalene muscles.
- Piriformis syndrome may mimic L5–S1 radiculitis, although the pain originates in the buttock. There are signs and symptoms that aid in the diagnosis of the syndrome. Injections of LA and steroids may ameliorate the pain. If relief from a series of local anesthetic/steroid injections is transient, botulinum toxin can be injected.
- Signs and symptoms of iliopsoas muscle pain are usually nonspecific. Diagnostic/prognostic local anesthetic injections may be performed, followed by botulinum toxin injection.
- The diagnosis of neurogenic TOS can be made from the patient's symptoms, physical examination, electromyographic findings, and imaging (also to rule out other pathologic conditions). LA injections into the anterior and middle scalene muscles are preferably performed under ultrasound guidance. A series of LA injections or botulinum toxin injections may be performed; first rib resection and scalenectomy may result in long-term benefits.
- ESPB is a regional technique first described in 2016 that is used to provide analgesia to the thoracic wall. Although the mechanism of LA spread and consistency of analgesia achieved are still under investigation, it is an attractive option because it can be performed on fully anticoagulated patients in whom neuraxial techniques are contraindicated.
- Truncal fascial plane blocks such as PECS II, SAPB, QL block are other ultrasound guided options for providing analgesia to the thorax.
- The injections should be part of a multi-disciplinary treatment program that includes physical therapy.

Minimally Invasive Procedures for Vertebral Compression Fractures

MITHUN NAMBIAR, LEE-ANNE SLATER, JOSHUA A. HIRSCH, RONIL V. CHANDRA, JULIAN MAINGARD

One in two women and one in five men aged >50 years will experience an osteoporotic fracture. These can result in substantial patient pain, morbidity, and healthcare utilization. A new osteoporotic vertebral fracture occurs every 22 s; 1.4 million occur worldwide every year.[1] The majority are asymptomatic or result in tolerable symptoms, with only a third of patients with new fractures seeking medical attention.[2] For the vast majority, acute back pain symptoms subside over a period of six to eight weeks as the fracture heals.[3]

Vertebroplasty and kyphoplasty are minimally invasive image-guided procedures that involve the injection of polymethylmethacrylate (PMMA) into a fractured vertebral body (Fig. 69.1–69.2). Most of these vertebral augmentation procedures are performed for a small subset of patients with symptomatic osteoporotic compression fractures that fail to respond to conservative medical therapy. Failure of medical therapy is variably defined but can be considered if pain persists at a level that severely compromises mobility or activities of daily living despite analgesic therapy or if unacceptable side effects such as confusion, sedation, or constipation occur as a result of medication doses required to reduce pain to tolerable levels. The first report of vertebral augmentation, published in 1987, was for neoplastic disease.[4] As survival rates in cancer patients continue to improve, symptomatic neoplastic vertebral fractures or neoplastic vertebral tumors have increased in prevalence. A selected sub-group of these patients, particularly those with symptomatic fractures from multiple myeloma and metastasis that fail to respond to conservative therapy, also benefit from vertebral augmentation.[5] The primary goal of vertebral augmentation is pain relief and enhanced functional status with the secondary goals of vertebral body stabilization in cases of fracture. Emerging population level evidence suggests a mortality benefit in patients treated with vertebral augmentation compared to conservative therapy.[6]

Indications and contraindications for vertebral augmentation are summarized in Box 69.1.

Conservative Medical Therapy

Conservative therapy aims to reduce pain (with analgesics and/or bed rest), improvement in functional status (with orthotic devices and physical therapy), and prevention of future fractures (with vitamin D and calcium supplementation and bisphosphonate therapy).

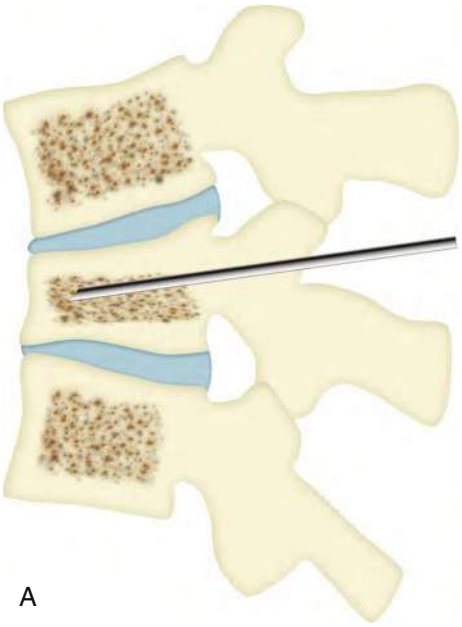
While conservative management for those with mild pain and no limitation of function is appropriate, conservative treatment for those with more severe pain or limitation of function is not benign. In this cohort, conservative therapy often involves a period of bed rest, which may lead to undesirable side effects such as bone mass and muscle strength loss, decubitus ulceration, and venous thromboembolic disease (VTE), all of which can prolong the recovery period and result in loss of independence. Bone loss occurs at approximately 2% per week,[7] muscle strength reduces by 10%–15%,[8] and infectious complications can lead to septicemia and osteomyelitis. Reduced lung capacity can also predispose patients to pneumonia. Moreover, the presence of fracture or malignancy combined with bed rest elevates the risk of VTE in this cohort. Overall, complications of prolonged bed rest, combined with opioid narcotic use and associated side effects, can result in a vicious cycle of physical deconditioning, poor nutrition, and a subsequent increased risk of vertebral insufficiency.

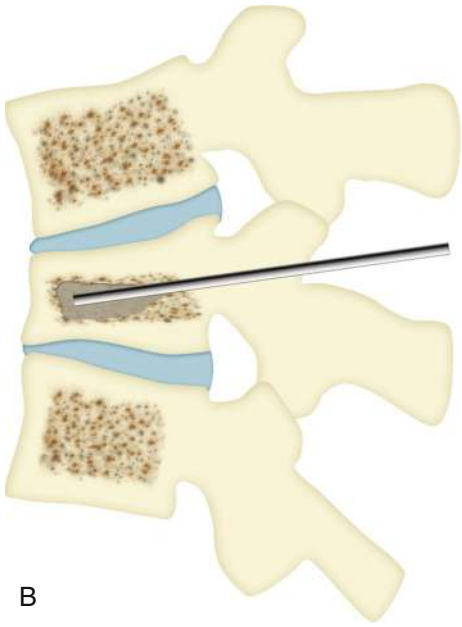
Technical Aspects

The evaluation of patients for vertebral augmentation should identify patients likely to benefit from vertebral augmentation, as well as screen for contraindications. The decision to proceed with treatment must be based on a good history, physical examination, appropriate laboratory evaluation, and imaging, as summarized in Box 69.2.

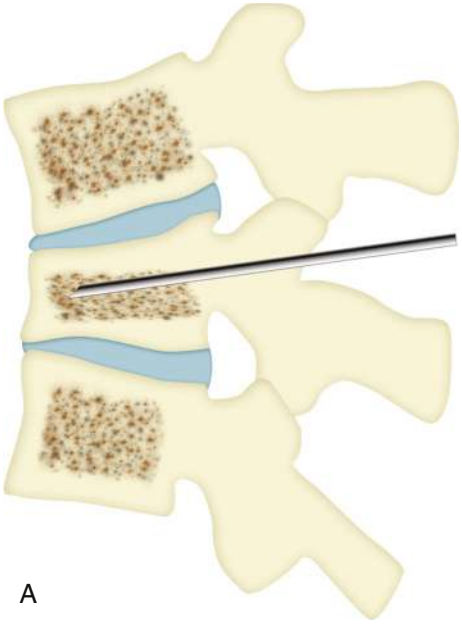
Sedation

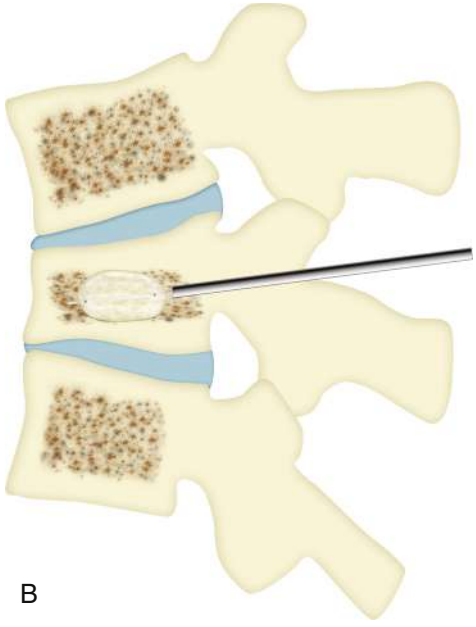
Analgesia is typically necessary for vertebroplasty and kyphoplasty. In most cases, this is achieved with a combination of local anesthetic (e.g. lidocaine with bicarbonate or bupivacaine) and moderate sedation (intravenous midazolam and fentanyl). In some cases, the preferred approach is to utilize general anesthesia to provide adequate comfort and safety, particularly in patients who a However, having the patient awake allows feedback (e.g. increasing pain and neurologic dysfunction) that can alert the operator to potential complications. In all cases, continuous monitoring was performed with a minimum electrocardiogram (ECG), blood pressure measurements, and pulse oximetry. Drug delivery and monitoring are performed by anesthesiologists, nurse anesthetists, or certified nursing personnel. In patients with substantial preexisting respiratory or cardiac disease, an anesthesiologist can be asked to evaluate the patient and determine if monitored anesthesia care is warranted. The patient should not eat or drink for at least 4–6 h prior to the procedure.

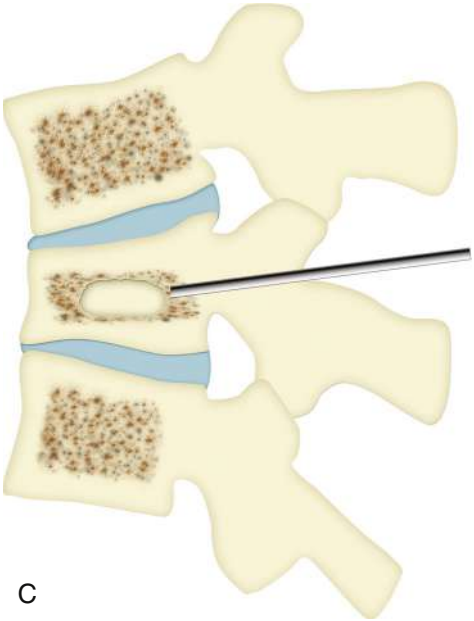


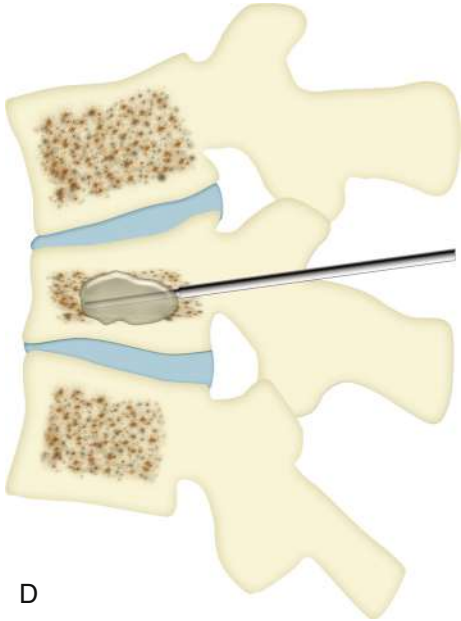


• **Figure 69.1** Vertebroplasty involves the insertion of a needle into the vertebral body **(A)** with subsequent delivery of cement **(B)** into the vertebral body.









• **Figure 69.2** Kyphoplasty. Once vertebral body access is achieved **(A)**, the inner stylet is removed, and a balloon tamp inflated within the vertebral body **(B)** to create a cavity within the bone **(C)** into which cement is delivered **(D)**.

• BOX 69.1 Indications

1. Treatment of symptomatic osteoporotic vertebral body fractures that are refractory to conservative medical therapy
2. Treatment of symptomatic vertebral bodies that are refractory to medical therapy weakened or fractured because of neoplasia

Absolute contraindications

1. Active systemic infection, in particular, spinal infection
2. Uncorrectable bleeding diathesis
3. Insufficient cardiopulmonary health to safely tolerate sedation or general anesthesia
4. Myelopathy resulting from fracture retropulsion or epidural tumor extension
5. Known allergy to bone cement

Relative contraindications (should only be treated by experienced practitioners)

1. Marked loss of vertebral body height (greater than 75% height loss)
   a. Makes the procedure more difficult because there may be little space for cannula placement.
2. Vertebroplasty above T5
   a. Challenges because of the small size of the vertebral bodies and pedicles. The shoulders often limit fluoroscopic imaging at these levels.
3. Severe osteopenia resulting in poor visualization of osseous structures on fluoroscopy
   a. Increases the risk of improper needle placement and cement leakage. This can be overcome with computed tomography (CT) guidance.
4. Disruption of the posterior cortex
   a. Increases the risk of posterior cement leakage and, therefore, the risk of the spinal cord or nerve root compression. This phenomenon is frequently observed in burst fractures and neoplasms. The integrity of the posterior cortex was best evaluated using CT scanning.
5. *Substantial canal narrowing* (without neurologic dysfunction)
   a. Increases the risk that even a small amount of cement leakage will produce neurologic compromise.
6. Retropulsion of fracture fragments
   a. Risk of further canal compromise with vertebral augmentation, particularly if the posterior vertebral body wall is unstable.
7. Epidural extension of tumor
   a. Pathologic fractures result in significantly higher rates of spinal canal leakage than osteoporotic fractures.

Patient Positioning

Prone or oblique prone is the ideal patient position for thoracic and lumbar procedures. Besides the clear advantage of easy access, this position with proper cushion support under the upper chest and lower abdomen maximizes extension of the fractured segments, promoting kyphosis reduction.[9] The patient's arms should be placed sufficiently toward the head to keep them out of the path of the fluoroscope. Analgesia should be considered prior to placement on the table, as this part of the procedure may be quite painful. Care must be taken when transferring patients who are aged, osteoporotic, or with myelomatous infiltration, as this may result in new rib or vertebral fractures.

Antibiotic Prophylaxis and Skin Preparation

The risk of infection is minimized by using standard operating room guidelines for sterile preparation of the skin, draping, operator scrub, and sterile gowns, masks, and gloves. There is little data to support or oppose antibiotic administration, but there are reports of spine infections after these procedures,[10,11] and the presence of PMMA makes these infections difficult to treat successfully. We routinely use antibiotic prophylaxis prior to skin incision, which includes intravenous antibiotics such as cefazolin (1 g) or clindamycin (600 mg if there is a penicillin allergy). Alternatively, polymethylmethacrylate (PMMA) may be mixed with an antibiotic, such as tobramycin (1.2 g) or vancomycin, as the cement is being prepared; this practice has diminished in favor of intravenous antibiotics.

Needle Placement

The most important aspect of needle placement is to keep the needle trajectory lateral to the medial cortex and superior to the inferior cortex of the pedicle. This prevents entry of the needle into the spinal canal or neural foramen. The needle may be placed via a transpedicular or parapedicular approach. The transpedicular approach takes the needle from the posterior surface of the pedicle, through the length of the pedicle, and into the vertebral body. The long intraosseous path protects the postganglionic nerve roots and other soft tissues. However, the pedicle configuration can limit the ability to achieve a final needle tip position near the midline. The parapedicular approach takes the needle along the lateral surface of the pedicle, penetrating the pedicle along its path or the vertebral body at its junction with the pedicle. This approach may permit a more medial tip placement, which can be useful during the treatment of levels with anatomically small pedicles, particularly in the thoracic spine.

For either approach, there are multiple potential image guidance strategies, an anteroposterior view or an end on ("down the barrel") view, with the latter technique employing ipsilateral oblique rotation of the image intensifier to place the fluoroscopy beam and needle tract parallel to each other.

1. Rotate the image intensifier (II) to a true AP position by aligning the spinous process midway between the pedicles (Fig. 69.3).
2. Change the craniocaudal angulation by bringing the pedicles to the midportion of the vertebral body. A lateral fluoroscope was used to aid in the determination of the correct craniocaudal adjustment required.
   a. For the end on view, rotate the II approximately 20° ipsilateral to the target pedicle so that the medial cortex of the pedicle is at the middle third of the vertebral body. The vertebra adopts the "Scotty dog" configuration. Place the needle so that it is "end on" to the image intensifier and appears as a dot.
3. Plan the trocar trajectory. For the AP and partial ipsilateral oblique views, the trocar entry position should be at the 3 o'clock position of the right pedicle or the 9 o'clock position of the left pedicle for the transpedicular approach. The view should be centered within the circle formed by the cortex of the pedicle. For the parapedicular approach, an entry position just lateral to the 3 or 9 o'clock positions of the pedicular cortex is the best.
4. The skin and periosteum were anesthetized with subcutaneous lidocaine or bupivacaine using a 22-gauge needle following the planned trajectory. A smaller gauge needle was used to assess and adjust the planned trajectory.
5. A small vertical skin incision was made (allowing easier craniocaudal needle angulation) and place the 11 or 13-gauge diamond-tip needle stylet (sheathed in a cannula).
6. The needle was advanced to the bone surface, making small corrections in the craniocaudal plane using the true lateral view (care is needed to angle the II so that a true lateral view

• BOX 69.2 Pre-procedural Workup

Identify those patients who will likely benefit from vertebral augmentation.
Screen for absolute contraindications.
Document failure of conventional medical therapy.

Symptoms

- Fractures may occur with little or no trauma.
- Deep pain with sudden onset
- Midline location
- Exacerbation by axial mechanical loading (worsening with standing or weight-bearing and often at least partially relieved by recumbency)
- Exacerbation by motion (especially flexion)
- Referred lateral radiation in a dermatomal pattern because of foraminal narrowing may be present.

Signs

- Point tenderness at the spinous process of fractured vertebra Local signs may be absent.
- Per Rad et al. up to 30% of patients may have subjective off-midline pain or tenderness over non-target vertebrae and still gain significant benefit.*
- Localization to a specific level if possible is important in targeting treatment in patients with multiple compression fractures, some of which may be healed and do not require treatment. In difficult cases, examination can be performed with fluoroscopic assistance to localize the pain to a specific anatomic level.
  Assess lower extremity neurologic function.

Laboratory evaluation

- Screening for infection, coagulopathy, and metabolic abnormalities
- Additional tests such as the performance of a urinalysis, electrocardiogram (ECG), and/or chest radiography are left to the discretion of the practitioner.

Imaging

- The role is to confirm the clinical diagnosis, identify and assess the acuity of the painful fracture, identify potential difficulties, and plan the procedure.
- Fracture imaging can be performed with magnetic resonance imaging (MRI) or nuclear scintigraphic bone scan to correlate symptoms with the vertebral level in question and confirm the acuity of the fracture.
- MRI sequences include short tau inversion recovery or T2-weighted sequences with fat saturation. These sequences identified marrow edema, distinguishing between acute and chronic fractures. MRI also distinguishes between benign osteoporotic and pathologic fractures, and assesses the degree of fracture retropulsion, epidural tumor extension, spinal canal compromise, and compression of the spinal cord or nerve roots. Fracture clefts appear as a linear band of T1 hypointensity and T2 hypo- or hyperintensity within the vertebral body. Fluid signal intensity should be interpreted with caution, as some studies demonstrate persistent signals many months after the known incident fracture.
- Nuclear scintigraphic bone scan or single-photon emission computed tomography (SPECT) combined with CT are the tests of choice. Acute fractures will take up the injected ^{99m}Tc-MDP tracer at much higher concentrations; CT evaluates the bony integrity and spinal contents. In patients with pathologic fractures, CT also helps define the extent of sclerosis and posterior wall osteolysis, which predicts increased technical challenges associated with the procedure.

*Rad AE, Kallmes DF. Pain relief following vertebroplasty in patients with and without localized tenderness on palpation. *AJNR.* 2008;29:1622-1626.

is obtained). For the parapedicular approach, the position at which the bone is encountered (i.e. at the junction of the pedicle and vertebral body) is more anterior in the lateral view.

7. Once in the bone, advance the needle with a drilling motion and controlled forward pressure or by carefully tapping the needle handle with an orthopedic mallet.
8. Kept II with a true AP view for needle advancement, unless the end on view is used, where the needle is kept as a dot through the initial placement through the pedicle. The needle must remain lateral to the medial cortex of the pedicle until it traverses the entire pedicle on the lateral view.
9. Once the needle has traversed the pedicle, the diamond-tip needle can be replaced with a straight bevel-tip needle or curved needle for better maneuverability (Fig. 69.4). The needle was advanced further using the lateral view to the anterior one-third to one-quarter of the vertebral body.

Additional Steps For Kyphoplasty

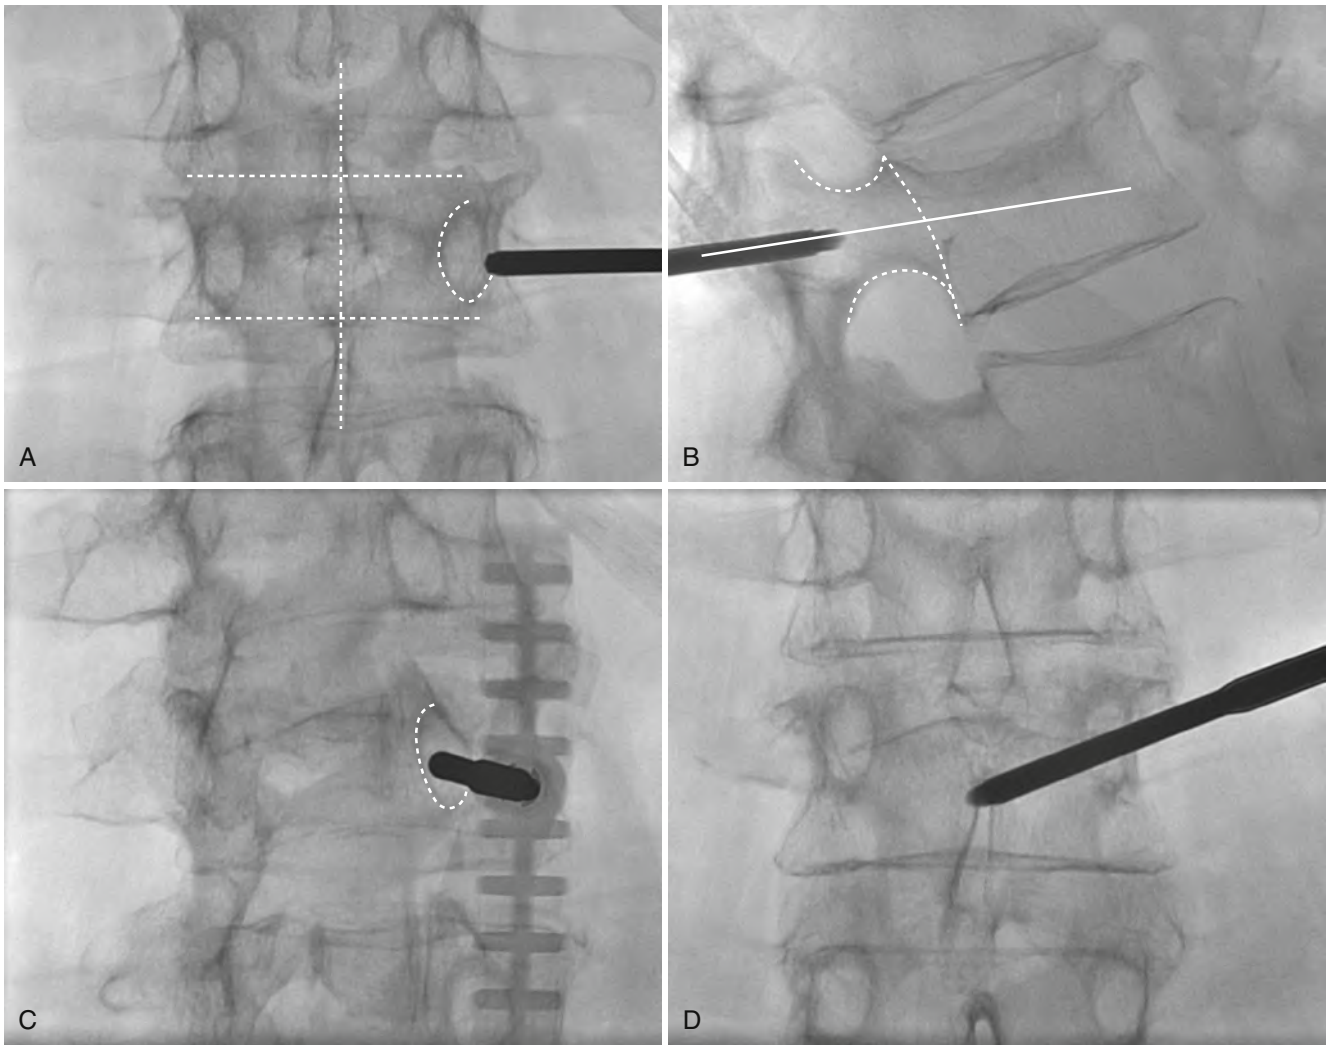
For vertebroplasty, PMMA is delivered through the cannula after the needle placement described above. Kyphoplasty involves additional steps of balloon tamp insertion and inflation to create a cavity within the bone (Fig. 69.5). For kyphoplasty, the cannula was pulled back to the posterior aspect of the vertebral body to allow for the insertion of the balloon tamp. After the needle stylet was removed, the balloon tamp was inserted through the cannula and slowly inflated with iodinated contrast. The balloon was attached to a locking syringe using a digital manometer (Fig. 69.6). Monitor the inflation both with the pressure transducer and intermittent fluoroscopy. Continue inflation until one of two conditions is met: the system reaches significant pressure or maximum balloon volume, or further inflation results in patient discomfort if performed with sedation. Balloon placement can be either unipedicular or bipedicular. Deflate and remove the balloon

Cement Placement

The consistency of the cement, when ready for injection, was similar to that of toothpaste. Wong et al. recommended a drip test in which the cement should ball up at the end of the needle and not drip downward, resulting in a cement that is slightly more viscous than toothpaste.[12] The working time varies from 10–20 min, depending on the temperature and the specific PMMA formulation being used. A variety of delivery systems are available for cement. These systems vary from a few 1 cc syringes with a spatula and a mixing bowl to self-contained delivery devices with automatic mixing. A screw-syringe injector with long, flexible delivery tubing has the advantage of minimizing radiation exposure to the operator.[13]

Vertebroplasty

- After removing the needle stylet, the cannula was filled with saline to prevent pressurized injection of air and air embolus. The delivery system is connected to the cannula, and the cement is injected slowly.
- The monitor was carefully monitored with fluoroscopic imaging to ensure that the cement remained within the vertebra.



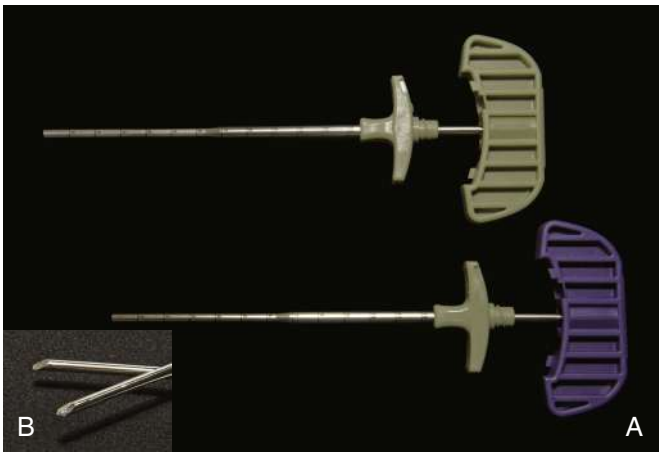
• **Figure 69.3** Initial positioning for needle trajectory for transpedicular approach. **(A)** Anteroposterior (AP) fluoroscopic image. The image intensifier is first rotated to a true AP position, aligning the spinous process midway between the pedicles (*vertical dotted line*). The craniocaudal angulation is changed to bring the pedicles to the midportion of the vertebral body (*horizontal dotted lines*). **(B)** Lateral fluoroscopic image. The image intensifier is rotated to a true lateral position by overlapping the cortices of both pedicles and ensuring that the posterior margin of the vertebral body is aligned (*dotted lines*). Note that the entire needle trajectory within the vertebral body should be considered during initial transpedicular access for optimal final needle position (*solid line*). **(C)** Near "end on" projection during needle placement with preservation of the medial and inferior cortices of the pedicle. Note that the "T-grip" needle handle can obscure bony landmarks, and slight II rotation may be required. **(D)** Midline needle position achieved with unilateral transpedicular approach, achievable with larger target pedicles, typically in lumbar vertebrae.

Posterior or posterolateral leakage could result in irritation or damage to the spinal cord or nerve roots and should be avoided. New pain with a different character should prompt immediate procedural pauses and additional views.

- The endpoints for cement injection include the passage of cement beyond the marrow space and/or cement reaching the posterior quarter of the vertebral body on the lateral projection. In the case of cement leakage, one may wait for 1–2 min to allow the cement to harden and then reinject to see if the cement is redirected within the vertebral body.[14] Ideally, the cement will extend across the midline and to the opposite pedicle by the end of the injection. However, the optimal amount of cement volume injection remains controversial.
- The final portion of the cement was delivered by inserting the needle stylet. Alternatively, the cement may be allowed to harden, and the needle is removed with a gentle rocking motion to ensure that the cement within the cannula separates at the cannula tip. However, care should be taken not to fracture the vertebral pedicle.

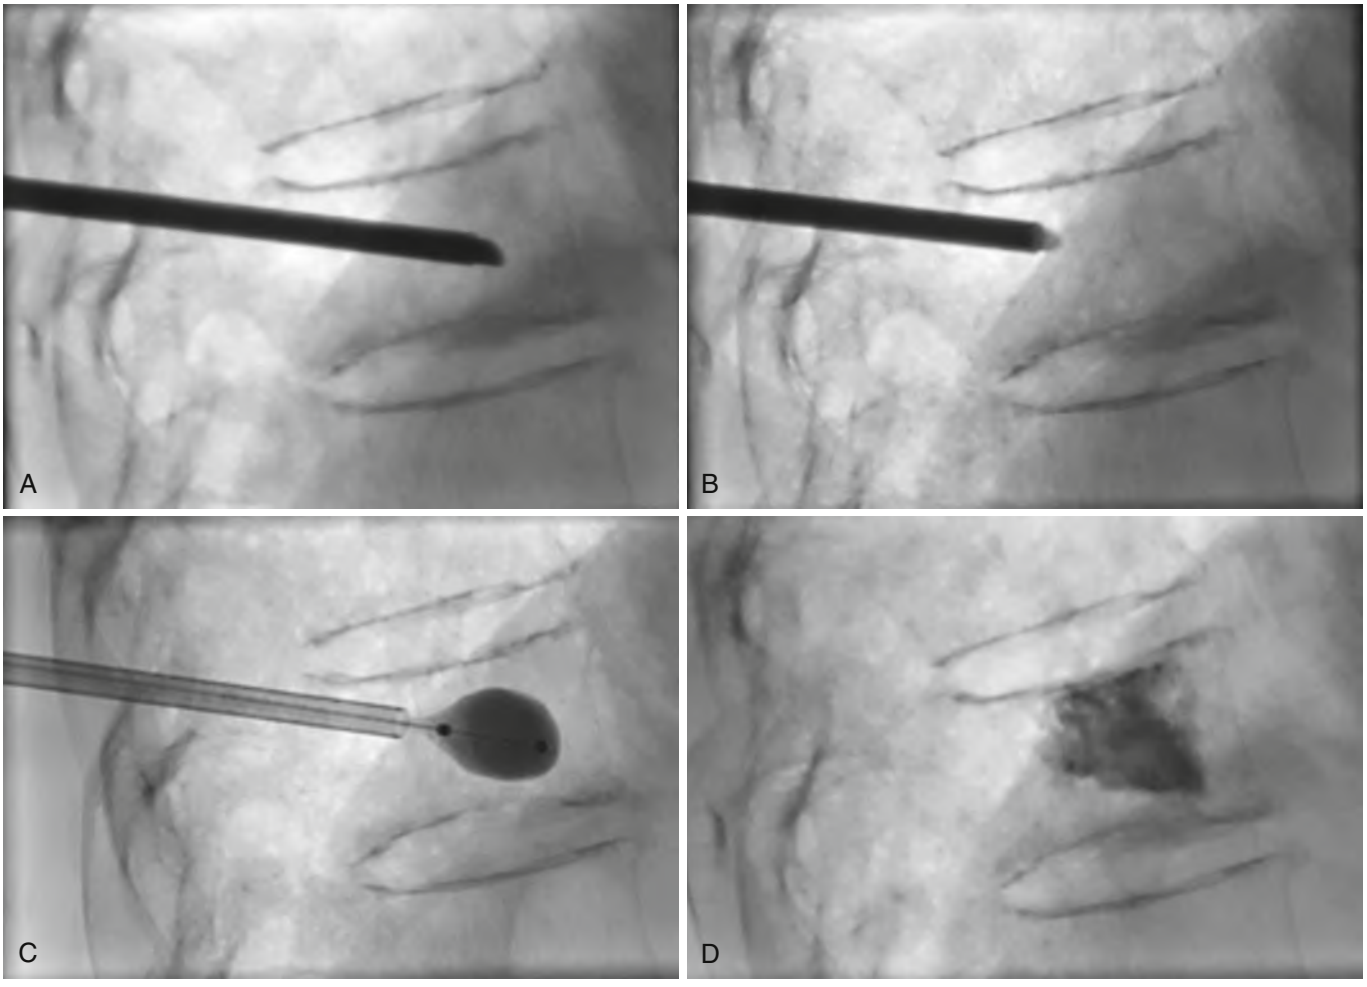
Kyphoplasty

- The cavity created by the balloon tamp allows for the injection of a more viscous cement than that typically used for vertebroplasty. The cavity and more viscous cement theoretically minimize the risk of cement extravasation. Sufficient time is allowed for the cement to reach a doughy consistency, with loss of the "sheen" of the initially mixed cement.
- Many practitioners use manual bone filler devices to inject cement, although injector systems can be used. The delivery



• **Figure 69.4** Photographs of typical vertebroplasty needles. **(A)** Typical co-axial vertebroplasty needle—the inner stylet locks into the outer cannula. Note the large handles to facilitate insertion and removal from the bone. Manufacturers may use different colored or marked handles to indicate the type of needle tip (magnified in **B**) The beveled tip needle can be used to facilitate needle direction along a desired trajectory.

• **Figure 69.6** Balloon kyphoplasty. The balloon is attached to a digital manometer that allows assessment of balloon pressure. Note the long flexible tubing that allows the operator's hands to remain out of the primary radiation beam during the fluoroscopic assessment of balloon inflation.



• **Figure 69.5** Additional steps for kyphoplasty. **(A)** Lateral fluoroscopic image. The unipedicular needle has been placed into the anterior thirds of the T10 vertebral body. **(B)** The needle is withdrawn to the posterior third of the vertebral body and the inner stylet removed. **(C)** The balloon tamp is introduced into the needle tract and inflated to create a cavity within the bone. **(D)** Cement opacifies both the cavity and extends into adjacent trabecular bone.

system was connected to the cannula, and the cement was slowly injected under fluoroscopic guidance. The cement fills the cavity from anterior to posterior, matching or slightly exceeding the volume of the inflated balloon tamp.

Controversies and Special Topics

Bipedicular Versus Unipedicular Approach

Vertebroplasty and kyphoplasty can be performed with the placement of bilateral needles or a single needle.[15] In either case, the goal is to place cement across the midline within the vertebral body—we use the placement of PMMA to the opposite pedicle as our general landmark. Therefore the use of a single needle with a relatively medial needle tip position is sufficient in many cases. If a unilateral approach is attempted during kyphoplasty and balloon expansion does not cross the midline, a second system may then be placed on the other side depending on the distribution of the cement fill. In many cases, the cement fill will continue across the midline, obviating the need for a second needle. Moreover, hemivertebral fill (cement traverses <10% of the contralateral unfilled vertebra) has been shown to reduce pain and improve function without increasing the risk of fracture.[16]

There is no statistically significant difference in pain relief achieved between the unipedicular and bipedicular vertebroplasty,[17] or kyphoplasty.[18] There are advantages to each approach. The advantages of a unipedicular approach include a decrease in procedure time and elimination of the risk associated with a second needle placement. A unipedicular approach is also associated with lower rates of cement leakage.[19] The major advantage of a bipedicular approach is that access is typically transpedicular with a less aggressive lateral-medial approach that may result in less paravertebral vessel and nerve injury and a potential biomechanical advantage to bilateral cement delivery.

Volume of Cement Injection

The optimal volume of cement is a matter of controversy, with some practitioners advocating injection of maximal amounts of cement to completely fill the vertebral body and others advocating lower cement volumes with an emphasis on safety. The theoretical goal of more complete filling is to achieve restoration of biomechanical strength within the vertebral body to prevent re-fracture without creating excess stiffness that may be transmitted to the adjacent levels. Based on an in vitro biomechanical study, Mathis et al. recommend cement filling of 50%–70% of the residual volume of the vertebral body.[20] However, much smaller amounts of cement (as little as 0.5 cc) appear to result in similar clinical outcomes, in terms of the primary goal of pain relief, when compared to larger volume injections, with no association between the volume of cement injected and the clinical outcomes of pain and medication use.[19] The decreased risk of cement extravasation with smaller volume injections and meticulous attention to the end of injection criteria outlined above recommends a smaller cement volume approach.

Vertebra Plana

When the vertebral body loses 70% of its original height, safe needle placement becomes a challenge. According to Stallmeyer et al., at least 8 mm of residual height is required for cannula placement.[21] The vertebra plana often adopts a bow-tie configuration, where the center is compressed the most. This usually requires a lateral needle position with the placement of bilateral needles.[22] Only a small amount of cement is needed to achieve pain relief.[23] If there is a cystic cleft within the fracture (Kummel disease), the needle may be placed near the midline within the cleft with the hopes of height expansion during needle placement and cement injection.

Fractures With Intraosseous Vacuum Phenomenon (Kummel Disease)

The intraosseous vacuum phenomenon is thought to be related to osteonecrosis. A fluid-filled cleft seen on magnetic resonance imaging (MRI) is an equivalent finding. Pain in this setting is believed to arise from the motion between the unhealed fracture fragments. Sometimes, this motion can even be seen under fluoroscopy as the height of the vertebral body changes with respiration. Prone positioning during the procedure promotes height restoration because of traction placed across the vertebral body. The needle should be placed into or as close to the cleft as possible so that the cement will fill the cleft. Vertebral augmentation yields significant rates of pain relief in the setting of intraosseous vacuum phenomenon,[24,25] and in our experience, can provide considerable height restoration. Keeping the patient prone for 15–20 min after the cement injection is important to allow the cement to harden within the cleft before moving the patient off the fluoroscopy table.

Malignant Fractures With Posterior Wall Osteolysis or Epidural Tumor Extension

Although vertebral augmentation may be performed in the setting of posterior wall osteolysis or epidural tumor extension, there should be a heightened awareness of the potential neurologic complications related to the epidural extension of cement or posterior displacement of the tumor. In a study of 51 patients with a vertebral lesion with epidural extension treated with vertebroplasty, 30% had pre-procedural symptoms of partial or complete cord compression/cauda equina syndrome.[26] These patients were terminally ill and not surgically decompressed because their paraplegia was deemed irreversible (present for greater than one month or associated with spinal cord atrophy) or their general condition contraindicated the surgery. Although no further clinical deterioration was observed in this subgroup after vertebroplasty, one of the 36 patients without neurologic symptoms developed cauda equina syndrome two days after vertebroplasty and required surgical decompression.[26] Any cement leakage (as detected on post-procedure computed tomography [CT]) occurred in 62%, with half of these leaks into the epidural space. Importantly, cement extension beyond the confines of the vertebral body but within the epidural tumor was still classed as a leak.[27] Nonetheless, the case mentioned above was the only symptomatic cement leak. No systemic complications were observed. Analgesic efficacy, based on 50% or greater improvement in pain as compared with baseline, was impressive—94% (48 of 51 patients) at day one, 86% (31 patients) at one month, 83% (19 patients) at six months, and 92% (11 patients) after one year (data are from surviving patients).[26] Safeguards to prevent complications in this cohort included performing the procedure with the patient awake (new pain may be the first sign of dangerous cement leakage) and more-modest cement injection than routine cases. Limiting the cement to the anterior two-thirds of the vertebral body may be a good rule of thumb, as well as injection of thicker cement, which may reduce the risk of epidural cement leakage.[28]

Safety of Multilevel Treatment

Patients presenting with vertebral augmentation may have multiple fractures that require treatment. Ideally, all levels are treated at one time. However, treating an excessive number of levels in a single session raises many concerns, including PMMA toxicity, difficulty for the elderly to lay prone and cooperate for the extended amounts of time this would require, discomfort post-procedurally related to multiple needle placements, and fat emboli being extruded from the marrow during the cement injections. There have been two reported deaths in patients who received vertebral augmentation at eight or more levels.[29] While there are no established guidelines, a good rule of thumb is to treat a maximum of three levels per session.[30,31]

Outcomes

The mechanism by which vertebroplasty and kyphoplasty relieve pain is uncertain.[32] Hypotheses include mechanical stabilization of mobile fracture fragments, thermal or chemical neurolysis, or inherent tumoricidal or cytotoxic effects on malignant fractures. A cadaveric study has also demonstrated new bone formation after PMMA injection.[33]

There are now four placebo-controlled randomized controlled trials published in the *New England Journal of Medicine, The Lancet*, and the *British Medical Journal*. These studies have demonstrated mixed results regarding pain outcomes in vertebroplasty. These trials employed a sham procedure in the placebo arm. This involves the injection of local anesthetic into the periosteum of the pedicle,[34] local anesthetic injections combined with the passage of a 13-gauge needle to rest on the lamina,[35,36] or subcutaneous local anesthetic only with needle insertion and tapping on the needle with manual skin pressure.[37]

Two highly publicized placebo-controlled randomized clinical trials in the *New England Journal of Medicine* found that there was no significant reduction in pain or pain-related disability in patients undergoing vertebroplasty compared to the sham procedure.[34,36]

The INVEST trial (NEJM) included 131 patients, with 68 patients randomized to vertebroplasty and 63 to the sham procedure.[34] Although, at one month, there was a trend toward a higher rate of clinically meaningful improvement in pain (30% decrease from baseline), there was no statistical difference in pain scores, back pain-related disability, or quality of life.[34] Buchbinder et al. (NEJM) studied 78 patients, with 38 patients randomized to vertebroplasty and 40 to the sham procedure.[36] After the procedure, both groups had similar improvements in pain, physical functioning, and quality of life. There were no significant differences between the groups at one week, one month, three months, and six months of follow up.[36]

These reports contrast with retrospective case series and conservative controlled trials that had documented impressive rates of pain relief from these procedures.[38–41] The NEJM trials were criticized for potentially including patients with chronic fractures of up to 12 months in duration. The average back pain duration was 18 weeks in the INVEST, with one-third of all patients randomized having pain for greater than six months. The Buchbinder trial included four patients randomized after six months. In the INVEST trial, marrow edema on MRI or increased uptake on bone scanning was only required for fractures of an uncertain age (rate of usage was not reported); in the Buchbinder trial, MRI demonstrating marrow edema and/or a fracture line was required. However, the determination of bone marrow edema was not described. Further criticisms include inconsistent use of physical examination, difficulties in recruitment, and the absence of a control group without intervention.

Subsequently, the VERTOS II investigators[40] performed a blinded randomized trial randomizing 202 patients with severe back pain for six weeks or less, focal tenderness at the fracture level, and MRI demonstrated bone edema, equally into vertebroplasty or conservative arms. All patients were prescribed analgesics that were individually titrated, bisphosphonates, calcium, and vitamin D supplements. Vertebroplasty was performed at a mean of 5.6 weeks after symptom onset. There were statistically significant reductions in mean visual analog scores (VAS) in favor of vertebroplasty at one month ($p<0.0001$), with the benefit persistent at one year ($p<0.0001$).[40] There were significant reductions in the use of drugs compared with conservative treatment at one day ($p<0.0001$), one week ($p=0.001$), and one month ($p=0.033$).[40] Moreover, significant pain relief (VAS reduction of ≥ three points) was achieved earlier and in more patients after vertebroplasty (29.7 days; 95% confidence interval [CI] 11.45–47.97) than with conservative treatment (115.6 days, 95% CI 85.87–145.40).[40]

The Vertebroplasty for Acute Painful Osteoporotic Fractures (VAPOUR) trial published in 2016 compared early vertebroplasty with sham procedure for patients with severe acute pain.[37] Forty-four percent (44%) of patients achieved the primary outcome of a numerical rating scale of less than four by 14 days compared to 21% in the sham group ($p=0.011$). This treatment effect was durable for six months. Additionally, there were greater reductions in the Roland-Morris Disability Questionnaire (RDQ) and QUALEFFO scores favoring vertebroplasty. Compared to the earlier INVEST and Buchbinder et al. a higher proportion (57%) of patients were hospital inpatients, with most fractures being less than six weeks old, 80% of which were less than three weeks old. In addition, the average PMMA volume injected was higher than in earlier trials, although the correlation between cement volume and pain outcomes remains a point of contention. The median length of admission was reduced by 5.5 days after vertebroplasty. Anatomic outcomes were also superior, with 30% greater vertebral height preservation compared with the sham procedure.

VERTOS IV, published in 2018, is the most recent randomized controlled trial (RCT) comparing vertebroplasty for vertebral fracture with a sham procedure.[42] Similar to Buchbinder et al. and INVEST trials, there was no overall benefit in pain outcomes with vertebroplasty compared to the sham procedure. The trial included patients with fractures of up to nine weeks old. Both groups had clinically and statistically significant reductions in pain and improved quality of life up to 12 months. However, there were no statistically significant differences between the groups. VERTOS IV only included outpatients, with a mean fracture duration of 6.1 weeks, compared to 2.1 weeks for the VAPOUR trial.[37] Furthermore, only 25% of fractures in VERTOS IV were less than four weeks old. This implies that fracture chronicity and severity are important in patient selection. In this data set, vertebroplasty was not a risk factor for further vertebral fractures.[42]

The FREE trial was another large trial supporting the efficacy of vertebral augmentation.[43] A total of 300 patients were randomized to receive kyphoplasty (n=149) or conservative therapy (n=151). Fractures had a minimum height loss of 15% and MRI evidence of edema. Although both osteoporotic and malignant fractures were included, 96% of fractures were related to primary osteoporosis. At randomization, fractures were a mean of six weeks

old. Kyphoplasty was performed at a mean of seven days after randomization, and patients with fracture ages greater than three months were excluded. The primary outcome measure was the mean short-form (SF)-36 Physical Component Summary (PCS) scale, a validated global quality of life measure weighted on physical abilities.[43] There were statistically significant improvements in the SF-36 PCS scores in favor of kyphoplasty at one month (p<0.0001) and 12 months (p=0.0004). There were greater reductions in the RDQ scores in favor of kyphoplasty at one month (p<0.0001) and 12 months (p=0.0012).[43] Patients in the kyphoplasty group also had greater reductions in back pain scores, lower rates of narcotic analgesic use, and fewer days of restricted activity compared to those managed with conservative therapy.[43] By 12 months, the differences between the conservative therapy and kyphoplasty groups were diminished, most likely because of fracture healing.[43]

Further RCT evidence comes from the Cancer Patient Fracture Evaluation (CAFE) study that reported the benefit of kyphoplasty over conservative therapy for malignant painful vertebral compression fractures.[5] CAFE recruited 134 patients with malignant fractures at 22 sites in Europe, the USA, Canada, and Australia. Approximately 50% of patients had breast, lung, or prostate cancer metastasis, and 40% had multiple myeloma-related fractures. Patients with osteoblastic tumors, primary bone tumors such as osteosarcoma, or plasmacytoma at the index compression fracture were excluded. Patients were randomly assigned to either kyphoplasty (n=70) or conservative therapy (n=64). The median estimated symptomatic fracture age was 3.5 months (IQR 1.2–6.8); 87 of 129 patients had edema on MRI. The primary endpoint was back-specific functional status, as measured by the RDQ at one month. There was a statistically significant reduction in the RDQ scores in favor of kyphoplasty at one month (p<0.0001).[5] The mean RDQ score in the kyphoplasty group reduced from 17.6 at baseline to 9.1 at one month; the mean score in the control group changed from 18.2–18.0; the kyphoplasty treatment effect on RDQ was -8.4 points at one month (95% CI -7.6 to -9.2; p<0.0001). Patients in the kyphoplasty group also had greater reductions in back pain, and both groups had a baseline mean back pain score of 7.3; the mean score at seven days was 3.5 compared with 7.0, in the conservative arm (p<0.0001), which remained significant at one month (p<0.0001). In addition, there were significant reductions in analgesic use, days of bed rest, improvement in quality of life (measured by SF-36 PCS), and Karnofsky performance status in the kyphoplasty group compared to the conservative arm. These improvements in pain, overall functional status, and quality of life continued for 12 months of the study period.[5]

Concerning long term outcomes, there are few data. Two-year outcome data from the FREE trial revealed that although there were no statistically significant differences in the SF-36 PCS or RDQ scores at 24 months, there remained a statistically significant reduction in back pain scores for patients in the kyphoplasty arm compared to conservative therapy at 24 months (p=0.009).[44] A similar benefit was also reported at 36 months following kyphoplasty in a smaller prospective non-randomized study of 60 patients.[45]

For the prevention of height loss, VERTOS IV demonstrated that vertebroplasty is protective, with significant further vertebral height loss seen in 8% in the vertebroplasty group versus 45% in the sham group (p=0.001) (odds ratio=9.84 [4.08–23.73]).[42] This has implications for further morbidity in an otherwise susceptible elderly population.

For height restoration, the results are less dramatic. Studies have shown that the magnitude of partial height restoration after vertebroplasty ranges from 2.5–8.4 mm and is similar to that reported after kyphoplasty.[46] However, many of these studies did not report the incidence of fracture clefts. Overall, height restoration appears to relate to the dynamic mobility of fracture fragments from the presence of a fracture cleft.[47] Dynamic mobility refers to a change in vertebral body height during changes in position, typically an increase in vertebral body height with supine or prone positioning compared to the erect position, which typically occurs in fractures at the thoracolumbar junction (T11–L1), where the relatively fixed thoracic spine joins the more mobile lumbar spine. A study of 65 vertebral compression fractures referred for vertebroplasty revealed dynamic mobility in a third of treated levels.[48] All fractures that were mobile had a fracture cleft, and all fractures that were fixed did not have a fracture cleft. Fractures that were mobile had an average absolute increase of anterior vertebral height of 8.4 mm (range, 2.0–17.4 mm) and decreased kyphosis angle of 7.2° (40%) after vertebroplasty. There was no height restoration or kyphosis correction in fixed fractures.[48] In general, restoration of vertebral body height and kyphosis correction may be desirable to improve postural endurance, reduce abdominal crowding, and improve overall pulmonary capacity. However, it remains unclear whether these results have clinical significance.[46]

Mortality Benefit

Osteoporotic vertebral compression fractures can result in deformity and have been associated with decreased pulmonary function as well as increased hospitalization and mortality.[49,50]

Several studies have investigated the potential for mortality benefit in patients undergoing vertebral augmentation.[51–53] A recent meta-analysis of more than two million patients with osteoporotic vertebral compression fractures demonstrated the benefit of vertebral augmentation over conservative therapy.[6] Those who underwent vertebral augmentation were 22% less likely (pooled hazard ratio [HR] 0.78, 95% CI 0.66–0.92, p=0.003) to die at up to ten years following treatment than those managed conservatively. Reduced pain, vertebral height loss, and kyphotic deformity resulting in improved mobility and pulmonary function is a likely cause of the decreased mortality after vertebral augmentation.[50,54,55] Interestingly, balloon kyphoplasty demonstrated some benefit over vertebroplasty (HR 0.77, 95% CI 0.77-0.78, P<0.001 versus 0.87, 95% CI 0.87-0.88, P<0.001).[6] This may be associated with greater vertebral body height restoration in kyphoplasty compared to vertebroplasty that has been noted.[56,57]

Complications

With adherence to careful technique and optimal visualization, the risk of morbidity or mortality from vertebral augmentation is low (Box 69.3). For treatment of benign osteoporotic fractures, complication rates are approximately 1%.[31] Not surprisingly, they are higher for inexperienced practitioners or those attempting the procedure without adequate image guidance or cement opacification.[31] Major complications occur in less than 1% of the vertebroplasty RCTs.[58]

Similarly, in FREE, complications referable to kyphoplasty in the 149 patients treated were one soft tissue hematoma and one urinary tract infection.[43] Of note, almost all kyphoplasties performed in FREE were performed under general anesthesia, and in neither cohort were the rates of urinary catheterization reported.

• BOX 69.3 Potential Complications

- Infection (osteomyelitis, epidural abscess)
- Paraspinal hematoma
- Fracture (of rib, pedicle, or vertebral body)
- Failure to improve pain or worsening pain
- Pneumothorax (for thoracic levels)
- Cement leakage
  - Nerve or spinal cord damage resulting in paralysis or bowel/bladder dysfunction
- Pulmonary embolus (secondary to cement or fat emboli)
- Hypotension or depressed myocardial function (secondary to free methyl methacrylate monomer or fat emboli)
- Death from cardiovascular collapse or anaphylaxis to the cement

In our experience, both vertebroplasty and kyphoplasty can be performed with local anesthesia and conscious sedation in most cases, and urinary catheterization is not required.

The risks are greater for malignancy related fractures, with an overall complication rate of 5%–10% reported.[59] In the CAFE trial, of the 70 patients treated with kyphoplasty for malignancy related fractures, the only complications referable to kyphoplasty were one superficial wound infection and one patient with a cement leakage to the adjacent disc who had an adjacent fracture the day after the procedure.[5] There were no serious adverse events that were deemed device related. Notably, kyphoplasty was not performed on those who had a vertebral fracture morphology deemed unsuitable as determined by the treating physician. Thus patients with vertebral plana, comminuted fractures, fractures with posterior wall involvement, or those with epidural involvement, which would incur higher risk, were excluded.

The extraosseous passage of cement is an important complication during vertebral augmentation. For vertebroplasty for osteoporotic fractures, small amounts of cement leakage are very common, with 72% of treated vertebral bodies demonstrating cement leaks on post-procedural CT, with majority discal or into segmental veins; none were into the spinal canal.[40] All patients remained asymptomatic. One patient (1%) had an asymptomatic cement segmental pulmonary embolus.[40] Similarly, high rate of cement leakage was noted on same day CT scans in the VERTOS IV study (91%), of which 39% was in the perivertebral soft tissue and 8% in the spinal canal.[35]

For kyphoplasty, a cavity is created and will fill first, theoretically resulting in a lower rate of cement leakage.[60–63] In FREE, cement extravasation occurred in 27% of treated vertebrae. However, this was assessed with intraoperative fluoroscopy and postoperative radiographs.[43] Most were endplate or discal leakages; there was one foraminal leakage, none were into the spinal canal, and there were no cement embolisms. All patients remained asymptomatic.[43] In a small retrospective series with post-procedural CT, the rate of local leakage of bone cement was 87.5% (21/24) for percutaneous vertebroplasty and 49.2% (29/59) for kyphoplasty.[64]

Cement leaks are also common in pathologic fractures.[59,65,66] A retrospective study of CT-guided vertebroplasty for 331 malignant vertebral lesions revealed a local cement leak in 59 (194 of 331 vertebrae).[67] Although osteolysis of the posterior wall was evident in 49% (162 of 331 vertebrae), only 6% (15 of 331) of leaks were into the spinal canal through the posterior cortex. Pulmonary cement emboli were detected in 1 of 53 (2%) chest radiographs and 10 of 88 (11%) chest CT scans.[67] A large single-center study of 106 patients with multiple myeloma treated with vertebroplasty revealed CT detected cement extravasation in 23% of treated vertebrae, mainly into the perivertebral veins (85%) and epidural veins (9%). Cement emboli were detected in the lungs of five patients (5 %). All the leaks were asymptomatic.[68]

Although most extraosseous cement produces no symptoms or long term morbidity, even small amounts of PMMA adjacent to a nerve root, including cement within the foraminal veins, can produce radicular pain.[59] When radiculopathy is produced by cement leakage, the pain can be treated with nerve root block or systemic steroids. The need for surgical decompression is rare,[30] but may be necessary when there is sufficient foraminal cement to cause frank root compression or when sufficient cement has been placed in the spinal canal to cause cord compression or cauda equina syndrome.[26]

Post-procedure and Follow Up Care

Immediately following the procedure, manual compression was applied over the needle access sites for 5 min to promote clotting and prevent hematoma formation, which might increase post-procedural pain. Transfer to the stretcher using log roll precautions may be performed immediately after the procedure, except in the setting of a vertebral cleft where we keep the patient prone on the fluoroscopy table for 15–20 min. The patient was kept supine and flat in bed for 2 h followed by a further hour with the head of the bed at 30 degrees after the procedure. To alleviate immediate post-procedural pain, the patient may be administered 15–30 mg of IV ketorolac unless renal insufficiency is present. Most patients can be discharged on the same day, although more fragile patients may be observed overnight in the hospital. Assessment of the patient shortly after the procedure commonly reveals improvement in back pain. Often, the patient will discriminate a new procedure-related pain, which is typically treated with non-steroidal anti-inflammatory drugs and should resolve over 24–72 h. In the setting of clinical deterioration suspicious for cement leakage, cross-sectional imaging should be performed.

Post-procedural follow up of the patient is important. The patient should be reviewed in the near term (e.g. three weeks) to assess pain and mobility levels and the need for analgesia. It is important to counsel the patient to report any sudden increase in back pain or new back pain, as it may indicate a new fracture, and imaging should be performed. Notably, up to one-third of patients will suffer a repeat fracture within one to three years, with the greatest risk of steroid-induced osteoporosis.[69,70] Thus, prevention of future fractures is particularly important. While the vast majority of recurrent fractures occur at new levels, there is a small percentage of patients that suffer recurrent fracture at a previously treated level, and may gain pain relief from repeat vertebral augmentation.[71] This is said, caution should be taken when interpreting marrow edema at a previously treated level because, according to one study, normal MRI findings following vertebroplasty include persistent or progressive marrow edema at the treated level in up to one-third of patients and up to six months after the procedure.[72]

Summary and Conclusions

Vertebral augmentation can be effectively utilized in symptomatic osteoporotic vertebral fractures as well as symptomatic fractures or lesions secondary to neoplasia which are refractory to conservative medical therapy. The decision to proceed with vertebral

augmentation is influenced by patient history, physical examination, and laboratory evaluation, including advanced imaging such as MRI or nuclear scintigraphy. Serious complications of vertebral augmentation are low, between 1% and 2%. Four placebo-controlled RCTs have demonstrated mixed results for vertebroplasty. Other retrospective case series and conservative controlled trials have demonstrated positive results, highlighting the importance of patient selection in favoring vertebral augmentation.

Key Points

- Vertebral compression fractures are a common cause of pain and loss of independence in middle-aged and elderly individuals.
- Vertebroplasty and kyphoplasty are minimally invasive, image-guided vertebral augmentation procedures that involve the injection of polymethylmethacrylate (PMMA) into a fractured vertebral body that fails conventional medical therapy. The primary goal of augmentation is pain relief and enhanced functional status, with the secondary goals of vertebral body stabilization in cases of fracture.
- Emerging population level evidence suggests a mortality benefit in patients managed with vertebral augmentation compared to patients undergoing conservative management.
- High-profile randomized controlled trials demonstrated mixed benefits for vertebroplasty compared to sham procedures. However, patient selection criteria are heterogeneous between trials.
- Additional randomized controlled trials of vertebral augmentation versus conservative therapy for both osteoporotic and malignant fractures have demonstrated significant improvements in back pain, reduction in disability, and improvement in quality of life in favor of vertebral augmentation.
- Complications are rare and generally result from unrecognized extraosseous leakage of the injected PMMA. These include radiculopathy, paralysis, and pulmonary embolism. These risks can be minimized, and vertebral augmentation can be safely performed by experienced operators using high-quality imaging, preferably with biplane fluoroscopy.

Biopsychosocial Pre-screening for Spinal Cord and Peripheral Nerve Stimulation Devices

ANDREW J.B. PISANSKY, AJAY WASAN, MOHAMMED A. ISSA

Overview

Pain is a complex and serious medical condition, with estimates from the Centers for Disease Control and Prevention in 2016 showing 50 million (20.4%) United States adults experiencing chronic pain, among whom 19.6 million experience high impact pain that limits life or work activities.[1] Beyond the element of human suffering, there are enormous economic costs associated with chronic pain in terms of lost productivity and medical care. Among individuals who continue to work, common pain conditions alone (back pain, headache, arthritis, and musculoskeletal pain) may account for up to $61 billion in lost productivity annually in the United States alone.[2] According to statistics from the Institute of Medicine (2011), the societal cost of all chronic pain and related disability in the United States is $560–635 billion each year.[3] Gaskin and Richard[4] note that these annual costs for pain were greater than the annual costs for heart disease, cancer, and diabetes. The Institute of Medicine Report, "*Relieving Pain in America*"[3] has highlighted the urgent need to develop more cost effective approaches to pain management because the ever-increasing costs associated with current treatment approaches cannot be sustained. In parallel with trends showing increasing chronic pain, there has been considerable concern regarding the use of opioids to treat chronic pain, given their widespread use and potentially lethal side effects.[5] Therefore there is still an urgent need to develop opioid-sparing and cost effective methods for managing chronic pain, especially when it becomes intractable.

Over the past two decades, there has been an expanding role for neuromodulation procedures such as spinal cord stimulation (SCS) and peripheral nerve stimulation (PNS) as treatment options for intractable chronic pain. Traditional neuromodulation has been presumptively operated by Melzack and Wall's[6] *gate control theory of pain*, which proposes that the activation of low-threshold afferent nerve fibers decreases the response of dorsal horn neurons to unmyelinated nociceptors, thereby "closing the gate" to pain transmission from the spinal cord. Shealy, Mortimer and Rewick[7] were the first to apply this when they stimulated the dorsal columns to treat chronic, intractable cancer pain. Since that time, level 1 evidence has accumulated in support of implantable dorsal column stimulation to treat axial back pain, lumbar radiculopathy or neuralgia, and complex regional pain syndrome.[8] Proposed mechanisms for SCS depend on the modality but have included action at the dorsal column,[9] dorsal horn,[10] dorsal root ganglion,[11] and supraspinal sites.[12,13]

Neuromodulation of targets not amenable to neuraxial stimulation has focused on the use of semi-permanent and implantable PNS with a history nearly as long as that of dorsal column stimulation.[14,15] Nerve regions that are more easily accessed by PNS include the trigeminal nerve, occipital nerve, and subcutaneous peripheral nerves. Conditions for which PNS may be indicated include trigeminal neuropathic pain,[16] occipital neuralgia,[17] supraorbital neuralgia, residual limb, and phantom limb pain,[18] and inguinal neuralgia (although emerging technologies such as dorsal root ganglion stimulation may be appropriate for inguinal chronic post-surgical pain). Headache disorders, including migraines and cluster headaches, might also benefit from cranial forms of PNS.[19,20]

Successful results with SCS and PNS have been defined variously in clinical trials. Some investigators and practice guidelines identified greater than 50% relief of pain 12-months following implantation as a potential benchmark.[21,22] Although success rates vary widely from 40%–80%, conditions commonly treated by SCS include failed back surgery syndrome, painful peripheral vascular disease, neuropathic pain, multiple sclerosis (MS), and complex regional pain syndrome (CRPS, previously known as reflex sympathetic dystrophy).[23–29] The initial expense of these implantable therapies has been shown to be potentially offset in the long term by the benefits and resultant reduction in treatment expenses. Early work by Kumar, Malik, and Demeria evaluated costs for patients who received SCS and compared them to the costs for treatment by conventional pain therapies (CPT).[26] While the cost for SCS was significantly higher than for CPT in the first 2.5 years, after that time the cost of treating patients with SCS not only became less than the cost for CPT, but it also remained less expensive during the remainder of the five-year follow up period.[26] Another analysis of SCS compared to conventional therapies has found SCS to potentially create cost and healthcare resource utilization savings, though perhaps at the risk of higher complication rates.[30]

Adverse events associated with spinal cord stimulators have been several, as have reasons for SCS therapeutic failure because of ineffective pain relief. Adverse events are typically separated into

either mechanical (e.g. lead migration, lead or implanted pulse generator failure, lead fracture) or biologic problems (e.g. surgical site infection or loss of efficacy). The incidence of complications of any type varies from 30%–40% in contemporary series.[31] The rate of explant for any reason has been shown to be approximately 8% per year in a large European multicenter cohort study.[32] The study consisted primarily of patients with post-laminectomy syndrome, approximately half of these devices were removed because of inadequate pain relief.[32] In a multicenter retrospective United States based study of SCS explant primarily among patients treated with SCS for post-laminectomy syndrome, Pope and colleagues found that the most common reasons for device explant consisted of loss of efficacy (43.9% of explanted devices) followed by mechanical complications or infection (20.2%).[33] These findings, among others, highlight the need for patient selection to hopefully reduce the rate of explanation for lost efficacy.

Efforts to improve patient selection for the surgical treatment of back pain, including post-laminectomy pain treatment with SCS, have a five-decade history. In an attempt to determine both the positive and negative outcome indicators for surgical procedures, Spengler and Freeman[34] initially performed a retrospective analysis of 30 patients who had unsuccessful outcomes from various surgical procedures for either low back pain or sciatica or both. Among their findings, the most commonly reported cause of the poor results was a poor initial candidate-selection process, despite indications for the surgical procedures. A more focused investigation identified instances of drug abuse, alcoholism, marital discord, and personality factors that were felt to have played a role in the patients' post-surgical success or failure. Therefore Spengler and colleagues[34] recommended pre-surgical psychological evaluation in order to reduce the likelihood of unsuccessful procedures. Following these reports, Long and colleagues[35] performed a retrospective analysis of their own patients, who received surgically-implanted dorsal column SCS between 1970 and 1973. At that time, the only method for identifying candidates for this procedure was continued self-report of pain after failing all other treatments. They found that only 33% of patients (12 of 36) achieved adequate pain relief over the seven-year follow up. Approximately one-half of those patients originally selected for the procedure would have been rejected using updated inclusion criteria for psychosocial factors, including substance use disorders.

Given the substantial burden of chronic pain, the numerous indications for neuromodulation therapy, high initial costs for implantation of neuromodulation systems, and the relatively high rate of explantation for loss of efficacy, there is a substantial value for improved patient selection before use of this therapy. This chapter will review the tools that have been developed to facilitate patient selection for surgical treatment of spinal pathology and its pain-related conditions treated with SCS. Specific attention will be devoted to initial research on patient selection for spine surgery, followed by the extension of these approaches to SCS. Before reviewing current research on this topic, a discussion of the biopsychosocial approach to assessment is warranted.

The Biopsychosocial Approach to Assessment

The biopsychosocial approach is recognized as the most comprehensive and heuristic approach to the evaluation of medical disorders.[36–40] The biopsychosocial model focuses on the complex interaction among biologic, psychologic, and medicolegal variables that patients encounter when coping with a persistent, distressing medical condition such as chronic pain. A range of psychological, social, and economic factors interact with the physical pathology to modulate a patient's discomfort and disability associated with the condition. This complex interaction accounts for the likelihood that a patient's life will be adversely affected in various ways by his or her medical condition, thus requiring a comprehensive assessment and treatment approach designed to address the biologic, psychological, and social aspects of care. This approach contrasts with the traditional biomedical reductionist approach, which assumes that most medical conditions, including chronic pain, can be separated into distinct, independent physical and psychosocial components.

A demonstration of this model and highlights how individuals significantly differ in the frequency of reporting physical symptoms, tendency to visit physicians when experiencing identical symptoms, and in their responses to the same treatment.[41] These, in turn, are not fully predicted by the physical findings. A comprehensive assessment of a patient proceeds from a global biopsychosocial diagnosis of the disorder in question to a more detailed evaluation of the most important interactive factors needed for the diagnosis.[37,38] For example, for a patient reporting low back pain, a comprehensive physical examination would initially be conducted to assess the bio-component of the equation. However, this becomes less valuable when it is non-specific or demonstrates pain inhibition, leading one to question the contribution from other elements in the biopsychosocial model. As such, contemporary models of treatment, particularly for back pain, now recognize that psychological and social influences may contribute substantially to symptoms, disability, and response to treatment.[42]

Thus, a comprehensive biopsychosocial assessment of each patient is needed before the development of a treatment plan. Current surgical risk assessment techniques for spine surgery and neuromodulation seek to account for both medical risk factors as well as the psychosocial attributes that may predict the likelihood of a successful outcome or, as it is often framed in the literature, association with a poorer outcome. Therefore any successful assessment of patients will need to evaluate these various factors comprehensively. The following discussion will focus primarily on the psychosocial evaluation for this process.

The Biopsychosocial Pre-screening Process

Clinical Framework for Biopsychosocial Pre-screening

The process of test selection for biopsychosocial pre-screening can be difficult for the clinician not experienced with this process, given the number of available instruments in the literature. A complete review of all these instruments is beyond the scope of this text. However, Block and colleagues have carried out foundational research in this area, and their work will be used as a frame for this discussion. They have broadly classified the psychosocial factors associated with poor surgical outcomes in the back pain patient as[43]: personality and emotional factors, cognitive-behavioral factors, and environmental factors. They also noted medical risk factors associated with poorer outcomes, including increased duration of pain, number of previous surgery for the same problem, invasiveness of the surgery, and smoking.[36,43–45] These can be used as a starting point for the clinician who has been asked to screen and evaluate patient candidates for SCS or PNS.

Intake Survey

A general survey of pain symptoms is a necessary starting point for any pretreatment evaluation in a pain program. Assessment should include a thorough history of the pain syndrome, including the date of onset and pertinent details of the pain condition as well as prior treatments or surgeries. Clinical factors that have been associated with positive outcomes with SCS for back pain include predominant neuropathic leg pain, SCS within three years of first back surgery, and absence of psychological risk factors.[46,47] Environmental, historical, and medical factors are also assessed during intake by investigating self-report items such as demographic information, employment status, education level, disability payment status, workers' compensation or personal injury litigation involvement, healthcare utilization, marital status, family support network, and other comorbid chronic health problems (i.e. smoking and obesity), all of which have been identified as potential predictors of worse outcomes with SCS.[44,48]

In addition to the general intake assessment, individual tools may be used to assess each of the domains identified by Block and colleagues.[44]

General Assessment: Pain Intensity, Disability, and Medication Use

First developed in 1976, the *Visual Analog Scale* (VAS), also referred to as the *Pain Drawing Analog* (PDA),[49] is a scale designed to rate the patient's degree of pain on a scale from zero (no pain) to ten (worst possible pain). Comprised of a 10 cm horizontal line divided at two-point intervals, patients mark an "X" on the line to represent current levels of pain. The psychometric properties and utility with chronic pain populations of the VAS/PDA are further described in the literature.[50,51]

A further development of the VAS/PDA is the *Million Visual Analog Scale* (MVAS).[52] The MVAS consists of 15 self-report items specific to perceived pain and disability. Patients respond on a 10 cm line, representing a range of possible answers from zero to ten, in which the total score is the sum of all responses. Various cutoff points have been described based upon psychometric testing of the MVAS. Scores of 0–39 indicate "mildly disabling" pain; 40–84 indicate "moderately disabling pain"; and 85 and above indicate "severely disabling pain." The MVAS is especially helpful for discrepancies, such as when self-reported pain is higher than expected based on physical findings. This is often suggestive of a potential psychosocial component in the patient's experience of pain.[53] Newer measures of global pain and multidimensional factors contributing to pain have been derived from national item data banks and include the Patient Reported Outcome Measure Information System (PROMIS 29).[54] This measure has been updated over time and is now in a second version,[55] and has been shown to adequately predict disability score (i.e. Oswestry Disability Questionnaire score) among patients presenting for lumbar spine surgery.[56]

The *Oswestry Disability Questionnaire* is a self-report scale designed to assess the degree of functional impairment because of the pain condition.[57] Consisting of ten items regarding limitations of activities of daily living because of pain, the Oswestry has demonstrated test-retest reliability of 0.99 with a 24 h interval between administrations, as well as acceptable levels of validity.[58,59] Each item is scored on a zero-to-five-point scale, with a potential range of scores from zero to 50, with higher scores significant for higher levels of pain-related limitations.

Adams and colleagues[60] developed the *Pain Medication Questionnaire* (PMQ) to determine the risk of medication misuse among chronic pain patients. Identified behavioral correlates and attitudes suggestive of medication misuse were used to develop the 26 self-report items that make up the PMQ. Higher scores indicate a greater likelihood of substance abuse potential, emotional distress, impaired coping skills, reduced physical functioning, as well as higher rates of unemployment.[60]

Additional tools designed to specifically assess the risk of mediation misuse and monitoring for adverse effects, specifically for opioids, include the Screener and Opioid Assessment for Pain Patients (SOAPP-R),[61] and the Current Opioid Misuse Measure.[62]

Emotional Factors: Assessment of Mood

Mood factors have been implicated widely in the patient experience of chronic pain, and pre-implant levels of distress, including depression and anxiety, have been associated with a lower level of pain reduction among patients receiving SCS implants.[48]

The *Beck Depression Inventory* (BDI-II) is a 21-item self-report inventory designed to assess the intensity of depressive symptomatology.[63] Each item is scored from zero to three, with a potential range of scores from zero to 63. A total score of zero to nine is considered normal, 10–15 is mild depression, 16–19 represents mild to moderate depression, 20–29 reflects moderate to severe depression, and 30+ indicates severe depression. Being able to identify symptoms of depression is important in chronic pain populations, as is being able to delineate between cognitive and somatic specific symptoms, which is an option allowed by the BDI-2. To obtain more than the subjective self-reported symptoms of depression available with the BDI-2, an experienced clinician will also want to perform a more objective assessment of depression to validate or clarify their findings. One tool that is widely available, but does require some training and experience, is the *Hamilton Rating Scale for Depression* (HAM-D),[64] which is administered by the clinician in a brief interview format and could potentially be incorporated into the overall clinical interview.

Anxiety has typically been measured using the *Hospital Anxiety and Depression Scale* (HADS),[65] which can be particularly useful for its separate anxiety and depression subscales as well as an additional option for measurement of depression.

Personality Factors

In addition to examining the current emotional status of the patient candidate prior to SCS or PNS implantation, long-standing personality traits are important to consider before a patient begins the life-changing process that implantable therapies entail. In general, neuroticism has been shown to be one of the most predictive personality factors determining the outcomes of pain-related treatments,[66] and has also been shown to be the personality psychopathology factor most strongly associated with negative outcomes among patients receiving SCS.[67]

Although personality inventories can be lengthy and time consuming, they have been used extensively in chronic pain populations. Third-party payers may limit the type or extent of testing that is performed with pre-surgical candidates; two inventories reviewed next provide valuable insight into the characteristic way these patients relate to the people and situations around them. If time and the situation allow, they should be considered part of the comprehensive pre-screening evaluation prior to SCS implantation.

The *Millon Behavioral Medicine Diagnostic* (MBMD) is a 165-item, self-report inventory that examines psychosocial factors that may impact treatment outcomes with medical patients.[68] The MBMD includes 29 clinical scales, three response pattern scales, one validity indicator, and six negative health habits indicators.

It is intended for adult clinical and rehabilitation patients (aged 18–85 years) who are undergoing medical care or surgical evaluation, making this a valuable resource for the pre-screening process.

A more widely recognized personality assessment that has been used extensively in chronic pain research, including that conducted by Block and colleagues, is the *Minnesota Multiphasic Personality Inventory-2* (MMPI-2).[69] The MMPI-2 is a 567-item, self-report measure of personality functioning and psychiatric symptoms. It is the most commonly used personality assessment for patients with chronic pain, who often demonstrate a higher prevalence of emotional distress, specifically depressive symptoms and potential personality disorders, relative to the general population.[70] There are ten empirically derived clinical scales, various supplementary scales, and validity scales provided to assess the test-taking attitudes of the patient. The MMPI-2 has great utility when used as part of the pre-screening process with chronic pain patients. Findings from the MMPI-2 can help in the identification of psychopathology, personality, and behavioral characteristics, treatment planning, and prediction of treatment outcomes.[70] However, one must keep in mind that the use of this test in chronic pain patients may present challenges because of the physical symptoms reported in this population.[71]

A revised form of the MMPI-2, the MMPI-2 Restructured Form (MMPI-2-RF)[72] has been used in more recent work by investigators.[73] Profiles obtained with this instrument have been shown to be approximately similar between cohorts of patient candidates for spine surgery and SCS implantation.[74] These profiles have also been associated with surgical outcomes, including pain level, Oswestry Disability Index, and work status following surgery.[75] Similar findings have been demonstrated in patients undergoing SCS implant, with poorer outcomes observed among patients with higher pre-implant MMPI-2-RF scores on scales that assess emotional dysfunction, somatic/cognitive complaints, and interpersonal problems.[67]

Cognitive and Behavioral Assessment

The clinician performing the pre-screening must identify the coping skills that patients already rely upon, as these will likely be the same skills employed during the trialing and post-implant phase of treatment. If there is a notable lack of healthy coping skills, this is something that might be managed prior to, and following, surgery with biobehavioral therapy.[76]

Pain-related beliefs also play an important role in functional recovery after SCS implant. Catastrophizing as a construct includes thought patterns of magnification of pain-related symptoms, rumination on pain, feelings of helplessness, and pessimism about expected outcomes. Greater degrees of catastrophizing are a strong predictor of negative outcomes for continued disability following spine surgery[77] and SCS implantation.[78] The degree of catastrophizing can be measured using the *Physical Component Scale* (PCS),[79] which is a well-validated self-report tool for catastrophic thinking related to pain.

The *Coping Strategy Questionnaire* (CSQ)[80] is a 42-item self-report inventory that assesses how often pain patients use six cognitive coping strategies and two behavioral coping strategies. These strategies include diverting attention or distraction, reinterpreting pain sensations, ignoring pain, praying and hoping, coping self-statements, increasing behavioral activities, and catastrophizing. Additionally, the CSQ measures the subjective ability to control and decrease pain. Patients rate some activities, in relation to pain, on a six-point scale: 0 = never do that, 3 = sometimes do that, and 6 = always do that.

Current quality of life is also an important factor for patients being considered for an implantable therapy device, as undergoing SCS implantation can interrupt current lifestyle during trialing, implantation, and surgical recovery. The *Medical Outcomes Survey 36-Item Short-Form Health Survey* (SF-36)[81] is a 36-item questionnaire that assesses health related quality of life, both physical and mental, from the patient's perspective. The SF-36, and variants of this measure, is widely used for assessment and follow up monitoring of healthcare treatment outcomes. The SF-36 consists of eight subscales and two standardized summary scales, the Mental Component Scale (MCS) and the Physical Component Scale (PCS). The MCS and PCS provide an overall gauge of the patient's sense of physical and mental well-being.

While these assessment tools are useful in performing a comprehensive pre-screening evaluation, it is up to the clinician to obtain the proper training to perform these assessments, along with a thorough clinical interview. These data can then be used to prepare a detailed report of their findings for the patient and physician performing the implantation procedure. In addition to performing these tasks, it should also be within the clinician's repertoire to know how to ask the following: what treatments the patient has found helpful in the past; what prescriptions and over-the-counter medications they are taking; what their activities of daily living entail now and prior to their pain condition; and what their realistic expectations are for life post-procedure.

Foundational Work on the Pre-screening Process for Spine Surgery

Initial work on pre-screening of patients who were being considered for spine surgery occurred throughout the 1970's–1990's.[44,45,82,83] Epker and Block[44] reviewed the methods for predicting positive outcomes for spine surgery in general and highlighted the positive and negative psychosocial risk factors that appeared to impact recovery from spine surgery. They delineated specific risk factors predictive of poor surgical outcomes and suggested the evaluation and quantification of these factors before performing spine surgery. Three major categories of psychosocial factors were described, as noted previously: 1) personality/emotional, 2) cognitive/behavioral, and 3) environmental/historical. Scale elevations on the MMPI-2 associated with pain sensitivity (Scales 1 and 3), depression (Scale 2), anger (Scale 4), and anxiety (Scale 7) were found to be associated with negative outcomes. Other significant factors included maladaptive coping strategies, workers' compensation status, litigation related to pain, and drug and alcohol abuse. Epker and Block also discussed "quasi-medical" risk factors that could predict poor results: the duration of pain and number of previous surgeries for pain are negatively correlated with positive outcomes, and smoking and obesity can also negatively affect recovery from surgery. Finally, they note that the presence of non-organic Waddell signs can help identify those candidates who will have poor outcomes.[84]

Subsequently, a comprehensive screening approach for spine surgery was presented by Block et al.[36] They developed a "scorecard" to clarify the spine surgery candidate's biopsychosocial risk factors, using various factors. The scorecard lists and quantifies psychosocial risk factors, along with additional medical risk factors. Based on the existing research demonstrating predictive ability, each risk factor is assigned an *a priori* weight of high risk,[2] or medium risk,[1] and the risk factors in each group (medical and psychosocial risks) are then totaled to arrive at a surgical prognosis.[45] In that study, 204 patients were referred for psychosocial screening and were evaluated no more than one month prior to surgery.

A semi-structured interview and two psychosocial questionnaires, the MMPI-2 and the Coping Strategy Questionnaire (CSQ), were used to evaluate the psychosocial and medical risk factors. Based on the results of screening, patients were placed into one of three predictive categories ("good", "fair", or "poor"). Analyses of results showed the screening achieved an 82% accuracy rate, with 82.3% patients in the "good group" experiencing a good outcome and 83.0% patients in the poor prognostic group resulting in poor outcome.[45] Logistic regression analyses were also conducted to determine which variables were the most significant predictors of outcome. These analyses yielded psychosocial test data as the most significant cluster of variables to correctly classify patients, with a correct classification rate of 78.4%. The addition of psychosocial interview data brought the model up to an 83.3% correct classification rate. Finally, the addition of the medical risk factors contributed slightly, bringing the total model to 84.3% correctly classified. This study was the first empirical investigation to show that many psychosocial and medical risk factors can be identified, quantified, and used to accurately predict surgical outcomes.[45]

The original screening "scorecard"[45] was subsequently replaced with a new prognostic algorithm by Block et al. in 2001.[36] This algorithm added several new features that enhanced its predictive utility:

- The algorithm placed psychosocial risk factors above all others because it has the most predictive power.
- A category termed "adverse clinical features" was also included to account for factors such as inconsistency, compliance issues, and medication seeking (that were often found in the patients' medical charts and observed during the clinical interview).
- A set of general treatment recommendations was added. The psychologists' recommendations can fall into several categories: 1) proceed with surgery; 2) surgery, but with postoperative psychosocial treatment sessions; 3) preoperative treatment psychosocial sessions prior to surgery; 4) only non-invasive therapy recommended.

This scorecard and screening algorithm were again updated in 2019 to account for the restructured form of the MMPI-2-RF.[73]

Advancement of Pre-screening Research and Use for SCS

Prior to the work by Block and colleagues examining the role of psychosocial risk factors in spine surgery, there were few studies that had systematically evaluated the predictive value of biopsychosocial risk factors and treatment outcomes for implantable SCS devices.[85–87]

Studies by Schocket et al.[88] and Heckler and colleagues[89] examined whether the screening algorithm used by Block for spine surgery pre-screening could predict outcomes in SCS or intrathecal medication therapy for back pain. These studies assume that psychological variables are broadly predictive of patient psychological resilience and response to the stresses of surgery. Their screening algorithm used a combination of clinical interviews, psychosocial testing (BDI, MCS, HAM-D, CSQ), and other psychosocial and medical risk factors (Table 70.1). One significant difference in their work compared with that by Block and colleagues was the decision to forego extensive personality testing with the MMPI-2 and instead rely upon other measures of mood and coping. Based on this algorithm, patients were classified into one of five groups: Green (proceed with surgery); Yellow I (proceed with surgery but administer postoperative psychosocial intervention); Yellow II (administer preoperative psychosocial intervention before surgery); Red (only non-invasive intervention is recommended). Data were collected from patients who were able to complete six- and 12-month follow up evaluations. The Green group showed 40% of patients to be taking no new medications at the six-month follow up. This percentage decreased as prognosis worsened (Yellow I, 27.3%; Yellow II, 25%; and Red I and II, 0%). When the Green group was compared to the Red group, significantly better outcomes were observed with respect to pain scores, disability measures, depression, and mental and physical status.

TABLE 70.1 The Psychosocial and Medical Risk Factors Used by Schocket (89) and Heckler (90)

Psychosocial Risk Factors
• Job Dissatisfaction
• Workers' Compensation Status
• Pending Litigation
• Spousal Solicitousness or Lack of Support
• Abuse and/or Abandonment History
• Substance Abuse
• History of Psychosocial Disturbance
• Pain Sensitivity
• Chronic and/or Reactive Depression
• Pathological Depression Profile
• Anger
• Anxiety
Medical Risk Factors
• Longer Duration of Pain
• Type of Surgery
• Presence of Non-organic Signs
• Abnormal Pain Drawing
• Previous Surgeries
• Prior Medical Problems
• Smoking Status
• Obesity

Subsequent studies in this line of the literature have contributed further insight into factors that may be associated with poor outcomes following SCS implantation. The addition of testing for mechanical allodynia using Quantitative Sensory Testing was shown to predict outcomes among patients with CRPS type 1 treated with SCS.[90,91] Additional work on the use of MMPI-2-RF for surgical outcome risk stratification suggested a similar predictive value for this test in both spine surgery and SCS implant populations,[74] thus suggesting that the risk factors and expected outcome findings in their work with spine surgery patients may generalize to patients referred or SCS implant. In a retrospective study,[92] the authors divided patients into those who maintained 50% pain relief at one-year follow up after SCS implant for various conditions (49% had post-laminectomy syndrome) and those who did not achieve pain relief. They found that pre-implant low scores for sleep interference, depression, catastrophizing, and low self-efficacy were associated with less than 50% pain relief at the one-year follow up. Although they noted that sleep interference seemed to be the strongest predictor, this was not measured using a validated questionnaire and therefore may have been a confounder in multivariate analysis.

Further evidence in a large, retrospective post-market survey of patients with SCS found that patients with a pre-implant PCS score of greater than 30 were associated with a five times greater risk of dissatisfaction with the SCS device and a three times greater risk of reporting poor quality of life at six- and 12-months post-implant.[93] In another small study,[78] the authors found that predictors for a patient receiving SCS implant to receive a meaningful clinical improvement in pain and health related quality of life

• BOX 70.1 Factors Associated With Failure or Success of SCS

Failure

- Unfavorable pre-implant scores in sleep interference, depression, catastrophizing, self-efficacy*
- Pain Catastrophizing Scale score greater than 30**
- Benzodiazepine use
- Depression and anxiety
- Low scores on patient activation (obtaining information, decision making, and resilience)

Success

- Greater than 80% coverage of the painful area
- Lower levels of anxiety and catastrophizing symptoms
- Shorter pain duration
- Female gender
- No opioid use

*Associated with less than 50% relief at one-year follow up
**Associated with five-time greater risk of dissatisfaction with SCS and three times greater risk of poor quality of life at six and 12 months after implant

included greater than 80% paresthesia coverage of the painful area, lower levels of anxiety, and catastrophizing symptoms, shorter pain duration, female gender, and no use of opioids before surgery. Other investigators found benzodiazepine use to be a predictor of poorer outcomes in patients with SCS.[94] Although the authors used chart review for measurement of coincident mood disorders. There is also evidence of a high prevalence of undiagnosed depression and anxiety in this population, confounding this association.[95] Investigation into mood disorders with SCS removal has shown that patients having explant display high rates of depression (64%) and anxiety (35%).[96]

Block and colleagues[97] published the most recent evidence for a novel predictor for poor outcomes in SCS. Their group, as well as other authors, have proposed that the construct of patient activation may mediate many of the identified risk factors for poor outcomes after SCS implantation.[98] Of particular interest is the finding that even among patients with known psychological risk factors for poor outcomes, higher scores on patient activation (i.e. involvement in obtaining information, decision making, and resilience) may substantially reduce the risks from these attributes. The factors that contribute to the failure or success of SCS are listed in Box 70.1.

In summary, the studies by Schocket[88] and Heckler[89] continue to provide robust models for a pre-screening algorithm prior to SCS implant. Subsequent investigations have identified additional potential risk factors, and there is a clear opportunity for an updated algorithm incorporating these supplementary insights for SCS and PNS patient pre-screening.

Future Directions for Patient Screening

Future directions in the area of patient screening prior to SCS and PNS implantation will continue to focus on expanding the validity and generalizability of models (described above). Additionally, tools to assess and monitor patients with chronic pain prior to SCS implantation will be more time efficient for both patients and personnel, more cost effective for systems and payers, and increasingly automated. Emerging technologies have shown promise for the characterization of pain states, facilitation of diagnosis,[99] and patient monitoring during trial for an implanted device.[100] In addition to instruments used in the research setting, guidelines are beginning to incorporate online patient pre-screening tools for SCS. A clinical guideline by a multi-disciplinary European panel on referral and selection of patients for spinal cord stimulation includes a web-based tool on medical and psychosocial factors on which SCS is likely to improve the patient's pain syndrome. This tool is freely available at https://www.scstool.org/.

Summary and Conclusions

When pain becomes intractable in nature, invasive pain control interventions may provide pain relief. Neuromodulation therapies such as spinal cord and PNS have strong evidence supporting their efficacy among select patient populations. However, surveillance data reveal that therapeutic failure because of loss of efficacy for pain control is challenging, highlighting the need for continued vigilance during patient pre-screening prior to device implantation. The body of work strongly suggests that psychological and/or social factors are important determinants of neuromodulation treatment outcomes for SCS and PNS. A comprehensive biopsychosocial evaluation and a suitable recommendation by a trained healthcare professional, such as a psychologist, is the minimum standard of practice and the best practice for patient evaluation prior to making the decision on neuromodulation. Similar recommendations have been found in bariatric and transplantation surgery. Familiarity with these assessment instruments is essential for any pain clinician considering the use of neuromodulation therapies.

Substantial progress has been made in identifying risk factors for poor outcomes after neuromodulation. These findings are being incorporated into clinical algorithms should they continue to show validity in the research setting. Given the substantial societal costs of chronic pain, there is great interest in the use of these technologies for the treatment of pain. However, cost effectiveness research has highlighted the need for several years of efficacious therapy for the value of these devices to be realized. In addition to the necessity for biopsychosocial evaluations in making the decision to proceed with neuromodulation, there is a strong argument to be made as well in favor of continued development of pre-screening tools that allow us to maximize the benefits of this technology and deploy it in a cost effective manner.

Key Points

- Use of neuromodulation technologies, SCS and PNS, for the treatment of chronic pain presents a strong value proposition. However, for value to be realized, these therapies require careful patient selection to avoid premature explantation of the device because of loss of efficacy.
- The biopsychosocial (BPS) model focuses on the complex interaction among biologic, psychological, and medicolegal variables that accounts for the likelihood a patient's life will be adversely affected in a variety of ways by his medical condition, thus requiring a comprehensive assessment and treatment

approach designed to address all aspects of required care (i.e. biologic and psychosocial).
- Employment of the biopsychosocial model in the clinical setting has resulted in more effective pre-screening of patients for spine surgery, and these instruments and methods are being utilized for patient pre-screening prior to neuromodulation device implantation.
- The major categories of psychosocial factors that negatively influence outcomes in spine surgery and SCS implantation to include 1) personality/emotional, 2) cognitive/behavioral, and 3) environmental/historical.
- A comprehensive biopsychosocial evaluation by a trained professional, such as a psychologist, with a recommendation to proceed, is a necessity for neuromodulation therapy.
- Investigators initially developed a screening algorithm for patients being considered for spine surgery. This modified pre-screening protocol was later modified for patients being considered for implantable devices.
- Based on prognostic algorithms for SCS implantation, a patient's suitability as candidates are classified into the following categories: Green (proceed with surgery); Yellow I (proceed with surgery but administer post-operative psychosocial intervention); Yellow II (administer pre-operative psychosocial intervention before surgery); Red (only non-surgical intervention is recommended).
- Additional clinical research is needed to refine the screening techniques and examine their predictive utility for long term outcomes.

Spinal Cord Stimulation, Peripheral Nerve Stimulation, Restorative Neurostimulation, Deep Brain Stimulation, and Motor Cortex Stimulation

LEONARDO KAPURAL, JAMES DEERING, CHRISTOPHER GILMORE

Introduction

Neuromodulation for chronic pain control has been used for several decades but recently has received much clinical interest mainly based on published improved therapy outcomes.[1] Spinal cord (SCS), dorsal root ganglion (DRG), and peripheral nerve stimulation (PNS) for chronic pain are the mainstay of neuromodulation therapies and will be the focus of this brief review. Over the last 30 years, traditional, low frequency, paresthesia-based (40–90 Hz) SCS stimulation has been used. However, only approximately 30%–50% of patients received more than 50% of pain relief when conventional low frequency SCS therapy was used.[2,3] Recently discovered SCS therapies, such as continuous stimulation at a higher frequency (10 kHz), DRG stimulation, closed-loop SCS, or differential target multiplex types of SCS, were found to be superior to traditional SCS when used for chronic severe back and leg pain.[4–8] Prior studies also showed an additional benefit when traditional low frequency SCS was modified into 1 kHz continuous SCS,[9,10] or 500 Hz burst pattern[11] of stimulation.

SCS Mechanisms of Action

Initial studies utilizing traditional low frequency SCS suggested activation of the gate control mechanisms, blockade of pain conduction via the spinothalamic tract, supraspinal sympathetic suppression mechanisms, and activation or release of the neuromodulators as major mechanisms of pain control.[12] When SCS is active, unmyelinated afferent fibers (A δ and C) are inhibited by the electrical stimulation of non-nociceptive, myelinated afferent fibers. Blockade of supraspinal sympathetic mechanisms by SCS results in an increase in peripheral blood flow with transitory inhibition of sympathetic vasoconstriction.[13] Activation or release of various neuromodulators such as σ-aminobutyric acid (GABA) in the dorsal horn,[14,15] glycine release in the extracellular space of the spinal cord, and inhibition of glutamate and aspartate release in the dorsal horn contribute to SCS, resulting in chronic pain relief.[16]

SCS affects heart function by reducing the intrinsic cardiac nervous system activity,[17] preemptive suppression of marked increase in sympathetic outflow,[18] which may then inhibit local heart circuits and decrease the frequency of arrhythmias in ischemic hearts.[19] SCS does not affect coronary blood flow during ischemic conditions, and there is no effect on left ventricular function or left ventricular blood flow distribution.[19,20] However, the positive and anti-ischemic effects of SCS include decreased oxygen demand, a significant increase in cardiac pacing tolerance, decreased ST segment depression, and improved myocardial lactate metabolism, which in turn results in an improvement in exercise tolerance and pain relief.[21]

SCS improves ischemic pain in the extremities by a vasodilator effect via calcitonin gene-related peptide (CGRP), peripheral prostacyclin release,[22] and profound neuronal increase of nitric oxide.[23] During SCS, there is a decreased sensitivity to vasoconstrictive sympathetic stimuli,[24,25] and an increase in skin blood flow measured by transcutaneous partial oxygen pressure and increased pulse-wave amplitude.[26]

Other mechanisms of SCS include a significant modulatory effect on dorsal horn pain pathways (in addition to dorsal columns) with the recruitment of inhibitory neurons when SCS is used at 10 kHz [27]. Such effects result in additional pain relief, not exhibited greatly when low frequencies (1–1200 Hz) of SCS were used.[27]

Recently, attention has been directed at the effect of SCS on glial cells, in addition to neurons. Glial cells respond to electrical field applications by depolarizing, releasing neurotransmitters, and communicating with each other. The differential target multiplex (DTM) type of SCS is directed toward the modulation of glial cell response. In an acute neuropathic pain model in rodents and mammals, the DTM type of SCS provided superior thermal and mechanical hypersensitivity suppression than low and high (1000 Hz) frequency SCS.[28] During DTM SCS in an animal model of neuropathic pain, gene expression is better restored toward the baseline, non-pain state, when compared to low and 1000 Hz frequency SCS,[29] including those genes related to neuroinflammation.[30]

Finally, a recent development in SCS waveform optimization is a closed-loop stimulation. During closed-loop stimulation, data regarding the spinal cord response to stimulation, measured as evoked compound action potentials (ECAPs), were recorded in real-time. This allows the spinal cord stimulator system to adjust its stimulation parameters to maintain an ideal therapeutic response.[31]

Dorsal root ganglia stimulation (DRG) acts directly on the development of neuropathic pain through inhibition of hyperexcitability and the spontaneous, ectopic firing of neuronal cell bodies contained within the DRG. These processes are known to contribute to central sensitization and clinical allodynia. DRG electrical stimulation reduces the propagation of action potentials to the dorsal horn, affects the release of neuromodulators in the dorsal horn aimed at decreasing excitability and excess neuronal firing and possibly deactivation of hyperexcitability of dorsal horn wide-dynamic range neurons, and an increase in membrane firing thresholds.[32,33]

Spinal Cord Stimulator Trial Technique

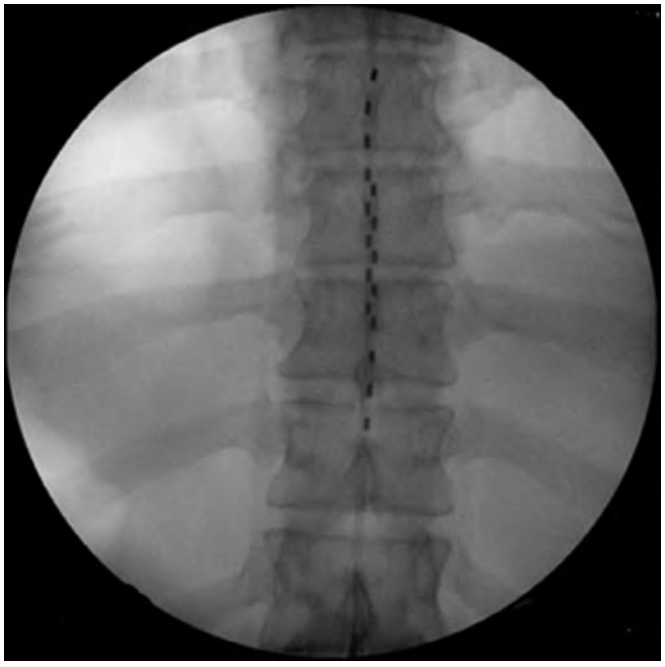
One advantage of SCS therapy is that patients can undergo temporary SCS trials. The time interval of SCS trials may vary between three and 30 days (most frequently seven to ten days in the United States). Based on the Neurostimulation Appropriateness Consensus Committee (NACC) Guidelines patients should be screened before the trial for the risk factors that may predispose them to complications from SCS, should be referred for a psychological evaluation to rule out any prohibitive psychological disorders that may hinder successful response to neuromodulation, and thorough history and physical examination should be performed (see Chapter 70).[34] If the patient is anticoagulated, the American Society of Regional Anesthesia and Pain Medicine (ASRA) guidelines should be strictly adhered to minimize the risk of catastrophic epidural hematoma formation or any other bleeding.[35] Attention should be given to the patient's body habitus, as an increase in body mass index may affect procedural technique and predispose patients to postoperative infection. Spine imaging should be carefully reviewed to rule out structural instability that would warrant surgical attention and central canal stenosis that may preclude safe insertion of SCS leads.

The patient is positioned prone, weight-based antibiotics are administered 30–90 min prior to epidural space needle access, and if sedation is required, it should be minimal to facilitate patient-physician communication throughout the procedure.

After obtaining an anterior-posterior fluoroscopic image, the skin was anesthetized, and a Tuohy needle was advanced under intermittent fluoroscopic guidance toward the target interlaminar space. The needle should approach in a paramedian fashion parallel to the spinous process. The angle of approach should be between 30° and 45° to optimize the ability to steer the lead once it has been introduced into the epidural space. Contact may be made with the cephalad aspect of the lamina immediately below the intended epidural space. Next, the needle was advanced using a loss of resistance technique and intermittent lateral fluoroscopy. Once entry into the epidural space is confirmed via loss of resistance, the lead is threaded through the needle and introduced into the epidural space.

The lead was advanced under continuous fluoroscopy. After a satisfactory lead location was established (Fig. 71.1), the Tuohy needles were removed, and leads were secured in a fashion that suits the physician's preference. This may include suturing in place using manufacturer-provided anchoring devices, suturing to the lead itself, securing it using steri-strips and dressing only, or tunneling leading to possible prolonged trials (Fig. 71.2).

• **Figure 71.1A** Lateral fluoroscopic view illustrating interlaminar needle entry into the epidural space with eight contact spinal cord stimulation lead threading into the posterior epidural space. Note that undesirable anterior migration of the lead in the lateral fluoroscopic view would be evident if the lead were visualized running adjacent to the vertebral bodies at the anterior border of the neural foramen.



• **Figure 71.1B** Anterior-posterior fluoroscopic view of two eight-contact spinal cord stimulation leads in the midline, parallel orientation. Note the staggering of lead contacts to obtain maximal coverage from the top of T8 (left lead) to the top of T11 (right lead) vertebral bodies.

• **Figure 71.2** Two epidural leads tunneled 4–5 cm under the skin for possible prolonged trial. Notice that the Tuohy needle is inserted where a small stab wound was placed to facilitate tunneling. The duration of the trial may range from three to ten days, depending on patient response and physician preference. Beyond a ten day trial period, the risk of infection increases but may be mitigated by tunneling leads, as shown above.

Spinal Cord Stimulator Permanent Implant

Permanent implantation of the SCS system was performed in a sterile operating room setting. The patient was positioned prone in a similar fashion as described for the SCS trial procedure, with adequate padding to reduce normal lumbar lordosis (or cervical lordosis for cervical SCS implant). Anesthesia was administered, and the patient was prepped and draped in a sterile fashion. Intravenous antibiotics have been administered within 1 h of an incision.[34–36] AP fluoroscopy is utilized for guidance similar to lead placement during the trial. A vertical incision site is marked starting at the level of the intervertebral disc immediately inferior to the intended interlaminar insertion site and extending inferiorly three-four centimeters.

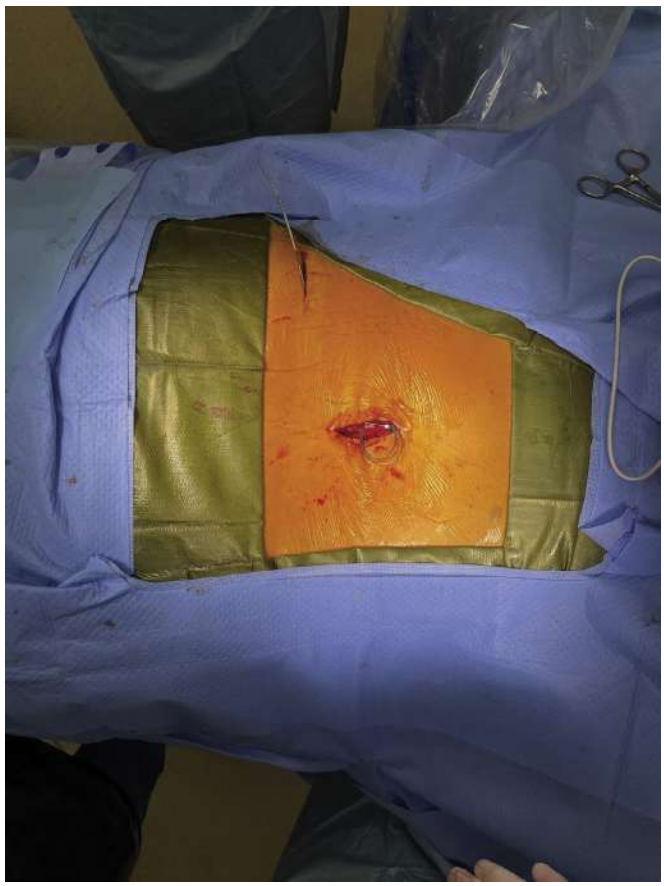
The epidural needles were removed, leaving the leads in place. The leads were then secured to the underlying fascia using the SCS manufacturer, which provided anchoring devices and non-absorbable sutures. A final fluoroscopy image was captured to ensure no lead migration occurred with needle removal and anchoring of the leads.

Another 4 cm horizontal incision was made, and blunt dissection was utilized to create a pocket for the implantable pulse generator (IPG) that was no more than 2 cm below the surface of the skin. This ensures the ability to charge the device effectively. It is essential to discuss the subcutaneous IPG location with the patient prior to implantation and examine the potential location while the patient is sitting.

Once the pocket has been created, and hemostasis has been achieved, the leads must be tunneled from the midline incision to the pocket (Fig. 71.3). The wounds were irrigated and closed in a layered fashion using simple interrupted absorbable sutures.

Complications

The SCS device-related infection rate was estimated to be 3.11% based on logistic regression (n=6615) over a 12 month postoperative period.[36-38] It is most commonly seen at the IPG pocket site. Lead migration has been reported as a possible complication of SCS, occurring at a rate of approximately 2.1%–12% of implants depending on the reference source.[39,40] Pocket site discomfort has also been noted with some frequency.[34,39] Other less common complications that have been described include electrode fracture, IPG failure, and CSF leak following a dural puncture, among others.[36–41]



• **Figure 71.3** Subcutaneous tunneling of two leads from the midline incision to the generator pocket. Notice formed lead loop at the midline incision site, which will be used as a strain relief loop, one of the strategies on how to minimize lead migration from the epidural space.

Clinical Outcomes

Traditional (0–1200 Hz) has been demonstrated to be a superior treatment option for patients with failed back surgery syndrome compared to conventional medical management or reoperation.[2,3] In addition to traditional SCS being more efficacious in improving pain scores and quality of life, it was also found to be less costly than long term medical management or reoperation for failed back surgery syndrome.[2,3,42] Low frequency SCS has traditionally relied on paresthesia coverage overlapping the distribution of a patient's pain. Compared to traditional tonic stimulation, some studies have demonstrated better or similar responses to sub-perception stimulation at 1000–1200 Hz.[9,10]

Burst stimulation is another recently studied waveform with considerable evidence to support its use. A "burst" is characterized by a five-pulse train with an internal frequency of 500 Hz delivered at 40 Hz utilizing a passive recharge pattern and waveform.[11,43,44] It was first described by De Ridder et al. in 2013.[45] Deer et al. conducted a large randomized controlled trial (RCT)

(SUNBURST) in which 100 patients were randomized to receive traditional or burst stimulation for 12 weeks. After the 12 week period, the patients were crossed over from traditional stimulation to the burst stimulation group for an additional 12 weeks. Burst stimulation was superior to traditional tonic stimulation, with slightly better average pain scores ($P < 0.017$). Of note, at one year post-implant, 68.2% of patients preferred burst stimulation.[11]

There is substantial level 1 evidence to support the efficacy and durability of high frequency (10 kHz) SCS for treating back and leg pain and the superiority of high frequency stimulation over traditional stimulation.[4,5] In a large prospective randomized control trial published in 2015 (SENZA-RCT), the response rates of 171 patients who were implanted with either a 10 kHz or traditional low frequency 2–1,200 Hz SCS system to treat back and leg pain were compared. At 12 months post-implantation, both groups had sustained response, but in the 10 kHz therapy group, 80% of patients reported more than 50% pain relief, compared to less than 50% responders in the traditional SCS group. Mean back pain was reduced from Visual Analog Scale (VAS) of 7.4 +/- 1.2–2.5 (67% decrease) in the 10 kHz group versus being reduced from 7.8 +/- 1.2–4.3 (44% decrease) in the traditional SCS group. These results were noted to be durable through a 24 month follow up, with a 76.5% ongoing responder rate in the 10 kHz SCS group versus a 49% responder rate in the traditional SCS group.[5] Evidence for the efficacy of 10 kHz SCS has been further substantiated in two large randomized prospective studies on chronic nonsurgical back pain patients and those with peripheral neuropathy in diabetes.[46,47] This therapy is currently the only one supported by three large prospective RCTs.[5,46,47] Furthermore, a recently published retrospective study measured 10 kHz SCS ability as the rescue therapy in patients who were previously implanted and failed conventional, low frequency SCS systems. Of the 105 patients analyzed, 81% experienced greater than 50% pain relief after transitioning from the traditional (less than 1200 Hz) to 10 kHz SCS.[48]

Closed-loop SCS was recently trialed in a multicenter, double-blind, parallel-arm RCT that enrolled 134 patients. The participants were randomized to the control group, which received fixed output, open-loop stimulation, or the experimental group that received ECAP-controlled closed-loop SCS. The primary outcome measure was the percentage of patients who achieved >50% pain relief in the back and legs at three and 12 months. The closed-loop group had an 82.3% responder rate at three months and 83.1% at 12 months, compared to the open-loop group, which had a responder rate of 60.3% and 61% at three and 12 months, respectively.[7]

DRG stimulation uses stimulation waveforms similar to traditional SCS, via stimulation lead(s) placed near the DRG and relatively low frequencies at approximately 20 Hz. The study that helped facilitate approval of the DRG stimulation system in the United States (ACCURATE study) randomized patients to DRG stimulation compared to traditional SCS therapy. The study was performed on 152 subjects with lower extremity pain due to mononeuropathies and complex regional pain syndrome (CRPS). DRG stimulation provided a significantly greater level of treatment success with ≥50% pain relief in 81.2% of patients vs. SCS (55.7%). Longevity of the pain relief was documented at 12 months post-implant as well.[6]

Peripheral Nerve Stimulation (PNS)

While the focus of this chapter was SCS, it should be noted that other central and extraspinal neural targets have been successfully stimulated to produce analgesia. PNS as a modality for the treatment of pain predates SCS in a short time, with both being introduced to the modern medical community in the mid-1960s by Wall and Sweet as well as others.[49]

PNS includes:

- open surgical implantation of electrodes overlying target nerves outside the central nervous system (CNS);
- percutaneous image-guided implantation of electrodes; and
- stimulation of terminal nerve endings in the receptive field of a larger target nerve, PNFS, or field stimulation.

Over the last ten years, there has been a mounting wealth of evidence supporting the use of PNS in the treatment of focal neuropathic pain and several other conditions, including post-amputation pain syndrome, post-surgical pain, chronic shoulder pain, chronic low back pain, and craniofacial disorders among others.[50–57] A variety of stimulation parameters have been utilized, from traditional paresthesia-based programming to high frequency sub-perception stimulation at 10 kHz. Qualitatively, the evidence in the medical literature has also improved with the recent completion of multiple prospective randomized, double-blind placebo-controlled clinical trials demonstrating positive results.[58–60]

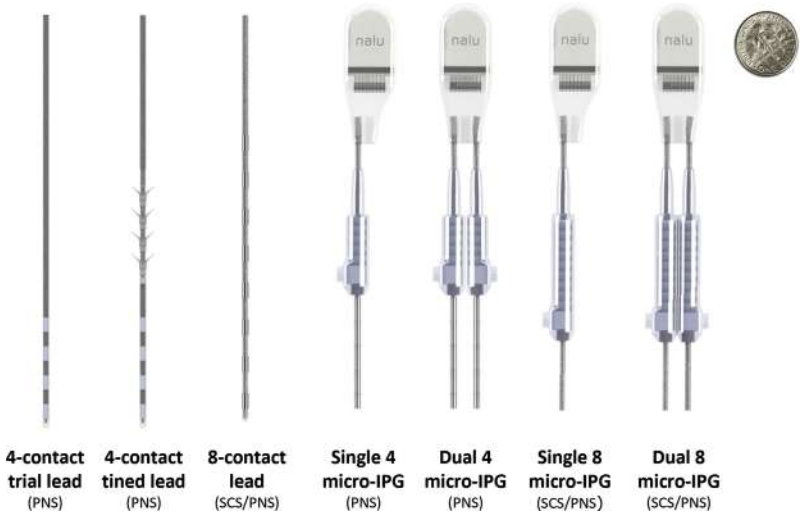
There have been three major developments that have led to the resurgence of PNS.

1. A shift from open surgical exposure of the target nerve to percutaneous implant techniques was first introduced by Weiner and Reed in the 1990s.[61]
2. Use of ultrasound guidance for lead implants.[62,63]
3. Development of devices specifically designed to be used in the periphery (illustration of leads from Nalu; Fig. 71.4) and SPR Therapeutics (Fig. 71.5) to address many of the shortcomings associated with adapting SCS devices for use outside the spinal canal, that is, lead migration, lead fracture, battery failure, surgical site infection, and neurologic injury.[64]

These advances have led to a growth in the number and variety of targeted conditions. However, the resulting reduction in the invasiveness of the implant procedure, moving away from open surgical exposure to a more commonly used percutaneous approach, has caused a concomitant shift in the background and training of implant providers. Surgical training, while helpful, is no longer a requisite.

Historically, the PNS has followed the same pattern of trial as permanent implantation as SCS. However, temporary percutaneous PNS (PPNS) has a growing body of literature supporting its use and demonstrating long term efficacy in various pain syndromes, including post-amputation pain, post-stroke shoulder pain, and chronic low back pain.[5,65,66] Enduring clinically significant pain relief has been shown in several studies using PPNS with an indwelling time of four to eight weeks. Lasting reductions in disability, pain interference and opiate requirements have been demonstrated as well.[67] The proposed mechanism of action for this sustained analgesia involves focal and robust physiologic peripheral signaling that is believed to be responsible for the reversal of maladaptive central plasticity of chronic pain.[68]

The current state of PNS is a combination of traditional techniques and newly developed strategies. First suggested more than 40 years ago, occipital nerve stimulation as a treatment for craniofacial pain is one of the more common uses of PNS to this day despite failure to meet primary endpoints in large multicenter clinical trials.[69-71] More recently, vagal nerve stimulation, an open surgical procedure long used to address seizures and refractory depression, has been reinvented as a non-invasive procedure to treat headache disorders.[55,56,60] The relatively newer concept of restorative neurostimulation targets the lumbar medial branch nerves to elicit episodic contractions of previously impaired



• **Figure 71.4** Development of leads that are amenable to implant outside the spinal canal and miniaturization of stimulator components has been an important development in peripheral nerve stimulation (PNS), used with permission from Nalu Neurostimulation System. *SCS*, Spinal cord stimulation.

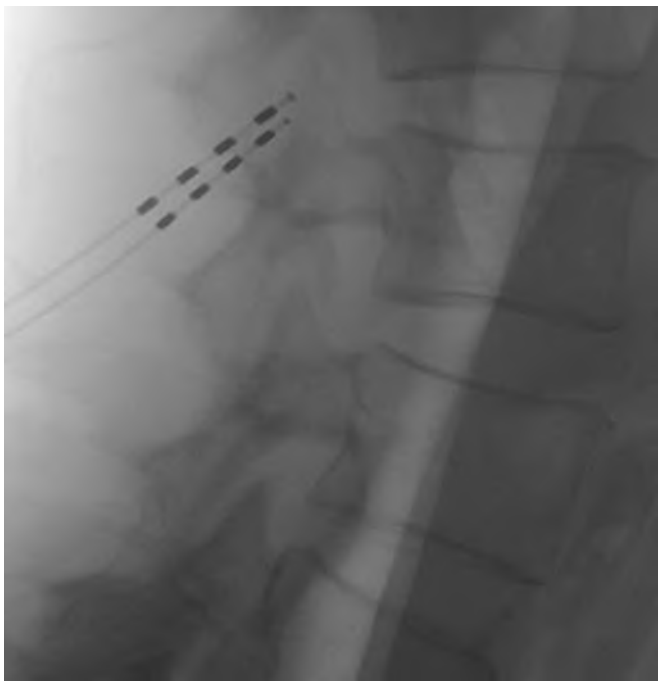
lumbar multifidus musculature in chronic low back pain patients (Fig. 71.6).[72] It is supported by a multicenter prospective, randomized, double-blinded clinical trial with a two year follow up in the peer-review process. Continued deciphering of the pathophysiologic mechanisms of therapeutic targets coupled with steady progress in device design and ergonomics, along with minimally disruptive delivery of the therapy, promises specifically tailored treatment and improved outcomes for PNS.

Motor Cortex and Deep Brain Stimulation

Motor cortex and deep brain stimulation have been explored to treat highly refractory neuropathic pain syndromes, including central pain, deafferentation syndromes, and trigeminal neuralgia.[73] Deep brain stimulation (DBS) has become a widely used technique for movement disorders and much less so for painful indications, although there have been many case reports on the treatment of highly refractory central pain syndromes.[74] Unfortunately, a multicenter study, promoted by the Food and Drug Administration, showed negative results of DBS therapy in the treatment of neuropathic pain.[75] These findings hinder the use of DBS in clinical practice in the United States, leaving only



• **Figure 71.6** Permanently implantable restorative neurostimulation for axial low back pain, used with permission of Mainstay Medical.

class III level evidence for DBS for phantom limb pain, trigeminal neuralgia, and other peripheral nerve pain syndromes. Since its introduction in the early 1990s, motor cortex stimulation (MCS) for the treatment of pain has been supported by several blinded RCTs (Class I evidence), including a 2009 clinical trial that enrolled 16 participants who had neuropathic pain related to peripheral lesions. The 12 monthly follow up included VAS, Brief Pain Inventory, McGill Pain Questionnaire, and Sickness Impact Profile scores. VAS and Sickness Impact Profile scores were significantly improved one year post-implantation.[76] Repetitive

transcranial magnetic stimulation (rTMS) and transcranial direct current stimulation (tDCS) are promising non-invasive cortical stimulation strategies for neuropathic pain treatment whose mechanisms of action are believed to be shared with MCS.[77–79]

Summary

Recent advances in neuromodulation, including efficacious new waveforms and expansion of indications, solidified clinical usage of SCS, PND, DBS, and MCS. High frequency 10 kHz SCS, closed-loop type of SCS, DTM, and DRG stimulation provided significantly improved outcomes when used for the treatment of chronic pain and may result in a significant increase in the utilization of SCS in the years to come. Similarly, improved expertise in PNS guidance using ultrasound increases the usage of this therapy, resulting in a higher level of evidence. DBS and MCS technologic advancements and new indications follow a similar suit. When this chapter was written, several large prospective trials were being conducted in neuromodulation, making this therapeutic area one of the most promising in neuroscience.

Key Points

- The major mechanisms of traditional low frequency SCS include activation of the gate control mechanisms, blockade of pain conduction via the spinothalamic tract, supraspinal sympathetic suppression, and activation or release of neuromodulators.
- Blockade of supraspinal sympathetic mechanisms by SCS results in an increase in peripheral blood flow with transitory inhibition of sympathetic vasoconstriction.
- Activation or release of neuromodulators such as GABA in the dorsal horn, glycine release in the extracellular space of the spinal cord, and inhibition of glutamate and aspartate release in the dorsal horn are additional mechanisms for pain control.
- SCS affects heart function by reducing intrinsic cardiac nervous system activity, preemptive suppression of a marked increase in sympathetic outflow, and a decrease in the frequency of arrhythmias in ischemic hearts.
- SCS improves ischemic pain in the extremities by a vasodilator effect via CGRP, peripheral prostacyclin release, and neuronal increase of nitric oxide.
- In an acute neuropathic pain model in rodents and mammals, the DTM type of SCS provided superior thermal and mechanical hypersensitivity suppression compared to low and high frequency SCS.
- Dorsal root ganglia stimulation acts directly on the development of neuropathic pain through inhibition of hyperexcitability and spontaneous ectopic firing of neuronal cell bodies contained within the DRG.
- In patients with chronic pain of the trunk and/or limbs, burst stimulation was noted to be superior to traditional tonic stimulation, with slightly better average pain scores. At one year post-implant, more patients preferred burst stimulation.
- There is substantial evidence to support the efficacy and durability of high frequency (10 kHz) SCS for treating back and leg pain and the superiority of high frequency stimulation over traditional stimulation.
- In patients with chronic back and leg pain, closed-loop stimulation was found to be superior to open-loop stimulation.
- The development of ergonomically designed devices in the periphery, combined with the use of ultrasound guidance for implantation, has facilitated a resurgence of the use of PNS for the treatment of many chronic painful conditions.

Intrathecal Drug Delivery

TIMOTHY FURNISH, CARLYLE PETERS HAMSHER, MARK S. WALLACE

Intrathecal drug delivery for the treatment of pain is an outgrowth of pioneering research into spinal cord mechanisms and receptors that modulate nociceptive signal transmission to and within the central nervous system. Since the 1970s, researchers have identified the peptide substance P in small dorsal root ganglion cells[1] and observed that opioids would produce analgesia.[2] These findings, as well as the observation that substance P release evoked from C fibers is blocked by morphine,[3] marked the beginning of the current trend toward focusing on the selective regulation of spinal afferent processing. Since then, there has been much research in this area, leading to the widespread use of intrathecal therapy to treat chronic intractable pain. Although this therapy has proven extremely beneficial to many patients, it is also associated with high costs, high maintenance, and risks requiring careful patient selection. The first section focuses on the patient selection, technologies used for chronic intrathecal drug delivery, system implantation, and troubleshooting. The second section reviews the medications used in intrathecal drug delivery systems.

Patient Selection, Trialing, and Implantation

Intraspinal Drug Delivery Techniques

There are essentially three methods of intraspinal drug delivery: (1) externalized systems, (2) partially externalized systems, and (3) totally implanted systems. The selection of the technique will depend on the goal of therapy, ranging from short term intrathecal trialing to long term therapy to treat chronic pain. Each technique has associated risks and costs, which must be considered when selecting the technique.

Externalized Systems

An externalized intrathecal catheter can be used for trialing intrathecal drugs or for short term therapeutic infusions. Such a system is best for infusions lasting hours to days but has been successfully used for longer term delivery in terminally ill patients lasting a few weeks. The use of an externalized catheter raises the concern for a local infection at the catheter exit site or that the catheter may serve as a conduit for either epidural or intrathecal spread of infection. Using a strict aseptic technique for catheter insertion can minimize the risk of insertion site infection, and the placement of a chlorhexidine impregnated catheter patch at the insertion site further reduces this risk (Fig. 72.1). There is no evidence that systemic antibiotics prevent these infections. In a terminally ill patient with a very short life expectancy, the risk-benefit ratio may favor the use of an externalized catheter for intrathecal drug delivery. Some practitioners tunnel these catheters under the skin for some distance to provide stability and reduce the likelihood of inadvertent catheter withdrawal. Currently, the United States Food and Drug Administration (FDA) has not approved any externalized intrathecal catheters, and it is common to use epidural or lumbar drain catheters for this purpose.

Partially Externalized Systems

Partially externalized systems are those in which the intrathecal catheter is tunneled and connected to a subcutaneous port. A needle then accesses the port percutaneously, and medication is delivered with tubing connected to an external pump. Compared to an externalized system, this permits greater patient freedom of movement and reduces the risk of inadvertent catheter removal. Partially externalized systems are intended for single bolus injections. There continues to be a risk of colonization and infection of the port pocket with prolonged or repeated needle access. These systems have limited application for long term, continuous intrathecal drug delivery.

Implanted Intrathecal Infusion Pumps

Totally implanted systems are the most common and have the catheter and pump completely internalized by surgical implantation. These are used for long term infusions and afford the patient much greater freedom of movement. A totally implanted system is more expensive and requires a more invasive surgical procedure than an externalized or partially externalized system. Although it is generally recommended that implanted pumps be reserved for patients with a life expectancy of greater than six months,[4,5] this therapy may improve quality of life in patients with life expectancy as low as two to three months. However, patients with a life expectancy of fewer than six months should be carefully selected.

There are two main types of intrathecal infusion systems, fixed-rate and variable-rate programmable pumps. All implanted pumps have two percutaneous access ports. One port is for refilling the drug reservoir, and there is a separate intrathecal catheter access port for bolus injection through, or aspiration from, the catheter. The infusion systems are generally implanted in the lower abdominal subcutaneous fat and connected to a catheter, which is tunneled subcutaneously around the abdominal wall into the intrathecal space.[6,7] However, the pumps may also be implanted subcutaneously in the lower back in selected patients

Drug/Dose	Hold Prior to Needle/Catheter Placement	Restart after Neuraxial Placement
Heparin SQ	1 hour	1 hour
Enoxaparin 40 mg SQ/day	12 hours	2 hours
Enoxaparin > 40 mg SQ/day	24 hours	2 hours
Warfarin	5 days & check INR < 1.3	Same day
NSAIDS/Aspirin	Not necessary	—
Clopidogrel (Plavix)	7 days	Same day
Ticlopidine (Ticlid)	14 days	Same day

• **Figure 72.1** Chlorhexidine impregnated patch, BioPatch, Johnson & Johnson.

(see the discussion that follows). The septum puncture life of the percutaneous refill port is very high: 500 punctures for the most commonly used pump, the Medronic Synchromed II pump. It would be unlikely to reach this number of punctures during the life of the pump (5.5 years for the Synchromed II).[8]

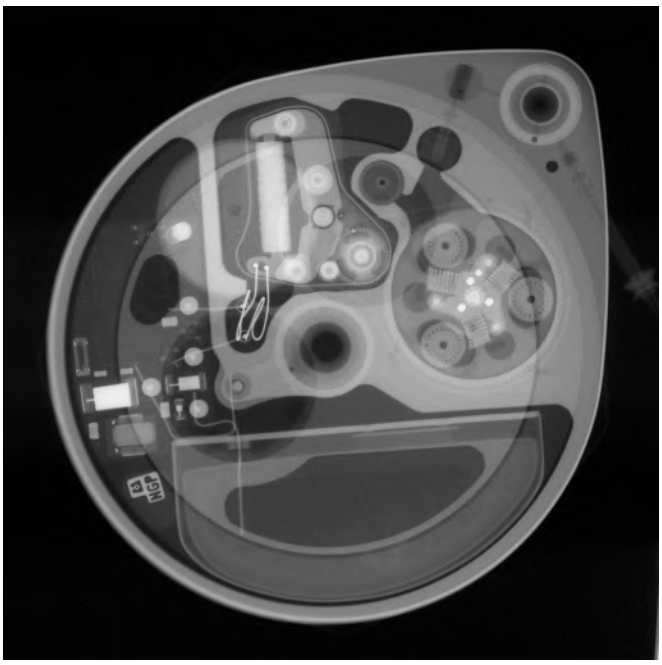
The first intrathecal pump, manufactured by Shiley Infusaid, became commercially available in 1982.[9] The Infusaid and other early pumps were non-programmable fixed-rate infusion systems. These pumps were simple devices without batteries, in which pressurized gas pushes the drug from a reservoir through a valve and into the catheter. The kinetic energy of the pressurized gas is increased every time a new drug is injected into the reservoir. The chief advantage of these pumps is the simplicity of design and lack of batteries. Unfortunately, they cannot vary the dose delivered without changing the concentration of the drug in the reservoir. The last of these pumps, the Codman 3000 (Fig. 72.2), was discontinued in 2018. Fixed infusion rate pumps have not been used with any frequency in the United States for many years. However, some of these pumps may still be implanted and functional in patients since there are no batteries; thus they never require replacing because of battery failure. The Codman pump was available in different sizes and various flow rates. The flow rate is controlled by a flow restrictor. Flow rates may vary for different drugs, drug combinations, and especially with high drug concentrations, based on differences in viscosity.[10] In addition, changes in body temperature and atmospheric pressure will change flow rate by affecting the gas pressure within the system.

Programmable pumps allow the clinician to vary infusion rates to increase or decrease the dose without changing the concentration of the drug or drugs in the pump. The original programmable pump was the Medtronic Synchromed, first introduced in 1991.[11] This device was upgraded to the Medtronic Synchromed II (Fig. 72.3), which allows patient-controlled intrathecal bolus dosing via a remote-control device. The Synchromed II uses a peristaltic roller system (Fig. 72.4) to move the drug from the reservoir to the implanted intrathecal catheter. The Synchromed II is available in 20 mL and 40 mL reservoir sizes and is FDA approved for baclofen, morphine, and ziconotide.

The other programable intrathecal pump on the market is the Flowonix Prometra II implantable pump. Similar to the older non-programmable pumps, the original Prometra and newer Prometra II use a pressurized gas chamber as the driving force. Unlike those older fixed-rate infusion pumps, a programmable flow-metering valve allows for a variable drug delivery rate.[12] The Prometra pump's low energy requirement is its main advantage. Since the batteries are used to control the electronics only, not to pump the drug, the battery has a ten-year life span before the need to surgically replace the pump. The Prometra is available in a 20 mL reservoir and is FDA approved for morphine. The issues with variable flow resulting from viscosity, temperature, and residual reservoir volume have been addressed by the advanced flow-metering valve.

Intrathecal Pump Magnetic Resonance Imaging (MRI) Compatibility

Both the Synchromed II and Prometra pumps are MRI conditional. However, the conditions for MRI management are different between the two.[13,14] As discussed above, the Synchromed



• **Figure 72.4** Synchromed II internal structures, Medtronic, Inc.

pump is driven by a peristaltic pump that can be programmed to rotate at different rates to adjust drug daily dose. When in the MRI, the peristaltic rotor will suspend in the magnet and stop the flow of the drug. When removed from the magnet, the rotator will restart the drug flow as programmed. The MRI might result in a permanent pump stall if the rotor does not resume functioning. The risk of a permanent pump stall increases as the pump moves closer to a 90-degree position in the magnet. This may occur in patients with the pump flipped 90 degrees to normal placement in the abdominal wall pump pocket. Pumps in the traditional position within the abdominal wall are closer to the 0-degree position with a lower risk.[14]

The Prometra pumps have a flow-metering valve that will move into the fully open position while in the MRI. Since the pump reservoir is under positive pressure, this would result in immediate release of the entire pump reservoir contents resulting in overdose. Therefore in the original Prometra pump, it is critical to remove all drugs from the reservoir prior to an MRI. The Prometra II pump has a safety mechanism that if the flow-metering valve abruptly opens, a secondary valve closes, thus stopping the flow. The pump will not restart until this secondary valve is reset. Despite the secondary valve's safety measure, the manufacturer's recommendations for MRI compatibility with the Prometra II pump are to remove the contents of the drug reservoir prior to an MRI.[14]

Patient Selection

Pain Type

Intrathecal drug delivery systems (IDDSs) are reserved for treating severe and refractory pain in two types of patients: those with cancer pain and those with non-cancer pain who have failed all conservative therapies.[15] The cost and invasive nature of IDDSs necessitate a careful evaluation to determine whether each individual patient is appropriate and likely to achieve benefit. A thorough assessment includes an evaluation of pain-generating pathologic conditions, medical comorbidities, psychosocial issues, patient compliance history, economic and healthcare coverage, and anatomic and technical considerations.[16]

In advanced stages of cancer, the prevalence of pain exceeds 60%. One-third of those patients report moderate to severe pain.[17] Comprehensive medical management (CMM) can significantly reduce pain and manage the adverse effects of opioids and other analgesics.[18] Despite aggressive therapy, some patients continue to endure severe pain. Others are unable to tolerate systemic opioids because of toxicity. A 2002 multi-center randomized trial compared CMM alone versus CMM plus an IDDS. They found that cancer patients receiving CMM plus an IDDS had reduced pain, fewer drug toxicities, and prolonged survival than controls.[18] Patients with significant toxicity or with refractory pain that has been inadequately controlled by the systemic administration of opioids and other analgesics are potential candidates for an IDDS (Table 72.1).[19] Intrathecal therapy may be especially valuable in patients with neuropathic pain from tumor invasion of neural

TABLE 72.1 Clinical Studies of Intrathecal Therapy for Cancer-Related Pain

Study	Number of Subjects	Type/Duration	Details	Efficacy
Smith et al. 2002[20]	200	RCT/four weeks	Advanced cancer pain; CMM (99) vs. IDDS (101)	IT plus CMM improved pain and reduced opioid adverse effects
Staats et al. 2004[21]	111	RCT/11 days	Refractory pain because of cancer or AIDS; ziconotide (71) vs. placebo (40)	IT ziconotide significant improvement in pain scores vs. placebo
Rauck et al. 2003[22]	119	Prospective Observational; up to 16 months	Refractory cancer pain; addition of IT morphine	Significant reduction in pain intensity and systematic opioid use
Mercadante et al. 2007[23]	55	Prospective Observational; up to six months	Advanced cancer pain; addition of IT morphine + levobupivacaine	Improved pain, decreased oral opioid, decreased opioid adverse effects
Dupoiron et al. 2012[24]	77	Prospective Observational; 90 days	Refractory cancer pain; ziconotide + morphine, ropivacaine, and/or clonidine	Improvement in numeric rating scale pain scores
Brogan et al. 2015[25]	58	Prospective Observational; 14–82 days	Refractory cancer pain; addition of IT analgesics	Decrease in numeric rating scale pain scores; decreased percentage with severe pain

plexuses, unstable pathologic fractures, painful impending spinal cord compression, and visceral tumors with or without autonomic dysfunction that results in gut dysmotility.

In patients with a life expectancy of less than two to three months, a percutaneous catheter and external pump can be used. These patients may be discharged from the hospital with hospice care or home-health services for the care of the catheter and infusion if appropriate services are locally available.

For the patient with chronic non-cancer pain, a comprehensive evaluation to establish the cause of the pain should be performed as part of the decision process regarding whether an intrathecal pump is appropriate. The evaluation should include a detailed history, physical examination, radiologic studies, and assessment of prior therapies and their outcomes.[26–28] Many diagnoses and painful conditions may be amenable to intrathecal drug delivery in certain cases. These include neuropathic syndromes, such as spinal cord injury, diabetic peripheral neuropathy, complex regional pain syndrome, postherpetic neuralgia, and phantom limb pain. Additionally, mixed nociceptive and neuropathic conditions, such as post-laminectomy pain syndrome or chronic pancreatitis, and nociceptive pain conditions, such as chronic vertebral compression fractures and severe spinal degeneration, may be appropriate for an IDDS in some circumstances after thorough patient selection and discussion.[16,28,29]

Implanted drug delivery therapy should be reserved for those patients who are refractory from more conservative treatment. A stepwise approach starting with the least invasive and costly therapies is recommended.[15,16] This may begin with exercise programs, relaxation techniques, and over-the-counter analgesics. Subsequent steps include adjuvant analgesics, muscle relaxants, physical therapy, and psychological therapies. More invasive therapies include neuraxial somatic and sympathetic blocks and spinal cord stimulation. The top tier of this stepwise treatment pyramid is reserved for the most invasive therapies, including intrathecal drug delivery and neuro-destructive procedures, such as cordotomy, myelotomy, and dorsal rhizotomy.[28,30] There are few controlled trials of intrathecal therapy for chronic non-cancer pain. However, observational studies suggest such therapy can provide pain relief in certain patients who have failed to achieve relief with more conservative treatments (Table 72.2).[31,32] Determining the efficacy of long-term intrathecal drug therapy remains one of the greatest challenges in chronic non-cancer pain management. One of the reasons for the lack of randomized controlled trials is that the high cost and invasiveness of such treatment pose ethical challenges in designing a double-blind, placebo-controlled study. Therefore one can only rely on the retrospective reviews of patients receiving this therapy and attempt to make conclusions on the efficacy of this treatment. Many studies have attempted to determine the efficacy of long-term intrathecal morphine therapy based on the classification of the pain. However, a review of these articles reveals large discrepancies in pain classification between studies. Because pain is often multifactorial (e.g. failed back syndrome versus HIV neuropathy versus complex regional pain syndrome), it is difficult to determine what pain syndromes are the most responsive to this therapy and have long-term benefits.

Patient Comorbidities

The aging, chronic pain patient may experience some of the same age-related comorbidities as any individual. Many of these comorbid conditions can complicate the implantation and use of an intrathecal pump. These medical issues and their potential interaction with intrathecal therapy must be considered during the patient selection process.

TABLE 72.2 Clinical Studies of Intrathecal Therapy for Non-Cancer Pain

Study	Number of Subjects	Type/Duration	Details	Efficacy
Winkelmuller et al. 1996[33]	120	Retrospective; six months to 5.7 years follow up	Mixed neuropathic/nociceptive pain; morphine, bupivacaine, hydromorphone	74% reported improvement in pain, averaging a 58% reduction
Anderson et al. 1999[34]	30	Retrospective	Failed back surgery; rotation from morphine to hydromorphone because of adverse effects or poor pain control	37% had improved pain control; the majority with decreased adverse effects (nausea, pruritis, edema)
Kumar et al. 2001[35]	25 trialed 16 implanted	Prospective, single-center, non-randomized	Non-malignant pain; morphine; follow up 13–49 months	Trial 64% with >50% pain reduction; implant avg reduction 57.5% at final follow up
Rainov et al. 2001[36]	30 trialed, 26 implanted	Prospective, single-center, non-randomized	Failed back surgery syndrome; polydrug infusion of morphine + clonidine, bupivacaine, or midazolam; mean follow up 27 months	Average pain intensity 8/10 to 3/10, remained in the range of 3–5/10 throughout follow up
Deer et al. 2004[37]	166 trialed, 136 implanted	Prospective, non-randomized, multi-center registry	Mechanical neuropathic, mixed low back/leg pain. Trialing and implant for non-malignant pain; follow up 12 months	93% trial success; 82% implanted; 48% reduction in the low back; 32% for leg pain at 12 months
Rauck et al. 2006[38]	220	Randomized, double-blind, placebo controlled	Ziconotide slow titration over three weeks; 112 ziconotide, 108 placebo	Statistical significance for ziconotide over three weeks; higher adverse effects

Diabetes Mellitus

Diabetes mellitus affects over 8% of the United States population and nearly 27% of those over 65 years.[39] Patients with diabetes experience poor wound healing and suffer from an increased incidence of surgical site infections.[40–42] Implantable devices pose a special risk of surgical wound infections. With implantable intrathecal pumps, wound infections have been found to be the most common device-related complication.[41] Patients with diabetes, especially if blood glucose control is poor, should be counseled on the increased risk, and implanters should check a hemoglobin A1C prior to surgical implant and consider postponing surgery for an A1C >8.[41]

Anticoagulant Therapy

Patients on anticoagulant therapy are at increased risk of epidural hematoma formation after placement or removal of epidural or spinal catheters.[43,44] Additionally, multiple new anticoagulant agents have made the management of anticoagulation for invasive pain procedures more of a challenge. Many of these agents carry specific warnings related to spinal injection procedures but may not provide clear guidance regarding perioperative or peri-procedural management. A group of chronic pain societies, including the American Society of Regional Anesthesia and Pain Medicine, the European Society of Regional Anaesthesia and Pain Therapy, American Academy of Pain Medicine, the International Neuromodulation Society, the North American Neuromodulation Society, and the World Institute of Pain, have published guidelines regarding the management of drugs that affect coagulation in the setting of invasive pain procedures (Box 72.1).[44] They divide pain procedures into three risk categories: low, intermediate, and high. The implantation of intrathecal pumps is considered by this guideline to be a high-risk procedure. Scattered case reports of anticoagulant therapy restarted after implantation of intrathecal pumps offered no clear evidence for or against the safe use of intrathecal pumps in these patients.[16]

Infections

Any active infection puts the patient at risk of a surgical site infection that may be superficial or deep into the pump pocket. While a superficial surgical site infection may be successfully treated medically, a pump pocket infection is virtually impossible to clear with antibiotic therapy and will require explanting the entire pump and catheter system. Any active or chronic bacterial or fungal infections, particularly with non-cancer pain patients, should be regarded as a contraindication to implantation.

Pulmonary Disease

More than 18 million Americans have obstructive sleep apnea (OSA).[45] In addition to the risks of carbon dioxide retention and both systemic and pulmonary hypertension, the OSA patient has increased sensitivity to the respiratory depressant effects of opioids.[46] There are no studies of intrathecal opioid use in OSA patients. However, case reports suggest that chronic use of oral opioids in those with OSA increases apnea duration and hypoxia severity.[46] Chronic obstructive pulmonary disease (COPD) also results in carbon dioxide retention and increased risk of respiratory depression with the administration of opioids. A retrospective case-controlled study of postoperative COPD patients administered opioids found an increased risk of respiratory events (odds ratio [OR] 5.09; 95% confidence interval [CI]) than patients without chronic lung disease.[46] Most of these events occurred within 24 h of surgery. The long-term risk of intrathecal opioid administration in patients with severe pulmonary disease is unknown. However, known risks of perioperative opioid administration in this population warrant careful monitoring during trialing as well as after implantation and initiation of therapy.

Additionally, patients who are chronic smokers are at increased risk of surgical site infections. The Polyanalgesic Consensus Conference (PACC) published several guidelines regarding intrathecal pump implantation and management. They recommend smoking cessation two months prior to elective intrathecal pump implant.[41]

Psychological Screening

The Centers for Medicare and Medicaid Services require a psychological assessment prior to the implantation of spinal cord stimulator systems. No such requirement exists for IDDS. Although not required, it is widely accepted that a pre-procedure psychological assessment is warranted and is at least as important if not more important for appropriate patient selection for an IDDS as spinal cord stimulation for non-cancer pain treatment.[5,15,16,26,27] Ideally, a psychological evaluation would aid in predicting positive response to an implantable therapy. In reality, there is limited evidence regarding the efficacy of psychological screening to predict long-term success. Psychological counseling should be used to establish well-care and goal setting and counsel on unlikely or irrational

• BOX 72.1 Summary of American Society of Regional Anesthesia (ASRA) Neuraxial Analgesia Anticoagulation Guidelines for High-Risk Procedures (Intrathecal Pump Implantation)

Drug/Dose	Hold Prior to Pump Implantation	Restart After Implant
Heparin SQ (BID or TID)	24 h	6–8 h
Enoxaparin 40 mg SQ/day	12 h	12–24 h
Enoxaparin >40 mg SQ/day	24 h	12–24 h
Coumadin	Five days & check INR<1.3	6 h
NSAIDS	Five half lives	24 h
Aspirin	Six days primary prophylaxis; shared decision-making secondary prophylaxis	24 h
Clopidogrel (Plavix)	Seven days	12–24 h
Prasugrel (Effient)	Seven to ten days	24 h
Ticagrelor (Brilinta)	Five days	24 h
Dabigatran (Pradaxa)	Four days	24 h
Rivaroxaban (Xarelto)	Three days	24 h
Apixaban (Eliquis)	Three days	24 h

(From Narouze S, Benzon H, Provenzano D, et al. Interventional spine and pain procedures in patients on antiplatelet and anticoagulant medications (second edition): guidelines from the American Society of Regional Anesthesia and Pain Medicine, the European Society of Regional Anaesthesia and Pain Therapy, the American Academy of Pain Medicine, the International Neuromodulation Society, the North American Neuromodulation Society, and the World Institute of Pain. *Reg Anesth Pain Med.* 2018;43:225–262).

patient treatment expectations. Much of the literature in this area concerns implantable spinal cord stimulators, and it is from this body of literature that guidelines regarding the use of psychological evaluation for IDDS have been extrapolated.[5,15,16,26,27]

The presence of suicidal or homicidal ideation, uncontrolled depression, active psychosis, severe cognitive deficits, and active drug abuse are contraindications to implantation. In a study by Celestin and colleagues, certain psychological factors and traits were associated with poor analgesic outcomes after implantation. These include somatization, depression, anxiety, and poor coping skills.[47] However, a study by Doleys and Brown found that those with a mild abnormality on the Minnesota Multiphasic Personality Inventory (MMPI) personality profiles had better long term analgesic efficacy than those with more normal scores.[48] Consensus guidelines have recommended the use of some form of psychological assessment in the selection process for IDDS candidates but caution against using the results to categorically rule out implantation in patients with psychological issues.[16,26,27]

The psychological evaluation should be used to identify factors that may affect the outcome of a trial or long term therapy, either positively or negatively. In addition to identifying severe psychopathologic conditions, the screening examination can evaluate for cognitive deficits, coping mechanisms, social supports, patient expectations, and comprehension of treatment goals that may affect therapy. This screening may also identify the need for psychological treatment that can improve the outcome of therapy. The psychologist should not be asked to give "clearance" but rather act as an additional source of information about whether IDDS therapy is appropriate, the patient has rational expectations, and this therapy is likely to succeed for an individual patient.

Trialing

Some type of therapy trial prior to permanent system implantation has been commonly performed and is often required by insurance payers such as Medicare. Trial options include a single bolus intrathecal injection or a continuous infusion via the percutaneous intrathecal or epidural catheter. The PACC guidelines on trialing for intrathecal therapy note that there is no data to suggest one trialing method is superior to another.[27] Further, the data are limited, suggesting that trialing can accurately predict efficacy after implantation.[16] While the PACC guidelines recommend a trial for non-cancer pain, an earlier expert consensus statement regarding guidelines for selection of patients for non-cancer pain recommended against the requirement of a pre-implant trial because of the trial's unsubstantiated predictive value.[16,27]

The selection of a trialing method for non-cancer pain will be made largely based on physician preference along with payer requirements. Most trials are performed in an outpatient setting with a single bolus intrathecal injection of a lipophilic opioid, such as fentanyl, and/or non-opioid, such as ziconotide. Alternatively, a continuous intrathecal or epidural infusion can be done, but this requires admission to a hospital and significantly adds to the cost and complexity of a trial. The advantage of epidural infusion is the simplicity of catheter placement and a much lower risk of post-dural puncture headache (PDPH). The development of a PDPH during trial may impair the patient's ability to determine the efficacy of the trial. An intrathecal catheter trial more closely mimics the permanent implant conditions and pharmacodynamics.[16] However, drug volume and concentration for a catheter trial may be substantially different from the conditions of an implanted infusion. An intrathecal bolus injection trial provides simplicity, reduced costs, and a low incidence of PDPH. However, it carries a significant risk of false-positive results. The PACC guidelines note that either bolus or catheter trials are acceptable.[27]

Trials for cancer pain can be performed in a similar fashion. However, the lack of prognostic evidence for trials calls into question their value in patients with rapidly progressive disease near the end of life. The PACC guidelines note that a trial is not required for patients with advanced cancer pain, and another consensus guide regarding intrathecal therapy for cancer pain noted that the risks associated with the trial and delay of therapy might not outweigh the alleged prognostic benefits.[5,27] However, other experts have recommended the use of a trial in cancer pain to give the patient and physician the opportunity to evaluate potential responses and possible side effects.[19]

Trials of intrathecal baclofen therapy for spasticity are considerably more straightforward than those for cancer and non-cancer pain. There are clear, objective outcome measures of spasticity that can be assessed to determine response. The commonly used criterion for a successful trial is a two-point reduction on the modified Ashworth scale for grading spasticity (Box 72.2).[49,50] Patients may also demonstrate improvements in joint range of motion.

The baclofen trial consists of a bolus intrathecal injection of 25–50 mcg of baclofen and is performed in an outpatient setting. The onset of effect occurs in 1–3 h and may last 6–8 h.[51] The patient is then evaluated with serial examinations to determine response. If the patient fails to respond, the trial may be repeated on a subsequent day at a higher dose.

Tolerance to intrathecal opioids develops over time, similar to systemically administered opioids. Therefore intrathecal dose escalation is common.[36,52,53] The PACC guidelines of both 2012 and 2016 include a maximum daily dose and concentration of intrathecal opioids and non-opioid analgesics. The 2016 guidelines added the recommendation to reevaluate doses of fentanyl that exceed 1000 mcg/day. Noting that high dose lipophilic opioid infusions may have limited additional efficacy and result in systemic concentrations similar to transdermal systemic delivery.[27]

Many patients being considered for intrathecal therapy to treat chronic pain are already receiving systemic opioids. Some studies have shown a total oral opioid dose reduction after implantation of IDDS. One retrospective study of insurance claims data found

• BOX 72.2 Modified Ashworth Scale for Spasticity

Ashworth Number	Description
0	No increase in muscle tone
1	Slight increase in tone manifested by a catch or minimal increased resistance at the end of ROM
1+	Slight increase in tone manifested by a catch followed by minimal resistance throughout the remainder of ROM
2	More marked increase in tone throughout ROM
3	Considerably increased tone, passive movement difficult
4	Affected part(s) rigid in flexion or extension

ROM, Range of motion.

(From Bohannon RW, Smith MB. Interrater reliability of a modified Ashworth scale of muscle spasticity. *Phys Ther.* 1987;67:206–207.)

that 43% of patients with chronic non-cancer pain who were on opioids before IDDS implant had discontinued all opioids one year after implant. Additionally, about three-fourths of those who failed to eliminate opioids saw a dose reduction in total oral morphine equivalents.[54] Regardless, both this and other studies show a significant portion of patients who remain on systemic opioids in addition to the intrathecal opioids.

There may be advantages to weaning the patient off systemic opioids prior to a trial. The PACC guidelines recommend reducing or eliminating systemic opioids prior to a trial or implantation of an IDDS.[27] A pre-trial drug holiday affords the opportunity to evaluate the patient and their pain without systemic opioids. This will also reduce tolerance, allowing for a better assessment of response to intrathecal therapy during the trial. The tapering process may uncover signs of opioid use disorder prior to proceeding with an implant. An addictionology consult should be considered for patients who cannot wean from opioids because of severe withdrawal symptoms.

Weaning patients off opioids prior to the implant may result in lower doses of intrathecal opioids. Evidence from small retrospective studies exists for the benefits of eliminating systemic opioids prior to an intrathecal trial.[55,56] These studies suggest that lower trial and IDDS starting doses can be achieved when systemic opioids are eliminated for several weeks prior to a trial. This approach has been referred to as micro-dosing because of the use of intrathecal morphine in the microgram dose range. Conversely, at least one study showed that lower systemic opioid doses at baseline did not protect against dose escalation after IDDS implantation.[57]

Consideration should be given for when and where to initiate intrathecal infusion after implantation. Compared to implantation of spinal cord stimulator devices, there is a significantly higher risk of mortality after implant or replacement of intrathecal pumps.[58] Initiating the infusion during an inpatient admission after pump implantation allows for close monitoring for adverse effects. When the pump implant is performed as an outpatient surgical procedure, more caution should be employed in initiating the infusion. The PACC guidelines recommend no more than one-half the trial dose as a starting daily infusion.[27] When starting drug infusion doses outside the PACC guideline starting dose range, it is recommended to initiate the infusion in an inpatient monitored setting.

Implantation

Location of Pump Placement

There are several considerations when choosing where to locate the pump. Patient comfort is of primary importance. To avoid rubbing, the pump must be located away from bony prominences, including the iliac crest and ribs. The amount of subcutaneous fat is also important. There may be too little space and tissue in the flank in the average-sized patient, whereas, in the morbidly obese patient, there may be too much subcutaneous fat in the abdomen. Have the patient sit up to mark the site to ensure that the pump will not lie below the beltline. Discuss the patient's sleeping habits to determine if the patient is a side sleeper. If so, then place the pump in the contralateral abdomen. In most cases, the most appropriate location for pump placement is in either the left or right lower quadrant of the abdomen.[59] Unlike spinal cord stimulator pulse generators, the size of intrathecal pumps may make placement in the flank or upper gluteal region uncomfortable for average-sized patients. Placement of the pump pocket in the abdomen necessitates positioning the patient in lateral decubitus for the surgical procedure. Proper attention to positioning is necessary to ensure that both the pump site and catheter insertion site are accessible without breaking scrub and repositioning.

Patients who have had multiple abdominal surgeries may pose a challenge in locating the pump pocket. If an abdominal site is impossible, a smaller 20 mL pump may be placed in the superior gluteal region. In larger patients, there may also be room to place the pump in the flank midway between the 12th rib and the iliac crest. A consultation with a plastic surgeon may be helpful in patients with limited implant site options.

When re-implanting a pump after a previous pump site infection, it may be useful to use a new location, such as the contralateral abdomen, to minimize re-infection risk. Placement of a pump into scar tissue is not recommended, as the blood supply can be erratic, limiting the delivery of antibiotics to the area during implantation. This is evident with pump re-implantations for battery failure in which the capsule surrounding the old pump has minimal bleeding when opened. In these cases, meticulous care must be taken with sterile technique to minimize the risk of infection with the re-implant. When replacing a pump using the existing pump pocket, it may be beneficial to excise the capsule prior to the implant of the new pump.

Anesthesia for Pump Implantation

Intrathecal pump implantation can be performed under local anesthesia with sedation, spinal anesthesia, or general anesthesia. The choice of anesthesia method will depend on physician preference and experience and patient comorbidities and comfort. One option is to place the intrathecal catheter percutaneously under local anesthesia followed by a spinal anesthetic for incision, catheter anchoring, tunneling, and creation of the pump pocket. If implanting under spinal anesthesia, the implanter will first place the Tuohy needle into the intrathecal space under local anesthesia. The implanter can then thread the intrathecal catheter through the Tuohy. Once the catheter is confirmed in the intrathecal space radiographically and by the free flow of cerebrospinal fluid (CSF), injection of 20–30 mg of preservative-free lidocaine will achieve adequate spinal anesthesia for both the posterior midline incision and abdominal pump pocket incision. The entire procedure can also be performed under local anesthesia with moderate sedation without the spinal anesthetic injection. These two methods allow for communication with the patient during catheter placement to minimize the risk of nerve injury.[41,59] Alternatively, general anesthesia may provide a more comfortable implant procedure for the patient or be preferred for patients with significant spasticity or in patients who would be unable to tolerate positioning and surgery under moderate sedation.[41]

Patient Positioning

Most commonly, the pump will be located in the abdomen, which necessitates either a lateral decubitus position or repositioning the patient from prone to supine midway through the surgery. Most implanters use the lateral decubitus position to avoid the time delay and potential infection risk of repositioning. Be sure to place the patient with the side of the planned pump pocket facing up. Careful positioning with pressure points padded and an axillary roll in place is necessary for patient comfort and to avoid intraoperative nerve compression injuries. The use of sticky rolls or bean bags to support the upper abdomen or posterior thorax

may assist in positioning the patient to hold them in the lateral decubitus position. Taking the time to ensure the patient is well supported and the sagittal axis is perpendicular to the operating room table will ensure a true anterior-posterior view with fluoroscopy. Position the patient's arms to avoid interfering with fluoroscopic visualization. As stated before, it is critical to mark the pump implantation site with the patient in the sitting position because the tissue will shift when in the lateral position. Marking the patient while in the lateral position risks having the pump end up in an uncomfortable location.

Surgical Technique

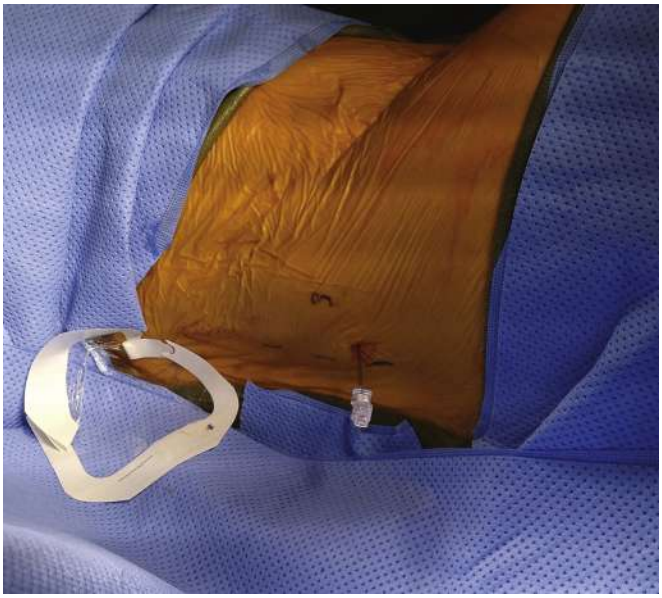
Sterile Technique

Good sterile technique and preoperative antibiotics are the two most important controllable factors in preventing wound infections. In a study of primary implantations and revisions of intrathecal baclofen pumps in pediatric and adult patients, an infection rate of 4%–5% was found.[60] In more than half of the infections, the primary organism was *Staphylococcus aureus*. In a multi-center prospective study of intrathecal pump implantations for both pain and spasticity, Follett found that the most common complication was an infection, with an incidence of 7%.[61] Most surgical site infections in clean surgeries are because of skin microorganisms.[62,64] Careful cleansing of both the surgeon's hands and the patient's skin at the operative site with either a *chlorhexidine-alcohol* or povidone-iodine scrub reduces skin bacterial counts. Scrubs of 2–3 min are superior to shorter scrub times. Several studies have suggested that chlorhexidine-alcohol scrubs may be superior to povidone-iodine scrubs.[64] Body hair should be removed if excessive, and removal should be performed with clippers instead of shaving. Shaving results in microtrauma of the skin, resulting in the inability of the antiseptics to reach the cracks and crevices that may be hiding bacteria.[62,41] Use of chlorhexidine skin preparation of the surgical site followed by the use of povidone-iodine-impregnated adhesive skin drapes is recommended, as this produces another barrier between the skin flora and wound.[41] If using these drapes, allow extra time for the skin prep to dry so that the adhesive will stick firmly to the skin. Adherence to the patient's skin is necessary for the antiseptic effect. Surgeons and assistants should double glove to reduce the infection risk associated with glove puncture.[41] Prophylactic systemic antibiotics against the most likely pathogens (skin flora) should be administered within 60 min of skin incision. Current guidelines for neurosurgical procedures are for cefazolin 2 g (3 g for adults >120 kg). If the patient has an allergy to cephalosporins, the recommended alternatives are clindamycin or vancomycin.[64] There is no evidence supporting the postoperative administration of oral antibiotics to prevent wound infections.[41]

Additional practices that may reduce the risk of infection include (1) limiting operative time, (2) limiting tissue trauma and maintaining hemostasis, (3) irrigating the incisions with saline prior to closure, and (4) re-gloving after surgical dissection is complete and before handling the pump. These practices may reduce the risk of surgical site infections.[41]

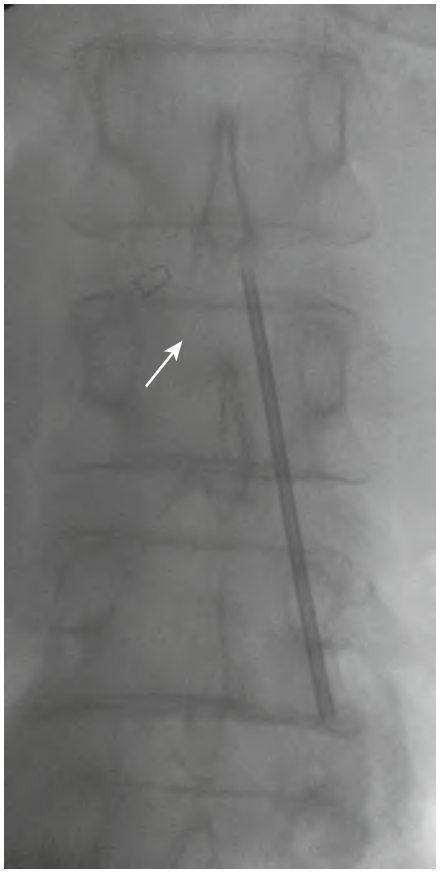
Posterior Incision, Catheter Placement, and Anchoring

If performing the implant under spinal anesthesia, the Tuohy needle will be placed percutaneously before making an incision. If using local/sedation or general anesthesia for the implant, most implanters will assess the needle entry then make an incision down to paravertebral fascia before placing the Tuohy. In either case, the spinous processes on either side of the planned intervertebral space for needle insertion should be marked on the skin. This will identify the midline incision to be used for dissection and anchoring. Next, mark a location for needle insertion to achieve a shallow-angle, paramedian oblique placement (Fig. 72.5). An angle of approximately 30 degrees off of the spine is ideal.[8] An insertion angle that is too steep will make it more difficult to thread the catheter. For an average-sized patient, the skin entry point will be 1–2 cm lateral to the midline on the side of the intended pump pocket and 1–1.5 vertebral levels caudad to the targeted interlaminar entry site. The typical entry site will range from the L2–L4 interlaminar spaces unless anatomic considerations or previous surgery dictates otherwise. When making an incision prior to needle placement, the incision should be approximately one-third above the needle entry into the fascia and two-thirds below the needle entry site.



• **Figure 72.5** Paramedian needle insertion, same side as the abdominal pump pocket.

With the stylet in place, the introducer needle should be advanced to the superior edge of the caudad lamina for the target space. After touching the lamina to gauge depth, the needle is then walked off the edge to the midline of the interlaminar space (Fig. 72.6). It is best to walk off the lamina just lateral to the midline. Further advancement into the intrathecal space will then be more midline. Next, rotate the bevel of the needle 90 degrees toward the midline so that the needle bevel will be parallel to the longitudinal fibers of the dura. This will spread rather than cut the fibers to reduce the chance of PDPH. The fluoroscopic view should then be rotated to a lateral view to monitor the needle depth as it is advanced into the intrathecal space. With gentle aspiration, the needle is advanced until there is a return of CSF. If there is no return of CSF despite adequate depth on lateral fluoroscopic view, rotate the needle back 90 degrees to the original position, which may result in CSF return. If there is no CSF return, rotate 90 degrees and gently advance the needle. Once the intrathecal space has been accessed, replace the needle stylet to stop CSF flow until ready to place the catheter. Turn the bevel tip cephalad. Ensure that the catheter guidewire is fully advanced into the catheter and is in place during the insertion and positioning of the catheter. Advance the catheter through the introducer to the desired level under fluoroscopic guidance (Fig. 72.7). Once



• **Figure 72.6** Needle advanced into the epidural space after walking off the superior edge of the L3 lamina. The *white arrow* indicates the edge of the lamina.

• **Figure 72.7** Lateral image with the needle (*white arrow*) in the intrathecal space and the catheter tip visible five vertebral levels above the entry site (*black arrow*).

the catheter tip is beyond the distal portion of the needle, extreme caution should be used should the catheter need to be withdrawn, as catheter shearing or damage may occur. If there is the slightest resistance when attempting to withdraw the catheter through the needle, it is recommended that the needle and catheter be removed together and the process restarted with needle placement.

If using the percutaneous needle placement technique, leave the needle in place to protect the catheter and make an incision in the midline over the spinous processes medial to the needle entry site down to the supraspinous ligament. The incision must be large enough to create a pocket for anchor placement, approximately 5 cm. Undermine the edges of the incision laterally along the fascial plane to create space for anchor placement and fully expose the traversing introducer needle (Fig. 72.8).

If the needle was placed percutaneously or within an incision, carefully withdraw the needle over the catheter with the catheter guidewire. To prevent inadvertent withdrawal of the catheter, hold the catheter steady, just distal to where it enters into the needle as the needle is withdrawn. Once the needle is removed, hold the catheter firmly at the entry site into the fascia at the level of the supraspinous ligament, and withdraw the guidewire. Recheck the catheter position under fluoroscopy to ensure proper placement (Fig. 72.9). Injection of a small amount of contrast may help to make the catheter visible under fluoroscopy.

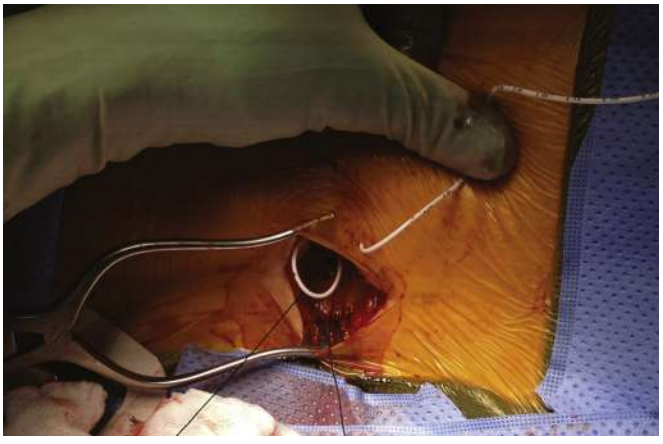
If using the percutaneous needle technique, continue holding the catheter at the fascia and bring the external portion of the catheter through the skin into the posterior pocket (Fig. 72.10).

• **Figure 72.8** Posterior incision medial to needle insertion down to the supraspinous ligament. Pocket undermined laterally to expose the needle within the pocket.

Clamp the end of the catheter with a rubber shod-covered clamp to prevent CSF loss while anchoring and tunneling.

Using a nonabsorbable suture, tie a purse-string suture through the fascia around the catheter to prevent CSF leak tracking back along the catheter.[11] Next, thread the catheter through the anchor deploy device and seat the anchor tip into the fascia. Hold the anchor with forceps and deploy the anchor. Place a 0–0 silk suture thru each anchor islet into the fascia and tie down tight. An additional 0–0 silk suture is then tied around the neck of the anchor, making sure the suture fits in the groove on the anchor.

• **Figure 72.9** Confirm catheter tip (*white arrow*) location on the fluoroscopic image prior to anchoring.



• **Figure 72.10** After carefully removing the needle and guidewire, bring the external section of the catheter into the pocket.

This will ensure a tight fit to hold the catheter. Ensure the anchor is attached firmly to the fascia and not to subcutaneous fat and that the distal tip of the anchor is buried into the fascia. Catheter migration out of the intrathecal space may occur if the anchor is not firmly attached to the fascia or if there is an extra catheter between the anchor and fascial entry point.

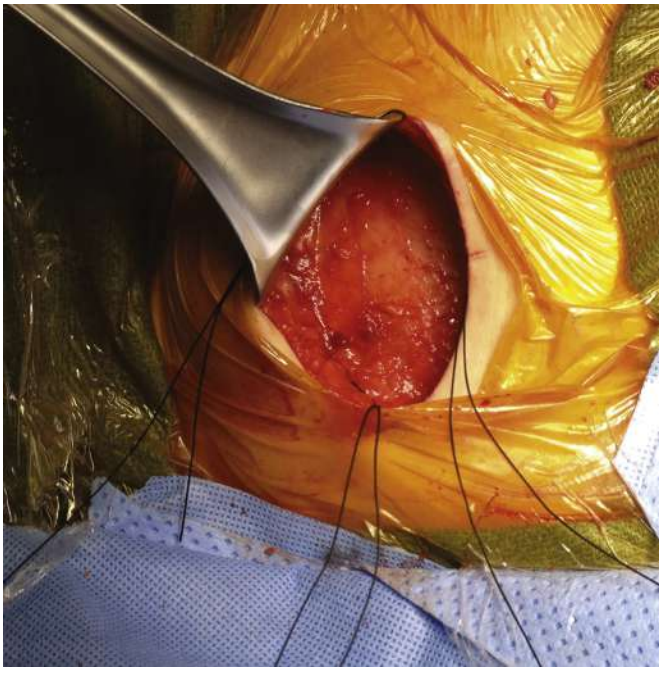
Pump Pocket

Once the catheter is securely anchored, the implanter can turn attention to creating a subcutaneous pocket for the pump. If performing the implant under sedation with local anesthesia, infiltrate a copious amount of local anesthetic around the planned pump pocket incision. At the abdominal site previously marked, make an incision down through the scarpa's fascia to subcutaneous fat. Obtain hemostasis with electrocautery as necessary and extend the incision to a depth of at least 1.5 cm but no more than 2.5 cm. Using careful dissection, undermine along a horizontal plane to create a pocket that just fits the pump. An oversized pocket increases the risk of seroma and shifting or flipping of the pump. The pocket should be undermined predominantly cephalad or caudad to the incision so that the final incision does not lie directly over the refill port of the pump. Accessing the refill port is much easier if the incision scar is not directly over the port. After ensuring proper fit of the pump, place 0-0 silk sutures into at least three corners of the pocket for anchoring the pump (Fig. 72.11). These sutures should be firmly anchored to the fascia. Failure to adequately anchor the pump at three or more sites may result in the pump flipping inside the pocket.

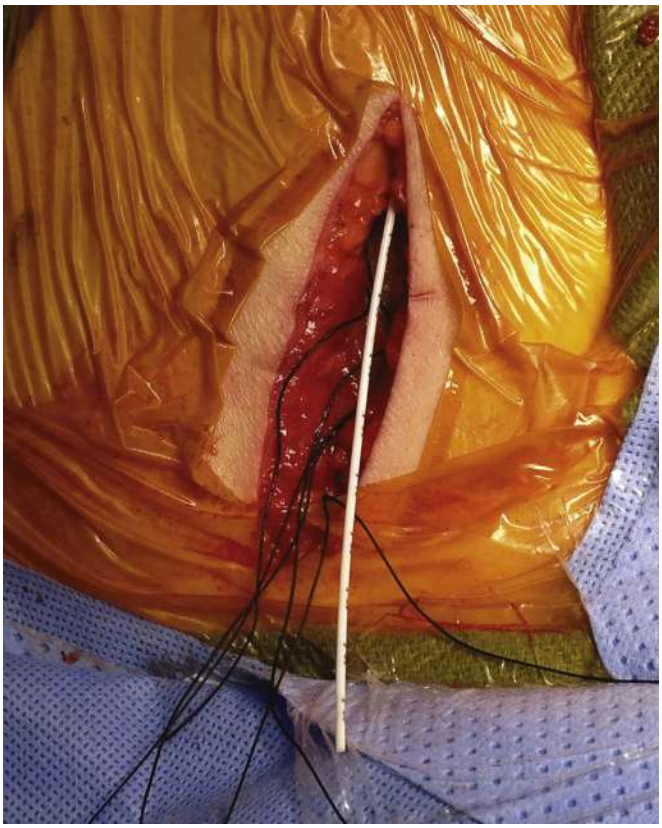
Tunneling

Once the pocket is prepared, the catheter must be tunneled from the posterior incision to the pump pocket (Fig. 72.12). The supplied tunneling device may be bent in a gentle curve to facilitate passage subcutaneously from the posterior incision to the pump pocket incision. Start inside the posterior pocket with pressure and a gentle twisting motion to begin passing the tunneling device toward the pump pocket. Place one hand on the skin surface over the tunneling device tip. The tip should be palpable without piercing the skin throughout the course to ensure it is neither too deep nor too superficial. Once the introducer has entered the pump pocket, remove the handle and begin passing the catheter through the introducer toward the pocket. Remove the introducer from the pump pocket side. Excess catheter length will be coiled beneath the pump.[8] Once the catheter has been tunneled, irrigate each pocket with copious amounts of normal saline.

Ensure patency of the catheter by observing CSF flow from the tip. Attach the catheter to the provided catheter connector. The



• **Figure 72.11** Sutures placed in three corners to tie down the pump through the attached suture rings.



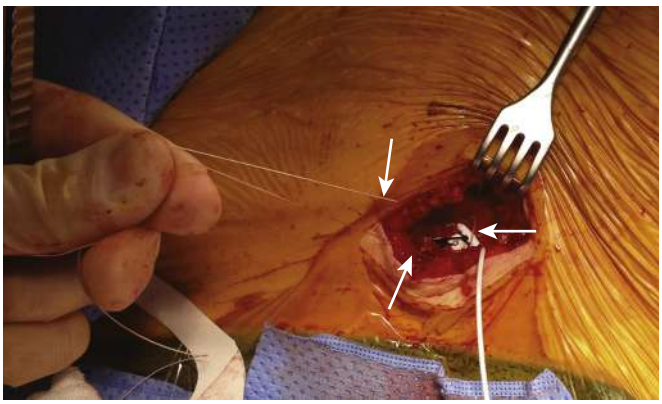
• **Figure 72.12** The catheter is tunneled into the pump pocket using the provided tunneling device.

• **Figure 72.13** Pump tightly in place within the pocket with the access port facing out.

connector is then attached to the pump. Ensure that it is firmly connected to the pump. Access the side port using the provided side port access needle and gently aspirate to make sure there is a flow of CSF. Insert the pump into its pocket and use the previously placed zero silk sutures to tie it down in three of the corner suture loops. Make sure the catheter is not entangled in these sutures to avoid kinking. Place coils of excess catheter behind the pump and ensure that the pump refill port is facing up (Fig. 72.13).[8]

Closure

Before closure of the posterior pocket, pass one 2-0 Vicryl suture through the dorsolumbar fascia alongside the anchor, then cross the suture over the anchor and through the fascia on the opposite side (Fig. 72.14). Pull the two sides together to tightly cover the anchor site and tie down (Fig. 72.15). This tight pocket over the anchor will help prevent catheter migration out of the intrathecal space. For deep incisions, the deep fascia may need to be closed using interrupted inverted absorbable sutures. For shallower incisions, only the subcutaneous fascia will need to be closed, using interrupted inverted sutures with the spacing close enough that a fingertip placed between sutures is unable to pass below the fascia into the incision. For the pump site, only the subcutaneous fascia will require closure, using interrupted inverted absorbable sutures similar to the posterior incision closure technique. Skin closure of both incisions may be performed with a running subcuticular closure of 3–0 Monocryl, Dermabond, and steri-strips or with staples. Last, place dressings over the incisions. Placement of an abdominal binder, with instructions to wear it for two weeks postoperatively, may decrease the incidence of seroma formation in the pump pocket.[41]



• **Figure 72.14** One suture was placed through the dorsolumbar fascia on one side of the anchor then crossed over to the other side *(arrows)* to close a flap of tissue over the top of the anchor. This will help prevent the migration of the catheter out of the intrathecal space.

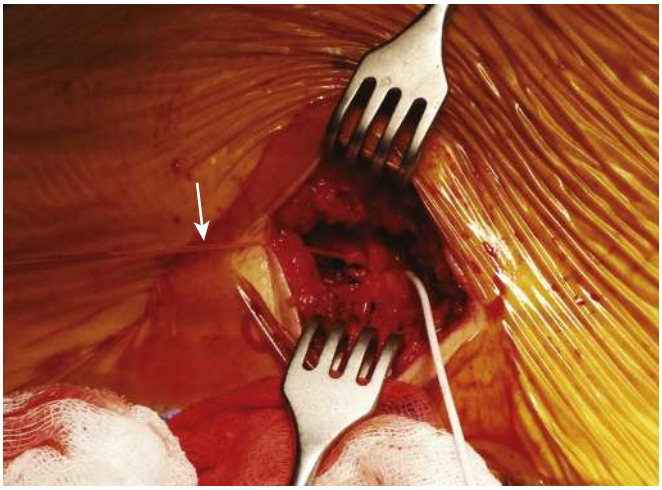
Complications

Perioperative Complications

The implantation of an IDDS exposes the patient to risks similar to those of other surgical or invasive procedures, such as bleeding, infection, wound dehiscence, and neurologic injury. In addition, there is a risk of CSF leakage with PDPH, migration of the intrathecal catheter, and pump site complications, such as seroma formation.

Bleeding

Intraoperative bleeding is most likely problematic in patients with a history of bleeding diathesis or hepatic disease or those on anticoagulant therapy. Patients with suspected coagulation disorders should be evaluated carefully prior to implantation. A multi-society group



• **Figure 72.15** Suture pulled tight (*white arrow*) to close a flap over the top of the anchor.

has developed guidelines regarding the management of anticoagulants for chronic pain conditions (Box 72.1). As noted earlier, these guidelines divide chronic pain procedures into three risk strata: low, intermediate, and high. The implantation of an intrathecal pump is categorized as a high-risk procedure. These guidelines should be followed to reduce the risk of potentially catastrophic spinal or epidural hematoma formation.[44]

Infection

The incidence of infection following intrathecal pump implantation has been reported to be between 2.5% and 9%.[42] Most infections occur at the pump pocket site and are present within 15–45 days after implantation. Pediatric patients implanted for treatment of spasticity have been found to have slightly higher rates of post-implantation infections.[60] In addition to local infection at the pump site, there is a risk of infection spreading to the CSF with resulting meningitis. This risk necessitates good infection control practices to prevent surgical site infections and carefully evaluate any suspected infection (discussed previously). In most cases, a pump pocket infection will require explanting both the device and the catheter.

The clinical presentation of a local pump pocket infection may include increased pain, fever, erythema, tenderness, swelling, purulent drainage, and warmth at the pump site. In the case of CSF infection and meningitis, the patient may present with nuchal rigidity, headache, nausea, vomiting, and fever. In either case, the patient may have an elevated white blood count (WBC), C-reactive protein, or erythrocyte sedimentation rate. The formation of a seroma within the pump pocket may mimic a local infection with swelling and erythema. Percutaneous drainage and culture of fluid may assist in making the diagnosis. The most common pathogens implicated are Staphalococcus.[42]

If an infection is suspected, the pump and catheter should be removed immediately. Antibiotics should not be administered until the pump is removed and wound cultures are obtained. Antibiotics administered before cultures are obtained can make it difficult to identify the bacteria, thus committing the patient to a longer course of broad coverage antibiotic therapy.

Cerebrospinal Fluid Leaks

CSF leaks may occur around the catheter via the dural puncture site or because of disconnection, fracture, or puncture of the catheter. The leakage of CSF may result in a PDPH. Generally, CSF leaks that are not because of catheter fracture or disconnection are self-limiting and may be treated conservatively. However, if the leak and symptoms persist, an epidural blood patch may be performed under fluoroscopic guidance to avoid damage to the catheter.[6,63]

Severe CSF leaks may result in CSF fluid collections in the posterior catheter site pocket. These can be difficult to treat, and if an epidural blood patch does not resolve the leak, injection of 1 mL of fibrin glue at the dural entry site under fluoroscopy can be considered. If this does not resolve the leak, explant of the system may be necessary.

Persistent or recurrent fluid collection in the pump pocket after percutaneous drainage should raise the suspicion of a catheter disconnect from the pump with a CSF leak into the pump pocket. Percutaneous side port access with an injection of contrast under fluoroscopy can diagnose this complication.

Catheter Complications

Catheter-related problems are the most common complications following the implantation of IDDSs. Although the reported occurrence varies, Follet and Naumann found a rate of 18.6% in a prospective study of catheter-related complications.[65] These problems include fracture, puncture, disconnection, migration, or dislodgement from the intrathecal space. Among these, catheter migration is the most common and usually results from improper anchoring of the catheter to the fascia.[65] Catheter failures may present as inadequate analgesia, CSF leaks, or withdrawal symptoms. Evaluation of catheter complications starts with accessing the side port. If CSF can be aspirated freely, then a fluoroscopic evaluation with an injection of contrast may help identify leaks and the location of the catheter within the intrathecal space. If CSF cannot be aspirated, one must fill the pump with saline and clear the catheter of the drug before injecting contrast to avoid bolus injection of drug intrathecally. Contrast studies may not detect small leaks, kinks, or breakage. A computed tomography (CT) myelogram following injection of iodinated contrast through the side port may be required to identify the location of a leak or the formation of a granuloma at the catheter tip. Gadolinium based contrast agent should not be used because of probable occurrence of encephalopathy or death from intrathecal gadolinium injection.[67–69]

Granuloma Formation

Granulomas are aseptic inflammatory masses composed of macrophages, neutrophils, and monocytes with granulation tissue.[4,65,66] The formation of a granuloma at the catheter tip may cause a loss of analgesic efficacy, progressive neurologic symptoms resulting from a mass effect on the spinal cord, and permanent neurologic injury. In a study of granulomas reported to the manufacturer of one pump system, the authors calculated an incidence of 0.49% of implanted systems.[66] Because many granulomas go undetected or unreported, the actual incidence is likely much higher. The most commonly reported symptoms are decreased efficacy of analgesia and pain. Neurologic symptoms reported include weakness, numbness, and incontinence.[4] Risk factors for granuloma formation include a high dose and high concentration infusion of opioids.[4,41,66] The most commonly implicated drug has been morphine, but other opioids and, rarely, baclofen have been associated with granuloma formation. Ziconotide has not been associated with granuloma formation.[4,41] Imaging by MRI with contrast or CT myelogram can aid in the evaluation of a suspected granuloma. However, in the authors' experience, CT myelogram is superior, as catheter identification can be difficult with MRI, and

we have seen two cases where MRI with contrast failed to demonstrate a granuloma, whereas subsequent CT myelogram diagnosed the granuloma. The treatment employed will depend on the presence and severity of any neurologic symptoms. Options include replacement of the intrathecal infusate with saline, removal of the catheter, or surgical exploration and mass resection.[4]

II Intrathecal Medications

There are currently only three FDA approved medications for use in IDDSs: morphine, baclofen, and ziconotide. Several medications are commonly used without FDA approval, and others less commonly used that are considered investigational.

This section will focus on FDA approved medications with a brief overview of commonly used off-label medications.

Opioids (Box 72.3)

Opioid analgesics exert their actions through the inhibition of target cell activity. Whereas peripherally located opioid receptors have been identified, the predominant analgesic sites are believed to reside in the central nervous system (CNS). In the brain, these receptor sites include the brainstem, thalamus, forebrain, and mesencephalon. In the spinal cord, they include the postsynaptic receptors located on cells originating in the dorsal horn and presynaptic receptors found on the spinal terminals of primary afferent fibers.[70]

The effects of opioids are determined by their affinity for endogenous receptors and their ability to reach those receptors. The onset of analgesia is similar for intrathecal and epidural opioids, suggesting that the penetration of neural tissue—and not the meninges—is the rate-limiting step.

Lipid solubility determines, in part, many important characteristics of intrathecal opioids, including the spread of analgesia and side effects. Highly water-soluble opioids, such as morphine, exhibit a greater degree of rostral spread when injected into the subarachnoid or epidural space than lipid-soluble compounds so that in pain conditions requiring higher spinal levels or more extensive coverage, the degree of analgesia they confer may be superior. Conversely, since many of the adverse effects of spinal opioids, such as nausea and vomiting and delayed respiratory depression, result from interaction with opioid receptors in the brain, the more water-soluble compounds are associated with a higher incidence of these problems.

Whereas the earliest studies evaluating the chronic use of intrathecal opioids were conducted in patients suffering from cancer pain, other studies have found intrathecal and epidural narcotics to be effective in non-malignant pain as well.[71–72] These conditions include not only nociceptive pain but also neuropathic pain, a heterogeneous group of disorders originally believed to be resistant to narcotics. Certain aspects of neuropathic pain, such as tactile allodynia, may be less responsive to the effects of spinal opioids. Therefore many neuropathic conditions require adding non-opioid analgesics to spinal opioids for successful pain relief.[73–75] The caveat with the treatment of non-malignant pain via intrathecal opioids is that these patients have a higher likelihood of complications resulting from opioid therapy because of their traditional life expectancy than those with cancer. Aside from the common intrathecal opioid side effects such as tolerance, constipation, sweating, nausea, and urinary retention, these patients are at risk for the development of intrathecal granulomas. Factors that are positively associated with the development of catheter tip granuloma include drug dosage, drug concentration, and the duration of intrathecal opioid therapy. In 2017, the PACC guidelines published recommendations for the maximum daily dose and maximum concentration of intrathecal medications (see section I).

When opioids are administered directly into the CSF, only a fraction of the systemic dose is required, as there are no anatomic barriers to be crossed, and vascular reuptake is slow. Not all side effects of intrathecal opioids are dose-related, but in many instances, the drastic reduction in dosage translates into reduced side effects. Among the adverse opioid effects reduced by switching from oral formulations to spinal administration are sedation and constipation. Effects that may be increased include pruritus, urinary retention, and edema. The mechanisms contributing to the various adverse effects of opioids are incompletely understood but probably multifactorial and include those mediated via interaction with specific opioid receptors and those that are not. Undesirable effects not mediated by opioid receptors, such as CNS excitation and hyperalgesia, cannot be reversed with naloxone. The incidence of various opioid-induced side effects depends on a number of different factors, including the opioid infused, route of administration and dosage, the extent of disease, concurrent drug (e.g. oral opioids, adjuvants), age, concomitant medical problems, and prior exposure to opioids. The most frequent side effects of intrathecal morphine are constipation, sweating, urinary retention, nausea and vomiting, and disturbances of the libido.[76–77]

• BOX 72.3 Intrathecal Opioid Medications and Dosing

Calcium Channel Antagonists (Box 72.4)

Voltage-dependent calcium channel (VDCC) conduction plays an integral role in pain transmission. The neuraxial administration of some VDCC modulators has been shown to produce antinociception, anti-allodynia, and anti-hyperalgesia in animals. High threshold VDCCs, including N- and P/Q channels, are primarily found at synaptic sites involved in the release of transmitters; L-type channels are mainly observed at cell bodies and dendrites.[78–79] Several VDCCs have been found to co-localize in the same neuron. Therefore antagonists to a given channel type usually

		Maximum 24 h dose	Maximum concentration
FDA approved:	Ziconotide	19.2 mcg	100 mcg/mL
Common use:	None		

block only a fraction of the VDCCs present, and hence may have additive effects when combined. Finally, the relative importance of the various channel types depends on the functional status of the neuron. For instance, in acute models of nociception in uninjured naive animals, there is a large body of evidence implicating N-types, limited evidence for L-types, and no evidence for P/Q types in producing antinociception. However, under conditions of persistent nociception induced in animals by chemical, inflammatory, or neuropathic stimuli, all three of these subtypes have been found to have anti-allodynic or anti-hyperalgesic properties.[80–81]

Ziconotide is a synthetic form of the peptide, ω-Conotoxin MVIIA, isolated from the venom of the marine cone snail, Conus magus.[82] It potently blocks N-type VDCCs *in vitro* and inhibits wind-up. The process of wind-up involves the activation of spinal NMDA receptors after injury, which induces a state of facilitated processing from repetitive small afferent fiber stimulation. This leads to an increased response to high and low threshold stimulation and enhanced receptor field size. Ziconotide is the first member in the new drug class of selective N-type voltage-sensitive calcium channel blockers. Ziconotide blocks N-type calcium channels in the spinal cord and inhibits the release of pain neurotransmitters from the central terminals of primary afferent neurons. By way of this mechanism, ziconotide has been found to effectively reduce pain. In a multi-center, double-blind, placebo controlled study evaluating intrathecal ziconotide for the treatment of refractory pain in 111 patients with cancer and AIDS, Staats et al. found that the treatment group obtained significantly enhanced pain relief than the control group (53% vs. 18% improvement).[83] The observation that there was no loss of efficacy for ziconotide in the maintenance phase is consistent with animal studies showing the absence of tolerance with calcium channel blockers. The most common side effects noted in this study were confusion, somnolence, and urinary retention. However, 97% of patients receiving ziconotide experience side effects, and 30% had serious adverse events. All side effects were reversible, with their incidence decreasing after the initial dosing period. In a randomized double-blind, placebo controlled trial, Wallace et al. demonstrated that IT ziconotide provides relief in patients suffering from severe chronic non-malignant pain who are unresponsive to conventional therapy.[84] Patients were treated over six days and were found to respond to dosing of 0.1–2.4 μg/h. The original starting dose of 0.4 μg/h was decreased because of a high incidence of side effects. The mean reduction in pain score from baseline was 31.2% in the treatment group compared to 6.0% in the placebo group. Patients in the treatment group reported suffering more side effects, including abnormal gait, amblyopia, dizziness, nausea, nystagmus, pain, urinary retention, and vomiting. However, Rauck et al. demonstrated that slow titration could provide comparable pain relief while minimizing the side effects experienced by patients.[85] Wallace et al. showed that ziconotide could be safely given for the long-term treatment of refractory pain.[86] Over 644 patients with severe chronic pain participated in this open-label, multi-center longer-term trial. Thirty-two percent of patients receiving ziconotide for over 360 days, with a dose range between 0.048 μg/day and 240 μg/day, experienced greater than or equal to 32.7% improvement in pain scores. Although only FDA approved as a single therapy, evidence suggests that ziconotide can be safely combined when administered intrathecally with baclofen, morphine, sufentanil, and bupivacaine.[87–89] Webster et al. added morphine to stable IT ziconotide therapy in 25 patients, which resulted in a mean 26.3% reduction in pain and a 49.1% reduction in opioid consumption at week four of treatment. This study suggests a synergism between morphine and ziconotide.[90] When IT ziconotide is combined with other drugs such as opioids and baclofen, the stability declines, which may necessitate more frequent refills.[91]

The main limitations regarding the use of IT ziconotide are its steep cost and the high incidence (> 80% in many studies) of side effects, which can include the neurologic, psychiatric, cardiovascular, gastrointestinal, and genitourinary systems. Although ziconotide is now considered the first line treatment for chronic pain in some guidelines, this therapy has an extremely narrow therapeutic window with substantial side effects and should be reserved for patients in which other agents and therapies have been exhausted.

γ-Aminobutyric Acid Agonists (Box 72.5)

Three types of γ-aminobutyric acid (GABA) receptors are currently recognized: $GABA_A$, $GABA_B$, and $GABA_C$. Only $GABA_A$ and $GABA_B$ receptors are present in significant quantities within the CNS. The $GABA_A$ receptor is a ligand-gated ion channel. Activation of this receptor by GABA results in an influx of chloride ions and stabilization of the membrane potential, which decreases neuronal excitability. The receptor possesses two binding sites for GABA and sites at which barbiturates, inhalational anesthetics, neurosteroids, and benzodiazepines bind to modulate the action of GABA. The receptor itself is a pentameric arrangement of different subunits. In contrast, the $GABA_B$ receptor is a metabotropic receptor. Activation of the $GABA_B$ receptor by GABA results in activation of inwardly rectifying potassium channels, inhibition of calcium channels, and/or inhibition of adenylate cyclase activity, all of which suppress neuronal excitability.

In laboratory animals, $GABA_A$ agonists, including muscimol, isoguvacine, and midazolam, have anti-allodynic and anti-hyperalgesic effects in chronic pain models, while the $GABA_A$ antagonists, bicuculline and picrotoxin, induce allodynia and hyperalgesia in naive rats. However, $GABA_A$ receptors are also closely linked to large-diameter afferents and thus are likely involved in modulating innocuous sensations as well. Similar to $GABA_A$ receptors, $GABA_B$ receptors are found in the greatest abundance in the superficial dorsal horn of the spinal cord. Within the GABAergic system, nociceptive transmission is primarily regulated by $GABA_B$ receptor activity. The $GABA_B$ receptor agonist, baclofen, blocks the activity of peripheral C and A-delta nociceptive fibers. Further, in the spinal cord, $GABA_B$ receptors are found on interneurons and terminals from primary afferent neurons. $GABA_B$ receptor agonists administered via the intrathecal or epidural route produce pre- and postsynaptic inhibition and therefore block the release of glutamate, substance P, and calcitonin gene-related peptide from primary afferents and GABA from interneurons.

In human studies, both $GABA_A$ and $GABA_B$ agonists have been shown to contain analgesic effects when injected into the intrathecal or epidural space. The literature shows that the neuraxial administration of $GABA_A$ agonists combined with local anesthetics

increases the duration of motor and sensory block, increases the time to first analgesic request, and decreases postoperative analgesic requirements. The administration of the $GABA_A$ agonist, midazolam, via either the intrathecal or the epidural route in combination with a mixture of other analgesics, including local anesthetics and opioids, was found to reduce opioid requirements and enhance postoperative analgesia for a variety of different surgical procedures.[92–96] Many other studies have reported the efficacy of intrathecal midazolam for various pain conditions. However, the safety of its neuraxial use is controversial. Numerous animal studies have shown evidence of neurotoxicity with intrathecal midazolam, and it is considered a fifth-line neuraxial treatment for chronic pain.

Numerous studies support the use of neuraxial baclofen for spasticity in humans, and it is the only FDA approved intrathecal agent for the treatment of refractory spasticity. Multiple uncontrolled studies show intrathecal baclofen to be effective for some central pain conditions and a variety of conditions with spasticity, including stroke, phantom limb pain, spinal cord injury, cerebral palsy, amyotrophic lateral sclerosis, and multiple sclerosis.[97–100] Intrathecal baclofen has also been found to be an effective treatment for peripheral neuropathic pain conditions, such as complex regional pain syndrome.[101–103] In a small study by Lind et al., the authors found that the addition of intrathecal baclofen in patients treated with spinal cord stimulation for neuropathic pain improved pain scores to a greater degree than concomitant treatment with oral baclofen.[104] The beneficial effect of intrathecal baclofen was dose-dependent, peaking at 50 μg. Furthermore, at follow up, Lind et al. found that patients treated for a mean of 67 months enjoyed the same degree of pain relief, requiring only a modest (30%) dose increase.[105] Van Rijn et al. found that intrathecal baclofen provides substantial improvement in patients with dystonia and those with CRPS.[106] Thirty-six patients received a pump for continuous intrathecal baclofen for 12 months. Patients experienced a decrease in pain and disability and an improved quality of life. However, patients did experience a high complication rate, most often associated with pump or catheter system defects. Neuraxial baclofen has also been found to be beneficial in the treatment of musculoskeletal pain. Loubser and Akman found that intrathecal baclofen reduced musculoskeletal but not neurogenic pain in 12 patients with chronic spinal cord injury-related pain.[107] Based on the results of this study and the temporal disparity regarding its analgesic effects on central pain and muscle spasm, it is likely that different pain-relieving mechanisms exist for these two conditions.

At therapeutic doses, baclofen is associated with numerous adverse effects, including drowsiness, flaccidity, headache, confusion, hypotension, weight gain, constipation, nausea, urinary frequency, and sexual dysfunction.[108,109] Intrathecal baclofen overdose can lead to respiratory depression, seizures, obtundation, and, if not adequately treated, death. Withdrawal from the abrupt cessation of intrathecal baclofen treatment can last days to weeks, or possibly longer, and can also be life-threatening.[110,111] There is evidence to suggest that replacement with oral baclofen may not always be adequate to control the symptoms, possibly because oral baclofen does not reach the central concentrations near the range achieved with intrathecal administration.[110,112] Baclofen is currently considered a fourth line treatment for chronic pain.

Local Anesthetics

Although not FDA approved for continuous IT use, bupivacaine is the most common local anesthetic used off-label in IT therapy and has a long track record of safety and efficacy alone or in combination with morphine.

Bupivacaine is an amide local anesthetic with high lipid solubility with several properties that make it ideal for chronic intrathecal delivery. [113] Bupivacaine has motor sparing properties minimizing motor weakness at doses up to 15 mg/day. [114,115] Catheter tip location, CSF flow dynamics, and patient mobility may influence sensorimotor loss.[116] For example, a catheter that shifts onto a nerve root may result in motor weakness with higher bupivacaine concentrations and bolus dosing. Although tachyphylaxis has been reported at extremely high dose, there is an absence of tachyphylaxis at the most commonly used doses of up to 20 mg/day.[117,118] The most recent PACC guidelines recommend a starting dose of bupivacaine of 1–4 mg/day with titration up to a maximum dose of 10 mg/day (maximum concentration of 30 mg/mL), which is consistent with published studies of intrathecal bupivacaine for chronic pain.[116] Although there is conflicting literature, bupivacaine appears to have opioid sparing effects when combined with an opioid. A retrospective study in 109 subjects with an intrathecal opioid/bupivacaine combination showed improved pain control and a reduction in oral opioid use,[119] and another larger study in non-cancer pain showed a blunting of the opioid escalation.[114] A small double-blind randomized prospective study suggested that the addition of bupivacaine (up to 8 mg/day) to morphine or hydromorphone in post-laminectomy pain patients did not improve pain control.[120]

Although bupivacaine has a long track record for safety with chronic infusion for pain management, there have been animal study reports of toxicity, including spinal cord vacuolation in a rodent model[121] and minor leptomeningeal infiltration in a dog model.[122] Postmortem analysis of cancer patients who received chronic bupivacaine infusion did not show any pathologic conditions of the spinal cord.[123,124]

Adrenergic Agonists (Box 72.6)

Adrenergic agonists have analgesic effects when applied for the management of chronic pain. α-Adrenergic receptors are widely distributed throughout the body and comprise two clinically significant classes: α_1 and α_2. α_1 Receptors are found in the smooth muscle cells of the peripheral vasculature and play an essential role in the regulation of systemic vascular resistance[125]; they have no known significant role in analgesia. However, α_2 receptors are present throughout the peripheral and CNS and play a substantial role in modulating pain signals. There are several known subunits of the α-receptor: 2a, 2b, and 2c. Clonidine binds to pre- and postsynaptic α2 receptors in the dorsal horn. Activation of these receptors depresses presynaptive C-fiber transmitter release and hyperpolarizes the postsynaptic membrane through the Gi-coupled potassium channel.[125,126] A different physiologic effect transpires, depending on the particular α subunit involved. The neuronal responses can be either inhibitory or excitatory.[127]

• BOX 72.6 Intrathecal Adrenergic Medications

FDA approved:	None	Maximum 24 h dose	Maximum concentration
Common use:	Clonidine		
		600 mcg	1000 mcg/mL

For example, the 2b subtype produces hemodynamic responses (primarily hypotension) while the 2a receptor is responsible for analgesia.[127,128] The mechanism of action of neuraxial α_2 agonists is similar to opioids in that they can exert effects on presynaptic and postsynaptic neurons.[128] On the presynaptic neuron, they bind to α_2 receptors of primary afferent neurons, resulting in hyperpolarization and depressed release of neurotransmitters involved in pain transmission. On postsynaptic neurons, α_2 agonists hyperpolarize the cell by increasing the transmission of potassium through G_i-coupled potassium channels.[126] Among the α-adrenergic agonists used for analgesia, clonidine remains the prototypical nonselective α_2 agonist, partly because it has been the most studied. Clonidine is a nonselective agonist that produces antinociception via interaction with the α 2a receptor. However, it also produces substantial hemodynamic side effects because of its interaction with the 2b receptor. The newer agent, dexmedetomidine, is a selective α_{2a} receptor agonist with analgesic and sedative properties, with less respiratory depression and fewer cardiovascular effects.[129–132] Dexmedetomidine demonstrates increased selectivity of the α 2a subunit than previous α-adrenergic agonists.[130,133] α-Adrenergic agonists have also been shown to activate spinal cholinergic neurons, which may contribute to their analgesic effects. In addition to their antinociceptive properties, α_2 agonists can produce dose-dependent sedation, presumably by inhibitory mechanisms involving the brainstem.[134,135]

α_2 Agonists have been administered intrathecally in humans since 1985. The antihypertensive medication clonidine is the most studied α_2 agonist for neuraxial use. Although it is FDA approved for epidural use only in cancer pain, clinical reports have shown it to be effective intrathecally and epidurally for non-malignant pain as well.[136,137] Intrathecal clonidine has been reported to provide significant analgesia in combination with opioids for neuropathic pain and cancer pain and has been used in the pediatric population for these reasons.[137] Clonidine has not consistently been shown to be effective as a single agent, but studies have shown it to prolong and enhance the effects of spinal and epidural anesthesia when co-administered with local anesthetics.[138–140] When added to opioids, clonidine can extend the duration of pain relief for labor analgesia and postoperative pain.[141–143] However, for acute pain, the evidence that adding clonidine to an epidural or intrathecal opioid is more effective than either analgesic alone is weak and inconsistent. Neuraxial clonidine has shown efficacy in treating central pain and spasticity after spinal cord injury.[144] Studies show that dexmedetomidine prolongs local anesthetic motor and sensory blockade compared to opioids.[143,144] α_2 Receptor agonists may also be suitable for patients suffering from neuropathic pain. In a randomized placebo controlled trial evaluating epidural clonidine in refractory reflex sympathetic dystrophy, Rauck et al. found that 300 μg of clonidine was equally effective but associated with fewer side effects than 700 μg.[145]

The interest in dexmedetomidine has grown in recent years because of its decreased cardiovascular and respiratory effects. Kanazi et al. showed, in a prospective, double-blind study, that 60 patients undergoing transurethral resection of prostate or bladder tumor under spinal anesthesia experienced a prolonged duration of motor and sensory blockade, with no increase in adverse hemodynamic effects or level of sedation.[140] Patients were randomized to three groups receiving either dexmedetomidine (3 μg) or clonidine (30 μg) added to bupivacaine or bupivacaine alone. These results suggest that low dose dexmedetomidine has similar analgesic efficacy to clonidine.

Clonidine has been studied extensively in animals and has produced no evidence of neurotoxicity.[146] The number of studies involving human exposure continues to grow and have not revealed any clinical evidence of neurotoxicity. Therefore clonidine appears to be a drug that can be administered safely in humans via the spinal route.

Conclusion

Since the 1980s, intrathecal drug delivery of opioids and nonopioid analgesics has become a promising option when more conservative therapies have failed. There are two main choices with regard to implanted intrathecal pump systems for the management of spasticity and cancer and chronic non-cancer pain. The challenges involved in the successful use of intrathecal therapy start with patient selection. Understanding the issues in selecting an appropriate candidate with cancer pain, chronic non-cancer pain, or spasticity will go a long way toward ensuring adequate therapy once the system is implanted. The main risks associated with the implantation of an intrathecal system are infection and catheter migration. Careful attention to good sterile technique during the surgical implantation and catheter anchoring can minimize these risks.

Key Points

- Intrathecal analgesia therapy has proven extremely beneficial to many patients; it is also associated with high costs, high maintenance, and risks requiring careful patient selection.
- The cost and invasive nature of an IDDS necessitate a careful evaluation to determine whether each individual patient is appropriate and likely to achieve benefit.
- A 2002 multi-center randomized trial compared CMM alone versus CMM plus an IDDS. The researchers found that cancer patients receiving CMM plus an IDDS had reduced pain, fewer drug toxicities, and prolonged survival than controls.
- The psychologist should not be asked to give "clearance" but rather act as an additional source of information about whether IDDS therapy is appropriate, the patient has rational expectations, and the treatment is likely to succeed or fail for an individual patient.
- There are only three FDA approved medications for use in IDDSs: morphine, baclofen, and ziconotide
- The use of intrathecal baclofen is typically reserved for conditions resulting in spasticity
- The high cost, high incidence of side effects, and narrow therapeutic window limit the use of ziconotide
- Granulomas are aseptic inflammatory masses composed of macrophages, neutrophils, and monocytes with granulation tissue. The formation of a granuloma at the catheter tip may cause loss of analgesic efficacy, progressive neurologic symptoms because of a mass effect on the spinal cord, and permanent neurologic injury.
- Iodinated contrast medium, and not gadolinium, should be injected through the side port to avoid encephalopathy or death from intrathecal gadolinium injection.

Radiation Safety and Radiographic Contrast Agents

JAMES P. RATHMELL, HONORIO T. BENZON

Overview of Radiation Safety

Pain practitioners have come to rely on fluoroscopy and, to a lesser but growing extent, on computed tomography (CT) to facilitate image-guided pain treatment techniques. Fluoroscopy and CT employ ionizing radiation to produce the x-rays required for imaging. Understanding the physics and biology underlying the biologic effects of ionizing radiation will help *pain* practitioners minimize radiation exposure to their patients, other involved personnel, and themselves during image-guided injection. The basic elements of the fluoroscopy unit are shown in Figure 73.1. x-rays emanate from an x-ray tube, typically positioned beneath the table and the patient, to minimize radiation exposure. The x-rays pass through the table and the patient strikes the input phosphor of the image intensifier, where they are converted to visible light and detected by an output phosphor that transfers the signal to a digital camera for visual display on a monitor or transferred to film. The size and shape of the x-ray beam can be adjusted after exiting the x-ray tube and before entering the patient, from side to side by an adjustable linear collimator or in a circular, concentric fashion by an iris collimator. The C-arm allows variation in the axis of the x-ray beam in numerous planes relative to the patient.

In recent years, the use of CT has become more common, particularly among radiologists. With the advent of fluoroscopy units that can rotate around the patient and acquire images at numerous angles and then reconstruct the images in multiple planes, the distinction between CT fluoroscopy and traditional CT has become blurred. These CT fluoroscopy units yield data that can be reformatted in multiple planes and produce final images of the quality of conventional CT. However, acquiring images in multiple planes with either CT-fluoroscopy or conventional CT requires significantly greater radiation exposure than conventional fluoroscopy.[1] Usually, the superior anatomic information provided does not warrant the routine use of these advanced imaging modalities (see further discussion of radiation dose later in this chapter). Patients undergoing high-risk procedures where small variations in anatomy can alter the risk/benefit ratio of a given technique may benefit from CT fluoroscopy or conventional CT guidance.

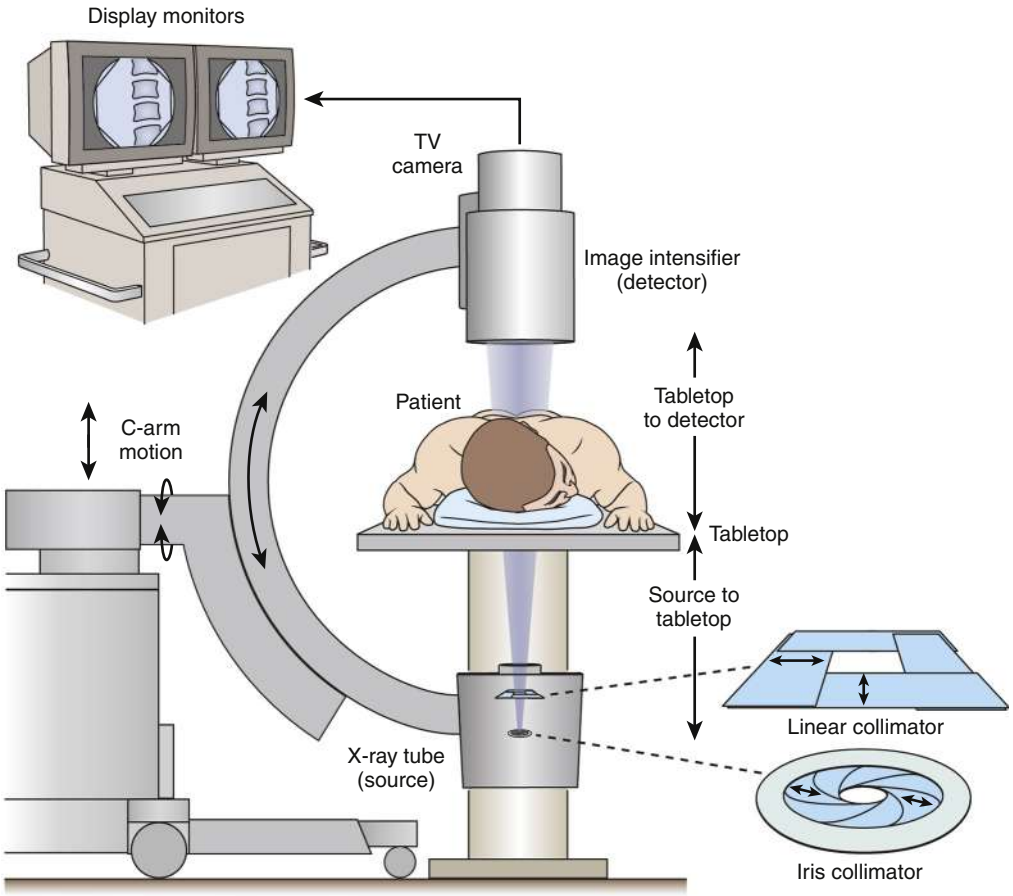
Basic Radiation Physics

Radiation is energy radiated or transmitted as rays, waves, or particles. x-rays are a portion of the electromagnetic radiation spectrum. As x-rays pass through matter, they impart sufficient energy to dislodge electrons (ionizing radiation), yielding free radicals that can lead to harmful biologic effects. In radiography, the x-rays that penetrate the body without effect emerge to strike an image intensifier where they are converted to visible light and can be displayed on a monitor or transferred to film, producing an image based on x-ray penetrability of various tissues.

Several factors and definitions are central to a basic understanding of radiation safety. The biologic effects of ionizing radiation are proportional to the time of exposure, whereas radiation exposure is inversely proportional to the *square* of the distance from the radiation source. Radiation exposure is expressed as roentgen or coulomb per kilogram, whereas the energy absorbed from radiation is expressed as the radiation absorbed dose (rad) or gray (Gy). Because different types of radiation can have different biologic effects, units of exposure are converted from rad to radiation equivalent in man (rem) or Sievert (Sv). The units used to express radiation exposure are listed in Table 73.1.[2] For x-rays, 1 roentgen (R) ~ 1 rad ~ 1 rem.

The electrical input to the tube that generates the x-rays can be varied to produce x-rays that differ in number and energy. Increased current applied to the x-ray tube (expressed as milliamps or mA) produces more x-rays, and the more X-rays that strike the image intensifier, the darker the image. Lengthening the exposure time also increases the number of x-rays reaching the image intensifier. Thus variations in current and exposure time are expressed as mAs (mA × s). An increased voltage (expressed as kilovoltage peak or kVp) applied to the x-ray tube results in x-ray emission at higher energy levels (i.e. with greater ability to penetrate). High kVp (75–125 kVp) and low mA (50–1,200 mA) were employed for fluoroscopy with short exposure times. This combination optimizes image quality while minimizing radiation exposure. High kVp/low mA combinations expose the patient to significantly less radiation than low kVp/high mA combinations. Modern fluoroscopy units typically employ automatic brightness control (ABC), which automatically adjusts kVp and mA to yield optimal brightness and contrast.

The x-rays generated during fluoroscopy are a form of ionizing radiation that can produce significant biologic effects. Small doses of ionizing radiation can produce molecular changes that take years to manifest in the form of cancerous transformation. Exposure to low doses of ionizing radiation is likely inconsequential because normal cellular mechanisms repair the damage. The International Committee on Radiation Safety Protection (ICRP) has produced estimates of the maximum permissible dose (MPD)



• **Figure 73.1** Diagram of the components of a typical fluoroscopy unit. (Reproduced with permission from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2012: Fig. 2.1.)

TABLE 73.1 Units Used to Express Radiation Exposure and Dose

Term	Traditional Units	SI Units	Conversion
Exposure	Roentgen (R)	Coulomb/kg (C/kg)	1 R = 2.5×10^{-4} C/kg
Radiation absorbed dose	rad	Gray (Gy)	100 rad = 1 Gy
Radiation equivalent in man	rem	Sievert (Sv)	100 rem = 1 Sv

TABLE 73.2 Annual Maximum Permissible Radiation Doses

Area/Organ	Annual Maximum Permissible Dose
Thyroid	0.5 mSv (50 rem)
Extremities	0.5 mSv (50 rem)
Lens of the eye	0.15 mSv (15 rem)
Gonads	0.5 mSv (50 rem)
Whole body	0.05 mSv (5 rem)
Pregnant women	0.005 mSv to fetus (0.5 rem)

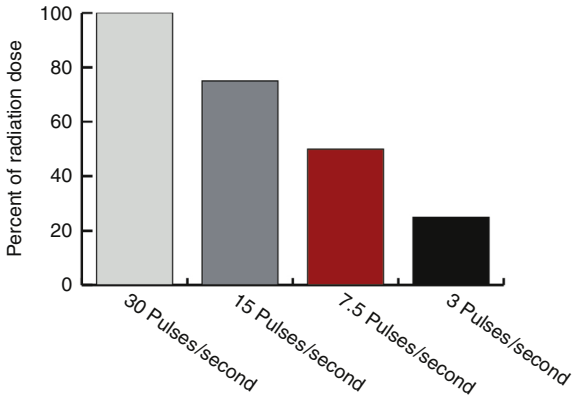
Data from the National Council on Radiation Protection and Measurements (NCRP). Report No. 116. Limitation of Exposure to Ionizing Radiation. Bethesda, MD: NCRP Publications; 1993.

of annual radiation to various organs (Table 73.2).[3] Exposure below these levels is unlikely to lead to any significant effects, but the ICRP recommends that workers should not receive over 10% of the MPD.

The use of fluoroscopy for interventional procedures grew rapidly during the late 1980s, leading to increased concerns about radiation exposure. In 1994, the United States Food and Drug Administration issued a public health advisory on serious radiation-related skin injuries resulting from fluoroscopic procedures. Today's equipment and techniques have dramatically reduced the risk of radiation exposure. Radiation exposure during a typical epidural steroid injection carried out with fluoroscopy and assuming the practitioner is at least 1 meter from the x-ray tube has been reported to be as low as 0.03 mR. In contrast, the typical entrance skin exposure during fluoroscopy ranges from 1 to 10 R per min. A typical single chest radiograph leads to a skin entrance exposure of 15 mR. Thus 1 min of continuous fluoroscopy at 2 R per min is equivalent to the exposure during 130 chest radiographs. The minimum target organ radiation doses that lead to pathologic effects are shown in Table 73.3. Radiation dermatitis still occurs in fluoroscopists with unknown long-term consequences.

TABLE 73.3 Minimum Target Organ Radiation Doses to Produce Organ Pathologic Effects

Organ	Dose (rad)	Dose (Gy)	Results
Eye lens	200	2	Cataract formation
Skin	500	5	Erythema
	700	7	Permanent alopecia
Whole body	200–700	2–7	Hematopoietic failure (4–6 week)
	700–5,000	7–50	Gastrointestinal failure (3–4 days)
	5,000–10,000	50–100	Cerebral edema (1–2 days)



• **Figure 73.2** Optimal spacing between the x-ray source and the patient to minimize radiation exposure. (Reproduced with permission from Rathmell JP. Minimizing Patient Radiation Exposure

Minimize Dose and Time

Practitioners using ionizing radiation should adhere to the ALARA principle ("As Low As Reasonably Achievable"), combining optimal techniques and shielding to minimize patient and personnel exposure.[4] Because no dose of ionizing radiation is without biologic effects and can be considered absolutely safe, radiographs should be used only when necessary, and the dose and exposure time should be limited. The dose is a factor of both the number of x-rays (proportional to mA × s of exposure) and the energy of the x-rays (proportional to kVp).[5] Modern fluoroscopy employs ABC, which automatically controls mA and kVp settings to optimize brightness and contrast while minimizing dose. However, if one chooses to use fluoroscopy in the manual mode (e.g. to increase penetration in an obese patient), kVp should be increased while minimizing mA. For an equivalent increase in exposure, the mA must be doubled, whereas kVp must be increased by only 15%. When using the ABC mode, the only element under practitioner control is the exposure time, and this should be held to the minimum required to complete the procedure. Short pulses of exposure, rather than continuous exposure, should be employed whenever feasible. Continuous fluoroscopy in the form of movies (cineradiography) and digital subtraction exposes patients to markedly higher doses than brief spot images. Many modern units include an option termed *the pulsed* mode for use instead of a continuous technique. This mode substitutes brief, periodic spot images separated by an interval without exposure (e.g. a new image is displayed one to two times per second). Use of this mode in place of continuous fluoroscopy can reduce overall exposure dramatically and is suitable for procedures in the pain clinic where continuous fluoroscopy is needed (e.g. while threading an epidural catheter or spinal cord stimulation lead; see Fig. 73.2).

Optimize the Position of the X-ray Tube

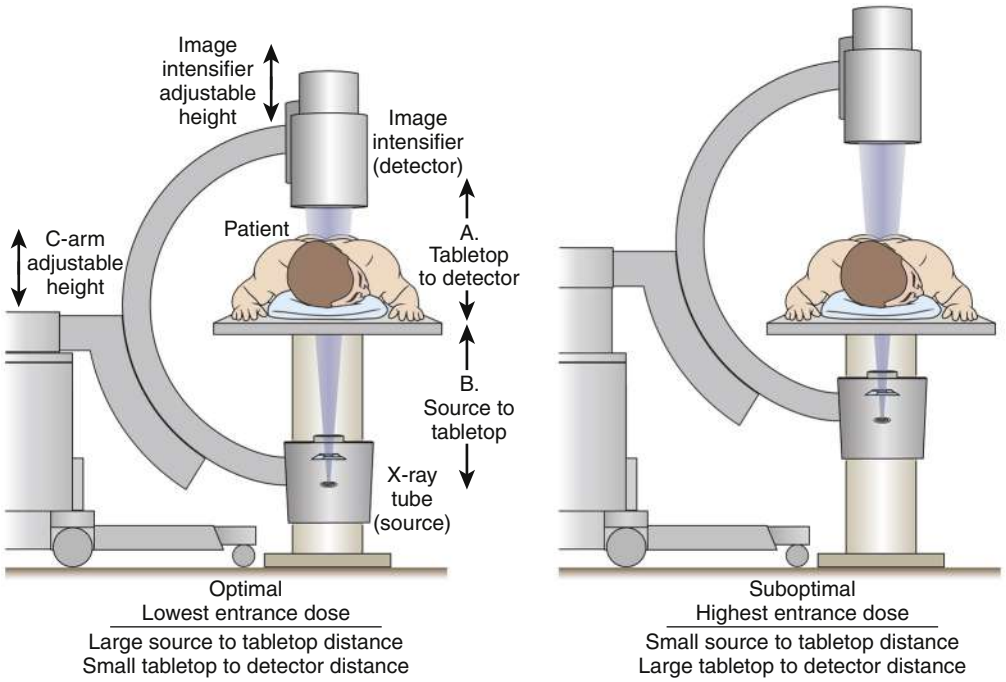
Radiation exposure to the patient is best minimized by ensuring an optimal distance between the patient and the x-ray tube (Fig. 73.3). When the x-ray tube is positioned close to the patient, a small area of skin will be exposed to radiation, but because of the close proximity of the x-rays, the dose to which this smaller area will be exposed is much higher. When the tube is positioned further from the patient, a larger area is exposed to a smaller dose of radiation. The x-ray tube should be positioned as far from the patient as possible without including unnecessary structures in the field of view.

Employ Shielding Whenever Possible

Using lead shielding can prevent exposure of regions adjacent to the area to be imaged from exposure to ionizing radiation. Small lead shields can be placed on the table underneath the patient, directly in front of the x-ray beam *before* it penetrates the patient to protect the gonads or the fetus, in rare instances where fluoroscopy is necessary for a pregnant patient. Although lead shields should be readily available in the fluoroscopy suite, they are seldom practical for use during image-guided injection of the lumbosacral spine because the shield lies directly in the path of the structures to be imaged.

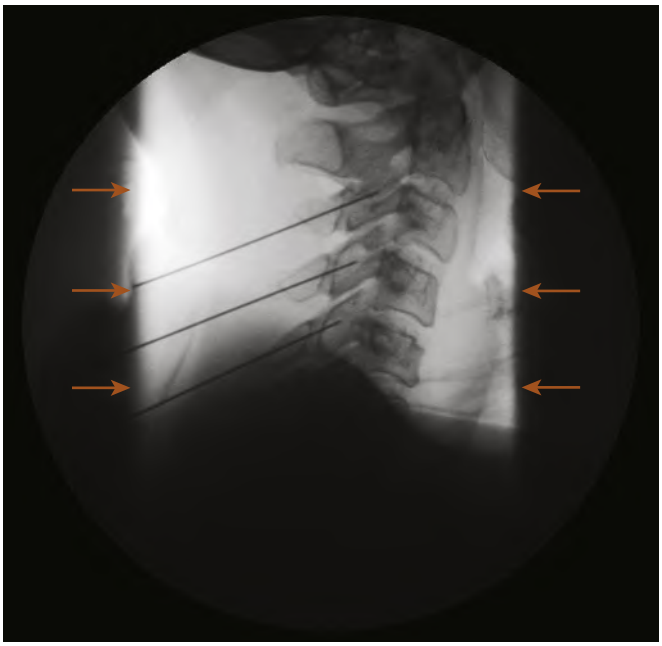
Employ Collimation

Fluoroscopy units have built-in mechanisms that allow the emitted x-ray beam to be reduced in size and changed in shape (or *collimated*), so the area of the patient exposed is minimized. All units had both linear and circular collimations. Linear collimation employs shutters that can be moved from either side of the exposure field and are helpful in imaging long, thin structures such as the spine (Fig. 73.4). Circular or "iris" collimation can be helpful when a small, circular area is to be imaged (Fig. 73.5). Collimation is also helpful in optimizing image quality because the ABC mode attempts to optimize the image quality by considering the exposure needed across the entire field of exposure, and it is often challenging to visualize radiodense and radiolucent areas in the same image. Useful employment of collimation can exclude areas of greatly varying radio-density to improve image quality by reducing the range of densities in the field. Two good examples are imaging of the thoracic spine, where the large density differences between the spine and the adjacent air-filled lungs can make it difficult to see the bony elements of the spine with any resolution. Linear collimation, which limits the field to the spine itself, dramatically improves image quality. Likewise, imaging of the cervical spine is fraught with the same difficulties when the air on



• **Figure 73.3** Effect of pulsed fluoroscopy on radiation dose (patient entrance skin dose). For example, by switching from continuous fluoroscopy (typically 30 pulses/second) to 15 pulses per second, dose savings of nearly 22% are achieved. (Adapted with permission from Mahesh M. AAPM/RSNA physics tutorial for residents Fluoroscopy: patient radiation exposure issues. *RadioGraphics.* 2001;21:1033-1045.)

either side of the neck is included in the x-ray field (see Fig. 73.4). Both linear collimation and circular collimation (see Fig. 73.5) can be used to limit the field to the area of interest, improve image quality, and reduce radiation exposure. Modern fluoro units may also allow *magnification* of the image by electronically magnifying the area of interest. Magnification allows better visualization of a smaller area but leads to increased radiation exposure as the system increases output to compensate for losses in gain. To minimize the



• **Figure 73.4** Use of adjustable (linear) collimator to decrease radiation exposure to the patient while improving image resolution by decreasing the range of tissue density in the image field. dose to the patient, the largest field of view should be employed in conjunction with tightest collimation.

Minimizing Practitioner Exposure

Employ Proper Shielding

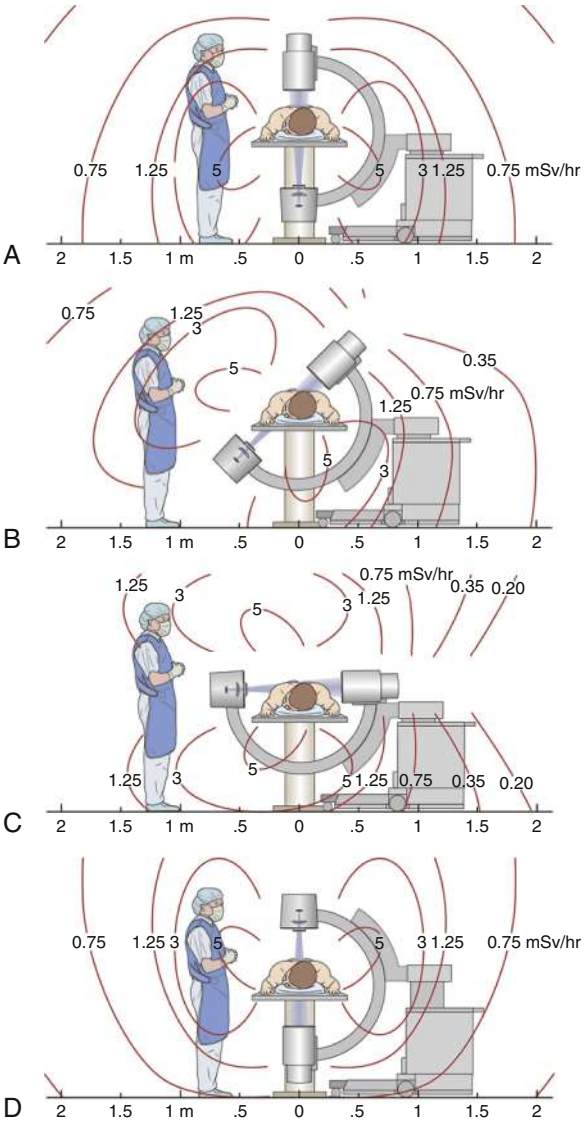
Only the personnel needed to conduct the procedure should be in the fluoroscopy suite. All personnel should be shielded with lead aprons *before* the use of fluoroscopy. The practitioner using the fluoroscopy unit should alert everyone in the room they are about to begin and ensure that personnel are shielded. Routine use of thyroid shields can minimize the long-term risk of thyroid cancer. Although protective lead gloves can reduce the exposure of the hands to radiation, they can produce a false sense of security. When leaded gloves are employed and the practitioner's hands are in the field of exposure, units with ABC will increase their output to compensate for the radiodense leaded gloves and negate their protective effects. Techniques that eliminate the practitioner's hands from direct exposure within the x-ray field should be used. Protective eyeglasses are available that dramatically reduce eye exposure during fluoroscopy; leaded eyewear is recommended for practitioners who accumulate monthly readings on collar badges above 400 mrem (4 Sv). Exposure levels in this range are typically encountered only in areas where continuous cine-angiography is frequently conducted (e.g. the cardiac catheterization laboratory).

Practitioner Position

The practitioner must understand the geometry of the radiation path as it passes from the x-ray tube to the image intensifier and adopt positions that minimize their exposure during fluoroscopy (Fig. 73.6). The dose drops proportionally to the square of the distance from the x-ray source. Thus standing as far from the x-ray tube as practical is the first means of minimizing exposure. Using an intravenous extension tube and taking a step back from the table during periods where contrast is injected under continuous or live fluoroscopy will reduce exposure. When the x-ray tube is rotated to obtain a lateral image, the practitioner should step completely away from the table beneath the x-ray tube and out of the path of the x-ray beam or move to the side of the table of the image intensifier. Inverting the C-arm so that the x-ray tube is above the table and the image intensifier is below the table is a means used by some practitioners to increase the C-arm's range of lateral movement beyond the typical 45° to 55° allowed by the unit. This practice dramatically increases the exposure to both patients and practitioners by bringing them near the x-ray source.

Optimizing Image Quality

Modern fluoroscopy units use ABC, which automatically adjusts mA and kVp to optimize image brightness and contrast while minimizing radiation exposure. These controls can be adjusted separately. An increased kVp produces x-rays of higher energy that penetrate without attenuation. Thus the resulting image is brighter with less contrast between different tissues, thereby reducing the image detail. The clarity of small structures, or image detail, can be improved by lowering kVP, reducing the distance between the patient and the image intensifier, and by using collimation to limit the field of exposure to only those structures of interest. Fluoroscopic images also have less sharpness at the periphery of the image because of a falloff in brightness and spatial resolution, a phenomenon called *vignetting*. Placing the structure of interest in the center of the image yields the maximum image detail. Finally, *pincushion distortion* occurs toward the periphery of the image because the x-rays emanate from a spherical surface and are detected on a flat surface.



• **Figure 73.6** Radiation exposure dosage during fluoroscopy. **A,** During routine use in the anterior-posterior plane, the x-ray tube (source) should be positioned below the patient and the detector above the patient to minimize radiation exposure to both the patient and the practitioner. **B,** The oblique projection results in markedly increased exposure to the practitioner. **C,** During use in the lateral projection, the practitioner should step behind the x-ray tube (source) to minimize radiation exposure. When it is necessary to work close to the patient during lateral fluoroscopy, the practitioner should step away from the x-ray tube and move to the side of the table opposite the x-ray tube to minimize exposure. **D,** Radiation exposure to both patient and practitioner is dramatically increased when the x-ray tube (source) is inverted above the patient. Some practitioners invert the C-arm to allow for a more extreme lateral angle (e.g. rotation beyond 35–45 degrees oblique to the side opposite the C-arm is impossible without inverting the C-arm on some units). Radiation exposure can be reduced by rotating the patient on the table and keeping the x-ray source below the table. (Reproduced with permission from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2012: Fig. 2.6.)

TABLE 73.4 Radiation from Interventional Pain Procedures

Study	Procedures	Radiation Time	Radiation Readings
Botwin et al. 2002[11]	TF ESIs	5–38 s	0.7 mrem at the ring, 0.4 mrem at glasses, 0.3 mrem on the outside lead apron
Manchikanti et al. 2002[12]	ESI, facet, joint, intercostal, percutaneous adhesiolysis, spinal endoscopy, stellate ganglion, sympathetic	13.2 +/– 0.3 s/patient, 7.7 +/– 0.2 s/procedure	1.345 mrem/patient, 0.78 mrem/procedure
Zhou et al. 2005[13]	ESI, facet block, sympathetic blocks SI joint, lumbar discography	46.6 + /– 4.2, 81.5 +/– 12.8, 64.4 +/– 11, 50.6 +/– 41.9, and 146.8 +/– 25.1 s, respectively

Radiation exposure well within safety limits (5 rem/year).

This results in an effect similar to that of a fisheye camera lens with a splaying outward of objects toward the periphery of the image. This can lead to particular difficulties when attempting to advance a needle using a coaxial technique if the needle is toward the periphery of the image. In the past several years, several manufacturers have developed electronic flat-plate detectors to replace conventional image intensifiers. Flat plate detectors employ a grid-like electronic detector that eliminates both vignetting and pincushion distortion, providing optimum image quality from the center to the peripheral portions of each image. Flat plate digital detectors are rapidly replacing traditional image intensifiers. Digital flat plate detectors can dramatically reduce radiation while improving image quality and eliminating the distortion of the image at the periphery of the detector that occurs with traditional image intensifiers.

Radiation From Interventional Pain Procedures

The most significant source of radiation exposure during interventional pain procedures is scattered radiation. Several factors determine this amount of radiation, including the experience of the radiographer and interventionalist, difficulty and length of the procedure, and the patient's habitus. The body weight of the patient and spinal pathology (e.g. spinal stenosis) have been correlated with radiation dose during interventional pain procedures.[6] The use of protective measures (lead apron, thyroid shield) reduces radiation exposure, as evidenced by lower scatter radiation readings.[7] Radiation-reducing gloves also reduce scatter radiation (reading at a location 20 cm from the table). Its attenuating effect is around 26%.[8] However, the use of lead gloves may make manipulation of the needle difficult. It also increases radiation because the ABC system automatically increases the kVp and current to compensate for the fuzzy image created by the gloves. Pulsed fluoroscopy reduces radiation compared to continuous fluoroscopy.[9] The incidence of inadequate image fluoroscopy with lumbar transforaminal ESI using pulsed fluoroscopy is 6%, and conversion to continuous fluoroscopy is sometimes required.[9] Despite the decreased quality of the image, it should be attempted first.

After interventional pain procedures, radiation readings are usually higher in badges worn outside the lead apron than inside the apron.[7] The highest scatter readings are at the knees during conventional fluoroscopy (x-ray tube below the table) and at the level of the physician's abdomen during lateral fluoroscopy.[10]

It appears that the amount of radiation from interventional pain procedures is within the MPD. Four studies on different interventional procedures showed safe readings in the eye, thyroid, gonads, extremities, or whole body (Table 73.4).[11–14] Two of the three studies showed zero readings in the badge inside the lead apron[11,12] while the other study calculated an annual radiation dose of 1.08 mSv under the apron.[14] Interestingly, the radiation doses were noted to be higher in a university setting than in private clinics, although in this study (the results in private practice groups were based on previously published studies).[13]

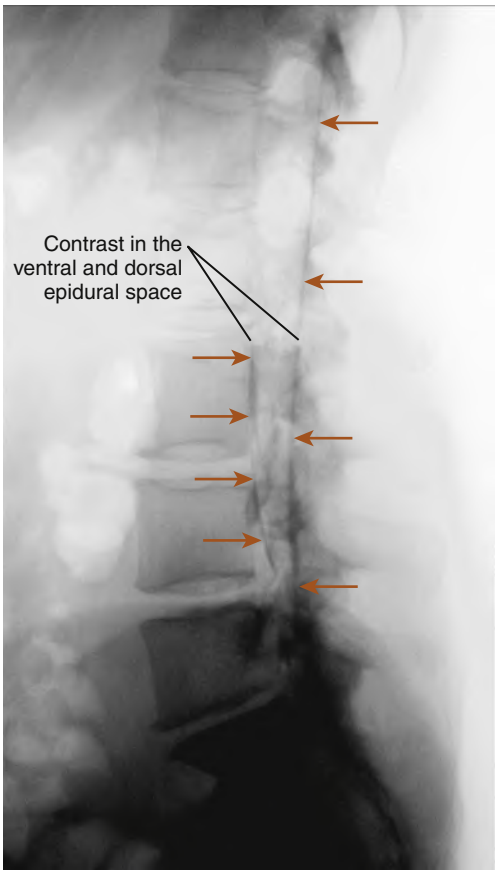
Although radiation exposure from interventional procedures appears to be within the safe limits, previously noted measures should be adopted. Reports of low radiation exposure may have instilled a false sense of security among pain physicians. A study showed that the usage of pulsed fluoroscopy is only around 10%.[13] Pain physicians in Korea wear lead aprons, thyroid shields, and lead glasses 93%–100%, 81%–100%, and 38%–40%, respectively.[15] The effectiveness of these measures and constant real-time coaching on optimal position[10] should be reinforced.

Overview of Radiographic Contrast Medium

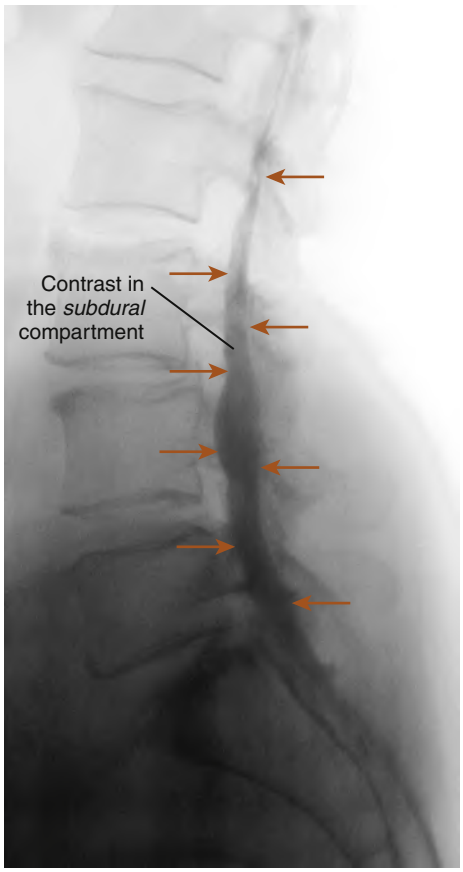
Iodine is the only element that has proven satisfactory as an intravascular radiographic contrast medium (RCM).[16] Iodine produces radiopacity, while the other portions of the molecule act as carriers for iodine, improving solubility and reducing the toxicity of the final compound. Organic carriers of iodine are likely to remain in widespread use in the foreseeable future. During image-guided injection, injection of RCM can prove invaluable in determining the final location and distribution of the injectate (Figs. 73.7–73.9). The use of RCM can improve the safety of many techniques by allowing for detection of intravascular (Figs. 73.10 and 73.11), subdural (see Fig. 73.8), or intrathecal (see Fig. 73.9) needle location before local anesthetic or steroid are placed.

Pharmacology of RCM

There are four chemical varieties of iodinated RCM that are widely used: ionic monomers, non-ionic monomers, ionic dimers, and non-ionic dimers.[17] On intravascular injection, all



• **Figure 73.7** Epidural contrast injection. This typical lateral lumbar epidurogram demonstrates the "double-line" or "railroad track" appearance of radiographic contrast in the anterior and posterior epidural space (*arrows*). (Reproduced with permission from Rathmell JP, Torian D, Song T. Lumbar epidurography. *Reg Anesth Pain Med.* 2000;25:541.)

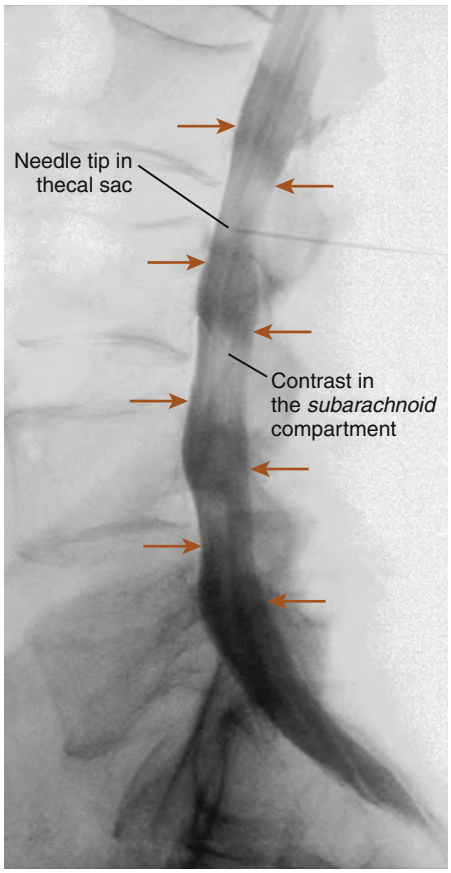


• **Figure 73.8** Subdural contrast injection. Injection of contrast in the subdural (epiarachnoid) space is recognized by the regular posterior border and irregular anterior border of loculated contrast collection on this lateral radiograph of the lumbar spine. The contrast is contained posteriorly by the dural membrane but extends only partially anteriorly, as it is contained by the thin arachnoid membrane. Compare with Figure 72.9, subarachnoid administration, where the contrast extends from the posterior to the anterior limits of the thecal space. Although the contrast does not extend to the anterior portion of the thecal sac, it is not limited to the epidural space. (Reproduced with permission from Ajar A, Rathmell JP, Mukerji S. Subdural compartment. *Reg Anesth Pain Med.* 2002;27:73.)

four are redistributed rapidly via capillary permeability to the extravascular space. They do not enter the interior of the blood or tissue cells. They are rapidly excreted, and more than 90% are eliminated via glomerular filtration within 12 h of administration. None of the four varieties exhibited marked pharmacologic actions. All RCM agents have a range of concentrations that vary in their radiopacity and viscosity. Because iodine is the element responsible for radiopacity, the iodine concentration in milligrams per milliliter represents the radiopacity. Non-ionic monomers are now used almost exclusively in pain medicine; non-ionic dimers offer increased radiopacity at low osmolar concentrations but are not in widespread clinical use and offer questionable clinical advantages.

Several important chemical properties determine the characteristics of RCMs for clinical use. Osmolality depends on the number of solute particles in the solution and is the highest for ionic contrast agents. Adverse reactions, particularly discomfort because of injection, have been reduced dramatically with the advent of low osmolar RCM. Contrast media with an osmolality below 500 mosm/kg of water are virtually painless. Radiopacity depends on the iodine concentration of the solution and therefore on the number of iodine atoms per molecule and the concentration of the iodine-carrying molecule in the solution. Digital subtraction electronically enhances the image, reducing the amount of contrast medium needed by a factor of two to three times. With the use of digital subtraction, RCM with as little as 150–200 mg/mL of iodine can be used even for intra-arterial use. Ionic molecules dissociate into cations and anions in the solution. Non-ionicity, or a molecule that does not dissociate in solution, is essential for myelography or use along the neuraxis, where inadvertent placement within the cerebrospinal fluid (CSF) is possible during the injection. The chemical properties of common RCMs used in clinical practice are compared in Table 73.5.

The most frequently used ionic monomers are diatrizoate (Urografin®), iothalamate (Conray®), and metrizoate (Isopaque®). All ionic monomers are salts of meglumine or sodium as the cation, and a radiopaque tri-iodinated fully substituted benzene ring as the anion. Ionic monomers are used for intravenous pyelography and similar applications. However, they have been completely replaced by the low osmolar, non-ionic RCM for many applications, including intrathecal administration. The most common non-ionic monomers in clinical use include iodixanol (Visipaque®), iohexol (Omnipaque®), iopamidol (Isoview®), and ioversol (Optiray®), and iohexol and iopamidol are labeled for intrathecal use. Non-ionic monomers appeared in the 1970s and represent



• **Figure 73.9** Subarachnoid (intrathecal) contrast injection. This typical myelogram demonstrates contrast within the thecal sac (*arrows*) on this lateral radiograph of the lumbar spine. The spinal cord and spinal nerves are visible as hypodense regions within the contrast collection. (Reproduced with permission from Rathmell JP, Torian D, Song T. Lumbar epidurography. *Reg Anesth Pain Med.* 2000;25:543.)

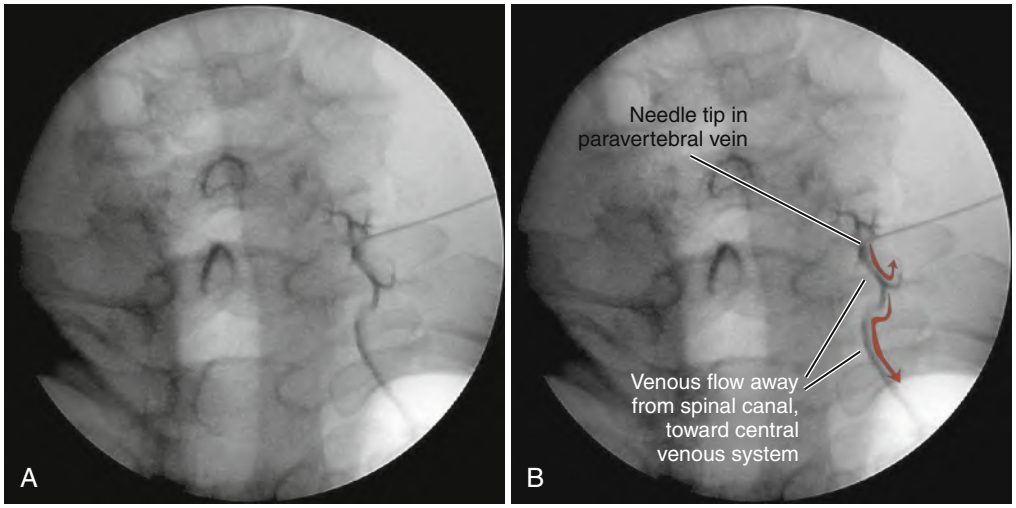
the most common RCM in clinical use. They are more stable in solution and less toxic than ionic monomers.

Adverse Reactions to RCM

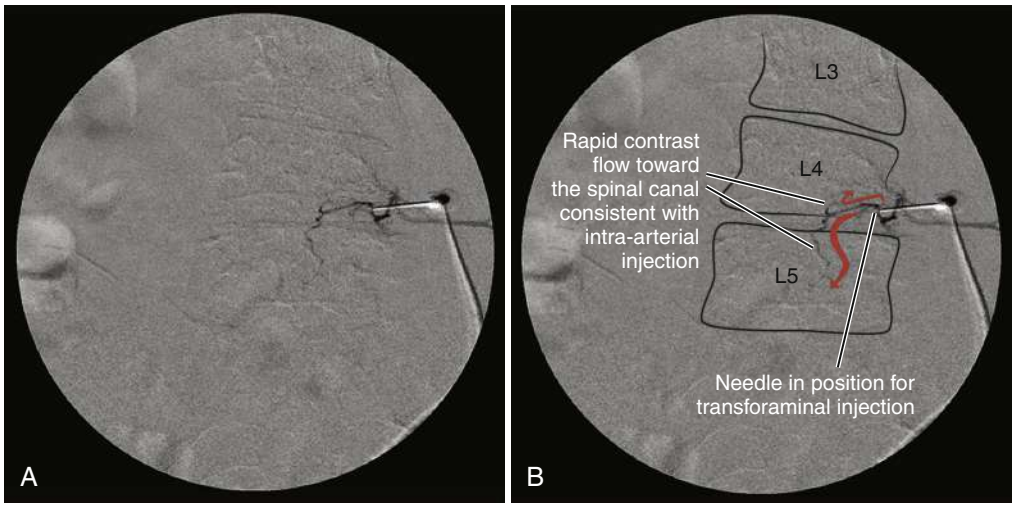
Modern contrast agents have been reduced, but are not eliminated, the risk of adverse reactions. To minimize the risk, RCM should be used at the smallest concentrations and in the smallest total dose that will allow adequate visualization. Adverse reactions associated with RCM can be divided into non-idiosyncratic or hypersensitive reactions (HRs). Nonidiosyncratic reactions are predictable, dose dependent, and related to the pharmacologic properties of the drug. HRs are dose-independent, not related to the pharmacologic properties of the drug, and unpredictable. HRs are further classified into allergic or non-allergic reactions. HRs were formerly called idiosyncratic reactions; they are also called anaphylactoid or non-allergic reactions, and the new (2020) and preferred term per the World Allergy Organization is "non-immunologic anaphylaxis." Allergy reactions require prior sensitization to culprit contrast medium (CM) with the production of immunoglobulin (Ig) E antibodies or allergen-specific T cells. Non-allergic HRs have similar manifestations as allergic reactions but are not immunoglobulin E (IgE) or T-cell mediated but are usually secondary to nonspecific mast cell release.[18] The risk of adverse reactions is significantly greater with the use of high-osmolarity ionic agents when compared with low osmolar, non-ionic agents. This discussion is limited to the risks associated with low osmolarity and non-ionic agents because they are used almost exclusively in pain medicine applications.

Nonidiosyncratic Reactions

Nonidiosyncratic reactions can be divided into chemotoxic reactions (chemical reactions to the iodine-carrying molecule) and osmotoxic reactions (those caused by the high osmolality of the CM). These nonidiosyncratic reactions are dose dependent; therefore this type



• **Figure 73.10** Intravenous contrast injection. **A**, Intravenous contrast injection is rarely seen on still images because the contrast material is rapidly diluted in the bloodstream. During real-time or live fluoroscopy, intravenous contrast injection appears as in this anterior-posterior radiograph of the cervical spine taken during the cervical transforaminal injection. The contrast can be seen flowing away from the spinal canal and toward the central venous circulation with the venous blood. **B**, Labeled image showing the direction of contrast flow. (Reproduced with permission from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2012: Fig. 3.4.)



• **Figure 73.11** Intra-arterial contrast injection (digital subtraction). **A**, Intra-arterial contrast injection is rarely seen on still images because the contrast material is rapidly diluted in the bloodstream. During real-time or live fluoroscopy, intravenous contrast injection appears as in this anterior-posterior digital subtraction radiograph of the lumbar spine taken during the lumbar transforaminal injection. The contrast can be seen flowing toward the end organ (in this image, toward the lumbar spinal cord) with the arterial blood. The use of digital subtraction cine-radiography allows for the detection of intravascular injection with small doses of radiographic contrast material. **B**, Labeled image showing the direction of contrast flow. (Reproduced with permission from Rathmell JP. Atlas of Image-Guided Intervention in Regional Anesthesia and Pain Medicine. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2012: Fig. 3.5.)

TABLE 73.5 Comparison of Common Radiographic Contrast Agents Used in Clinical Practice[a]

Chemical Composition	Trade Name	Iodine (mg/mL)	Osmolality (mosm/kg H_2O)	Viscosity (cps @ 37 °C)	RCM Agent Type
Sodium/meglumine diatrizoate 30%	Urografin 150	146	710	1.4	Ionic, high-osmolar
Sodium/meglumine diatrizoate 67%	Urografin 325	325	1,650	3.3	Ionic, high-osmolar
Iohexol 180 mg/mL	Omnipaque 180	180	360	2.0	Non-ionic, low osmolar
Iohexol 300 mg/mL	Omnipaque 300	300	640	6.1	Non-ionic, low osmolar
Iopamidol 41%	Isovue 200	200	413	2.0	Non-ionic, low osmolar
Iopamidol 61%	Isovue 300	300	616	4.	Non-ionic, low osmolar

[a]The ionic, high-osmolar agent diatrizoate and the non-ionic, low osmolar agents iohexol and iopamidol. Iohexol and iopamidol are commonly used in image-guided pain treatment. These agents provide a non-ionic, low osmolar RCM that balances a low risk of adverse reaction, demonstrated safety for intrathecal use, and sufficient radio-opacity to identify intravascular and intrathecal placement.

RCM, Radiographic contrast media.

of reaction should be exceedingly rare in patients receiving small volumes of RCM required to facilitate needle localization during image-guided pain treatment.

Chemotoxic reactions are rare and may result in direct organ toxicity, including cardiac (direct and prolonged decrease in cardiac contractility), neurologic (seizures), and renal toxicity (oliguria, impaired creatinine clearance, and reduced glomerular filtration rate that may progress to acute renal failure).[19]

Osmotoxic reactions are much more common in high-osmolar contrast media, where the osmolality of the RCM can reach several times that of physiologic osmolality of 300 mosm/kg H_2O[20]; toxic reactions have been dramatically reduced with the advent of low osmolar, non-ionic agents such as iohexol and should be exceedingly rare after administration of the small volumes used in pain medicine applications. Hyperosmolar reactions include erythrocyte damage (hemolysis), endothelial damage (capillary leak and edema), vasodilation (flushing, warmth, hypotension, cardiovascular collapse), hypervolemia, and direct cardiac depression (reduced cardiac contractility).

Hypersensitivity Reactions

HRs are mostly anaphylactoid in nature, comprising 80%–90% of HRs to iodinate contrast media (ICM). Acute HRs occur within 1 h, usually within 20 min of CM administration. Delayed HRs occurred 1 h to one week later. These are usually mild and cutaneous in nature.[21–23] The risk of anaphylactoid reaction is increased in patients with a previous reaction to RCM. Other factors include asthma, atopy, drug allergy, female sex, and severe cardiovascular disease.[24,25] For patients with seafood allergy, their risk of a reaction

to RCM appears to be similar to that of patients with other food allergies, or asthma, and experts concluded that allergy to shellfish does not increase the reaction to contrast more than other allergies.[26,27] Iodine cannot be an allergen since it is found throughout our body and added to most salt and medicinal compounds.[26] Patients who develop reactions to povidone-iodine skin prep react to allergens in the solution rather than iodine.

Recognition and Treatment of Reactions to RCM

The American College of Radiology (ACR) classified the reactions into mild, moderate, or severe; it can be life threatening (Table 73.6).[16] The incidence of these reactions following the use of small volumes of RCM in pain medicine is extremely rare. A recent study noted the absence of HRs after 6471 pain procedures; 108 patients had previous ICM allergy.[28] The absence of breakthrough reactions (reactions in patients with previous HRs) after an interventional pain procedure was previously reported in six patients injected with the same culprit ICM.[18] The authors ascribed the lack of breakthrough reactions to the small volumes injected, concomitant injection of steroids, and the extravascular route. In another study, 25 patients who had extravascular ICM injections (gastrointestinal, genitourinary, abdominal cavity, CSF) had no breakthrough reaction compared to 19% in patients who had intravascular ICM injection.[29]

The overall reaction rate to intravenous administration of large volumes of low osmolar ICM is 0.6%.[21,30,31] The overall incidence of HRs and severe HRs is 0.7% and 0.01%, respectively.[25] Most

TABLE 73.6 The Severity of HRs Acute HRs

Mild	
Mild signs and symptoms are self-limited without evidence of progression.	
Allergic-like	*Physiologic*
Limited urticaria/pruritus	Limited nausea/vomiting limited
Cutaneous Edema	Transient flushing/warmth/chills
Limited "itchy"/"scratchy" throat	Headache/dizziness/anxiety/altered taste
Nasal congestion	Mild hypertension
Sneezing/conjunctivitis/rhinorrhea	Vasovagal reaction that resolves spontaneously
Moderate	
Signs and symptoms are more pronounced and require medical management. Some of these reactions have the potential to become severe if not treated.	
Allergic-like	*Physiologic*
Diffuse urticaria/pruritus	Protracted nausea/vomiting
Diffuse erythema, stable vital signs	Hypertensive urgency
Facial edema without dyspnea	Isolated chest pain
Throat tightness or hoarseness without dyspnea	Vasovagal reaction that requires and is responsive to treatment
Wheezing/bronchospasm, mild/no hypoxia	
Severe	
Allergic-like	*Physiologic*
Diffuse edema, or facial edema with dyspnea	Vasovagal reaction resistant to treatment
Diffuse erythema with hypotension	Arrhythmia
Laryngeal edema with stridor and/or hypoxia	Convulsions, seizures
Wheezing/bronchospasm, significant hypoxia	Hypertensive emergency
Anaphylactic shock (hypotension + tachycardia)	

Adapted from the American College of Radiology manual (with permission).

TABLE 73.7 Suggested Treatment for Reactions to Radiographic Contrast Media of Moderate Severity

Adverse Reaction	Suggested Treatment
Urticaria	Diphenhydramine 25–50 mg PO, IM, or IV
Anxiety	Diazepam 5–10 mg PO or midazolam 1–2 mg IV
Bronchospasm	Mild: Inhaled albuterol
	Severe:
	Hydrocortisone 100 mg IV
	Epinephrine 0.05–0.1 mg SQ, IM, IV
Anaphylaxis	Epinephrine 0.01 mg/kg SQ, IM, IV (maximum adult dose 0.5 mg)

cases are mild (83%), and the incidences of moderate and severe HRs are 16% and 1%, respectively. Mild reactions in those receiving intravenous contrast include flushing anxiety, nausea, arm pain, pruritus, vomiting, headache, and mild urticaria. These are generally mild and self-limiting, and require no specific treatment. Occasionally, an oral antihistamine (diphenhydramine, 25 mg) can be useful in managing pruritus and anxiety. More serious reactions include more pronounced severity of mild symptoms and moderate degrees of hypotension and bronchospasm. The suggested treatments for moderate reactions are listed in Table 73.7.

Severe reactions are life-threatening, occurring in 0.01%–0.04% of those receiving intravenous RCM, and include convulsions, unconsciousness, laryngeal edema, severe bronchospasm, pulmonary edema, severe cardiac arrhythmias, and cardiovascular collapse.[16] Treatment of these life threatening reactions is urgent, necessitating the immediate availability of full resuscitation equipment and trained personnel, along with a routine practice for responding to these rare events. The airway must be secured, and oxygen, mechanical ventilation, external cardiac massage, and electrical cardiac defibrillation must be administered as required. Epinephrine is the drug of choice for the treatment of anaphylaxis; the usual adult starting dose is 0.01 mg/kg (maximum of 0.5 mg) subcutaneously, intravenously, or intramuscularly. Death may ensue following this type of severe adverse reaction; the incidence is not known with accuracy but likely lies between 1/14,000 and 1/170,000 intravenous administrations of RCM.

Prevention of Reactions to RCM

Any history of HRs should be recorded in the patient's chart: the CM used, amount injected, and the signs, symptoms, and treatment given. Prevention of breakthrough reactions involves identifying the culprit CM and identifying the factors that predispose patients to adverse reactions when they receive the RCM.

The risk of breakthrough reactions is increased in those who had severe initial HRs, diabetes, drug allergies, urticaria, and chronic steroid intake.[32] No known premedication regimen can reliably eliminate the risk of severe reactions to RCM.[24] The most common strategies suggested combining pre-treatment with corticosteroids (e.g. oral prednisone 50 mg doses 12 and 2 h before RCM administration) and antihistamines (e.g. oral diphenhydramine 50 mg doses 1–2 h before RCM administration). Some authors recommend the addition of H_2-antagonists (e.g. oral ranitidine). The protective effect of steroids has not been consistent.[24,33] Additionally, an increase of 40–150 mg/dL of blood sugar can occur within the first 24–48 h (ACR manual). Changing the ICM and premedication with antihistamine has been shown to reduce breakthrough HRs.[33,34] It has been our practice to avoid radiographic contrast altogether in those at elevated risk for an adverse reaction. Most procedures in pain medicine can be performed safely without the use of radiographic contrast. In some instances (e.g. epidural placement), the location can be established using the loss of resistance alone, and the final needle position can be verified using anteroposterior and lateral radiography without contrast. However, some injections should not be attempted without radiographic contrast injection (e.g. transforaminal injection), in which case, injection of contrast under live or real-time fluoroscopy (with or without digital subtraction) is the only means to detect intra-arterial needle location and to prevent catastrophic injection of particulate steroids directly into critical vessels supplying the spinal cord.

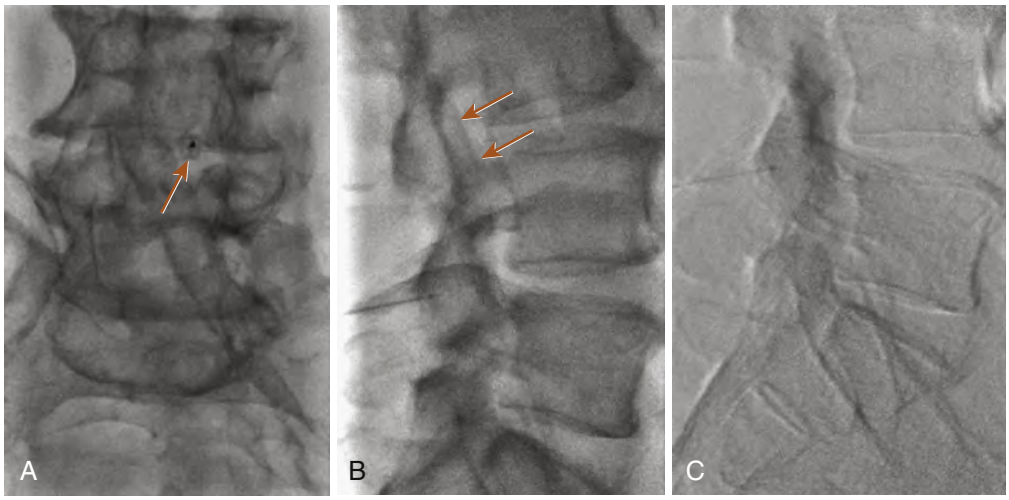
A multi-specialty multi-society group developed practice guidelines for RCM. The position statements (PS) and recommendations related to HRs are discussed in conjunction with gadolinium based contrast agents (GBCAs).[35]

Use of Gadolinium as an Alternative to Iodinated RCM

GBCAs, for example, gadopentetate dimeglumine (Magnevist), are commonly used intravenous contrast agents used to enhance vascular structures during diagnostic magnetic resonance imaging (MRI). Gadolinium chelates also have an intrinsic ability to attenuate x-rays and have been used successfully in place of ICM for angiography and spinal injections used in image-guided pain treatment. The radio-opacity of gadolinium is less than that of ICM (Fig. 73.12A, B).[36] Of the GBCAs, images with gadobutrol are more conspicuous because of their higher concentration (Table 73.8)[37] Nonetheless, 1–3 mL of undiluted gadopentetate dimeglumine (Magnevist) has been used successfully and reliably to identify the epidural space; the visualization can be further enhanced through the use of digital subtraction in combination with gadolinium (Fig. 73.12C).

GBCAs have been used as an alternative to iodinated contrast agents (ICM) in patients with known HRs to ICM.[36] This is because GBCAs have a lower incidence of HRs when compared to ICM: 0.013%–0.48% immediate HRs and 0.001%–0.01% severe reactions versus 3%–13% for immediate and 0.01%–0.04% for severe reactions for ICM.[21] Similar to the ICMs, HRs to GBCAs are mostly mild in nature. The risk factors are the same as those for ICM.[38,39] HRs are more common with GBCAs that are macrocyclic and ionic than the linear non-ionic GBCAs, partly because of their higher osmolality.[40,41] Among the linear ionic GBCAs, linear ionic GBCAs with high protein binding (gadofesveset, gadobenate, gadoxetate) have higher rates of immediate allergic-like reactions than ionic linear chelates without protein binding (gadopentetate).[42] Linear GBCAs that do not readily bind to proteins (gadodiamide) have lower rates of immediate allergic-like reactions than macrocyclic agents (gadobutrol, gadoteridol, gadoterate). Macrocyclic agents do not bind to proteins.

GBCAs are classified as either linear or macrocyclic based on the nature of the chelating agent.[43] For macrocyclic agents, Gd ions are caged at the center of the chelating agent, whereas linear GBCAs have an open-chain chemical structure in which the



• **Figure 73.12** Utility of digital subtraction fluoroscopy for visualization of the gadolinium-based contrast epidurogram. A nonselective epidural steroid injection was performed on a 62-year-old male at L4-L5 employing an interlaminar approach. **A,** Right anterior oblique (RAO) projection of the lumbar spine shows a needle (*arrow*) inserted into the interlaminar space at L4-L5. **B,** Conventional fluoroscopy permits visualization of an epidurogram in the lateral projection (*arrows*). **C,** Digital subtraction fluoroscopy in the lateral projection more clearly demonstrates the distribution of the gadolinium chelate in the epidural space. (Adapted with permission from Shetty SK, Nelson EN, Lawrimore TM, Palmer WE. Use of gadolinium chelate to confirm epidural needle placement in patients with iodinated contrast reaction. *Skeletal Radiol.* 2007;36:301-307, Fig. 2.)

TABLE 73.8 Gadolinium Based Contrast Agents

Gadolinium Based Contrast Agent	Type, Stability[b]	Concentration mmol/mL	Usual MRI Dose mmol/kg (mL dose in 70 kg person)[c]	Lowest Dose Associated With Gadolinium Deposition in the Brain (70 kg person)[d]
Gadodiamide (Omniscan®)	Nonionic linear, Low	0.5	0.1 (14 mL)	37.8 mL
Gadoversetamide (Optimark®)	Nonionic linear, Low	0.5	0.1 (14 mL)	37.8 mL
Gadobenate dimeglumine (MultiHance®)[a]	Ionic linear, Intermediate	0.5	0.1 (14 mL)	37.8 mL
Gadopentetate dimeglumine (Magnevist®)	Ionic linear, Intermediate	0.5	0.1 (14 mL)	37.8 mL
Gadofesveset trisodium (Ablavar®, Vasovist®)	Ionic linear, Intermediate	0.25	0.03 (8.4 mL)	75.6 mL
Gadoxetate disodium (Eovist®, Primovist®)[a]	Ionic linear, Intermediate	0.25	0.025 (7 mL)	75.6 mL
Gadoteridol (ProHance®)	Nonionic macrocyclic, High	0.5	0.1 (14 mL)	37.8 mL
Gadobutrol (Gadavist®)	Nonionic macrocyclic, High	1	0.1 (7 mL)	18.9 mL
Gadoterate meglumine (Dotarem®)	Ionic macrocyclic, High	0.5	0.1 (14 mL)	37.8 mL

chelating agent is wrapped around the Gd ion.[44,45] Macrocyclic agents are more stable and dissociate less. Among linear GBCAs, non-ionic GBCAs are less thermodynamically stable than ionic GBCAs and therefore release more gadolinium than ionic agents (Table 73.8). The stability of the GBCA explains the more frequent occurrences of nephrogenic systemic fibrosis (NSF) and gadolinium brain deposition/retention with linear GBCAs than with macrocyclic agents. These adverse events are secondary to the release of gadolinium—a toxic ion. Gadolinium is released through the dechelation of the ligand.

A multi-specialty multi-society practice guideline on HRs to contrast media issued the following recommendations:[35]

- When an HR occurs, the interventional physician should document the incident. The report should include the name and volume of injected CM.
- The physician should be notified immediately if a patient scheduled for a procedure with contrast injection has a history of HR to CM.
- Patients with a history of mild HRs to CM may receive appropriate pretreatment and receive a different low osmolar non-ionic CM if the culprit ICM is known.
- Patients with a history of moderate or severe HRs to ICM should be pretreated and injected with a different low osmolar non-ionic ICM, if culprit ICM is known, and if alternative contrast choices such as GBCM or air (with CT) are contraindicated.
- In the absence of an immediate reaction, prophylaxis for late reactions is not recommended, and treatment should be symptomatic.
- Patients with a history of true IgE-mediated allergic HRs and a positive skin test (performed within six months of HR) should receive premedication with steroids and H1 antihistamine medication.
- Patients with a history of true IgE-mediated allergic HRs should be injected with a different ICM, which is skin test-negative.
- Acute HRs should be managed symptomatically.
- Recommendations for the duration of monitoring in patients with a history of HR and CM.
- Premedicated patients with a history of mild HRs and no symptoms following exposure to CM: 30 min
- Non-premedicated patients with a history of mild HRs and no symptoms following exposure to the same CM: 30 min
- Patients with a history of moderate/severe HRs but no reaction in the first 15 min (irrespective of premedication status): 30 min–1 h
- For staff associated with interventional pain procedures, there should be an annual review of (1) grading system for the severity of hypersensitivity reactions, (2) components of documentation for witnessed or historical HRs, (3) emergency preparedness of the staff, and (4) steps involved in cardiopulmonary resuscitation.
- Emergency equipment, including airway supplies, defibrillators, and cardiovascular support medications, should be immediately available during interventional procedures involving the administration of CM, especially in patients with a history of HR to CM.

The continued use of GBCAs has been questioned because of adverse events.[46] Besides NSF, including trending gadolinium brain/deposition/retention and catastrophic encephalopathy after unintentional intrathecal (IT) gadolinium injection.

Nephrogenic Systemic Fibrosis

NSF is characterized by cutaneous and systemic symptoms resulting from gadolinium administration, with renal insufficiency being the dominant risk factor. NSF is related to free gadolinium after the ion is released from its chelate (dechelation).[47] Gadolinium activates the production of profibrotic cytokines, resulting in fibroblast formation. Gadolinium is a lanthanide element, and lanthanides are known to cause fibrosis and enhance the polymerization of skin collagen *in vitro* and fibril formation. The symptoms include thickened skin and subcutaneous tissue resulting in stiffness and contractures.[48,49] There is also fibrosis of internal organs.[49] Thomsen et al. categorized the GBCAs according to the risk of development of NSF.[50] The GBCAs with the highest risk, because of the greatest dissociation, include the linear non-ionic GBCAs gadodiamide (Omniscan^{R}) and gadoversetamide (Optimark^{R}) and the linear ionic gadopentetate (Magnevist^{R}). The intermediate-risk group consists of the linear ionic agents gadobenate (MultiHance^{R}) and gadoxetate (Eovist^{R}, Primovist^{R}). The lowest risk group, that is, the GBCAs with the lowest degree of dissociation, includes the macrocyclic agents gadoteridol (ProHance^{R}), gadobutrol (Gadavist^{R}), and gadoterate (Dotarem^{R}).

There are several guidelines on the use of GBCAs in relation to NSF, all related to the use of GBCAs in radiologic diagnostic procedures involving intravascular administration.[16,43,50] The recommendations of the multi-specialty multi-society practice guideline on NSF to contrast media include:[35]

- Patients at risk of developing NSF should be identified before administering a GBCA.
- Screening for renal function in interventional pain procedures may not be necessary with stable macrocyclic GBCAs (gadobutrol, gadoteridol, gadoterate) and the linear ionic GBCA gadobenate dimeglumine.
- The lowest possible dose of GBCA to obtain necessary clinical information should be administered.
- In *interventional* pain procedures, the low-risk macrocyclic (gadoteridol, gadobutrol, gadoterate) and medium-risk linear/ionic (gadoxetate, gadobenate dimeglumine) GBCAs can be administered to patients with moderately reduced kidney function (CKD3, eGFR between 30 and 59 mL/min/1.73 m^2).
- In *interventional* pain procedures, when GBCA is necessary, low risk macrocyclic (gadoteridol, gadobutrol, gadoterate) and medium-risk linear/ionic (gadoxetate, gadobenate dimeglumine) GBCAs may be used with caution in patients with severely reduced kidney function (CKD4, eGFR 15–29 mL/min/1.73 m^2; CKD5, eGFR <15 mL/min/1.73 m^2) and those on dialysis.
- In *interventional* pain procedures, GBCAs in the high-risk category (gadodiamide, gadoversetamide, gadopentetate dimeglumine) are contraindicated in patients with CKD 4 or 5 (eGFR <30 mL/min/1.73 m^2), patients with end-stage renal disease on chronic hemodialysis, and patients with acute kidney injury.
- In anuric patients with no renal function, GBCA should be avoided. Instead, the lowest dose of iodinated contrast medium should be considered if contrast is essential.

Brain Deposition/Retention

After gadolinium is released from its ligand, transmetalation—the exchange of gadolinium for other endogenous ions such as iron, copper, zinc, or calcium—occurs in tissues prone to this process (e.g. dentate nucleus, globus pallidus, lentiform nucleus, and pulvinar of the thalamus). The gadolinium deposits appear as high-relaxivity complexes that cause visibly increased T1 signal intensities on non-contrast MRI examinations and remain for months to years after exposure.[51] The deposition of gadolinium in the brain is dose-related,[52,53] case reports showed patients who had

5–35 MRIs,[46] some for follow-up of their brain tumors. Gadolinium brain deposition/retention is not associated with kidney function.[54] Besides the brain, gadolinium has been demonstrated in the liver, skin, and bone.[55,56] Similar to NSF, the gadolinium deposition/retention in the brain occurs more with the linear GBCAs such as gadodiamide and gadopentetate and at much lower levels with the macrocyclic chelates. Current research suggests that it is almost certain that all GBCAs, regardless of structure or ionicity, are associated with some level of gadolinium deposition.[51]

No definite clinical consequences of GBCA retention in the brain have been established.[57,58] The symptoms reported by patients include flu-like symptoms, headache, bone/joint pain, vision/hearing change, skin changes, and digestive and chest symptoms.[59] These symptoms may not be attributed to gadolinium brain deposition since these occur within six weeks of exposure, hence overlapping with the symptoms of NSF. A large population-based study (246,557 patients; 99,739 received gadolinium) showed that the incidence of parkinsonism was the same in the patients who received at least one gadolinium dose (1.16%) than in patients who had non-contrast MRI (1.17%).[60] Knowledge in this area is incomplete, and studies are evolving. There has been no documented gadolinium deposition in the brain after an interventional procedure, partly because most patients referred to the pain clinic already had a contrast-enhanced MRI.

Published practice guidelines apply to diagnostic radiologic procedures involving large volumes of intravascular GBCA injection.[61] Recommendations from these guidelines relevant to interventional pain procedures include limiting the use of GBCA to only when medically necessary, dose not exceeding recommended dosages, avoidance of repeated GBCA administrations, and monitoring the literature for development.

The recommendations of the multi-specialty multi-society practice guideline on NSF to contrast media include:[35]

- Interventional pain physicians should be aware of patients who have incurred a gadolinium administration burden from multiple gadolinium-enhanced MRI examinations.
- Gadolinium is a drug that should be used with caution in interventional pain procedures. It should be administered only when necessary.
- Several factors need to be considered when selecting a GBCA, including diagnostic efficacy, rate of adverse reactions, dosing/concentration, radio-opacity, and propensity to deposit in organs such as the brain.
- Ongoing research and emerging evidence need to be monitored, and relevant information incorporated into clinical practice as this field of inquiry evolves.

Encephalopathy After Unintentional Intrathecal Gadolinium Injection

There have been case reports of encephalopathy after unintentional intrathecal (IT) injection of gadolinium after interventional pain procedures[62–65] and after diagnostic settings.[66–69] In pain medicine settings, the IT injection occurred during an attempted epidural injection[62,64] or a minimally invasive lumbar decompression procedure.[65] The volume injected ranged from 1.5 mL–5 mL. All the patients showed gadolinium in their subarachnoid space on MRI.[62,64,65] One patient had leg pain and spasms, one had to be intubated, and another patient died 14 days later. The patients in the non-pain settings received intrathecal injections of 10–20 mL. One patient took 56 days to recover,[66] while another showed no sequelae after 60 days (**Li**). The third patient had visual disturbances at one month,[67] while the fourth patient stayed in intensive care for at least two months.[69]

Radiologists inject gadolinium intrathecally when they evaluate dural leaks, hydrocephalus, and other CSF disorders (arachnoid cyst communications, aqueductal stenosis, obstruction of the fourth ventricle) and in their investigation of the glymphatic pathway.[70–72] Other authors prospectively looked at the safety of an intrathecal injection of 0.5 mL gadobutrol and 3 mL iodixanol (Visipaque^{R}) in 100 patients.[72] The adverse events included severe HA (28%) and severe nausea (34%) that resolved after four weeks. A patient with a known allergy to ICM developed anaphylaxis. The authors concluded that the intrathecal injection of 0.5 mL gadobutrol was safe.[72] The safety of these injections may be explained by the dilution of the gadolinium with either 4 mL saline or 1 mL CSF or 5 mL ICM (e.g. iohexol) and the slow duration of injection, e.g. over a 3 min period.[73] This is in contrast to the bolus injection of gadolinium after "wet taps." The findings of gadolinium accumulation in the cerebrospinal fluid (CSF) after *intravenous* injection in humans,[74,75] apparently without clinical symptoms, support the lack of or minimal sequela from the slow accumulation of gadolinium in the intrathecal space.

The possible mechanisms of gadolinium neurotoxicity and cell death include impairment of mitochondrial function, alterations in cell signal processes and signal transduction, and inhibition of cellular calcium hemostasis.[65] After intracisternal application in rats, the LD50s (μmol per kg) were noted to be lower for the macrocyclic GBCAs gadoteridol, gadoterate meglumine, and gadobutrol than the linear agents' gadodiamide and gadopentetate.[76] Despite their findings, the authors considered the margin of safety between a diagnostic dose and LD50 in humans to be very high, with a safety factor of 80.[76]

Encephalopathy and death after unintentional intrathecal injection of small doses of gadolinium are alarming. This is compounded by the preponderance of pain injections around the spine. This was the primary reason why the multi-specialty group developed a practice guideline.[35] The recommendations, as it pertains to encephalopathy after unintentional intrathecal injection, include:

The use of GBCA is contraindicated in subarachnoid (intrathecal) *interventional* pain injections.

Patients with an increased risk of intrathecal injection should be identified, including spinal stenosis, previous spine surgery, or kyphoscoliosis.

Because of the likelihood of unintentional intrathecal spread of gadolinium, a GBCA is recommended in epidural injections via an interlaminar approach.

Because of the likelihood of unintentional intrathecal spread of gadolinium, a GBCA is recommended for transforaminal epidural injections.

Suppose that gadolinium is necessary for an interventional pain procedure where there is a very low risk of possible unintentional intrathecal administration (e.g. lumbar sympathetic blocks, facet joint injections, medial branch blocks). In such cases, the low risk of intrathecal gadolinium administration should be adequately explained to the patient.

If gadolinium is considered essential to the pain procedure and injected near the epidural/subarachnoid space, measures should be taken to avoid advancing the needle tip into the subarachnoid space.

If gadolinium is employed, digital subtraction imaging guidance may be considered.

If there is a concern for unintentional intrathecal or subdural administration of a GBCA, appropriate radiographic imaging, such as MRI and CT, should be considered.

Differences Between Interventional Pain Procedures and Diagnostic MRIs and CT

In interventional pain procedures, small volumes are injected extravascularly and may be repeated after 1–3 weeks. These procedures are distinct from CT or MRI, in which large volumes of contrast are injected intravascularly. Most patients' medical issues have been identified and treated before they are referred to the pain clinic. Injections are not performed on an emergency basis because the patient's pain can be partially controlled with medications and other non-pharmacologic alternatives until the medical issue has been controlled or stabilized. These differences explain the PS and recommendations of the multi-specialty practice guidelines,[35] compared to the guidelines by radiology specialties.

Concluding Statements

The principles of radiation safety are outlined in this section. Although studies have shown that the accumulated radiation from interventional pain procedures is below the MPD, measures should be followed to minimize radiation exposure. The use of contrast media is essential in some interventional procedures. It appears that HRs to ICM and GBCAs are rare, probably because of the small doses employed and the extravascular route of injection. The clinical significance of gadolinium brain deposition/retention in the brain is unknown, and its occurrence after interventional pain procedures is very rare. The occurrence of NSF after pain is rare. Encephalopathy after unintentional intrathecal injection of gadolinium is an alarming development. Linear GBCAs are less stable, explaining the greater occurrence of NSF and gadolinium brain deposition with these agents than macrocyclic GBCAs. However, macrocyclic GBCAs have a higher incidence of HRs—although still lower than ICM—and have lower LD50s when injected intrathecally. These differences should be considered when deciding on the use of GBC. Since NSF and gadolinium brain depiction is less of a concern in interventional pain procedures, linear agents may be employed in perispinal injections. The availability of these agents is low, as some agents are withdrawn. Awareness of these adverse effects, shared decision making with patients, and observance of preventive measures to avoid these complications is paramount.

Key Points

- The biologic effects of ionizing radiation are proportional to the time of exposure, whereas radiation exposure is inversely proportional to the *square* of the distance from the radiation source.
- Modern fluoroscopy units typically employ ABC, which automatically adjusts kVp and mA to yield optimal brightness and contrast.
- The ICRP has produced estimates of the MPD of annual radiation to various organs. Exposure below these levels is unlikely to lead to any significant effects, but the ICRP recommends that workers should not receive more than 10% of the MPD.
- Continuous fluoroscopy for 1 min at 2 R per min was equivalent to the exposure during 130 chest radiographs.
- Practitioners using ionizing radiation should adhere to the ALARA principle ("As Low As Reasonably Achievable"), combining optimal techniques and shielding to minimize patient and personnel exposure.
- The x-ray tube should be positioned as far from the patient as possible without including unnecessary structures in the field of view.
- To minimize the dose to the patient, the largest field of view should be employed in conjunction with tightest collimation.
- Although protective lead gloves can reduce the exposure of the hands to radiation, they can produce a false sense of security.
- Leaded eyewear is recommended for practitioners who accumulate monthly readings on collar badges above 400 mrem (4 Sv).
- Digital subtraction electronically enhances the image, reducing the amount of CM needed by a factor of two to three times.
- The annual amount of radiation from interventional pain procedures is within the MPD.
- Of the common non-ionic monomers in clinical use, only iohexol and iopamidol are labeled for intrathecal use.
- The most common premedication regimen to reduce the risk of severe reactions to contrast media combines pretreatment with corticosteroids and antihistamines. However, the efficacy of steroid premedication is not consistent. Changing the ICM has been shown to decrease the breakthrough reactions.
- GBCAs have been used as alternatives to iodinated contrast agents in patients with known contrast allergies. This is because GBCAs have a lower incidence of overall and severe HRs compared to ICM.
- HRs are more common with macrocyclic ionic GBCAs and linear ionic GBCAs than with linear non-ionic GBCAs, partly because of their higher osmolality.
- In patients with previous HRs, a multi-specialty multi-society practice guideline recommended the use of a different iodinated CM and appropriate pretreatment.
- Macrocyclic GBCAs are more stable and dissociate less than linear GBCAs. The stability of the GBCA explains the more frequent occurrences of NSF and gadolinium brain deposition/retention with linear GBCAs than with macrocyclic agents.
- NSF is a systemic disease related to fibroblast formation enhanced by free dechelated gadolinium ions. It occurs mostly with linear non-ionic GBCAS followed by the linear ionic GBCAS; the lowest incidence occurs with the macrocyclic agents.
- For patients with renal insufficiency, a multi-specialty multi-society practice guideline recommends low-risk macrocyclic GBCAs and medium-risk linear ionic GBCAs. The smallest dose necessary to obtain clinical information should be used.

- Gadolinium brain deposition/retention in the brain occurs after repeated GBCA-enhanced MRI. This is mostly associated with linear GBCAs. Its occurrence is dose-related and not associated with kidney function. Its clinical sequelae have not yet been established.
- Gadolinium brain deposition/retention has not been reported after interventional pain procedures, partly because small extravascular doses are injected. Interventional pain physicians should be aware of the research developments in this area.
- An alarming development is encephalopathy after unintentional intrathecal injection of gadolinium. The volumes injected ranged from 1.5 to 5 mL of the GBCA. Macrocyclic GBCas have lower ED50s than linear GBCAs when injected intrathecally.
- A multi-specialty multi-society practice guideline issued Statements and recommended against intrathecal and transforaminal injections of GBCAs.

Infection and Anticoagulation Considerations in Pain Procedures

MICHAEL C. HANES, HONORIO T. BENZON, DAVID A. PROVENZANO

SECTION 1 RISK OF INFECTION IN INTERVENTIONAL PAIN PROCEDURES

David A. Provenzano, Michael C. Hanes

Introduction

Infections related to interventional pain procedures and implantable devices vary considerably based on the target location, causative pathogens, anatomic structures involved, collateral damage, and severity. Surgical site infections (SSIs) have been shown to significantly increase mortality, prolong hospital length of stay, and reduce health-related quality of life.[1–2] In addition, SSIs cost the United States healthcare system an estimated $3.5 to 10 billion dollars annually.[3] The total cost of a single spinal cord stimulator (SCS) infection has been estimated to range from $28,500 –$54,500 in the United States.[4]

Recently, there has been a global emphasis by national and international agencies and societies to create and promote recommended best practices to reduce SSI rates.[5–10] Despite these efforts, SSI rates have not significantly declined.[11] SCS infection rates are higher than those of other implantable devices, including cardiac pacemakers and total joint replacements.[11] An international survey of 506 physicians who performed SCS implants was conducted to examine compliance rates for the Centers for Disease Control and Prevention (CDC), National Institute for Health and Care Excellence (NICE), and Surgical Care Improvement Project (SCIP) infection control practice recommendations.[5,7,10] Only four of the 15 questions had compliance rates of ≥80%, thus further highlighting the need for physician education in the field. Both current infection rates for implantable pain devices and survey responses suggest a need for improved education for interventional pain physicians in infection control practices.

This section summarizes the literature and recommendations for commonly performed interventional pain procedures, with a distinction made between implantable device surgery including SCS and intrathecal drug delivery systems (IDDS) and non-implantable device procedures including epidural steroid injections, facet blocks, neuraxial and peripheral nerve blocks, joint injections, sympathetic blocks, radiofrequency, discography, and vertebral augmentation.

Definition of SSIs

Identification of SSI is based on physical examination findings of localized pain/tenderness, swelling, erythema, heat, or purulent drainage, cultures, and radiologic findings (Fig. 74.1).[5] Superficial SSIs involve the skin and subcutaneous tissues. Deep SSIs involve the fascia, muscle layers, and organ/space infections. Site infections occurring in the absence of an implantable device are defined as occurring within 30 days of the operation. When implantable devices are involved, the time is extended, and infections may occur within 12 months following a device implant.

Pathogens Associated With SSIs

Organisms that cause SSIs can be categorized as endogenous or exogenous sources. The most common pathogens are *Staphylococcus aureus*, *Staphylococcus epidermidis, Streptococcus*, *Escherichia*

• **Figure 74.1** A surgical site infection of a spinal cord stimulator generator site.

coli, and *Pseudomonas aeruginosa*. The most common source of infection is from the patient's own flora.[8,12,13] It has been shown that pathogenic *Staphylococcus aureus* isolated from an infected wound matches cultures from the patient's nares 80%–85% of the time.[14]

Scope of Interventional Pain Procedures and Risk of Infection

Interventional pain procedures and surgeries vary considerably based on the pain syndrome being treated, surgical technique, and surgical theater environment. The invasiveness of procedures varies, and thus different infection control practices must be considered. Recommendations to prevent SSIs have been published by the CDC, NICE, and SCIP (Tables 74.1, 74.2, and 74.3).[5,8,10,15]

Infection Rates

Despite an emphasis on reducing SSIs, the rate of infection has remained relatively stable over the past two decades. In the United States, approximately 500,000 SSIs occur annually, accounting for 17% of all nosocomial infections.[16] The relative risk of central nervous system infection following paraspinal injections has been estimated to be about 0.1%.[17] The risk of developing an epidural abscess from an indwelling catheter for postoperative analgesia has been reported to be 0.05%.[18] There have only been a few reports of infectious complications related to facet injections. Thus the true incidence is unknown.[19–24] Incidence of disc infection with discography has been estimated to be 0.15% per patient and 0.08% per disc injected.[25] Published systematic reviews on SCS and IDDS report infection rates ranging from 3.4%–12.4% and 2.4%–4.6%, respectively.[16,26-31]

Preoperative Risk Reduction

Patient Risk Factors

Physicians should recognize patient-related risk factors, including older age, poor nutritional status, diabetes mellitus, smoking, obesity, coexisting infection on a remote body site, colonization with *Staphylococcus aureus*, and altered immunity (e.g. immunosuppressive agents) prior to performing a procedure, and efforts should be made to correct any modifiable risk factors (Table 74.4).[32–35] Post-market surveillance data on SCS and IDDS implants revealed that 38% and 70% of patients with SCS and IDDS infections, respectively, have a medical comorbidity that increases the risk of infections.[12] Smoking has been associated with an increased risk of SCS infections, likely secondary to the development of microvascular disease leading to tissue ischemia and poor wound healing, and worse pain scores and opioid consumption post-SCS implant.[27,36–38] Although the biologic effects of cancer and chemotherapeutic drugs can weaken host immunity, a retrospective study demonstrated that implantable pain therapies can still be utilized in cancer patients without significantly increasing the risk of SSI when appropriate infection control measures are taken.[39]

A thorough history and physical examination should be performed preoperatively to identify patient risk factors prior to surgery. Many measures can be taken to reduce the risk of SSIs, such as glucose optimization, tobacco cessation (for at least four weeks), optimizing viral load in HIV patients, minimizing/avoiding perioperative steroids, and treating remote infections (e.g., urinary tract). Non-modifiable risk factors need to be documented, and a discussion with the patient regarding the associated increased risk of infection should occur prior to the pain intervention.

Staphylococcus Aureus Carriers

Staphylococcus aureus is the leading cause of SSIs, accounting for approximately 20% of all SSIs and 30% of ICD implant infection.[40–42] More than 80% of nosocomial *Staphylococcus aureus* infections are endogenous, and the number of cases of methicillin-resistant *S. aureus* (MRSA) SSIs is increasing.[5,43] Staphylococcus aureus nasal colonization rates range from 20%–50%.[44–48]

Methicillin-sensitive *S. aureus* (MSSA) and MRSA carriers have been shown to have a significantly higher risk of developing an SSI (two to nine times higher).[48–50] Therefore identification of carriers followed by decolonization is critical in reducing SSI rates, and is cost effective.[26,44,45,51–53] Prior to implantable pain therapies, patients can be screened for MSSA and MRSA. If positive, the patient can be decolonized, and preoperative antibiotic therapy is tailored based on the results.

Decolonization protocols involve the application of mupirocin 2% nasal ointment applied twice daily combined with chlorhexidine gluconate soap total-body washes daily for a duration of five days immediately preceding surgery.[44,54] Utilization of decolonization protocols in individuals colonized reduces the rate of postoperative infections by >50%.[44,56,56] No data exists to support the use of routine decolonization protocols in patients who are not found to be colonized with *S. aureus*.[49]

Antibiotic Prophylaxis

Preoperative antibiotic prophylaxis has been shown to significantly reduce the risk of SSIs, and the incidence of wound infection by approximately 50%, regardless of the type of surgery.[57] Antibiotic prophylaxis (Table 74.4) is recommended for implantable pain therapies (i.e. trials and implant stages). Proper antibiotic selection, route of administration, dosing, and timing are critical, as suboptimal implementation has increased the risk of infection by two- to six-fold.[58,59] Cephalosporins are recommended as first line agents. Clindamycin or vancomycin are alternative antibiotics if a patient has a β-lactam allergy. In individuals colonized with MRSA or at high risk for MRSA (e.g., institutions with a high rate of MRSA infections), vancomycin is recommended.[7,60] In individuals with vancomycin allergies, daptomycin may be considered.[61]

For effective antibiotic prophylaxis, minimum inhibitory concentrations must be reached prior to surgical incision and maintained throughout the duration of the surgery. Therefore weight-based dosing is critical. Preoperative antibiotics should be administered intravenously (IV) prior to breaching the skin (30–60 min or 120 min for vancomycin). Re-dosing is needed when the duration of surgery is longer than two half-lives of the administered antibiotic (Table 74.5).

The continuation of antibiotics in the postoperative period is not recommended beyond 24 h for clean surgical wounds. Prolonged antibiotic use in the postoperative period does not improve outcomes and may result in poorer outcomes.[62,63] Specifically, the continuation of antibiotics in the postoperative period has been associated with delayed normalization of body temperature and elevated C-reactive protein level.[62] The SCIP guidelines recommend discontinuation of antibiotics within 24 h of surgery.[7]

TABLE 74.1 Preoperative CDC, SCIP, NICE, and Author Recommendations for Reducing SSIs

Recommendations	CDC Evidence Rankings	SCIP Process of Care Performance Measures	NICE Guidelines	Authors' Additional Recommendations
• Identify and treat all remote infections.	IA			
• Identify patient risk factors				✓ [12,32–35]
• Optimize glucose control	IB			
• Discontinue tobacco use	IB			
• Require patients to shower or bath with an antiseptic agent prior to surgery.	IB			
• Preoperative screening and decolonization for SA carriers				✓ [43,44,51,53,54]
• Do not routinely use nasal decontamination for SA			✓	
• Appropriate selection of intravenous antibiotic prophylaxis based on hospital pathogens and type of surgery/procedure	IA	✓	✓	
• Weight-based antibiotic dosing				✓ [61,62]
• Appropriate prophylactic antibiotic received within one hour prior to surgical incision (two hours for vancomycin)	IA	✓	✓	
• Appropriate agent selection for skin antisepsis (povidone-iodine or chlorhexidine)	IB		✓	
• Vancomycin should not routinely be used	IB			
• Preoperative surgical scrub for at least 2–5 minutes using an appropriate antiseptic. Scrub the hands and forearms up to the elbows	IB		✓	
• Keep nails short and do not wear artificial nails	IB		✓	
• Sterile gown and gloves	IB			
• Do not wear hand or arm jewelry	II		✓	
• Do not use hair removal routinely	IA		✓	
• If hair is removed, use electric clippers immediately before surgery	IA	✓	✓	
• Evaluate for skin lesions or areas of local infection				✓
• Apply preoperative antiseptic skin preparation in concentric circles moving toward the periphery	II			
• Wide prep and drape	II			

CDC, Centers for Disease Control; *SCIP*, Surgical Care Improvement Projects; *NICE*, National Institute for Health and Clinical Excellence; *OR*, operating room; *SSI*, surgical site infection; *HEPA*, high-efficiency particulate arrestance

CDC Recommendation Ranking Categories:

IA: Strongly recommended for implementation and supported by well-designed experimental clinical or epidemiologic studies.

IB: Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and strong theoretical rationale.

II: Suggested for implementation and supported by suggestive clinical or epidemiologic studies or theoretical rationale.

There are no recommendations or evidence for the use of antibiotic prophylaxis in the majority of routine interventional pain procedures, i.e. such as epidural steroid injections and facet blocks. However, for procedures with a higher risk of infection (i.e. indwelling catheters, kyphoplasty, and device trials/implants), antibiotic prophylaxis is recommended.[5,8] For discography and other intradiscal procedures, controversy exists regarding the need for IV and/or intradiscal antibiotic administration.[8,64]

TABLE 74.2 Intraoperative CDC, SCIP, NICE, and Author Recommendations for Reducing SSIs

Recommendations	CDC Evidence Ranking	SCIP Process Care Performance Measures	NICE Guidelines	Authors' Additional Recommendations
• Wear a surgical mask in the OR if sterile instruments are exposed	IB			
• Wear a cap or hood to fully cover hair in the OR	IB			
• Wear two pairs of sterile gloves when there is a high risk of glove perforation and the consequences of contamination are high			✓	✓[87]
• Use sterile surgical gowns that are effective barriers when wet	IB		✓	
• If an incise drape is used, use an iodophor-impregnated drape			✓	
• Laminar flow and HEPA filters in OR	IB			
• Limit OR traffic	II		✓	
• Keep OR doors closed during procedure	IB			
• Adhere to principles of asepsis when placing spinal or epidural catheters	IA			
• Limit tissue trauma, maintain hemostasis, eradicate dead space, and avoid the electrocautery at tissue surface	IB		✓	
• Vigorous wound irrigation with bulb syringe				✓[99,101]
• Limit surgical time				✓[37,92]

Administration of intravenous antibiotics did not reliably achieve adequate intradiscal concentrations. Therefore only intradiscal antibiotics are recommended. However, *ex vivo* studies examining the effects of high antibiotic concentrations on cultured human intervertebral disc annular cells demonstrated deleterious effects on cell survival, cell proliferation, and metabolic rates; therefore these risks must be considered as well.[65]

Surgical Hand Washing

Appropriate surgical scrubbing of the hands and forearms is a CDC Category IB and NICE recommendation.[5,10] Commercially available antiseptic solutions in the United States contain alcohol, chlorhexidine, and/or povidone iodine. There is evidence that chlorhexidine-based scrubs reduce the number of colony-forming units (CFUs) compared to povidone-iodine scrubs. However, data supporting its clinical relevance are lacking. Therefore there is a lack of strong evidence to strongly support the use of one agent over another.[66] The duration of the surgical scrub appears to be the most important factor in ensuring adequate hand hygiene and limiting bacterial counts. Surgical hand washing lasting between 2 and 5 min results in statistically fewer CFUs than hand washing techniques of lesser duration.[67]

The removal of hand and wrist jewelry prior to surgical scrub is a CDC Category II and NICE recommendation as well as a recommendation by the American Society of Anesthesiologists and American Society of Regional Anesthesia and Pain Medicine (ASRA) when performing neuraxial procedures.[68] The presence of hand jewelry increases bacterial counts on the hands of healthcare workers even after hand washing.[5,10,15,69]

The method of hand hygiene required to minimize the risk of infections associated with interventional pain procedures has not been established. A full surgical scrub is recommended for implantable and indwelling catheters.

Appropriate Hair Removal

The CDC Category IA and NICE do not recommend removing hair routinely to reduce the risk of SSI, and if hair is removed, clippers should be used.[5,10] The timing and method of hair removal appear to be the most important factors to consider. A meta-analysis examining hair removal techniques concluded that there was no difference in SSI rates when comparing no hair removal to hair removal with chemical or clipper methods. However, shaving methods increase the risk of SSIs.[70] Both clipping and shaving hair 24 h or more before an operation significantly increases the risk of SSI.[5,71,72]

Intra-procedural Risk Reduction

Patient Skin Preparation in the Operating Room

Antiseptic solutions containing isopropyl alcohol, povidone iodine, and chlorhexidine gluconate are most commonly used for skin preparation in patients. Prior to applying a skin antiseptic, gross contamination around the incision site should be removed (CDC Category IB).5 A randomized controlled trial and meta-analyses have shown that chlorhexidine significantly reduces the rate of SSIs and results in cost savings in comparison to povidone iodine.[73–75]

TABLE 74.3 Postoperative CDC, SCIP, NICE, and Author Recommendations for Reducing SSIs

Recommendations	CDC Evidence Ranking	SCIP Process of Care Performance Measures	NICE Guidelines	Authors' Additional Recommendations
• Prophylactic antimicrobial discontinued within 24 hours of surgery		✓		
• Occlusive dressing for a minimum of 24 to 48 hours	IB		✓	
• Do not routinely use topical antimicrobial agents for surgical wounds that are healing by primary intention			✓	
• Continued comorbidity optimization				✓
• Close postoperative wound surveillance				✓ [27]
• When SSI is suspected, prescribe an antibiotic that covers the likely causative organisms. Consider local resistance patterns and the results of microbiological tests in choosing an antibiotic.			✓	
• Consult an infectious disease specialist if any sign or warning signals of infection are present				✓ [163,164]
• Wash hands before and after dressing changes	IB			
• Use sterile technique for dressing changes	II		✓	
• Educate patient and family on proper incision care, symptoms of SSI, and importance of reporting symptoms	II		✓	

For interventional pain procedures, the United States Food and Drug Administration has not approved the use of chlorhexidine for neuraxial procedures because of the lack of clinical safety trials. However, the use of chlorhexidine for spinal anesthesia has not been shown to increase neurologic complications.[76] The use of chlorhexidine prior to epidural catheterization has been shown to be superior to povidone iodine in reducing catheter colonization rates.[77] Although there are no studies directly comparing infection rates with the use of chlorhexidine gluconate versus povidone iodine for interventional pain procedures, based on extrapolation of data from other surgical subspecialties, chlorhexidine-based products may offer improvements in infection control rates.

TABLE 74.4 Patient-Related Risk Factors for Surgical Site Infection

Older age
Poor nutritional status
Diabetes mellitus
Smoking
Obesity
Coexisting infections at a remote body site
Colonization with *Staphylococcus aureus*
Altered immune status

Modified from Mangram et al. 1999.[5]

Draping

Iodophor impregnated drapes may reduce the number of positive post-procedural skin cultures.[78–80] However, there are no data to support their routine use for the reduction of SSIs.[81,82] While the use of iodophor impregnated drapes may be considered for high risk patients, the literature does not support universal usage.

Surgical Attire

Maximal sterile barrier precautions (surgical cap, mask, and sterile gloves and gowns) for surgical procedures are recommended by the CDC (Category IB), NICE, and SCIP. In 2004, the CDC and Healthcare Infection Control Practices Advisory Committee released a statement recommending the use of face masks for neuraxial procedures after eight cases of bacterial meningitis following neuraxial procedures were linked to practitioners who were not wearing masks.[83]

Sterile gloves are recommended for interventional pain and implantable therapies. While there are no studies directly comparing the risk of SSIs with single versus double gloving techniques, double gloving has been shown in multiple studies to reduce the

TABLE 74.5 Prophylactic Antibiotic Recommendations

Antibiotic	Standard Intravenous Dosing	Timing Prior to Incision	Redosing Interval	Indications
Cefazolin	1 g ≤ 80 kg 2 g > 80 kg 3 g > 160 kg	Within 30–60 min	3–4 h (CrCl > 50 mL/min) 8 h (CrCl 20–50 mL/min) 16 h (CrCl < 20 mL/min)	1) First-line
Clindamycin	600 mg ≤ 80 kg 900 mg > 80 kg 1200 mg > 160 kg	Within 30–60 min	6 h (CrCl > 50 mL/min) 6 h (CrCl 20–50 mL/min) 6 h (CrCl < 20 mL/min)	1) β-lactam allergy
Vancomycin	1 g ≤ 80 kg 2 g > 80 kg 3 g > 160 kg	Within 120 min	8 h (CrCl > 50 mL/min) 16 h (CrCl 20–50 mL/min) None (CrCl < 20 mL/min)	1) β-lactam allergy 2) Known methicillin-resistant *S. aureus* colonization

Modified from Bratzler et al. 2004 and Alexander et al. 2011[60,62]

number of inner glove perforations.[84] Glove perforations result in higher surgical infection rates. Therefore double gloving should be considered for implantable device surgeries to reduce the risk of SSI and protect the practitioner.

Surgical Technique and Procedural Efficiency

Appropriate surgical training and efficiency have also been shown to help reduce SSIs. Inadequate physician experience, low procedural volumes, and extended operative times have been suggested as possible risk factors for SSIs.[85–87] A retrospective review of IDDS and SCS implants for cancer patients suggested that extended operative times may be a risk factor for SSIs.[39] Therefore an attempt should be made to limit surgical time.[26] In addition, recent survey data for SCS demonstrated an inverse relationship between procedural volume and operative times.[88]

Wound Irrigation

The efficacy of wound irrigation depends on the delivery method, volume, type of solution, and additives delivered. Controversy exists regarding the use of high-pressure and low-pressure pulsatile lavage as they may result in the deep seeding of bacteria into exposed tissues and impaired wound healing.[89] There is no consensus on the optimum volume of irrigation to use. However, animal studies suggest that larger volumes are superior.[90]

Irrigation solutions typically consist of normal saline, detergents, or antibiotics. Bacitracin solution has not been shown to be superior to normal saline in reducing the presence of wound bacteria.[91,92] However, both benzalkonium chloride and bacitracin have been associated with impaired wound healing.[92,93] If wound irrigation is performed for implantable therapies, it is recommended to use normal saline through a bulb syringe.[94]

Topical Antimicrobials

Topical antimicrobials for SSI prophylaxis have been studied in the form of impregnated dressings, topical powders, and device envelopes. Randomized controlled trials using chlorhexidine impregnated dressings for epidural catheters have shown a greater than seven fold reduction in catheter-site bacterial colonization with a mean catheter duration of 3.6 days.[95–97] The use of chlorhexidine impregnated dressings should be strongly considered in any procedure where a catheter/lead is left exposed for an extended period in a patient at high risk for SSI (i.e. SCS trials, IDDS catheter trials, indwelling epidural catheters).

Intrasite vancomycin powder has gained popularity, specifically in spine surgery.[98] However, the FDA does not currently approve its use. The reported efficacy of vancomycin powder for SSI reduction is conflicting.[99–105] Meta-analyses and systematic reviews suggest that intrasite application of vancomycin powder is effective in preventing SSIs, specifically when hardware is implanted.[106–109] Furthermore, animal studies have demonstrated a reduction in SSI at the implant site with local vancomycin.[110] However, there is concern that intrasite vancomycin may increase the risk of seroma formation, which can impair wound healing. In addition, it may increase the incidence of gram-negative and polymicrobial SSIs.[111] Further studies are warranted to support the routine use of vancomycin powder for implantable pain therapies.

An antimicrobial envelope is a bio-absorbable polypropylene mesh that releases antibiotics. An antimicrobial envelope containing minocycline and rifampin has been shown to reduce ICD infection rates by 60% when used empirically and by more than 87% when used selectively in patients considered at high risk for SSI.[112–114] There is currently no specific data to support its use in SCS and IDDS implants. However, its use could be considered in patients at a high risk of SSI.

Operating Room Environment

Ventilation and OR traffic likely affect SSI rates. Laminar-flow ORs and high-efficiency particulate air filters have been shown to reduce SSI and wound contamination compared to conventional airflow systems.[115–117]

Personnel are the major source of contamination in the OR.[118] The number of personnel and traffic flow rates in the OR positively correlate with the degree of airborne contamination.[119] Education, preoperative planning, communication, and limiting surgical time are the most effective measures to decrease traffic flow.

There are many potential sources of contamination from equipment within the OR (i.e., light handles, fluoroscopic C-arm, and ultrasound probe). Contamination of sterile light

handles has been reported to be as high as 14.5%. Therefore the handling of OR lights should be minimized.[118,120] Biswas et al. evaluated the sterility of 25 C-arm drapes placed with the aseptic technique after their use during spine surgery.[121] All locations were contaminated at the end of the surgical case. The front, top half, and superior end of the image intensifier were associated with highest contamination rates. All OR personnel should avoid contact with the C-arm.

Wound Closure

It is important to minimize dead space during wound closure, which allows for the accumulation of serous fluid and blood, serving as a medium for bacterial growth. Layered closure techniques also help minimize dead space and tissue tension, which also promotes wound healing.[122] Certain suture types and materials are thought to promote bacterial colonization. For example, multifilament sutures (i.e. silk and vicryl) may promote bacterial colonization between filaments. However, there is a lack of evidence to support the use of one type of suture to reduce SSI.[123,124]

There is conflicting evidence on the benefit of the closure method (suture vs. staples).[125] A meta-analysis of randomized controlled trials in obstetrics/gynecology, general, head/neck, and vascular operations suggested that staples were associated with significantly fewer SSIs.[126] A Cochrane review concluded insufficient evidence to suggest a difference in SSI rates when comparing suture versus staple closures for leg wounds after vein graft harvesting during cardiopulmonary bypass surgery.[127]

Needle Contamination

Needle contamination occurs despite adequate skin preparation. Epidural needle contamination rates have been reported to be as high as 35% despite adequate skin preparation with 10% povidone iodine.[128] Higher rates of discitis following discography using a non-styleted, single-needle technique than a styleted,

TABLE 74.6 Case Reports of Contaminated Ultrasonography Coupling Gel Causing Nosocomial Infection

Author	Gel Used	Antimicrobial Agent	Identified Microorganism	Source of Contamination	Associated Procedure	Type of Nosocomial Infection
Chittick, P. et. al.[148]	Other-Sonic; Pharmaceutical Innovations, Inc., Newark, NJ	Not indicated	*Pseudomonas aeruginosa*	In-use and unopened gel bottles	Transesophageal echocardiography	Respiratory tract infection

TABLE 74.7 Guidelines for Infection Control Practices for Ultrasound-guided Procedures

- Follow the Centers for Disease Control and Prevention's guidelines for disinfection and sterilization in healthcare facilities for reprocessing ultrasound transducers.
- Prior to performing ultrasound scanning, confirm that the equipment was cleaned and disinfected appropriately.
- Use a sterile ultrasound sheath or sterile adhesive transparent dressing.
- Single-dose sterile ultrasound transmission gel should be used for the following procedures:
  1. Performing a biopsy or puncture
  2. Procedures involving mucous membranes
  3. Scanning non-intact skin
  4. Scanning near a surgical wound
  5. Scanning neonates and critically ill pediatric patients
- Non-sterile ultrasound gel may be used for low-risk, non-invasive procedures on intact skin and for low-risk patients.
- Seal multidose, non-sterile gel containers and replace when empty.
- Do not reuse ultrasound gel containers and replace when empty.
- When warming ultrasound gel, dry heat is the preferred method.

Modified from Oleszkowicz et al. 2012 and Narouze et al. 2012.[142,147]

double-needle technique (1.4% versus 0.4% per disc) have been reported.[13] Styleted needles should be used for all neuraxial procedures to reduce the risk of needle coring, which can introduce skin bacteria into the injection site. A double-needle technique should be considered intradiscal procedures. For discography, minimizing intradiscal needle time has also been suggested to reduce the incidence of discitis.[129]

Ultrasound Guided Regional Anesthesia and Pain Procedures

Both the ultrasound gel and probe can serve as vectors for infection (Table 74.6). Individuals performing ultrasound guided regional anesthesia and pain procedures should try to minimize infection and cross-contamination through the ultrasound gel and probe.

Contaminated ultrasound gel has been implicated in several nosocomial infections, which led to an FDA safety communication calling for the use of sterile ultrasound gel for transthoracic echocardiography.[130–137] Guidelines by Health Canada were published in 2004 recommending the use of sterile gel in all procedures that pass a device through tissue.[138] Recently, in the United States, recommendations based on expert opinions have been proposed to minimize clinical risk (Table 74.7).[134] These recommendations are based on the Health Canada recommendations recommending the use of single-use sterile gels for invasive procedures involving neonates, for all procedures involving sterile equipment or non-intact skin, and for procedures involving mucous membranes. In addition, several expert opinion publications have recommended the use of sterile gel for all interventional pain procedures.[134,139–142] Non-sterilely packaged ultrasound gel typically contains parabens. However, antimicrobial resistance to parabens has been described, and bacterial and fungal contamination of ultrasound gel packaged in bottles has been shown to be present prior to patient use.[140] Single-use, sterile ultrasound gel packets are recommended for use in interventional pain and regional procedures.[141]

Ultrasound equipment can also serve as a potential vector for nosocomial infection.[143–145] While there are no data evaluating the efficacy of sterile probe covers or adhesive transparent dressings for reducing procedure infection rates, their use is recommended for interventional pain and regional anesthesia procedures.[139]

The risk of infection is low when appropriate steps are taken. A retrospective review evaluating 7476 patients who received an ultrasound guided single injection peripheral nerve blockade using a low-level disinfection technique combined with a sterile transparent film barrier dressing to cover the ultrasound transducer and sterile ultrasound gel demonstrated no indications of block-related infections.[146]

Medication Vials

The misuse of single-use vials (SUVs) for multiple patients has resulted in outbreaks of *Staphylococcus aureus* infections. In 2012, the CDC issued a statement emphasizing the importance of proper usage of SUVs because of an outbreak of *Staphylococcus aureus* infections in 10 patients treated with interventional pain procedures.[147] The final recommendations were 1) contents of an SUV should be withdrawn using a sterile syringe in an aseptic manner; 2) contents should be used promptly; 3) the vial and any remaining contents should be disposed of; 4) SUVs should not be used on multiple patients; 5) if SUVs are used on multiple patients, the medication should be separated only from an unused SUV into SUV or syringes by qualified healthcare personnel under a laminar flow hood using strict adherence to the *United States Pharmacopeia* 797 standards.[148]

Postoperative Risk Reduction

Wound Dressings

The CDC and NICE recommend the use of sterile occlusive dressings for 24–48 h for incisions closed by primary intention (Category IB).[5] Early studies suggested that occlusive dressings augment wound healing and decrease the rate of SSI.[149,150] There is currently insufficient evidence to support any type of wound dressing to reduce SSI rates.[151,152]

Patient Education and Postoperative Wound Surveillance

During the postoperative period, the optimization of medical comorbidities should continue, including tobacco cessation and glucose control. Patients and family members should be educated on signs and symptoms of an emerging SSI, incision care, and the importance of reporting any signs of infection. Patients should be seen within 10–14 days of surgery to evaluate for appropriate wound healing and signs of SSI, and any dressing changes should

be done using a sterile technique.[26] Any evidence of a developing SSI requires closer follow up.

Infection Management

Prompt identification is the most important step in the appropriate management of SSI. Laboratory tests, such as white blood cell (WBC) count, C-reactive protein (CRP), and erythrocyte sedimentation rate (ESR), can aid in the identification process. It is common for WBC, ESR, and CRP values to rise transiently in the postoperative period because of the appropriate perioperative inflammatory response. CRP levels rise 4–6 h after acute tissue injury, peaking around the second or third postoperative day following total joint arthroplasty and spine surgery.[153,154] ESR levels rise more slowly, peaking around the fourth or fifth postoperative day. C-reactive protein also returns to normal more rapidly (14–21 days) and predictably compared to ESR.[154,155] Postoperative CRP kinetics are more responsive to and predictive of infection.[154] Therefore failure of CRP levels to normalize or an unexpected rise in CRP is a highly sensitive predictor of an SSI. Likewise, a normal CRP level is highly specific for the lack of an SSI.

If any purulent drainage is identified, samples should be sent for culture and sensitivity. Imaging is often recommended for neuraxial procedures and implantable pain therapies to determine if an infection exists in the epidural space. Magnetic resonance imaging with and without gadolinium is the imaging modality of choice, but device MRI conditionality must be considered.[156]

Sometimes, superficial infections can be managed with wound care and antibiotics, but implantable device infections often require explants.[157] When the device is removed, all hardware should be sent for culture and sensitivity. The formation of biofilms makes eradication of an infection involving hardware exceedingly difficult. Relapse of infection has been reported to occur in over half of patients with ICDs left in place when generator pocket infections were identified.[158] Similarly, conservative management of deep brain stimulator infections is successful in less than 40% of cases.[159] Specifically for SCS SSIs, a multicenter retrospective review demonstrated that explantation was required in approximately 78% of patients.[157] Re-implantation should only be considered when the complete resolution of the infection is established, and an alternative site for the IPG or pump reservoir site should be considered.

Conclusion

Surgical site and procedural infections are associated with significant morbidity, clinical consequences, and economic costs. Physicians performing interventional procedures must understand and implement appropriate infection control guidelines. Tables 74.8 and 74.9 provide summary infection control recommendations based on the pain procedure classification. When infections occur, prompt recognition and appropriate treatment are required. In addition, further research is warranted specifically for interventional pain procedures to further define the guidelines and recommendations.

TABLE 74.8 Pain Procedure Classifications to Guide Infection Control Measures

SECTION 2 ANTICOAGULATION CONSIDERATIONS IN INTERVENTIONAL PAIN PROCEDURES

Honorio T. Benzon

Introduction

The American Society of Regional Anesthesia and Pain Medicine (ASRA) published several guidelines on regional anesthesia in patients on anticoagulants,[1] including the occurrence of spinal hematoma after epidural steroid injections or SCS placements when the regional anesthesia guidelines were adhered to or when the coagulation studies were normal led ASRA to create another guideline specifically for interventional pain procedures.[2,3] The reasons for these occurrences include pain in elderly patients, spinal stenosis with diminished epidural space, or scarring after laminectomy with scarring. SCS placement involves the use of large-bore needles with several advancements and retractions to optimally place the electrodes. Pain clinic patients may also be on medications usually considered not to affect hemostasis but may impede clotting. These drugs include anti-convulsants and selective serotonin reuptake inhibitors (SSRIs).[4,5] This section will deal with interventional pain procedures in patients on anticoagulants. The GPIIB inhibitors will not be discussed because they are administered for a short period, and the patients are usually maintained on P2Y12 antiplatelet inhibitors.

Stratification of Risks

The ASRA pain guidelines stratified the risk of bleeding according to the type of interventional procedure (Table 74.10). The risks of bleeding, progression, and consequences of hematoma vary with different procedures. For example, the abdominal and pelvic sympathetic blocks are close to large vascular structures, cannot be easily compressed, and symptoms associated with hematoma from these injections are vague. Intravertebral procedures are associated with compression of the spinal cord, with devastating consequences. Trigger point injections, superficial nerve blocks (e.g. occipital nerve blocks in the scalp), and joint injections are in avascular areas and are associated with minor bleeding complications. Mild anticoagulation is probably acceptable when the risk and consequences are small to prevent the patient from having a stroke, myocardial infarction, or venous thromboembolism (VTE).

Patients at high risk for bleeding undergoing low-or intermediate risk procedures should be treated as intermediate or high risk, respectively. Patients with a high risk for bleeding include the elderly, concurrent use of anticoagulants, low body weight, or advanced liver and renal disease.

TABLE 74.10 Pain Procedures According to the Potential Risks for Serious Bleeding

High Risk Procedures	Intermediate Risk Procedures	Low Risk Procedures
SCS trial and implant	Interlaminar and transforaminal ESIs	Peripheral nerve blocks
IT catheter and pump implant	Cervical facet MBB and RFA	Peripheral nerve stimulation
Vertebroplasty, kyphoplasty	Intradiscal procedures	Pocket revision, IPG, and IT pump replacement
Epiduroscopy and epidural decompression	Sympathetic blocks (stellate, lumbar, visceral)	Thoracic and lumbar facet MBBs and RFA
Percutaneous decompression laminotomy	Trigeminal and sphenopalatine ganglia blocks	Sacroiliac joint injections and LBBs
Dorsal root ganglion stimulation		Peripheral joints and musculoskeletal injections
		Trigger point and piriformis injections

ESIs, Epidural steroid injections; *IT*, intrathecal; *IPG*, implantable pump generator; *LBB*, lateral branch block; *MBB*, medial branch block; *RFA*, radiofrequency ablation.

Interventional spine and pain procedures in patients on antiplatelet and anticoagulant medications: guidelines from the American Society of Regional Anesthesia and Pain Medicine, the European Society of Regional Anesthesia and Pain Therapy, the American Academy of Pain Medicine (AAPM), the International Neuromodulation Society, the North American Neuromodulation Society, and the World Institute of Pain. *Reg Anesth Pain Med.* 2018;43:225-262 (with permission).

Aspirin and Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Aspirin irreversibly inactivates COX-1 through the acetylation of the amino acid serine, blocking thromboxane production and inhibiting platelet activation, platelet aggregation, and thrombosis.[6] The drug inactivates the COX-1 isoenzyme in the bone marrow megakaryocytes, which are responsible for the production of platelets. Aspirin also impairs secondary hemostasis and stability of the thrombus by acetylating fibrinogen and enhancing fibrinolysis.[7] At higher doses, aspirin prevents endothelial cell prostacyclin production by inhibiting COX-2.

Low dose aspirin, up to 100 mg, has been recommended by several United States guidelines for the primary prevention of cardiovascular disease in the elderly.[8,9] Recent studies have questioned this practice. While one large study showed a small but statistically significant benefit, the improvement was seen primarily in the first five years and mostly in diabetic patients.[10] The salutary effect was not duplicated in six other trials.[8]

A recent publication compared the clinical efficacy of aspirin with warfarin, heparin, dabigatran, and rivaroxaban in preventing VTE after total hip replacement (THR) and total knee replacement (TKR).[11] A separate analysis of the THRs and TKRs showed no statistically significant difference in VTE risk and pulmonary embolism (PE) between aspirin and the other anticoagulants. The risk of adverse events, including major bleeding, was also not statistically different.[11] In addition, and aspirin had a VTE risk not statistically significantly different from low molecular weight heparin (LMWH). These conclusions support the endorsement by the American College of Chest Physicians (ACCP) that aspirin is used in VTE prophylaxis after THR and TKR.[12]

Peak levels occur 30 min after aspirin ingestion, and significant platelet inhibition is present at 1 h.[13] For enteric-coated aspirin, peak plasma levels may be delayed until 3–4 h after ingestion. The average life span of a platelet is 7–10 days.[14] Approximately 10% of the circulating platelet pool is replaced every day,[15] resulting in 50% of the circulating platelets not affected by aspirin at five days.

The patient can continue to take aspirin when low risk pain procedures are performed.[3] While the regional guidelines permit neuraxial injections in the presence of aspirin, the pain guidelines do not. The length of discontinuation depends on the reason for the patient to be on aspirin: six days for primary prevention (aspirin in patients with no overt cardiovascular disease) and four days for secondary prophylaxis. The drug was resumed 24 h after the procedure (Table 74.11).

Phosphodiesterase (PDE), dipyridamole, and cilostazol hinder PDE isoenzymes expressed by platelets. PDE-3 inhibitors increase the levels of secondary messenger cyclic adenosine monophosphate (cAMP), while PDE-5 inhibitors increase cyclic guanosine monophosphate (cGMP) levels. Cilostazol inhibits PDE-3, while dipyridamole inhibits PDE-3 and PDE-5; dipyridamole has been combined with aspirin for a more pronounced effect. By blocking cAMP, cGMP, and PDEs, these drugs reduce platelet aggregation by approximately 40%[16]; they also increase vasodilatation. Dipyridamole had a half-life of 10 h. The extended-release dipyridamole, used in combination with aspirin, has a half-life of 13.6 h.[17] Cilostazol reaches peak plasma concentrations at 2 h. Maximum platelet aggregation occurs at 6 h.[16] Similar to dipyridamole, cilostazol has an elimination half-life of 10 h. Five half-lives, where 97% of the drug is eliminated,[18] is equivalent to 50 h. Stopping the drugs for two days should be adequate, with the safe resumption of the drugs occurring 24 h after the procedure.

NSAIDs reversibly blocked COX. Five half-lives resulted in a discontinuation period of 1–2 days for ibuprofen, diclofenac, ketorolac, and indomethacin, four days for naproxen and meloxicam, six days for namebutone, and ten days for oxaprozin and piroxicam. The drugs were resumed one d after the procedure.

P2Y12 Inhibitors

ADP released from platelet dense granules binds to two platelet G-protein-coupled receptors, $P2Y_{1,}$ and $P2Y_{12}$ receptors. $P2Y_1$ initiates ADP-induced platelet aggregation, while $P2Y_{12}$ facilitates platelet aggregation by inhibiting the adenylate cyclase-mediated signaling pathway and decreasing intracellular cAMP levels. P2Y12 inhibitors include clopidogrel, prasugrel, ticagrelor, and cangrelor. Patients with cardiovascular problems are usually prescribed a combination of a P2Y12 inhibitor and aspirin, known

TABLE 74.11 Recommended Intervals between Stoppage and Resumption of the Antiplatelet Medications and Medium and High Risk Pain Procedures

Drug	The Interval Between Discontinuation and Pain Procedure	Resumption of the Drug
Aspirin	Four for secondary prophylaxis, six for primary prophylaxis	24 h
Cilostazol	Two days	24 h
Dipyridamole	Two days	24 h
Clopidogrel	Seven days, five days if platelet function studies show adequate recovery	12 h when loading dose is given, 24 h for the usual maintenance daily dose
Prasugrel	Seven days	24 h
Ticagrelor	Five days	24 h
Cangrelor	1–2 h	[a]

[a]Patients who are administered cangrelor are usually maintained on oral P2Y12 inhibitors.

as "dual antiplatelet therapy." After percutaneous coronary intervention and an initial period of short-term dual therapy, monotherapy with a P2Y12 inhibitor appears to be a superior strategy in terms of balancing bleeding and thrombotic risks after PCI.[19]

Clopidogrel and prasugrel are irreversible P2Y12 inhibitors. Both are pro-drugs that require two-step metabolism to be converted to their active metabolites. Clopidogrel is susceptible to genetic polymorphisms, and 9% of patients do not respond to the drug. Clopidogrel causes 60% inhibition of platelets, while prasugrel results in 90% inhibition.[20] For this reason, a seven day stoppage is recommended for medium and high risk procedures (Table 74.11). One study showed that most patients had no platelet inhibition after five days, while the rest had minimal inhibition.[21] A five day period may be reasonable in patients at high risk for VTE or cardiac events and scheduled for an SCS trial. This is prescient because a trial occurs over 5–7 days. Platelet activity should be tested in cases with a five day stoppage. The commonly used tests of antiplatelet activity of P2Y12 receptors include either the VerifyNow P2Y12 assay or the platelet mapping portion of thrombelastography.

Ticagrelor, in contrast to clopidogrel and prasugrel, is a direct-acting P2Y12 inhibitor. It inhibits the aggregation of platelets by 90%; platelet function recovery is adequate five days after stopping the drug.[22] Cangrelor, another direct P2Y12 inhibitor, is administered intravenously and is approved for clinical use in patients undergoing percutaneous coronary intervention.[23] Cangrelor has a fast onset of a few minutes and a half-life of 3–7 min. Platelet function was normalized 1 h after it was stopped. If a pain procedure is necessary, at least a 1 h interval should be observed.

Prasugrel and ticagrelor should be resumed 24 h after the procedure, as these drugs take effect within 2–4 h. If given in its usual 75 mg dose, clopidogrel can be started 12 h after the pain procedure since it takes one or two days to reach full effect. However, a 300–600 mg loading dose of clopidogrel takes effect after a few hours and should be started 24 h later.

Two novel P2Y12 receptor antagonists are currently in clinical development. Vicagrel is an analog of clopidogrel that enhances the formation of its active metabolite. Orally administered, the time to peak effect is 4 h, while the offset takes 5–10 days, similar to clopidogrel.[24] Selatogrel is injected subcutaneously, has a rapid onset, and the offset is approximately 24 h. The appropriate clinical doses of vicagrel and selatogrel are yet to be determined.

Vitamin K Antagonists

Warfarin inhibits γ-carboxylation of vitamin K-dependent coagulation factors. These clotting factors (CF) have different half-lives: 6–8 h for CF VII, 20–24 h for CF IX, 20–42 h for CF X, and 48–120 h for CF II.[25,26] The initial anticoagulation results from inhibition of clotting factor VII. This effect is antagonized by a reduction in anticoagulant protein C, making the international normalized ratio (INR) unreliable during the early phase of warfarin therapy. The full anticoagulant effect of warfarin does not occur until four days later when the levels of factor II are significantly decreased. Concentrations of CFs of 40% or more are considered adequate for hemostasis; levels below 20% are associated with bleeding.[27] Whereas warfarin is used in the United States, acenocoumarol is prescribed in Europe. The difference is the normalization of the INR between the two drugs: five days for warfarin and three days for acenocoumarol.

Warfarin has a narrow therapeutic index, wide interpatient dosing variability, and genetic factors account for variations in dose requirements. Patients with variations in CYP2C9 and/or VKORC1 enzymes require lower doses of warfarin. However, studies on genetic-based dosing have not been uniform in their findings,[28] and comparisons with validated dose-response nomograms have not been adequately studied, and pharmacogenetic testing is not cost effective.[29]

For patients who require emergency surgery (within 4 h of the decision to operate), the American College of Cardiology and the American College of Chest Physicians recommend 4-factor prothrombin complex concentrates (PCCs) for reversal of vitamin K antagonists.[30,31] Concurrent administration of vitamin K is advised to allow for the liver synthesis of clotting factors since the CFs in PCC have short half-lives, ranging from 6–72 h.[31] Interestingly, a study of American Society of Anesthesiology members preferred to administer fresh frozen plasma instead of the FFP.[32]

In patients who have not taken warfarin, an INR of 1.4 is acceptable for neuraxial injections. This is because studies have shown that the activities of vitamin K-dependent CFs are adequate at this INR level. In patients who discontinued warfarin, usually for five days, the ASRA guidelines recommend normalization of the INR (1.2 or less) before medium and high risk procedures are performed (Table 74.12).[3] This recommendation is supported by a study that showed the levels of CF X and II to be below 40%

in two patients with INR's of 1.3 and 1.4.[33] This is in contrast to the European and Scandinavian guidelines, which accept an INR of 1.4 or less as long as the warfarin was stopped for five days.[34,35]

During the discontinuation of warfarin, an LMWH "bridge" therapy may be considered in patients at high risk for venous thromboembolism. However, a study in patients with atrial fibrillation showed that the discontinuation of warfarin without bridge therapy was non-inferior to bridge therapy with dalteparin.[36] This study looked at patients with atrial fibrillation and may not apply to patients with prosthetic cardiac valves.

Heparin and LMWH

Heparin inactivates thrombin (factor IIa) and factors IXa and Xa.[1] Intravenous heparin acts immediately while subcutaneous heparin takes 1 h to work. The therapeutic effect of intravenous heparin ceased at 4–6 h after administration. The half-life of heparin increases with increasing dose: 30 min for the 25 U/kg dose, 60 min half-life of 100 u/kg, and 150 min for the 400 U/kg dose.[37] The anticoagulant effect of heparin was monitored through the activated partial thromboplastin time (aPTT). Therapeutic anticoagulation is achieved when the aPTT is 1.5–2.5 times the initial value. Reversal was achieved with protamine at a dose of 1 mg of protamine per 100U of heparin.

Interventional procedures should be avoided in patients receiving *intravenous* heparin, as these are elective procedures. The patient's pain can be controlled with medications and adjunctive treatment. If a procedure needs to be performed, it should be postponed for at least 6 h after IV heparin is discontinued. The drug is restarted 2 h after the neuraxial injection. If a moderate- or high risk procedure was performed, especially if it was bloody, then a 24 h interval is observed (Table 74.12).

TABLE 74.12 Recommended Intervals Between Stoppage and Resumption of Warfarin, Heparin, and Low Molecular Weight Heparin for Interventional Pain Procedures

Drugs	Drug Discontinuation and Pain Procedure	Resumption of Drug
Warfarin	Five days, INR back to normal	24 h
IV heparin	4 h	2–24 h
BID subcutaneous heparin	6–24 h	2–4 h
TID subcutaneous heparin[a]	6–24 h	2–4 h
LMWH, prophylactic dose	12 h	4–24 h
LMWH, therapeutic dose	24 h	4–24 h
LMWH, dalteparin	24 h	4–24 h
Fibrinolytic agents[a]	48 h	[b]

[a]Interventional pain procedures only when necessary

[b]See text

BID, Twice a day; *INR*, international normalization ratio; *IV*, intravenous; *LMWH*, low molecular weight heparin; *TID*, three times a day.

The ASRA guidelines on regional anesthesia allow the continued use of *BID subcutaneous* heparin, while the pain guidelines recommend that interventional procedures should not be performed until at least 6 h after subcutaneous heparin administration. The drug could be restarted at a minimum of 2 h after the procedure. Regarding *TID subcutaneous* heparin, two studies showed the safety of administering neuraxial injections in patients on subcutaneous TID heparin; 714 and 928 patients were studied.[38,39] These findings led to the recent ASRA guidelines allowing pain injections to be performed 6 h after the subcutaneous heparin but after 24 h in high-risk surgical interventions.[3]

Subcutaneous long-term daily LMWH is the recommended treatment for cancer-associated VTE.[40,41] In patients on LMWH, the ASRA pain (and regional) guidelines recommend a 12 h interval between discontinuation of a prophylactic dose of enoxaparin and interventional pain procedures. For therapeutic doses of enoxaparin (1 mg/kg) and dalteparin, a 24 h interval is recommended. The drug can be resumed 4 h after a low risk pain procedure (Table 74.12).

In cases of moderate or high risk procedures, the resumption of warfarin, heparin, and LMWH should be delayed for 24 h after the procedure (Table 74.12). Drugs that affect hemostasis (antiplatelet, NSAIDs, SSRIs, and other anticoagulants) should not be used concomitantly in patients on these anticoagulants.

Fibrinolytic Agents

Intravascular fibrin clots are dissolved by plasmin, which is derived from the inactive precursor plasminogen. Fibrinolytic agents dissolve fibrin clots. Streptokinase and urokinase dissolve thrombi by activating plasminogen, while alteplase and tenecteplase are more fibrin-selective and have minimal effects on plasminogen. The half-life of fibrinolytic agents is only a few hours, but fibrinogen and plasminogen are decreased for up to 27 h. The ASRA pain guidelines recommend that interventional pain procedures be avoided in these patients. If a pain procedure needs to be performed, a minimum of 48 h should elapse from the time the drug was given to the time the procedure was performed. The 48 h interval is longer than the Scandinavian guidelines, which recommend a 24 h interval between the stoppage of the drug and a neuraxial block.[35] Longer intervals may be preferable given the absence of data on these patients. The time to resume the drug is not known because of the lack of data and the ability of these drugs to dissolve clots. A 24 h interval is reasonable based on the inability of thrombolytic drugs to lyze a cerebral embolic clot after 6 h.[42]

Fondaparinux and the Direct Oral Anticoagulants (DOACs)

CF X is located at the junction of the intrinsic and extrinsic pathways of the coagulation cascade. Fondaparinux is a synthetic factor Xa inhibitor. Direct oral anticoagulants (DOACs) include the factor X inhibitors rivaroxaban, apixaban, and edoxaban. The other DOAC is dabigatran, a direct inhibitor of thrombin, which is the end product of coagulation.

Fondaparinux is a selective CF-Xa inhibitor. Unlike heparin, fondaparinux has a minimal inhibitory effect on thrombin. The drug has complete bioavailability subcutaneously, immediate onset of action, a half-life of 15–20 h, and a direct renal excretion without any metabolism.[43] Fondaparinux is used to prevent

TABLE 74.13 Recommended Intervals Between Stoppage and Resumption of the Direct Oral Anticoagulants and Interventional Pain Procedures, Laboratory Tests, and Reversal

Drug	Drug Discontinuation and Pain Procedure	Resumption of Drug	Laboratory Test	Reversal
Fondaparinux	Four days	24 h		
Dabigatran	Four days (Six days in renal patients)	24 h	Dilute TT ECT	Activated charcoal within 2 h Idarucizumab
Rivaroxaban	Three days	24 h	PT Anti Xa assay	Activated charcoal within 8 h Andexanet alfa
Apixaban	Three days	24 h	Anti Xa assay	Activated charcoal within 3 h Andexanet alfa
Edoxaban	Three days (Six days in renal patients)	24 h	Anti Xa assay	[a]
Betrixaban	Five days	24 h	Anti Xa assay	[a]

[a]Andexanet alfa has not received US Food and Drug Administration approval for the reversal of edoxaban and betrixaban as of July 2020.

ECT, Ecarin clotting time (not readily available); *PT,* prothrombin time; *TT,* thrombin time.

VTE in patients who have had total joint arthroplasty and for the treatment of VTE and PE. Its use is limited in the elderly, patients with low weight, and those with kidney impairment. The ASRA guidelines recommend a five half-life interval or 3–4 day discontinuation before a medium-or high-risk interventional pain procedure is performed (Table 74.13). The drug was resumed 24 h later.

The introduction of DOACs revolutionized the care of patients with VTE and the prevention of stroke in patients with atrial fibrillation. This class of drugs is now recommended by the 2016 American College of Chest Physicians and the 2017 European Society of Cardiology guidelines for deep vein thrombosis and PE.[40,41] The same guidelines suggested DOACs over vitamin K inhibitors or aspirin in the extended treatment of VTE in patients without cancer. DOACs have a wide therapeutic window, require less laboratory monitoring, and are associated with less bleeding than vitamin K antagonists. However, bleeding still occurs, especially in the elderly and inpatients with renal disease.[44] There are no published studies on the safety of DOACs in regional anesthesia and interventional pain procedures, so discontinuation is based on their pharmacokinetics. After five half-lives, 97% of the drug is eliminated compared to 25%, 12.5%, and 1.6% after two, three, and six half-lives, respectively.[18] To ensure that the plasma levels of the anticoagulant are low but not delay the intervention further, the ASRA pain guidelines recommended a five-half-life interval between the last dose and injection.

Dabigatran is approved for the prevention of stroke in patients with non-valvular atrial fibrillation and VTE after knee or hip arthroplasty.[45] Dabigatran is a pro-drug with an onset of 1.5–3 h and a half-life of 14–17 h. It was eliminated by 80% by the kidneys. The presence of renal insufficiency results in the doubling of its half-life, from 14–28 h.[46] Five half-lives, corresponding to four days, is the recommended interval between the stoppage of the drug before performing a pain procedure (Table 74.13). A longer interval of six days should be observed in patients with renal problems. The drug was resumed 24 h after the procedure.

Rivaroxaban is approved for the prevention of stroke in non-valvular atrial fibrillation, prophylaxis, and treatment of VTE, and prevention of VTE after orthopedic surgery in the United States, Europe, and Canada.[45,47] Peak concentrations of rivaroxaban reach 2.5–4 h after intake, and its half-life is 5–13 h.[48,49] Dosing adjustments for rivaroxaban are not required for older patients (>65 years old) with adequate renal function.[50] A five-half-life interval, or three days, is recommended between discontinuation of the drug and medium-and high risk procedures. The drug may be resumed 24 h later (Table 74.13).

Apixaban is a factor Xa inhibitor drug indicated for the prevention of stroke in patients with non-valvular atrial fibrillation and for VTE prophylaxis after hip and knee arthroplasty. Peak plasma concentrations are attained within 3–4 h, and it has a half-life of 8–13 h.[51,52] In patients who are not at high risk for bleeding, three days is recommended between the stoppage of the drug and medium-and high risk interventional pain procedures. The drug was resumed 24 h later.

Edoxaban is a factor Xa inhibitor approved for the prevention of stroke in patients with atrial fibrillation and for the treatment of VTE and PE. The maximum concentration was attained 2 h after intake, and anticoagulation effects were noted within 2 h. The drug is 60% bioavailable, 50% is excreted by the kidneys, and 50% is excreted by the biliary system. Age, sex, and race did not affect the pharmacokinetics of edoxaban. There is a marked reduction in the clearance of edoxaban in patients with severe renal impairment.[53] Its half-life is 10–14 h.[53,54] Five half-lives (55 h or 2.5 days) translates to a three day discontinuation interval before interventional procedures can be safely performed in patients without renal problems. A longer interval (e.g. five–six days) should be considered in patients with renal disease. The drug was resumed 24 h later (see Table 74.13).

Betrixaban is the only CF Xa inhibitor approved by the FDA for thromboprophylaxis in acutely medically ill patients.[55,56] Approval was based on the study that showed betrixaban to be as effective as enoxaparin in preventing VTE in acutely ill patients.[57] The study was supported by two meta-analysis papers that concluded the CF Xa inhibitors, including betrixaban, were associated with a significant decrease in VTE when compared with standard-duration LMWH.[58,59] Betrixaban has 35% bioavailability; the time to reach maximum plasma concentration is 3–4 h, and the half-life is 19–27 h. The primary route of elimination is hepatobiliary (82%–89%); the P-450 system does not play a major role in its metabolism; hence, drug interactions are not a major concern. The recommended dosage is an initial dose of

160 mg orally followed by 80 mg daily for 35–42 days. As with other CF Xa inhibitors, bleeding is a concern. The long half-life is a concern for interventional pain physicians. Five half-lives mean that the drugs should be stopped for five days prior to the pain procedure (Table 74.13).

Laboratory Tests, Reversal, and Management of Direct Oral Anticoagulants Before Emergency Surgery

The mean and trough concentrations of DOACs have been noted, but they are not targeted because their efficacy and safety are not based on specific plasma levels.[49] The activated partial thromboplastin time (aPTT) is prolonged after dabigatran, although the relationship is not linear. There was a greater than linear increase at lower concentrations (at or below 200 ng/mL) and a linear relationship at higher concentrations (>200 ng/mL) (Table 74.13).[60,61] The thrombin time (TT) is highly sensitive to the effects of dabigatran. The ecarin clotting time (ECT) directly measures thrombin generation and is linearly and dose-dependently related to dabigatran concentrations. Prothrombin time (PT) is the least sensitive test, while dilute TT and ECT are the tests of choice for dabigatran.[60]

A linear correlation exists between the effects of rivaroxaban and PT, especially when neoplastin was used as the test reagent (Table 74.13). Compared to rivaroxaban, apixaban had little effect on PT. Edoxaban prolonged PT in a dose-dependent manner, but the assay was not adequately sensitive. There is marked variability in the sensitivity of PT reagents to the CF Xa inhibitors, so every laboratory should calibrate the PT specifically for rivaroxaban, apixaban, and edoxaban to determine the effect of each drug on the test. The anti-FXa chromogenic assay for monitoring direct Xa inhibitors includes analyte-specific calibration. It provides the best choice for monitoring the anticoagulant effect of these drugs.[60]

Activated charcoal prevents the absorption of dabigatran within the intestine, but it needs to be administered within 2 h of dabigatran ingestion (Table 74.13). Idarucizumab is a monoclonal antibody fragment that binds free and thrombin-bound dabigatran. Studies have shown the efficacy of the drug in reversing dabigatran in healthy volunteers,[62] and in patients who had serious bleeding or urgent procedures.[63] The dose of idarucizumab is 5 g intravenously, administered as two 50 mL bolus infusions (2.5 mg), given no more than 15 min apart. The 2019 update of the ACC/AHA/HRS guidelines recommend idarucizumab for the reversal of dabigatran in cases of life-threatening bleeding or urgent procedures.[64]

Activated charcoal must be administered within 8 h of rivaroxaban intake to decrease the absorption of rivaroxaban. Activated charcoal, administered within 3 h of apixaban ingestion, may be effective. Andexanet alfa is a recombinant modified human factor Xa decoy protein that binds and sequesters factor Xa inhibitors. A two-part randomized placebo-controlled study showed andexanet alfa to effectively reduce the anticoagulant effect of rivaroxaban and apixaban.[65] A subsequent trial evaluated the efficacy of andexanet alfa in reversing major bleeding associated with the CF Xa inhibitors (and enoxaparin). After the bolus administration, the median anti-factor Xa activity decreased by 89% from baseline among the patients who received rivaroxaban and by 93% among the patients on apixaban.[66] These levels remained similar during the subsequent 2 h infusion. Andexanet alfa can be administered at a high dose (800 mg IV bolus at a target rate of 30 mg/min) followed by 8 mg/min continuous infusion for 2 h (960 mg) in patients receiving rivaroxaban >10 mg, apixaban >5 mg, or unknown dose, or if given less than 8 h from the last dose of the anticoagulant. Otherwise, a low dose is employed (400 mg IV bolus at a target rate of 30 mg/min) and then a 4 mg/min continuous infusion for 2 h (480 mg).[67] The AHA/ACC/HRS recommends andexanet alfa for the reversal of apixaban and rivaroxaban in patients with life-threatening or uncontrolled bleeding.[64] Studies on the efficacy of PCCs in reversing DOACs are not conclusive.[68] Its use is counterintuitive since the CF levels in these patients are not diminished.[32]

Anti-depressants

Tricyclic anti-depressants and non-serotonergic anti-depressants were not associated with increased bleeding. Serotonin reuptake inhibitors (SRIs) exert antiplatelet effects. These SRIs reduce the serotonin content of platelets and inhibit serotonin-mediated platelet aggregation.[69-71] Increased bleeding has been noted in patients on SRIs.[72] The antiplatelet effect of SRIs is equivalent to a low dose of ibuprofen. However, patients with pain may be taking other medications that potentiate the antiplatelet effects of SRIs.

Herbal Medications

Garlic affects platelet aggregation, and doses as small as 25 mg/day inhibit platelet aggregation. There is a case report of spontaneous spinal hematoma in an older man who was taking 2000 mg/d of garlic.[73] Garlic, when taken in large amounts, should be stopped for seven days before a painful procedure. Dong Quai potentiated the effect of warfarin, whereas danshen decreased the elimination of warfarin. Therefore the INR should be checked in patients taking these drugs before an interventional procedure is performed. Gingko Biloba inhibits platelet activation factor, and a 36 h discontinuation has been recommended.[3]

New Anticoagulants Targeting CF XI

A new anticoagulant undergoing phase 2 and phase 3 trials targets CF XI of the intrinsic coagulation pathway.[44] Animal studies showed that decreased CF XI and CF XII activities prevent the development of thrombosis, with antibodies to CF XI reducing platelet and fibrin deposition more than CF XII.[74] Patients with an intrinsic deficiency of CF XI have a reduced risk of developing VTE leading investigators to speculate that bleeding from drugs inhibiting CF XI is limited. Two mechanisms of inhibition of CF XI are through the antisense oligonucleotide or monoclonal antibodies.[75] Factor XI antisense oligonucleotide (FXI-ASO) was compared with enoxaparin in preventing VTE after total knee arthroplasty (TKA). FXI-ASO was administered subcutaneously 36 days before surgery, three times for one week during treatment, and four once-weekly doses. In comparison, enoxaparin 40 mg was injected subcutaneously the night before surgery or 6–8 h after surgery and once daily for at least eight days postoperatively.[76] The 200 mg FXI-ASO regimen was noninferior and the 300 mg regimen was superior to enoxaparin. Bleeding was lower with FXI-ASO, and the number of clots was small. The authors considered 0.2 units per mL as the cutoff for CF XI level for effective antithrombotic effect. FXI-ASO has a slow onset of action, making it unsuitable when a rapid anticoagulant effect is desired. A human monoclonal immunoglobulin GI antibody that binds to the active site of CF XIa, preventing it from activating CF XI,

is osocimab. A randomized clinical trial compared osocimab with enoxaparin and apixaban to prevent VTE after TKA. Single intravenous doses of osocimab were compared with 40 mg of subcutaneous enoxaparin or 2.5 mg oral apixaban twice daily for at least ten days.[77] The postoperative 0.6 mg/kg, 1.2 mg/kg, and 1.8 mg/kg doses of osocimab met criteria for noninferiority while the preoperative 1.8 mg/kg met criteria for superiority compared with enoxaparin. The investigators considered doses between 0.6 and 1.2 mg/kg as most promising.[77] Bleeding was observed in 4.7%, 5.9%, and 2% of patients who received osocimab, enoxaparin, and apixaban, respectively.

The mechanism of action of osocimab differs from FXI-ASO: osocimab inhibits CF XI, whereas FXI-ASO blocks the liver synthesis of CF XI. Osocimab rapidly inhibits CF XI: aPTT increases within 2 h of infusion,[78] while it takes several weeks for FXI-ASO to decrease CF XI levels to therapeutic levels.[79] FXI-ASO has a long elimination half-life and suppresses FXI activity by greater than 50% more than one month after the last dose.[75] (there are not enough studies to tighten the tmax and half-lives of the drugs). The long half-life put the interventional pain physician in a quandary about when the drugs should be stopped prior to neuraxial or interventional procedures. The CFXI protein has been endorsed as a possible reversal agent. Both FXI-ASO and osocimab are expensive; hence, cost-benefit analyses must be performed.

COVID-19 Induced Coagulopathy

Infection with SARS-CoV-2, which results in COVID-19, is characterized by coagulopathy and disseminated intravascular coagulation (DIC)-like massive intravascular clot formation. The coagulation is initiated by the activation of monocytes by the virus and damage-associated molecular patterns (DAMPs), release of inflammatory cytokines and chemokines stimulating platelets, neutrophils and lymphocytes. The monocytes express tissue factor initiating coagulation. Additionally, damaged endothelial cells develop procoagulant activity. Laboratory findings include elevations in D-dimer, fibrin/fibrinogen degradation products, and fibrinogen.[80,81] The coagulopathy in COVID-19 is different from classic DIC in that the fibrinogen levels are elevated instead of low, thrombocytopenia is mild and the prothrombin time is only slightly prolonged. These laboratory findings, especially the D-dimer, are markers of critical disease and grave prognosis.[82] Forty percent of patients with COVID-19 have a higher risk of venous thromboembolism (VTE), a ≥4.[83] A rapid systematic review of four studies showed a 25%–53% incidence of VTE.[84]

Thromboprophylactic doses of LMWH, or unfractionated heparin in patients with renal impairment, has been recommended for COVID-19 patients hospitalized unless such treatment is contraindicated; mechanical prophylaxis, such as pneumatic compression devices, is advocated for those with contraindications. This recommendation was echoed by the Italian Society on Thrombosis and Haemostasis[85] and the International Society of Thrombosis and Haemostasis (ISTH).[86] The coagulopathy from COVID-19 can be challenging to control with prophylactic doses of heparin because of low levels of anti-thrombin and high levels of fibrinogen in these patients.[87] Therapeutic anticoagulation has been advised in this scenario and also for patients who deteriorating clinically.[88] This suggestion is based on the findings of fibrin deposition in the lung parenchyma and fibrin-platelet microthrombi in the pulmonary vasculature.[88] Extended thromboprophylaxis after discharge, usually for 35 to 45 days, is proposed for patients with a higher risk of VTE.[85,89] Renal failure is frequent in COVID-19 patients making the heparins (unfractionated heparin, LMWH) the drugs of choice.

The pain medicine physician will not see symptomatic COVID-19 patients but may treat patients who just recovered. Basic coagulation parameters should be determined and the bleeding risk of the procedure stratified before interventional procedures are performed.

Summary and Concluding Statements

The ASRA guidelines on interventional pain procedures stratified the procedures according to the risk of bleeding, allowing the continued use of anticoagulants when the risk is minimal. In contrast to the regional anesthesia guidelines, it is recommended that aspirin and NSAIDs be stopped before medium-and high risk procedures. The two guidelines are mostly similar in their recommendations with respect to warfarin, LMWH, fibrinolytic agents, and fondaparinux. A five-half-life interval between the stoppage of the drug and the interventional pain procedure is recommended for direct oral anticoagulants. Advances in the reversal of DOACs have resulted in better patient care. CF XI inhibitors are currently undergoing clinical trials. Coagulopathy in patients who just recovered from COVID-19 is not known and needs to be studied.

Key Points

Risk of Infection in Interventional Pain Procedures

- SCS infection rates are higher than those of other implantable devices, including cardiac pacemakers and total joint replacements.
- Identification of an SSI is based on physical examination findings of localized pain/tenderness, swelling, erythema, heat, or purulent drainage and cultures, labs, and radiologic findings.
- The most common source of infection is from the patient's own flora.
- Infections involving implantable pain therapies most often require complete explantation for successful treatment.
- Preoperative antibiotics should be administered intravenously (IV) prior to the incision (30–60 min prior to the incision or 120 min of incision for vancomycin).
- Continuation of antibiotics in the postoperative period is not recommended beyond 24 h for clean surgical wounds.
- Appropriate surgical scrubbing of the hands and forearms is a CDC Category IB and NICE recommendation.
- The CDC categories IA and NICE do not recommend routine removal of hair to reduce the risk of SSI, and if hair is removed, clippers are the method of choice.
- The use of chlorhexidine significantly reduces the rate of SSIs and results in cost savings compared to povidone iodine.
- Utilization of decolonization protocols in individuals colonized with MSSA or MRSA reduces the rate of postoperative infections. No data exist to support the use of routine decolonization protocols in patients who were not found to be colonized with *S. aureus*

Anticoagulation Considerations in Interventional Pain Procedures

- Patients with pain are at greater risk for the development of hematoma because they are elderly and may have spinal stenosis; post-laminectomy patients have epidural scarring, decreasing the capacity of the epidural space; larger needles are used in SCS placements; several manipulations of the SCS electrodes are required for optimal placement; and patients may be on SRIs that have antiplatelet effects, in addition to their anticoagulant medications.
- The ASRA guidelines stratified the risk of bleeding according to the type of interventional pain procedure. In low-risk procedures, anticoagulation therapy may be acceptable.
- Aspirin should be stopped for six days if it is being taken for primary prevention (patients with no overt cardiovascular disease) and four days for secondary prophylaxis.
- The duration of NSAID stoppage was based on the five half-lives of the drug.
- For the SCS trial, clopidogrel may be stopped for five days if a test of platelet function, such as the P2Y12 assay, shows adequate platelet activity.

Pain Management in Primary Care

KATHERINE E. GALLUZZI

Background and Introduction

Of the myriad problems that present to the primary care clinician, pain is the most common and arguably the most concerning. Since pain can herald something as serious as a heart attack or as routine as an inflamed carbuncle, primary care providers (PCPs) must answer the complaint of pain with alacrity and focused attention. Misdiagnosis can cause an unfavorable outcome for the patient; injudicious or inadequate treatment can undermine trust and devastate a therapeutic relationship.

Basic primary care principles have much to offer in the assessment and treatment of pain. The core values in primary care are compassionate care, embodied by the desire to help through the care of patients and their families; a holistic approach to the person that includes family, culture, and society; continuity of care through the maintenance of an interpersonal bond of trust and respect; reflective mindfulness, which manifests as self-awareness of one's own thoughts and emotions with a sense of presence and attentiveness, and lifelong learning, a practice that requires iterative professional development with the goal of improved patient outcomes. Successful primary care incorporates care coordination, preventive care, access, competence, and appropriate utilization of community-based resources.[1]

PCPs include physicians from the specialties of family, general internal medicine, pediatrics, and emergency medicine; some women also rely upon gynecologists for primary care visits. Recent decades have seen a change in the provision of primary care. The traditional model of a family doctor who knows the patient well and maintains continuity of care has evolved to include independent and collaborative practitioners at the same time that patients increasingly rely upon freestanding urgent care centers and hospital-based emergency departments (EDs). Thus

EDs and urgent care centers function as PCPs for both acute pain presentations and ongoing chronic pain treatment. However, patients seen in these settings are typically advised to follow up with their PCP, making collaboration with other healthcare providers inherent in the delivery of primary care pain management. Members of the primary care pain team include physicians, psychologists, physical therapists, advanced practice providers (nurse practitioners [CRNPs], physician assistants [PAs]), dietitians, exercise physiologists, and others. Specialist consultants for pain management likewise encompass many disciplines, including anesthesiology, neurology, orthopedics, palliative care, psychiatry, physical medicine and rehabilitation, and others.

The concept of a patient-centered medical home (PCMH) arose, in part, as a response to the increasing reliance on multiple healthcare venues and the subsequent potential for fragmentation of care. The Agency for Healthcare Research and Quality (AHRQ) of the United States Department of Health and Human Services[2] characterizes a PCMH as providing comprehensive, coordinated, patient-centered care that is accessible, safe, and of high quality. Establishing primary care clinics or offices as advanced medical homes has been advocated by the American College of Physicians as a care model to provide patient-centered, physician guided care that links patients with a personal physician in the setting of a practice that provides focused, continuity care.[3] This model is ideal for the successful management of pain since peripatetic, episodic contact with multiple health care providers discourages a holistic, coordinated, and inclusive treatment approach.

Patients with chronic persistent pain are some of the most challenging; they are likely to derive the greatest benefit from ongoing, focused care coordinated by a trusted clinician.

Physicians and other staff members within primary care practices have observed that the care of chronic pain patients can be onerous and burdensome, which may reflect a lack of formal education and training regarding pain medicine or inadequate systems for providing such care. Research evidence shows that PCMHs provide higher levels of adherence to treatment guidelines and screening recommendations. Such findings spotlight the need for coordinated patient care systems that provide support for the entire treatment team, including clinicians and staff members.[3,4] Besides the implementation of the PCMH model for pain treatment, an interdisciplinary approach is recommended; with input from appropriate collaborating medical disciplines, a multimodal approach to pain management may include nonpharmacologic, complementary and alternative medicine (CAM) techniques, behavioral therapies, non-opioid pharmacologic treatment, and when indicated and carefully managed, opioid analgesics.

See Chapter 4, interdisciplinary outpatient pain care, for a detailed discussion of collaborative care for persons with pain.

This chapter is concern with the crucial responsibility that PCPs bear in evaluating, diagnosing, and collaborating with other clinicians to treat pain. The focus is upon the primary care approach to common pain conditions. *Using low back pain (LBP) as a model, we will review the biopsychosocial approach to care; patient-provider communication; use of well-validated pain rating scales; and evaluation that includes a physical exam and functional assessment.* The use of provocative maneuvers for determining the cause of pain, the development of a thorough differential diagnosis, and the selection of appropriate diagnostic modalities will also be discussed. Available and well-validated treatments for common pain conditions seen in primary care will be discussed. We will review the use of non-opioid and opioid therapies through the lens of continuity care and emphasize the importance of establishing a therapeutic

relationship based on mutual trust and responsibility. Salient points from the Centers for Disease Control (CDC) guideline for opioid prescribing, which provides PCPs a basis for safe use of opioids in pain management, will be detailed.

Is Pain a Diagnosis or a Symptom?

It is tempting to view "pain" as its own diagnostic entity. There may be instances in which an etiologic injury, lesion, disease process, or other pain generator may not be readily evident (e.g. fibromyalgia). In contrast, some chronic pain states may have disease designations that specify causation, such as postherpetic neuralgia or painful diabetic peripheral neuropathy. ICD 10 includes designated G-codes for "chronic pain, unspecified" and "chronic pain syndrome," which may be construed as useful and consistent with our current understanding of the neuroplastic change that can occur in the peripheral and central nervous systems to generate persistent pain.

However, the initial complaint of pain should always be viewed as a symptom needing careful assessment, not only of its physical manifestation but also its attendant psychosocial effects. Many PCPs hold the privileged position of having had long-term relationships with patients that enable them to assess biopsychosocial contributors to pain that go beyond its immediate physical expression. Experiences of pain have been linked to adverse childhood events (e.g. domestic violence, sexual abuse), which leave permanent yet invisible scars. It has been shown that attention and expectation have been linked to one's experience of pain such that these behavioral traits may worsen or mitigate the intensity of how pain is experienced.[5] The following quote, attributed to Sir William Osler, speaks to this fact: "*It is more important to know what kind of patient has a disease than what kind of disease a patient has.*"

Developing rapport, trust, and understanding allows a full assessment of potential sources of pain (immediate, remote, or ongoing), development of a detailed differential diagnosis, and thorough medical workup that supports or confirms the pain source, which will lead to appropriate next steps in ameliorating or mitigating the patient's experience of pain. Thus pain must be approached as a symptom, with the goal of identifying an accurate diagnosis to facilitate an effective treatment approach. PCPs must also recognize when a consult or referral to a specialist is needed and be ready to collaborate with other healthcare professionals in continuity care for the patient with pain.

Definitions and Types of Pain

In 2020, the International Association for the Study of Pain (IASP)[6] agreed to modify its longstanding definition of pain, "An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage." A fourteen-member international committee voted unanimously to revise this term to: "An aversive sensory and emotional experience typically caused by, or resembling that caused by, actual or potential tissue injury." The new language, which is supported by evidence-based understanding, highlights that the experience of pain is always subjective and can result from physical injury, tissue damage, or disease states but may also manifest as a reaction to a remote or potential injury. While pain is felt in specific part(s) of the body, there is an underlying and always unpleasant emotional component to the experience of pain, which may stem from psychologic trauma (e.g. adverse childhood experiences, sexual abuse) and/or injury-related experiences earlier in life. The new definition also acknowledges the fact that persons who are unable to verbally express themselves also suffer from pain.[7]

The human experience of pain differs in intensity, quality, and duration as a result of pathophysiologic mechanisms with contributions from an individual's psychological and emotional response. Pain embodies the holistic construct of mind-body-spirit, so a complete understanding of pain requires acknowledgment of the contribution of all three domains. Palliative care teaches that, in addition to physical pain, persons with serious illness and/or those who are facing the end of life experience pain that may encompass psychologic and existential or spiritual pain. Persons who are receiving palliative care that includes psychological support in addition to usual care report better quality of life and greater pain relief.[8]

Pain can be characterized by its timing and duration, type, and location. In terms of timing, pain may be acute (sudden onset), recurrent (relapsing/remitting), or chronic (persistent).

Acute pain is a priority in terms of urgent evaluation, diagnosis, and treatment; it has an abrupt onset that is usually because of a specific cause and has a duration that is limited to three to five months. It represents a large healthcare burden in the United States because of several contributing factors, including about 40 million injury-related visits to EDs and approximately 100 million surgical procedures performed annually.[9] Moreover, 80% of surgical procedures and accidental trauma result in acute pain that affects approximately 100 million individuals. Severe acute postoperative pain may be predictive of persistent postoperative pain, with clinical discomfort that is not referable to other causes (e.g. infection or pain from a preexisting condition) lasting two or more months post-surgery.[9]

Table 75.1 is a partial list of common acute painful conditions that present in primary care.

Episodic, recurrent pain, such as that seen in migraine headache, can represent a unique treatment challenge for the PCP. Because of the unpredictable onset of the headache, some utilize EDs for acute treatment and only infrequently present to their PCP for acute and ongoing treatment.

Most acute pain resolves within a relatively brief timeframe, but it can sometimes persist to evolve into chronic pain. Research evidence has demonstrated that because of neuroplasticity of central

TABLE 75.1 Common Acute Painful Conditions in Primary Care

Acute Pancreatitis	Appendicitis
Arthritis, osteo- and rheumatoid	Bone fracture
Cluster or migraine headache	Endometriosis

Postsurgical pain	Sciatica
Sickle cell disease/crisis	Herniated nucleus pulposis, "slipped disc"
Stomach or peptic ulcer	Trigeminal neuralgia

nervous system regions involved in pain perception, delayed or inadequate treatment of acute pain can lead to the development of chronic pain.[9–11] Recognition that untreated acute pain may evolve to chronic persistent pain is a mandate for PCPs to address acute pain as timely and effectively as possible.

Over half of patients with chronic pain are managed in primary care practices.[3] Chronic pain is defined as nonmalignant pain persisting beyond the usual time needed for healing that has been present on most days for greater than three to six months.[12,13] According to the National Academy of Medicine (formerly the Institute of Medicine) white paper "Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research,"[14] the prevalence of chronic pain in the industrialized world is projected to increase as a consequence of an aging population, rising rates of obesity (body mass index greater than 30), improved survival rates for catastrophic injuries such as spinal cord injuries and traumatic limb amputations, increased outpatient surgery with inadequate postoperative pain control, and better public understanding of chronic pain, all of which will increase the use of healthcare resources.

Table 75.2 presents a partial list of common chronic pain syndromes presenting to primary care.

Pain may be further categorized because of type, based on the etiology of the pain, as follows:

Nociceptive pain is caused by an identifiable injury or disease process and may occur after thermal, chemical, or mechanical injury. In response to noxious stimuli, a message is transmitted via the primary afferent nociceptor axon from the periphery to the central nervous system (CNS), e.g. postoperative pain, myocardial or other visceral ischemia, bone fracture or metastasis, sprain or strain.

TABLE 75.2 Common Chronic Pain Conditions in Primary Care

Cancer Pain	Chronic Regional Pain Syndrome
– Type 1 ("causalgia")	
–Type 2 ("reflex sympathetic dystrophy")	
Gynecologic pain Headache	
Dyspareunia-migraine	
Cyclical ovulatory pain -cluster	
Menstrual cramps-tension cephalgia	
Pelvic pain	
Fibromyalgia	**Irritable Bowel Syndrome**
Low back pain	Osteoarthritis
Mechanical-knee	
Sciatica-hip	
Herniated nucleus pulposis -spine	
Degenerative disc disease -hands	
Spinal stenosis	
Post-Operative Pain	**Rheumatoid Arthritis**

Neuropathic pain is defined by IASP as "pain arising as a direct consequence of a lesion or disease affecting the somatosensory system. It develops as a result of damage to, or dysfunction of, the nervous system." It is caused by damage to the peripheral and central nervous system by disease, injury, drugs, or deficiency, e.g. painful diabetic peripheral neuropathy, phantom limb pain, postherpetic neuralgia, B12 deficiency neuropathy, HIV neuropathy.[10]

Nociplastic pain is pain that occurs without evidence of an identifiable injury or inciting event. This new terminology was developed by IASP to define non-nociceptive/inflammatory, non-neuropathic pain, e.g. irritable bowel syndrome, fibromyalgia.[5]

Patients may experience more than one type of pain at the same time. Examples include the patient with painful diabetic peripheral neuropathy (neuropathic pain) who also has hypertrophic osteoarthropathy of the knee (nociceptive pain); or the patient with shoulder pain that is found to be because of cervical spinal stenosis (neuropathic pain) who also has a longstanding history of fibromyalgia (nociplastic pain).

Pain Assessment

Effective pain management requires accurate assessment and diagnosis, but the first step toward resolving pain is gaining the patient's rapport and trust. Since pain is subjective, clinicians must acknowledge the patient's experience of pain by reassuring them that their complaint is valid and that their pain is real. A useful communication technique involves asking open-ended questions and then allowing the patient adequate time to describe what they are feeling and how it concerns them without interrupting or guiding the conversation. The technique of "ask-tell-ask" [15] used by palliative care clinicians involves "asking" the patient what they feel and believe or understand to be the problem, then repeating to them what was heard with feedback or expanded information from the clinical perspective ("tell"), and then closing the loop by "asking" the patient to repeat what they understood to have been said.

Listening closely to how patients describe their pain can give insight into the type of pain and/or the possible pain generator(s). For example, colicky pain described as "cramping, pressing, crushing, or wrenching" may have a visceral source, while words like "sharp, aching, sore, tender" are indicative of somatic pain. A constant dull ache with an intermittent sharp pain that is provoked by movement suggests musculoskeletal strain or sprain. "Pulsing, throbbing, shooting, stabbing, burning, tingling, electric-shock like, crawling, numb" are descriptions that are characteristic of paresthesia and may indicate that the pain is neuropathic in origin.[16]

During the decade of pain (2001–2010) in America,[17] The Joint Commission mandated that pain be measured as "the fifth vital sign." In response, several well-validated rating scales were developed and implemented, particularly in inpatient settings. Validated questionnaires include the brief pain inventory (BPI),[18] and Wong-Baker faces scale,[19] originally developed for use in children and utilized for nonverbal patients. The utility of these scales has been shown in multiple studies. However, in recent years the focus has shifted from assessment of pain using a numerical or visual scale to an evaluation of the effect of pain upon physical function. A basic assessment of physical function can be performed using the Katz activities of daily living (ADLs) scale, commonly used by geriatricians. The basic ADL functions are dressing, bathing/grooming, feeding, toileting, and ambulating. [20] Eliciting measures of functional status is important since setting goals for analgesia ideally should target specific functional

TABLE 75.3 Pain Scales

Assessing Pain Level	Assessing Impact of Pain on Function	Assessing Multiple Dimensions of Pain
Faces pain scale Numeric rating scale (NRS) Verbal descriptor scale	– Katz basic activities of daily living scale (BADLs) – Functional pain scale – Pain disability index – Roland-Morris disability questionnaire (RDQ)* – Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC)*	– Brief pain inventory-short form – PEG (pain, enjoyment, general activity) scale – McGill pain questionnaire-short form – Oswestry disability form
Pain Level Assessment in Individuals Unable to Communicate		
Pain Assessment in Advanced Dementia Scale (PAINAD)		
Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC-II)		

*Roland-Morris Disability is used in patients with low back pain, while WOMAC is employed in arthritis.

measures; e.g. does the patient hope to be able to run a marathon or do they simply want to be able to transfer from the bed to the commode without significant pain?

For evaluation of the effect of pain on functional disability, specifically with regard to LBP, the Oswestry LBP disability questionnaire has been well validated.[21] The brief pain inventory-short form (BPI), in addition to directly assessing the severity of pain, also assesses interference of pain with work, sleep, mood, and enjoyment. However, it is not easily used for non-verbal patients or those with cognitive impairment.[18] A differential assessment of dementia, its presenting neuropsychiatric symptoms, and the potential presence of pain is crucial to provide the correct treatment.[22,23]

The inability to verbally communicate does not negate the possibility that a person is experiencing pain. Thus tools required to adequately assess pain may differ depending on a patient's age, condition, and ability to understand. These patients will require the use of alternative assessment tools such as the Wong-Baker faces scale or, in the case of dementia, the pain assessment in advanced dementia (PAINAD) scale.[24] The evaluation and management of patients with dementia are discussed in Chapter 79.

Table 75.3 lists pain assessment tools, and Table 75.4 is a modified version of the PAINAD scale.

TABLE 75.4 Modified PAINAD Scale

Breathing (independent of vocalization)	Normal = 0 Occasionally labored breathing or short periods of hyperventilation +1 Noisy, labored breathing, long periods of hyperventilation, or Cheyne-Stokes respirations +2
Negative vocalization	None = 0 Occasional moan/groan or low level speech with negative quality +1 Repeated trouble calling out, loud moaning/groaning/crying +2
Facial expression	Smiling or inexpressive = 0 Sad/frightened/frown +1 Facial grimacing +2
Body language	Relaxed = 0 Tense, distressed, pacing, fidgeting +1 Rigid, fists clenched, knees pulled up, pulling/pushing away, striking out+2
Ability to console	No need to console = 0 Distracted or reassured by voice/touch +1 Unable to console, distract or reassure +2

Scoring: 0 is no pain, and 10 indicates severe pain

Diagnostic Assessment

Besides the use of a pain scale for rating pain, the following questions are useful in diagnostic assessment:

Is the pain constant, intermittent, or transient?
What relieves the pain?
What worsens the pain?
Where is the pain localized?
Does the pain radiate?

The location of pain is frequently a clue to the origin of the pain. The query "tell me where it hurts" can be modified for patients who can comply to "please point to where the pain is the worst." Visual inspection and manual palpation of the area may yield findings that indicate the source of pain, such as an inflammatory process.

For patients who do not require urgent evaluation, a careful "hands-on" physical exam may provide clues to the painful stimulus. Manual palpation of body regions that are identified by the patient as painful may discover somatic dysfunction(s). Somatic dysfunction is defined in the glossary of osteopathic terminology,[25] as "impaired or altered function of related components of the somatic (body framework) system: skeletal, arthrodial and myofascial structures, and related vascular, lymphatic and neural elements." Somatic dysfunction is further characterized as acute or chronic; the former is an acutely painful lesion accompanied in early stages by vasodilation, edema, tenderness, and muscle contraction, while chronic somatic dysfunction is an impairment or altered function of inter-related parts of the somatic system, and is characterized by tenderness, itching, fibrosis, paresthesia, and contracture.[26–28]

The mnemonic TART[27–29] is used by osteopathic physicians to guide palpatory examination. TART stands for "tenderness, asymmetry of position, restricted motion, and tissue texture changes." The presence of one or more of these findings points to somatic dysfunction, which may be because of the musculoskeletal lesion itself or secondary to disease or derangement in a body part within the same dermatome. Palpation of a painful body region may also reveal point tenderness or trigger points (focal areas of hyperalgesia) and other subtle clues to the etiology of the pain. Besides trigger points, palpatory findings may reveal altered skin turgor (swelling or bogginess) and/or asymmetry, such as decreased and/or painful range of motion. Asymmetry of the musculoskeletal structures may be because of splinting, favoring, or compensating for the pain generator. Examples of somatic dysfunctions directly associated with musculoskeletal injuries include acute psoas muscle spasm (LBP) or tendon stretch/strain (sprained ankle). Passively moving an affected body part through its normal range of motion may reveal a restriction or physiologic barrier. The term somatic dysfunction has been used as a diagnosis. However, many authors feel that its relevance lies not in naming a diagnosis but rather as a descriptive physical finding.[27,28] Osteopathic manipulative technique (OMT) is directed at restoration of normal anatomic position, range of motion, and function of body structures.

Somatic dysfunction can also occur secondary to neuronal pathways that are "facilitated" or upregulated because of an underlying condition in an organ or viscera. In this case, superficially palpated lesion(s) may signal disease or dysfunction remote from the physical finding, a condition referred to as viscero-somatic reflex.[29,30]

Thus identifying pain's origin solely by its location may be confounded by the phenomenon of referred pain, which is pain felt in one part of the body that is caused by injury or disease of internal structures or organs (e.g. shoulder or upper back pain caused by acute cholecystitis). Viscero-somatic reflexes are representative examples of referred pain. The physiologic mechanism is thought to involve the convergence of multiple sensory neurons on the ascending spinothalamic tract, causing the inability of the brain to distinguish visceral pain signals from more common signals arising from somatic receptors.[30]

Examples of pain that is referred to the back are found in Table 75.5.

Besides localized or referred pain presentations, the location of pain may be diffuse, as seen in fibromyalgia or irritable bowel syndrome. These pain conditions are examples of nociplastic pain, in which the pain location does not specifically point to a diagnostic process.

TABLE 75.5 Examples of Referred Back Pain

Vascular	Genitourinary
Abdominal aortic aneurysm	Endometriosis
Ischemic bowel	Ectopic pregnancy
	Prostatitis
Renal	Gastrointestinal
Pyelonephritis	Cholecystitis
Renal calculi	Pancreatitis
Perinephric abscess	Penetrating ulcers
Infectious	Malignancy
Herpes zoster	Colon cancer
Vertebral abscess	Renal cell carcinoma

See Chapter 37 on chronic widespread pain.

Reassurance that a complaint of pain is valid and warrants concern is the first and ongoing step in the treatment of chronic pain. While complete elimination of the pain may not always be possible, there are several nonpharmacologic and pharmacologic options for the treatment of chronic pain. An optimal outcome relies upon careful selection and trial of appropriate medications coupled with adjunctive therapies such as cognitive behavioral therapy, lifestyle modification, OMT, massage, physical therapy, and others.[31]

Model of Pain in Primary Care: Low Back Pain

Since fundamental principles of low back pain (LBP) management are applicable as an initial approach for many pain presentations in primary care, LBP will serve as an exemplar for diagnosis and management of acute and chronic pain. This approach includes:

- focused triage to determine urgent/emergent status;
- biopsychosocial history and physical examination based upon patient rapport and trust;
- comprehensive, appropriate diagnostic workup;
- selection and application of appropriate therapeutic modalities;
- therapeutic trial(s) with frequent follow up evaluations of efficacy; and
- referrals and consultation(s) as indicated.

A further complete and detailed description of the etiologies and treatment options for LBP is available in Chapter 29.

A review of the major causes of disability in the United States, including spinal cord injury, stroke, limb loss, and other catastrophic events, found that back pain and arthritis are the leading causes of disability.[32] Most people will experience at least one episode of LBP during their lifetime; as noted, most episodes are self-limiting and, with conservative treatment, will resolve within weeks. However, many patients experience recurrence(s) and up to 44% report further episodes within a year; approximately 2% to 7% will go on to develop chronic LBP.[33,34] *PCPs provide the initial evaluation and treatment in 65% of cases and frequently provide the ongoing care as sole providers for patients with LBP.*[35]

LBP can be categorized as acute (immediate onset with less than four weeks' duration), subacute (slow onset with four to 12 weeks' duration), chronic (greater than three months' duration), or recurrent (LBP that reoccurs after a pain-free interval).[34] A summary of LBP diagnostic recommendations in a joint clinical practice guideline from the American College of Physicians and the American Pain Society[36] supports initial triage of patients into one of three broad categories: non-specific LBP; LBP potentially because of spinal stenosis or radiculopathy; or LBP potentially associated with another specific spinal issue for which prompt assessment is necessary or for which there is specific treatment needed. A published review of 15 clinical practice guidelines[37] regarding the initial assessment and diagnosis of LBP in primary care recommends:

diagnostic triage;
history and physical examination to identify red flags;
neurologic testing for radiculopathy;
no routine imaging in the absence of concern for serious pathology; and
assessment of yellow flags based on psychosocial factors.

Diagnostic triage of LBP targets red flag clinical findings that may indicate the presence of systemic illness (e.g. infection, cancer) or imminent neurologic compromise (e.g. spinal cord compression).[35–37] Spinal cord or cauda equina compression are emergencies that are

characterized by rapidly progressive neurologic deficits. Spinal cord compression can be caused by unstable spinal structure, herniation of intervertebral disc(s), trauma, malignant tumor, benign tumor, or infection (e.g. epidural abscess). Patients who present with LBP accompanied by evidence of infection, history of or suspicion for cancer, or rapidly progressive neurologic deficits require urgent neurologic, radiographic, and laboratory evaluation, which are most expeditiously available in a hospital/ED. Pain is usually the first symptom of spinal cord compression. However, motor weakness and sensory findings are present in most patients at diagnosis, and bilateral leg weakness may be elicited in multiple nerve root distributions (L3-S1). Bowel and bladder dysfunction are later findings.[34]

Since early diagnosis and prompt treatment improves outcomes, PCPs must recognize the red flags for cauda equina syndrome that include perineal numbness, difficulty initiating urination or urinary retention, fecal incontinence, or hyporeflexia. Red flags for tumor, infection, or pathologic fracture include age over 50 years, fever, chills, recent urinary tract or skin infection, penetrating wounds near the spine, significant trauma, night pain or pain at rest, steroid or immunosuppressive therapy, substance abuse or intravenous drug use, unexplained weight loss, and progressive motor or sensory deficit.[34–36]

Table 75.6 lists red flag findings for urgent evaluation delineated by potential cause.

Red flags require an immediate evaluation that includes X-rays, computed tomography (CT) scan or magnetic resonance imaging (MRI), laboratory studies, and urgent neurologic assessment. On the other hand, available evidence shows that routine advanced imaging (CT or MRI) is not associated with enhanced patient outcomes in patients who do not present with red flags. Clinical practice guidelines are uniform in their recommendation that imaging or other diagnostic tests in patients with non-specific LBP should NOT be routinely performed. In general, radiographic studies can be delayed for one month, during which time 90% of patients will have reported improvement or resolution of the pain.[38,39]

TABLE 75.6 Red Flag Findings in Low Back Pain

Cancer or Infection	Spinal Fracture	Cauda Equina
Prior cancer or recent infection	History of significant trauma	Acute onset urinary retention
Fever > 100° F	Prolonged use of corticosteroids	Loss of anal sphincter tone
Unexplained weight loss	Age >70 years +/–limited trauma	Saddle anesthesia
Immunosuppression		Global/progressive lower extremity weakness
Intravenous drug use		
Corticosteroid use		
No change or worse with rest		
Age >50 years		
Persistence >1 month		

TABLE 75.7 Yellow Flags for Low Back Pain

Affective depression, anxiety, irritability

Behavioral poor coping skills, sleep disorders, suboptimal adherence to physical therapy/rehab, decreased activities of daily living, multi-substance abuse, social withdrawal

Belief pain is uncontrollable, misinterpretation, somatization. An expectation of technologic cures

Social lack of support, life stressors, punitive social environment, low educational level, history of abuse (e.g. domestic violence, sexual abuse, adverse childhood experiences)

Occupational poor work history, poor job satisfaction or work environment, secondary gain, pending litigation, compensation issues

PCPs should also be able to identify yellow flags that may be predictive of prolonged bouts of LBP and/or poor prognosis. These factors are psychosocial in nature and include affective, behavioral, belief, social, and occupational features.[38] Besides the above, certain pain factors should cause concern, such as the severity of symptoms and impairment of functional capacity. Patients with these characteristics are at risk of developing persistent pain that is difficult to manage with routine care and may develop long term disability. Identification of these risk factors can guide the PCP in making appropriate referrals for psychological and/or social service support. These patients will require an interdisciplinary approach to achieve the best outcome.

Table 75.7 lists yellow flag issues in LBP.

Timing and Description of Low Back Pain

As with any pain complaint, how the patient experiences and describes LBP offers clues to its origin. Clinical communication should validate the complaint and encourage the patient to fully describe the onset and experience of the pain; body diagrams such as that found in the BPI are available in electronic health records, may be used to document the location, dermatomal distribution, and possible referred areas of pain.

PCPs must first establish whether the LBP had an acute versus a slow onset. Sudden, abrupt onset of pain is characteristic of muscle strain/sprain or herniated disc; patients typically are able to pinpoint the activity that caused the pain. Those with disc herniations may describe pain that is worse when sitting. In contrast, LBP with a slow, insidious onset suggests the presence of spondylolisthesis (slippage of one vertebral body on the adjacent one), osteoarthritis, or spinal stenosis. Spinal stenosis pain is aggravated by lumbar extension but improved by sitting or leaning forward (hence, the "handlebar" or "shopping cart" signs).[39]

History/Physical Exam and Provocative Maneuvers

The initial goal of the history and physical examination is to distinguish patients with non-specific (mechanical/musculoskeletal) LBP from those with serious non-spinal or spinal pathology, utilizing red flags as indicators of the latter. For patients without red flag findings, clinicians may proceed by obtaining a holistic medical history (including biopsychosocial factors) and physical examination with a focused neurologic assessment.

The history should include open-ended questions regarding symptom onset, intensity, and location of the pain and its effects on the patient's mobility and function. Specific psychosocial factors to note are the patient's body habitus (frail, overweight, obese) and activity levels, cigarette smoking, alcohol or drug use (especially intravenous drug use), and employment status. Questions regarding the history of psychiatric illness such as depression or anxiety are also appropriate, taking note of any responses that might indicate yellow flag findings.

Observation of the patient's gait and posture can be accomplished by having the patient walk a short distance, turn/pivot, and return. Postural and gait abnormalities and the presence of painful (antalgic) gait should be noted. The patient should then be asked to disrobe adequately to allow a full assessment of the back. This includes a visual assessment of the lumbar lordosis, thoracic kyphosis, and vertebral alignment, noting the presence of scoliosis or other deviations from the normal anatomic structure. Osteopathic assessment includes standing and seated flexion tests to assess for changes in the position of the ilia and ischial tuberosities that may indicate pelvic tilt or sacral un-leveling. Leg length discrepancies should be noted as they may contribute to vertebral strain patterns. Visual inspection and manual palpation may reveal evidence of trophic (neurovascular) change such as hair loss, color or temperature changes, and tissue texture changes (swelling, bogginess, spasm) that give clues to whether the pain is because of specific lesion(s), somatic dysfunction, or from an underlying change in the musculoskeletal/axial structure(s).[28]

Focused neurologic assessment should be part of every evaluation of the complaint of pain. In the case of LBP, muscle strength of the hip flexors, lower extremities, and deep tendon reflexes and presence/absence of the Babinski sign should be assessed. If radiculopathy is suspected, monofilament testing may be useful to locate sensory loss. Clinicians may then utilize several provocative maneuvers to further locate the origin of the pain, including the straight leg raise (SLR), Crossed SLR, and FABER tests. The SLR test is the only sign consistently reported to be sensitive for sciatic nerve involvement secondary to vertebral disc herniation.[40] The test is performed with the patient in a comfortable supine position. The clinician passively elevates the patient's leg to 90 degrees (or to tolerance). If pain that matches the patient's accustomed leg pain occurs at an angle between 30 and 70 degrees, the patient is experiencing radicular pain. The SLR test has shown high sensitivity for detecting the presence of radicular involvement but low specificity for identifying a herniated disc.[41] The Crossed SLR test is done by performing the SLR maneuver on the contralateral leg. If pain occurs, it may indicate a large central lumbar disc herniation.

A related provocative maneuver is the Patrick or FABER test (also called "the sign of four"), which is used to assess hip or sacroiliac problems. FABER is an acronym for *F*lexion, *Ab*duction, and *E*xternal *R*otation. With the patient supine, the knee and hip are flexed to 90 degrees. The foot of the extremity being examined is placed atop the opposite knee. The examiner then slowly abducts the patient's thigh to the physiologic barrier and externally rotates it toward the examining table. The presence of pain or spasm in the groin or limitation of movement is suggestive of hip pathology. There are several tests to confirm sacroiliac joint pain.[29] These are discussed in Chapter 30.

The Schober index is a measure of how well the spine opens, useful for patients in whom spondyloarthropathy is suspected. With the patient in a neutral standing position, the clinician locates and makes a mark at L3 (dimple level). Two more marks, one at 10 cm above and one 5 cm below L3, are made, a total of 15 cm apart. The patient is then instructed to bend forward and touch their toes while the clinician measures between the two marks. Normal spinal motion will result in the two marks being at least 3 cm farther apart in a lumbar-flexed position (e.g. 18/15). A result less than 18/15 indicates that the spine is restricted in range of motion and is indicative of a spondyloarthropathy. This test is similar to the routine osteopathic assessment of musculoskeletal structure in which a standing and seated flexion test is performed.[29]

In the physical exam, objective findings that may supplement the yellow flag evaluation can be assessed through a series of tests named for the orthopedic surgeon who first described them, the Waddell tests for functional back pain.[42] They include the patient's over-reaction during physical examination, superficial or widespread tenderness, a distraction test, lack of an anatomic or dermatomal pattern to the pain complaint, and pain on simulated axial load (top of head pressure). In 1998, Main and Waddell published their concern that these signs had been misinterpreted and misused both clinically and medico-legally and emphasized the importance of viewing back pain within a biopsychosocial context.[43] They state that behavioral signs can develop as a reaction to perceived injury and loss of functional capacity and are therefore not a test of credibility. Thus patients displaying Waddell signs may require both medical management of their pain pathology and psychiatry/psychology consult(s) for the psychosocial and behavioral aspects of their pain.

Waddell scores of three or higher were associated with increased odds of the patient exhibiting somatic over reporting. A recent editorial recommended that the Waddell signs should be utilized as a psychological screener to guide appropriate and continued treatments and befitting referrals.[44]

Description of the Waddell signs can be found in Table 75.8.

TABLE 75.8 Waddell Signs

Superficial tenderness– skin over a wide area of the lumbar region is tender to light touch/ pinch

Nonanatomic tenderness– deep tenderness over a wide area that is not localized to one structure and crosses over nonanatomic boundaries

Axial loading– downward pressure on the top of the head elicits lumbar pain

Acetabular rotation– with the patient standing, lumbar pain is elicited within the first 30 degrees of rotation when the clinician passively externally rotates the patient's shoulder and pelvis together in the same plane

Distracted straight leg raise discrepancy– pain is elicited during a straight leg raise when supine during formal testing, but not on distraction when the clinician extends the knee with the patient in a seated position

Regional sensory disturbance– decreased sensation fitting a stocking-like distribution rather than a dermatomal pattern

Regional weakness weakness, cog-wheeling, or the giving way of many muscle groups that are not explained on a neuroanatomic basis

Overreaction– a disproportionate and exaggerated painful response to a stimulus that is not reproduced when the same provocation is given later. These responses can include verbalization, facial expression, muscle tension, or tremor

Differential Diagnosis and Indications for Consultation

The differential diagnosis of LBP is extensive; a useful schema is to consider causes that are:

mechanical, such as alterations in the bony and/or muscular structures such as herniated discs, spondylolisthesis or non-specific muscle strain/sprain;

non-mechanical (inflammatory, infectious, tumor); or

visceral causes (pain referred from internal organ pathology).[31]

Table 75.9 presents a partial list of diagnostic causes of LBP.

Red flag findings in the setting of acute LBP mandate referrals for an urgent consult and further diagnostic workup. Acute LBP with concern for neurologic compromise requires consultation with orthopedic, neurologic/neurosurgical, and radiologic specialists.[45] If an infectious or inflammatory etiology is suspected, in addition to appropriate laboratory and imaging studies, infectious disease or rheumatology referrals are in order. The vital role of the PCP in differential diagnosis is to swiftly assess the need for and expedite the next-step care of the patient with acute LBP through consultation with other providers; many PCPs will provide aftercare and continuity treatments as indicated.

Inflammatory back disease is typically accompanied by systemic features. The characteristic presentation is of early morning generalized stiffness that improves over the course of the day and with exercise. The onset of pain occurs early in life and presents a lifelong condition. The seronegative spondyloarthropathies include ankylosing spondylitis, psoriatic spondylitis, reactive arthritis, and inflammatory bowel disease.[46]

LBP associated with psoriatic arthritis may be accompanied by dermatologic findings such as plaques, pustular psoriasis, and mouth sores. Gastrointestinal or genitourinary symptoms that precede the onset of LBP may be indicative of reactive arthritis (formerly known as Reiter syndrome). A relatively rare cause of LBP, reactive arthritis can present with extra-skeletal findings such as ocular inflammation, conjunctivitis, and iritis. There may be peripheral joint involvement ("sausage digits") and changes in the sacroiliac joint because of erosion and calcification of anterior longitudinal ligament contributing to the pain. Characteristic X-ray findings of psoriatic arthritis include unilateral sacroiliitis and paramarginal syndesmophytes, findings that differ from ankylosing spondylitis in which sacroiliac involvement is bilateral and paramarginal syndesmocytes are uncommon findings.[47]

Patients with inflammatory disease as the etiology of their LBP should be referred to a rheumatologist for definitive treatment. Conservative treatment may include gentle neck extension exercise and counseling to use caution with the use of neck pillows. Disease modifying anti-rheumatoid drugs, such as the TNF α blockers etanercept, infliximab, and adalimumab, have been shown to decrease vertebral and joint erosion. However, there are currently no longitudinal studies that show they can prevent the need in the long term for surgical vertebral fusion.[46,47]

Infectious causes of LBP, including spinal or epidural abscess and vertebral osteomyelitis, are heralded by fever, rigors, and/or an immunocompromised state. Patients who present with one or more of these findings will generally complain of LBP with localized tenderness. They will be able to point to the painful area on the spine. The infectious source may be a recent spinal injection or epidural catheter, intravenous drug use, trauma, surgery, dialysis, genitourinary, or skin infection. On physical exam, patients will exhibit focal tenderness with palpable muscle spasms and are often unable to bear weight; they may have evidence of needle track marks. Prompt laboratory evaluation will reveal elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein levels, typically associated with mild anemia. Patients with suspicion for an infectious or visceral cause for acute LBP, as previously noted, should be admitted to hospital for a complete workup and immediate medical treatment.[45]

An extremely painful cause of acute LBP is vertebral compression fracture because of severe osteoporosis, which may occur with or without warning or trauma. Patients with severe bone mineral density loss may experience spontaneous compression fractures or occur because of a jarring step or fall. Even in the absence of an established diagnosis of osteoporosis, the presence of a fragility fracture should prompt a thorough workup for causes of metabolic bone disease.

Patients with cancer metastases (breast, prostate, lung, thyroid, or kidney malignancy) may present with pathologic vertebral fractures characterized by extremely high pain levels. A physical exam will reveal marked paravertebral spasm and exquisite point tenderness; the patient may have difficulty with even minor movement or repositioning. Plain film X-rays are adequate to visualize vertebral fractures. However, fractures of the sacrum are not easily seen on standard X-rays or bone scans. If a sacral fracture is suspected, a CT scan or MRI are the radiologic studies of choice. Many vertebral metastases are because of cancer, and more than half of patients with myeloma will present with lytic lesions. Night pain, tenderness to palpation, or percussion of the spinal structures are typical symptoms that should trigger laboratory evaluation that may reveal an elevated ESR, anemia, and serum protein electrophoresis abnormalities indicative of multiple myeloma.[45]

The management of acute lumbar compression or pathologic fracture is directed at allowing the patient to resume normal activity as soon as possible. This may require short term use of immediate-acting opioids for breakthrough or incident (e.g. because of movement or specific treatment) in addition to non-opioid analgesic therapy. Most severe cases will require a surgical consult for vertebroplasty or kyphoplasty. See Chapter 69 for discussion regarding procedures for vertebral compression fractures.

Spinal stenosis is more common with advanced age; it rarely presents prior to age 50. Three age-related processes work together to lead to the spinal cord and nerve root compromise: posterior

TABLE 75.9 Differential Diagnosis of Low Back Pain

Mechanical	Non-Mechanical	Visceral
Lumbar strain/sprain	Neoplasia	Pelvic organs
Degenerative disease Disc	Infection Renal	
Facet joint		
Spondylolisthesis	Inflammatory	Aortic aneurysm
Herniated disc	Osteochondrosis	Gastrointestinal disease
Spinal Stenosis	Paget disease	Fat herniation
Osteoporosis		
Fractures		
Congenital disease		

disc herniation, facet joint changes/spurring, and thickening of the ligamentum flavum. A resultant complaint is of bilateral pain in the buttocks and posterior thighs and ambulation-induced neurogenic pain that localizes to the distal lower leg and calf ("pseudoclaudication"). Physical examination may reveal sensory loss and weakness in the legs, or alternatively, patients may exhibit a completely normal neurologic exam. A diagnostic clue is a report that the pain tends to resolve with sitting or leaning forward.[34] The Kemp test is a simple, provocative physical maneuver in which the examiner passively extends and rotates the patient's spine. If localized pain results indicate vertebral facet disease, pain radiates below the knee usually signals nerve root involvement.

Osteoarthritis (OA), as previously noted, is one of the leading causes of painful disability, and it is increasing in prevalence because of an aging United States population and high rates of obesity. OA is the most common cause of knee and hip pain. Like spinal stenosis, it is an age-related condition. However, genetic factors may influence the development of OA, and obesity may accelerate its onset. OA has three characteristic x-ray findings: osteophyte formation (spurs), joint space narrowing, and marginal sclerosis.[33,44]

Since most acute LBP cases are mechanical/non-specific in origin, most will resolve with conservative treatment. Therefore it follows that most chronic LBP cases are mechanical/non-specific, i.e. caused by persistent and/or recurrent alterations in the musculoskeletal structures. Having ruled out urgent causes or conditions needing emergent or urgent evaluation, consultation, and specific treatment(s), PCPs must next determine whether the patient with non-specific LBP is experiencing radicular symptoms. Since L4-5 and L5-S1 are the most common vertebral levels of disc herniation, L4, L5, and S1 nerve roots may be affected.[44]

Conservative treatment consists of maintenance of mobility and ambulation, avoidance of heavy lifting, progressive exercise as tolerated, and pharmacologic treatment if needed. Multiple studies suggest that most patients with sciatica will recover eventually without surgery. However, for severe, progressive neurologic deficits showing a lack of improvement (six to eight weeks of conservative treatment), radiographic studies and consultation are warranted.[38]

Shared Decision Making

For patients with LBP because of disc herniations who have concomitant high risk medical conditions, PCPs must weigh the risks versus potential benefits of surgery. Essential components of the shared decision making process are to determine the impact of the pain on the patient's quality of life, assess how the patient's physical function is affected (activities of daily living [ADLs]), identify the goals of surgery and potential for full rehabilitation, and determine whether there are other viable nonsurgical alternatives. Such discussions are best undertaken by a trusted PCP but may include the opinions of consultants and other providers in the decision making.

The American Pain Society guideline recommendations[35] for LBP caused by herniated disc disease suggest that there is:

no need for provocative discography to determine if a disc herniation is the source of LBP;

no utility for facet joint or intradiscal corticosteroid injections, or prolotherapy for patients with non-radicular LBP; and

no evidence to guide recommendations for vertebral disc replacement.

The panel further recommends:

discussion of risk versus benefits of epidural steroid injections (including lack of long term benefit);

discussion of risk and benefits of spinal cord stimulation for chronic radicular pain (in light of the high rate of complications following stimulator placement); and

discussion of risks and benefits of surgery for disabling radiculopathy because of herniated lumbar disc.

Recent studies showed that nonsurgical interventional interventions compare favorably with surgery. A four-year follow up study of 124 patients with symptomatic lumbar disc degeneration of greater than one year's duration compared the outcomes of surgical versus nonsurgical therapy. One group underwent surgical lumbar fusion while the others were given a cognitive intervention and exercise therapy. The subjects were analyzed for physical function, global disability, work, medication use, emotional distress, and quality of life measures. The outcome analysis showed that 24% of the cognitive intervention and exercise group ultimately underwent surgery, and 23% of the surgical group underwent a second surgery. There were no differences in return to work, pain, disability index, or emotional distress between the two groups. The researchers concluded that long term improvement was no better in the surgical group compared with nonsurgical management consisting of cognitive intervention and exercise.[48]

The spine patient outcomes research trial (SPORT) was a large multicenter study involving 13 centers in 11 states in the United States.[49,50] Patients with chronic LBP because of intervertebral disc herniation, spinal stenosis, and degenerative spondylolisthesis (slippage of the vertebral segment on the adjacent one) were followed for nine years. One group underwent standard open discectomy while the comparison group received nonoperative treatment individualized to the patient. It was found that both groups continued to improve with time (i.e. over the course of six to 12 months). The researchers concluded that for chronic LBP, surgical versus nonsurgical outcome results are equal. In contrast, surgery may be superior for patients with radicular symptoms with respect to improvement in pain, function, and disability throughout the ensuing two and four years postoperatively. However, no significant treatment benefit of surgery was found for chronic LBP from intervertebral disc herniation, spinal stenosis, degenerative spondylolisthesis in six to eight years of long term follow up. Both groups (surgery versus nonsurgical treatment) tended to improve with time.

Management of Chronic Low Back Pain

Most cases of LBP because of musculoskeletal strain/sprain and many because of vertebral disc herniation or degenerative disc disease will resolve with conservative therapy. Unfortunately, a high rate of recurrence and development of chronic LBP are also common, necessitating the expertise of PCPs for providing long term pain management.

Several expert panels have developed clinical practice guidelines for the approach to diagnosis and management of LBP, including the American College of Physicians (ACP) and the American Pain Society (APS), who have published joint recommendations.[36–38,51,52] The North American Spine Society's evidence based clinical guideline for the diagnosis and treatment of LBP recently completed an exhaustive guideline summary review of evidence based recommendations for diagnosing and treating adult patients with non-specific LBP. An interdisciplinary panel of pain experts developed 82 clinical questions, for which the

answers are summarized in their publication. The authors state that the statements reflect the literature as of February 2016."[53]

The following is a brief summary of the recommendations and levels of evidence for treatment of chronic LBP (CLBP) by the clinical guidelines committee of the ACP.[51]

1. The initial approach to chronic CLB should focus on:
   - nonpharmacologic treatment, including exercise, multidisciplinary rehab, acupuncture, mindfulness-based stress reduction (moderate evidence);
   - tai chi, yoga, motor control exercise, progressive relaxation, EMG biofeedback, low level laser therapy, operant therapy, cognitive behavior therapy, or spinal manipulation (low quality evidence).
2. If there is an inadequate response to nonpharmacologic therapy, consider pharmacologic treatment:
   - nonsteroidal anti-inflammatory drugs (NSAIDs) as first line or tramadol or duloxetine as second line;
   - opioids only if failed other treatments and only if the benefits outweigh the risks (weak recommendation).
3. The ACP clinical guidelines committee has rated the evidence for nonpharmacologic treatment of CLBP[51] and concluded that:
   - superficial heat moderately improved pain relief (at five days) and disability (at four days) and, combined with exercise, improved Roland disability questionnaire (RDQ) scores at seven days, with better outcomes than acetaminophen/ibuprofen treatment;
   - acupuncture was found to have conflicting evidence for efficacy but did show a moderate improvement in pain intensity;
   - massage therapy gave some relief to some patients and is considered safe;
   - spinal manipulation therapy improved pain and function if used for four weeks or less, but there was no long term benefit observed;
   - exercise, including stretching, strengthening, or flexion/extension, are not recommended by either the United States or European guidelines. However, exercise is known to confer other benefits;
   - optimal time to start exercise after the onset of LBP symptoms is unclear; for patients in the subacute phase (less than four to eight weeks), rehabilitation (physician, physical therapy, psychological or vocational interventions) are moderately effective (yoga and tai chi have had some promising outcomes for CLBP).

The role of psychiatric and/or psychologic therapy is integral as part of self-management techniques for chronic pain in general, and this applies equally to patients with CLBP.[54] PCPs should be familiar with the resources available for psychiatric and psychologic support and comfortable with making referrals for patients with chronic pain. Good evidence supports the effectiveness of cognitive behavior therapy (CBT), a psychological approach that identifies problematic thought or behavior patterns and works to modify them through active change. A related psychotherapeutic option is acceptance commitment therapy (ACT), which assists the patient in coping with a diagnosis through the steps of acceptance and commitment to improved outcome. These therapies are useful adjuncts to a comprehensive pain approach since they assist patients in setting appropriate goals, recognizing personal barriers, and promoting self-management and self-efficacy. A comprehensive review of nonpharmacologic CAM therapies for pain management is found in Chapter 61.

The following discussion will examine some of the recent evidence for massage, manipulation, acupuncture, exercise, and structured practices such as yoga and tai chi. Massage therapy is considered safe and potentially beneficial for patients with subacute and chronic non-specific LBP, especially when combined with exercise and self-management education. However, two systematic reviews yielded insufficient evidence to make definitive recommendations.[55,56] The authors did note that moderate evidence suggests that combination therapy (massage plus another active treatment such as acupuncture) improved pain and function better than monotherapy alone. Further, as previously noted, spinal manipulation showed improved function for patients with LBP of less than four weeks' duration, but there was no evidence for long term benefits. With respect to acupuncture, data is limited and conflicting. Cherkin et al.[57] reviewed the evidence for safety and effectiveness of acupuncture, massage, and spinal manipulation and concluded that some initial studies have found massage to be effective for CLBP and that the benefits of spinal manipulation are equivalent to those of other therapies; the cost effectiveness of massage, but not for manipulation or acupuncture, may reduce costs after an initial course of therapy.

It seems counterintuitive, but neither the United States nor European guidelines recommend exercise (stretching, flexion, extension, or strengthening) because of a lack of evidence to support its use. Two clinical practice reviews[58,59] do support exercise as important in the maintenance of physical function and note that for patients in the subacute phase of LBP (less than four to eight weeks of pain), rehabilitation that includes the primary care physician, physical therapy, and psychological and/or vocational interventions is moderately effective. "The bottom line is that any physical therapy approach that encourages and enables the individual with acute LBP to resume his or her normal activities is the one to be recommended."[58]

A recent study of 479 patients with chronic LBP compared yoga and physical therapy stretching and strengthening and found outcomes that were similar in acute pain outcomes. Yoga and PT were also found to be similar for secondary outcomes such as pain medication use, global improvement, satisfaction with the intervention, and health related quality of life. In brief, they found that a manualized yoga program for non-specific CLBP was noninferior to PT for improvement in function and pain.[60]

In general, the current evidence is insufficient to determine the effectiveness of transcutaneous electrical nerve stimulation (TENS), electrical muscle stimulation, short-wave diathermy, traction, cold, lumbar supports, motor control exercise, psychological therapies (CBT, imagery relaxation, cognitive coping), Pilates, ultrasound, or taping for CLBP.[35] However, many patients dissatisfied with conventional medical treatment do seek and employ CAM therapies and anecdotally report good effects. Thus PCPs should be knowledgeable about these options and maintain an open mind regarding the utility of nonpharmacologic and/or CAM therapies as part of a multimodal approach to CLBP.

Pharmacologic Therapy for Low Back Pain

The goal in prescribing medications for acute non-specific LBP is not curative; instead, medications may be indicated to reduce symptoms of pain and spasm, which can cause positional discomfort or splinting and consequent reduced movement/mobility as well as difficulty sleeping. The treatment goal is to enable the patient to remain as physically active as possible during the acutely painful period, allowing a transition to healing, hopefully with complete resolution of the pain.

PCPs should determine whether medication(s) will be needed for a brief time (acute/subacute LBP or recurrence) or as ongoing therapy for CLBP. Many medications that are helpful in the short term (acetaminophen, smooth muscle relaxants [e.g. cyclobenzaprine], NSAIDs [e.g. diclofenac, ibuprofen, naproxen sodium], opioids [e.g. codeine, oxycodone]) have contraindications and limitations for long term use. Good evidence exists for the effectiveness of NSAIDs. In terms of analgesia, there is no significant difference between cyclooxygenase inhibitors (cyclo-oxygenase [COX] 2-selective) or traditional NSAIDs. However, their use is limited by the class effect on renal function, gastrointestinal mucosal erosion, and importantly, the black box warning against thromboembolic cardiovascular events, as noted in the subsequent section on general precautions for non-opioid pharmacologic therapy.

The 2007 ACP clinical guideline that reviewed noninvasive treatments for acute, subacute, and chronic LBP[36] was updated in 2017 by a systematic review of systemic therapies for LBP.[49] The following summarizes the 2017 ACP clinical practice guideline:

Acetaminophen (APAP): appears to be no different from a placebo for acute or subacute LBP regarding pain intensity or function through four weeks; no indication for chronic LBP (moderate quality evidence); NSAIDs showed no difference than acetaminophen at three weeks or less; although estimates favored NSAIDs for pain relief, acetaminophen had a lower risk for side effects.

NSAIDs: were associated with greater mean improvements in pain intensity than placebo for acute back pain; for chronic LBP, NSAIDs were associated with greater mean pain relief than placebo after 12 weeks; no clear differences between NSAIDs for acute or chronic LBP; for radiculopathy, small and inconsistent effects were found. NSAIDs were associated with more adverse effects than placebo, but COX-2 inhibitors had a lower risk for adverse events (AEs).

Opioids, tramadol, and tapentadol: no difference for acute LBP between oxycodone or acetaminophen plus naproxen or placebo plus naproxen; for chronic LBP, strong opioids were associated with greater short term relief than placebo; tramadol also resulted in greater short term relief than placebo. Opioids had a higher risk for nausea, dizziness, constipation, vomiting, somnolence, and dry mouth than placebo.

Skeletal muscle relaxants: superior to placebo for short term pain relief; evidence insufficient to determine effects on function or for CLBP; no significant differences among various skeletal muscle relaxants on any outcome.

Benzodiazepines: no clinically significant benefit compared with placebo were associated with CNS AEs (somnolence, fatigue, and lightheadedness).

Anti-depressants: no difference in pain between tricyclic anti-depressants or selective serotonin reuptake inhibitors for CLBP; can be effective, but their mechanisms of action are not clearly understood; serotonin norepinephrine reuptake inhibitor (SNRI) duloxetine was associated with lower pain intensity at 12 to 13 weeks, although effects were small; duloxetine associated with greater improvement in function on the BPI.

Anti-convulsant medications: gabapentin provides small short term benefits for radiculopathy; evidence insufficient to determine effects of pregabalin versus other medication or pregabalin plus another medication versus the other medication alone.

Systemic corticosteroids: no differences were found for non-radicular and radicular LBP compared with placebo when given parenterally (single injection) or a short oral taper; serious harms were not reported.

Consensus panels[36,49] agree that opioid therapy is not useful for the long term treatment of CLBP. Short term, low dose opioids may be needed for patients with traumatic back injuries or fractures, but their use should reflect best clinical practice recommendations, such as the 2016 CDC guideline for prescribing opioids for chronic pain (a guideline review follows).

General Precautions for Non-opioid Pharmacologic Therapy

When considering the use of pharmacologic agents for treatment, providers should be familiar with the mechanism(s) of action (MOA), routes of administration, dosages, pharmacokinetics, side effects, drug interactions, and risks for AEs. These details are presented to supplement the pharmacologic choices outlined by the ACP[49] noted above.

Acetaminophen (APAP)'s analgesic effect may include metabolism to a prodrug that acts partly as a cannabinoid because of the indirect activation of cannabinoid CB-1 receptors. A dual MOA may result in both direct analgesic and modulation effects.[61,62] While considered a first line option, acetaminophen is a slightly weaker analgesic than NSAIDs (equivalent to ten points on a 100 point visual analog pain scale). The main adverse event associated with acetaminophen is hepatotoxicity.[36,38]

Concomitant administration of drugs that induce or regulate CYP2E1 may alter APAP metabolism and increase hepatotoxic potential. Chronic high dose APAP can increase the international normalized ratio in some anticoagulated patients.[63]

The mechanism of action of NSAIDs is inhibition of COX, which is the enzyme responsible for the biosynthesis of prostaglandins and thromboxane. Nonselective NSAIDs inhibit both COX-1 and COX-2, while COX-2 selective NSAIDs only inhibit COX-2. The APS-ACP review[38] showed that NSAIDs were associated with small to moderate pain improvement compared with placebo (moderate quality evidence) and no to a small improvement in function (low quality evidence). Most head-to-head trials of one NSAID versus another showed no differences in pain relief in patients with chronic LBP. Nevertheless, NSAIDs were positioned as first line therapy; there were no data regarding COX-2-selective NSAIDs.

An important contraindication that applies to the entire class of NSAIDs is the risk of thromboembolic cardiac and cerebrovascular events; there is a Food and Drug Administration (FDA) warning of risk for heart attack and stroke as early as the first weeks of use. Thus NSAIDs must be avoided in individuals with known coronary artery disease (CAD), angina, or history of stroke and those at greater than average risk for these conditions. It is further recommended that NSAIDs be avoided in individuals with kidney disease, congestive heart failure (CHF), or cirrhosis. They are not recommended in the third trimester of pregnancy.

AEs associated with NSAIDs include gastrointestinal (GI) toxicity, although the COX-2 selective NSAID (celecoxib) has less potential to cause ulcers or GI bleeding, liver and kidney toxicity, hypertension, and CHF. In terms of drug interactions, NSAIDs must be used with caution in patients on diuretics. They also pose a significantly increased risk of bleeding in patients on low dose acetylsalicylic acid or taking any anticoagulant. They should not be co-prescribed with phenytoin or cyclosporine. NSAIDs are available in oral, topical, IV formulations.[64,65]

TABLE 75.10 NSAID Dosages

Drug	Starting Dose	Maximum Dose
Celecoxib	100 mg PO BID	200 mg PO BID
Diclofenac DR	50–75 mg PO BID	150 mg/day
Diclofenac ER	100 mg PO QD	100 mg PO QD
Ibuprofen	200–400 mg PO TID–QID	2400 mg/day
Meloxicam	7.5 mg PO QD	15 mg/day
Naproxen*	250–500 mg PO BID	1000 mg/day

*Naproxen 250, 500 mg = naproxen sodium 275, 550 mg.

Table 75.10 lists starting and maximum dosages for NSAIDs.

Tricyclic anti-depressants (TCAs) have an MOA that involves inhibition of the reuptake of both serotonin and norepinephrine. Although well studied in various pain conditions and despite their use for many decades as first line treatment for neuropathic pain, none of the tricyclics carry an FDA indication for pain management. The doses used for pain must be slowly up-titrated over several weeks (e.g. 10 mg/day to a maximum dose of 100 mg/day). TCAs are absolutely contraindicated for use in patients taking monoamine oxidase inhibitor (MAOI)s, and they should be avoided in patients with severe cardiac disease (pretreatment electrocardiogram [ECG] is recommended because of effects on the QTc interval) and in patients with severe GI dysfunction. The FDA lists a class effect black box warning for suicidal thinking and behavior in children, adolescents, and young adults. Because of their strong serotonergic effect and metabolism with CYP3A4 and CYP2D6 substrate, TCAs may lower the seizure threshold or cause hyponatremia.[66] The AEs that are associated with TCAs are generally anticholinergic: blurred vision, cognitive changes, constipation, dry mouth, orthostatic hypotension, sedation, sexual dysfunction, tachycardia, and urinary retention.[67–69]

SNRIs are a class of anti-depressants that cause inhibition of the reuptake of two neurotransmitters: serotonin and norepinephrine. They have indications and uses for pain management as well as for depression. APS-ACP review[36] (moderate quality evidence) showed no difference in pain between tricyclic anti-depressants (TCAs) or selective serotonin reuptake inhibitors versus placebo and showed no differences in function for anti-depressants (low quality evidence). However, moderate quality evidence showed that duloxetine was associated with a small improvement in pain intensity and function compared with placebo, so it is recommended as second line therapy.

Duloxetine has indications for chronic musculoskeletal pain such as LBP and OA, fibromyalgia, and painful diabetic peripheral neuropathy; milnacipran is indicated for fibromyalgia. Venlafaxine, which is indicated for depression and anxiety, may be effective in acute and chronic neuropathic pain and painful diabetic peripheral neuropathy (PDPN). Usual starting doses for duloxetine are 30 mg/day for chronic musculoskeletal pain and fibromyalgia and 60 mg/day for PDPN with a maximum dose of 120 mg/day. SNRIs are contraindicated for use with monoamine oxidase inhibitors (MAOIs).

TCAs carry a black box warning for suicidal thinking and behavior in children, adolescents, and young adults. Since SNRIs are potent inhibitors of CYP1A2 and 2D6, it is recommended to monitor liver function during use.[38,66]

The MOA of anti-convulsants is dependent upon the specific drug. The gabapentinoids (pregabalin and gabapentin) and valproic acid act through voltage-gated calcium channel modulation while carbamazepine, oxcarbazepine, lamotrigine, topiramate, valproic acid act via voltage-gated sodium channel modulation. Carbamazepine, oxcarbazepine, lamotrigine, gabapentin cause inhibition of glutamate release, while valproic acid topiramate increases GABA inhibition.

Anti-convulsants have several indications and use for pain management. Gabapentin is indicated for postherpetic neuralgia and may be effective in painful diabetic neuropathy. Pregabalin is indicated for painful diabetic neuropathy, postherpetic neuralgia, fibromyalgia, and neuropathic pain associated with spinal cord injury.

Carbamazepine has an indication for trigeminal neuralgia. Other anti-convulsants have been studied in pain conditions and may be considered as the second line if other options have failed.

Coadministration of gabapentinoids and opioids increases the risk of respiratory depression. Commonly reported side effects (incidence greater than 5% and more than twice the rate observed with placebo) are dizziness, somnolence, and peripheral edema.[67]

Regarding the efficacy of anti-convulsants in LBP, evidence was insufficient to determine the effect of anti-convulsant medications on acute, subacute, or chronic low back pain, nor was there sufficient evidence to determine the effect of anti-convulsant medications on radicular low back pain.[38]

Table 75.11 lists typical dosages for anti-convulsants.

TABLE 75.11 Anti-convulsant Dosages

Drug	Starting Dose	Target Dose	Side Effects	Renal Exc	Hepatic Pathways
Gabapentin	100–300 mg	3600 mg	Weight gain, dizziness, sedation, ataxia, diplopia, twitching, HA*	>95%	No
Pregabalin	25–50 mg	900 mg	Weight gain, dizziness, sedation, ataxia, diplopia twitching, HA*	>95%	No
Oxcarbazepine	300 mg	2400 mg	Hypo Na^{++}, SJS, ** and EM***	30%	Yes, ~50%

*headache.
**Stevens-Johnson Syndrome.
***erythema migraine.

Summary of Treatment Recommendations for Low Back Pain

The choice of medication for LBP should be evidence based and tailored as much as possible to suit the individual patient. Acetaminophen, mild opioids, and NSAIDs are the first line drugs for LBP, but there is no evidence that one is more effective than the others. Nonbenzodiazepine muscle relaxants (with or without pain medication) could be considered second line drugs in acute LBP and cyclic antidepressants in chronic LBP. The risk of adverse side effects can be reduced by taking into account the patient's medical history and using a test dose. The realization that symptoms other than pain are sometimes more important and/or easier to overcome can increase the benefits of medication. The long term effects of medication can be improved when combined with non-drug interventions.[70]

Recognizing that most patients with acute and subacute LBP without red flag findings will improve over time regardless of treatment, PCPs may decline to order costly tests and potentially harmful treatments. Genuine acknowledgment of the patient's complaint of pain within the context of a trusted patient-provider relationship is a springboard to focus patient education on the benefits of nonpharmacologic treatment options and lifestyle adaptations such as weight loss, maintenance of physical activity, and progressive exercise. Since few differences in recommended therapies were found in comparison trials, treatment recommendations should be based on patient preferences, cost, and harm avoidance. Preserved function is the important goal that should supersede attempts at complete resolution of pain.

As noted by the American Board of Internal Medicine's choosing wisely guidelines,[71] initial nonpharmacologic treatment for LBP may include superficial heat, spinal manipulation (e.g. osteopathic manipulation or chiropractic treatment), massage, or acupuncture. Patients should be advised to remain as active as tolerated, and prolonged bed rest should be discouraged. However, PCPs may prescribe modifications to work duties such as avoidance of heavy lifting, bending, twisting, and/or prolonged sitting. Multimodal therapy, or a combination of treatments, may provide additional benefit (e.g. heat coupled with massage and other nonpharmacologic treatment).

If pharmacologic treatment is needed, topical analgesics, acetaminophen, NSAIDs, or skeletal muscle relaxants may be considered. However, steroids have shown no appreciable effect, even in radicular LBP. For patients with CLBP and inadequate response to nonpharmacologic therapy, consider pharmacologic therapy with NSAIDs first with tramadol or duloxetine as second line therapy. Opioids should be considered only for patients with moderate to severe pain who have failed to adequately respond to non-opioid and nonpharmacologic treatments and for whom the potential benefits outweigh risks.[72,73] A comparison of long term opioid versus non-opioid pain management therapy for patients with LBP, hip, or knee osteoarthritis showed that the two treatment groups had similar levels of pain reduction. However, opioids have many associated side effects and significant risks.[74]

If opioid therapy is contemplated, shared decision making and use of a patient-provider agreement or therapeutic contract that delineates the roles and responsibilities of each is recommended. A discussion of opioid use in primary care with an emphasis on the FDA blueprint and CDC guideline follows. Finally, with respect to the management of LBP, basic knowledge of the available interventional procedures is useful so that PCPs can make appropriate referrals, educate patients regarding potential risks and benefits, and provide aftercare and ongoing management as needed. A discussion of interventional procedures for LBP is beyond the scope of this discussion. However, detailed information about interventional pain management can be found in part IV: neural block and interventional techniques of this text.

Table 75.12 lists interventional procedures for LBP.

TABLE 75.12 Interventional Procedures for Low Back Pain

Epidural steroid injections Spinal drug delivery
Steroid intraarticular injections Discography
Spinal cord stimulation for LBP and neuropathic pain Botulinum toxin
Intrathecal therapy for LBP Trigger point injections
Sacroiliac joint injection and RFA
Facet joint injection and RFA
IDET, nucleoplasty, disc RFA

IDET, Intradiscal electrothermal therapy; *LBP*, low back pain; *RFA*, radiofrequency ablation.

Musculoskeletal Pain in Adults

Many pain complaints (e.g. strains, sprains, bursitis, tendonitis, arthritis) that present to the PCP have their origin in the musculoskeletal system. The Global Burden of Disease Study showed that musculoskeletal injuries of the neck, shoulder, knee, and other body parts cause diminished quality of life, disability, and increased healthcare costs.[75] A systematic search (including Cochrane Reviews) of potential therapies for musculoskeletal pain was conducted by the Arthritis Research United Kingdom Primary Care Centre, Research Institute for Primary Care & Health Sciences, Keela University, Keela, United Kingdom.[76] Moderate evidence showed that exercise therapy and psychosocial interventions are effective for relieving pain of musculoskeletal origin. While NSAIDs and opioids reduced pain in the short term, the effect size was modest, and the risk for adverse effects signals need for consideration. For knee and shoulder pain, corticosteroids were found to provide short term pain relief. However, based on the evidence, the findings were equivocal regarding dose, intensity, frequency, or mode of application for these therapies.

Four out of five injuries treated in physician's offices are musculoskeletal, with an estimated cost of $176.1 billion in 2010.[77] A joint guideline published by the ACP and American Academy of Family Physicians (AAFP)[78] gave recommendations regarding management of acute pain from non-low back musculoskeletal injuries in adults considered the following treatment parameters: pain relief at one to seven days, physical function, treatment satisfaction, symptom relief, AEs (dermatologic, GI, and neurologic) and comparative harms of nonpharmacologic and pharmacologic treatments. The review also considered patient values and preferences, costs, areas of inconclusive evidence, and clinical considerations for patients with multiple chronic conditions. The guideline's expert panel noted that those with more chronic conditions have a higher probability of receiving opioids for prolonged periods. The ACP/AAFP guideline:

1. Recommends that clinicians treat patients with acute pain from non-low back, musculoskeletal injuries with topical NSAIDs with or without menthol gel as first line therapy to reduce or relieve symptoms, including pain; improve physical function; and improve the patient's treatment satisfaction.

2. Suggests that clinicians treat patients with acute pain from non-low back, musculoskeletal injuries with oral NSAIDs to reduce or relieve symptoms, including pain, and to improve physical function, or with oral acetaminophen to reduce pain; and suggests that clinicians treat patients with acute pain from non-low back, musculoskeletal injuries with specific acupressure to reduce pain and improve physical function, or with TENS to reduce pain.
3. Suggests against clinicians treating patients with acute pain from non-low back, musculoskeletal injuries with opioids, including tramadol.[78]

The ACP/AAFP guideline rationale notes that topical NSAIDs improved all outcomes compared with placebo and were not associated with increased risk for harm. Few harms were reported except for oral NSAIDs, which caused GI AEs: it emphasized that clinicians must assess GI risk factors prior to prescribing oral NSAIDs. The rationale for recommendation[3] notes that treatment with opioids was associated with significant increases in risk for neurologic and GI AEs and cites evidence that showed a relationship between prescriptions lasting longer than seven days. It was again noted that prolonged use of opioids carries the risk for long term addiction and overdose.

Multimodal Therapy and Nonpharmacologic Options for Managing Pain

The choice of medication, dose, route, and duration of therapy should be individualized to implement multimodal therapy (i.e. synchronous administration of two or more pharmacologic agents or approaches, each with a distinct mechanism of action). The rationale for multimodal therapy is that different modalities target different receptors and pain pathways such that multiple agents provide a synergistic or enhanced effect. This technique allows for dose reduction of individual agents, which may lead to less risk of an individual drug's adverse effects, assuming, of course, that there are no adverse drug-drug interactions.

While the evidence for some nonpharmacologic modalities is mixed and/or limited, they nonetheless serve as a complementary approach for pain management and, in some circumstances, may reduce the need for opioid medications. PCPs may promote nonpharmacologic therapies by ensuring that patient preferences are discussed and by identifying community resources that provide complementary therapies relevant to their patient population. Nonpharmacologic strategies include but are not limited to physical modalities (acupuncture, aqua therapy, chiropractic therapy, osteopathic manipulative treatment, massage therapy, and physical therapy); movement therapy (dance, tai chi, yoga); psychological (behavioral modification, cognitive restructuring, CBT, ACT, psychiatric therapy); and relaxation therapy (mindfulness, meditation). Other CAM modalities include balneotherapy (heat), aromatherapy, and music therapy.

Table 75.13 lists alternative nonpharmacologic and non-opioid pharmacologic treatments.

TABLE 75.13 Alternative Treatments for Pain

Nonpharmacologic Therapies	Non-opioid Pharmacologic Therapies
Psychological approaches Cognitive behavioral therapy (CBT)	NSAIDs and acetaminophen
Physical rehabilitative approaches Physical therapy Occupational therapy	Anti-convulsants
Surgical approaches	Anti-depressants
Complementary therapies Acupuncture Chiropractic	Local anesthetics Topical Blocks
Osteopathic manipulative medicine	Other adjuvant medications

Pharmacologic Approach to Pain and Opioid Use

The "decade of the brain" (1991–2000) in the United States resulted in many advances in neurosciences. It was followed by "the decade of pain control and research" (2001–2010) through the passage of House of Representatives bill, H.R. 3244, which President Clinton signed into law. The goal of this program was to bring "a much needed focus on pain disorders, to benefit both the public and private sectors by stimulating further advances in research, education and clinical management of pain disorder."[17] This enhanced interest in assessing and treating pain may have led to the joint commission recommendation that every patient's level of pain be regularly measured as the "fifth vital sign." Within this setting, pharmaceutical manufacturers developed and brought to market several new, potent, extended-release, long-acting opioid formulations, most of which were heavily marketed. The subsequent decades saw a significant increase in the use of opioid analgesics.

In response to increased opioid use and the observed rise in prescription opioid overdose deaths in the United States, the FDA imposed a risk evaluation mitigation strategy (REMS) for extended-release/long-acting (ER/LA) opioids in 2012 and mandated that prescribers receive ER/LA opioid REMS education. Many states have required that prescribers complete mandatory REMS continuing medical education to maintain prescriptive privileges for scheduled medications (most opioids are FDA Schedule II). PCPs can obtain this education through online or live educational programs.

The 2018 FDA *opioid analgesic REMS,* in addition to ER/LA opioids, includes all immediate-release (IR) opioids used in outpatient settings that are not already covered by other REMS programs. The *FDA education blueprint for healthcare providers involved in the treatment and monitoring of patients with pain* (FDA blueprint)[79] requires that prescribers: know the basic principles of pain physiology; identify alternatives to opioids (multimodal, CAM therapies, non-opioid pharmacologic agents); utilize risk stratification and screening for patient selection for the trial of opioid therapy; recognize side effects and drug interactions; anticipate and mitigate AEs (respiratory depression and overdose); and be knowledgeable about dose selection, titration, and equianalgesic dosing using morphine milligram equivalents (MMEs). It also details the use of opioids in special populations (e.g. pregnant women and older persons) and requires updated, increased knowledge about the problem of addiction (opioid use disorder).

PCPs must be cognizant of the evidence indicating that even relatively short term use of opioids can result in their continued

use, reliance, and possible addiction. The FDA has explicitly stated that PCPs treating patients with pain should be knowledgeable about the basic elements of addiction medicine, such as the definition, neurobiology, and pharmacotherapy of addiction.

Because of its pejorative and negative connotations, the term addiction can lead to stigmatization or blaming of individuals. The *Diagnostic and Statistical Manual of Mental Disorders* fifth edition (DSM-V)[80] has modified the term addiction to substance use disorder (SUD); in the case of opioid abuse/addiction, the preferred term is opioid use disorder (OUD). The DSM-V criteria make a clear distinction between a patient who misuses an opioid analgesic (by taking it differently than prescribed) to manage pain versus one who abuses an opioid analgesic with the intent of getting high. It has been estimated that the prevalence of OUD in patients with chronic non-cancer pain (CNCP) on chronic opioid therapy in primary care settings is 3% to 26%.[79] A mnemonic for identifying SUD is the five C's: control (loss of), compulsive use, craving drug, continued use (despite evidence of use causing harm), and chronic problem.

Table 75.14 lists the criteria for OUD.

TABLE 75.14 Diagnostic Criteria—Opioid Use Disorder DSM-V

A. A problematic pattern of opioid use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
   1. Opioids are often taken in larger amounts or over a longer period than was intended.
   2. There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
   3. A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
   4. Craving, or a strong desire or urge to use opioids.
   5. Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home.
   6. Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids.
   7. Important social, occupational, or recreational activities are given up or reduced because of opioid use.
   8. Recurrent opioid use in situations in which it is physically hazardous.
   9. Continued opioid use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
   10. Tolerance, as defined by either of the following:[a]
      a. A need for markedly increased amounts of opioids to achieve intoxication or desired effect.
      b. A markedly diminished effect with continued use of the same amount of an opioid.
   11. Withdrawal, as manifested by either of the following:[b]
      a. The characteristic opioid withdrawal syndrome (refer to Criteria A and B of the criteria set for opioid withdrawal, pp. 547–548).
      b. Opioids (or a closely related substance) are taken to relieve or avoid withdrawal symptoms.

Specify if:
- In early remission: After full criteria for opioid use disorder were previously met, none of the criteria for opioid use disorder have been met for at least 3 months but for less than 12 months (with the exception that Criterion A4, "Craving, or a strong desire or urge to use opioids," may be met).
- In sustained remission: After full criteria for opioid use disorder were previously met, none of the criteria for opioid use disorder have been met at any time during a period of 12 months or longer (with the exception that Criterion A4, "Craving, or a strong desire or urge to use opioids," may be met).

Specify if:
- On maintenance therapy: This additional specifier is used if the individual is taking a prescribed agonist medication such as methadone or buprenorphine and none of the criteria for opioid use disorder have been met for that class of medication (except tolerance to, or withdrawal from, the agonist). This category also applies to those individuals being maintained on a partial agonist, an agonist/antagonist, or a full antagonist such as oral naltrexone or depot naltrexone.
- In a controlled environment: This additional specifier is used if the individual is in an environment where access to opioids is restricted.

[a]Note: This criterion is not considered to be met for those taking opioids solely under appropriate medical supervision.
[b]Note: This criterion is not considered to be met for those individuals taking opioids solely under appropriate medical supervision.

CDC Guideline for Prescribing Opioids for Chronic Pain

The CDC guideline for prescribing opioids for chronic pain-United States 2016[81] was published to help guide the prescriptive use of opioids by PCPs. This was in direct response to estimates that prescriptions from PCPs account for approximately 50% of opioid pain medications dispensed. At the same time, PCPs reported having received insufficient training and acknowledged their concerns about medication misuse and addiction. The guideline was specifically directed at clinicians in outpatient settings who treat patients over the age of 18 with chronic pain (defined as lasting greater than three months or past the time of normal tissue healing). An important and sometimes overlooked caveat is that the CDC guideline recommendations were not intended to guide the care of patients receiving active cancer treatment, palliative care, and/or care at the end of life.

The 2016 CDC guideline updated a 2014 AHRQ-sponsored review that researched key questions regarding the effectiveness of long term opioid therapy, harms, and AEs, effectiveness of methods for initiation, titration and dosing, accuracy of prediction instruments, and effectiveness of REMS, and effects of prescribing opioids for acute pain on long term use. Please see Chapter 48 for a review of guideline development.

The CDC's literature review showed that the evidence for outcomes regarding long term opioid therapy for chronic pain was very limited, with insufficient evidence to determine long term benefits; of concern, it suggested an increased risk of serious harms that appears to be dose-dependent. Newer studies revealed additional harms of long term opioid therapy, including increased risk of androgen deficiency among men receiving IR opioids; increased risk of overdose among patients receiving methadone; increased risk of overdose with the initiation of opioid therapy with ER/LA opioids compared with an initiation with IR opioids, and increased risk of long term use of opioids when opioids are used for acute pain. Newer studies also revealed new information about the sensitivity and specificity of the Opioid Risk Tool (ORT), the Screener and Opioid Assessment for Patients in Pain (SOAPP-Revised), and the brief risk interview, illustrating insufficient accuracy of these screening tools. The guideline review revealed that more research is needed to understand the long term benefits versus risk of abuse and related outcomes, effectiveness of different opioid prescribing methods and risk mitigation strategies, and accuracy of risk prediction instruments.

Therefore the CDC made 12 recommendations for safe opioid prescribing:

1. Nonpharmacologic therapy and non-opioid pharmacologic therapy are preferred for chronic pain. Clinicians should only consider adding opioid therapy if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic treatment and non-opioid pharmacologic therapy as appropriate.
2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how therapy will be discontinued if benefits do not outweigh risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3. Before starting and periodically during opioid therapy, clinicians should discuss with patients the known risks and realistic benefits of opioid therapy and patient and provider responsibilities for managing therapy.
4. When starting opioid therapy for chronic pain, clinicians should prescribe IR opioids instead of extended release/long-acting (ER/LA) opioids.
5. When opioids are started, clinicians should prescribe the lowest effective dosage.
6. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when increasing dosage to greater than or equal to (≥) 50 MME per day, and should avoid increasing dosage to ≥90 MME per day or carefully justify a decision to titrate to ≥90 MME per day.
7. Long term opioid use often begins with the treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of IR opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.
8. Clinicians should evaluate benefits and harms with patients within one to four weeks of starting opioid therapy for chronic pain or dose escalation. Providers should evaluate the benefits and harms of continued therapy with patients every three months or more frequently. If the benefits do not outweigh the harms of continued opioid therapy, providers should work with patients to reduce opioid dosage and discontinue opioids.
9. Before starting and periodically during the continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms.
10. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors increase the risk for opioid overdose, such as a history of overdose, history of a SUD, or higher opioid dosages (≥50 MME), are present.
11. Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving high opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every three months.
12. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications and other controlled prescription drugs and illicit drugs.
13. Clinicians should avoid prescribing opioid pain medication for patients receiving benzodiazepines whenever possible.
14. Clinicians should offer or arrange evidence based treatment (usually medication assisted treatment with buprenorphine or methadone combined with behavioral therapies) for patients with OUD.

The CDC guideline faced criticism by pain advocacy groups over the risk of underprescribing for patients with chronic non-cancer pain and reports of insurers placing caps on both the number of pills and dosages of opioids prescribed. These unfortunate concerns reflect a lack of understanding of the original purpose of the guideline, which was intended to assist PCPs in their decision-making; it was not intended to constrain individual clinical practice patterns or dictate insurance policy. The goal was and remains the safe use of opioid analgesia by PCPs to protect patients and the public. Additionally, the guideline clearly states that it is directed at the treatment of patients with chronic non-cancer pain, and its recommendations do not apply to those living with active cancer or who are receiving palliative care for serious, life-limiting illness and/or at the end of life.[84]

Table 75.15 lists CDC guideline-congruent steps for initiating opioids.

The following caveats regarding opioid dosing were dosing included in the CDC guideline:

Higher dosages of opioids are associated with a higher risk of overdose and death; even relatively low dosages (20–50 MME per day) can increase risk. Higher dosages have not been shown to reduce pain over the long term.

Dosages at or above 50 MME/day increase risks for overdose by at least two times the risk at less than 20 MME/day.

TABLE 75.15 Initiating Opioid Therapy, Congruent With CDC Guideline

Begin a therapeutic trial with an immediate release (IR) opioid
Prescribe the lowest effective dosage
Use caution at any dosage, but particularly when: Increasing dosage to ≥50 morphine milligram equivalents (MME)/day Undertaking opioid rotation (switching from one to another opioid) Up-titrating the dose of an existing opioid
Carefully justify a decision to titrate dosage to ≥90 MME/day
Always include dosing instructions, including daily maximum
Be aware of interindividual variability of response
Have Patient-Prescriber Agreement (PPA), baseline urine drug test (UDT), and informed consent in place
Co-prescribe naloxone (if indicated) and bowel regimen
Re-evaluate risks/benefits within one to four weeks (could be as soon as three to five days) of initiation or dose escalation
Re-evaluate risks/benefits every three months; if benefits do not outweigh harms, optimize other therapies and work to taper and discontinue

Source: CO*RE-REMS program. Available at: www.core-rems.org.

Patients prescribed higher opioid dosages are at higher risk of overdose death. In a national sample of Veterans Health Administration patients with chronic pain receiving opioids from 2004–2009, patients who died of opioid overdose were prescribed an average of 98 MME/day, while other patients were prescribed an average of 48 MME/day.

Calculating the total daily dose of opioids helps identify patients who may benefit from closer monitoring, reduction or tapering of opioids, prescribing of naloxone, or other measures to reduce the risk of overdose.[81]

While perhaps an oversimplification of the approach to opioid prescribing, it may be useful to remember the geriatric adage regarding medication dosing, "start low and go slow." However, when treating pain, the adage may be modified to "start low but go." The latter statement acknowledges the need for caution and safe prescribing while also calling for frequent reassessment to determine the need for dose titration (up or down), rotation to another opioid, or additional interventions as indicated.

Table 75.16 lists recommended starting dosages for opioids.

TABLE 75.16 Opioid Dosages

Drug	Recommended Starting Dose	Comments
Hydrocodone	2.5–5 mg q4–6 h	Dose limited by non-opioid in combination-dose varies by product
Hydromorphone	1–2 mg q3–4 h	For breakthrough pain or around the clock dosing
Morphine Immediate release (IR) Sustained release (SR)	2.5–10 mg q4 h 15 mg q8–24 h	SR scheduling is product specific. Usually started after initial dose determined by IR. Toxic metabolites may limit usefulness with a high dose.
Methadone		Use ONLY by experienced clinicians
Oxycodone Immediate release Controlled release	 2.5–5 mg q4–6 h 10 mg q12 h	Significant interaction with food & alcohol
Tapentadol	50 mg PO q4–65 h	Dual action; may have a lower risk of gastrointestinal side effects vs. comparator opioids
Tramadol	12.5–25 mg q4–6 h	Dual action
Transdermal buprenorphine	5 mcg/h patch q7 days	A good option for older adults with dementia
Transdermal fentanyl	12–25 mcg/h patch q72 h	After the dose is determined by IR, the peak is 18–24 h. Duration 48-96 h

AGS panel on pharmacological management of persistent pain in older persons. *J Am Geriatr Soc.* 2009;57(8):1331–1346.

Pergolizzi JV, et al. Safety of buprenorphine transdermal system in the management of pain in older adults. *Postgrad Med.* 2017;129(1) 92–101.

Recognizing that there are differences in benefit, risk, and expected outcomes between patients with CNCP and those who are suffering from cancer pain or receiving palliative care and/or hospice services, prescribers of opioids should be aware of and ready to offer anticipatory guidance for opioid side effects. Patients whose pain is because of severe, life-limiting illness may be willing to tolerate or mitigate some side effects of opioids to obtain the needed level of analgesia. Thus for certain patients, PCPs may elect to treat side effects in the short term to achieve the longer term pain management goals, e.g. administering antihistamines to mitigate opioid-induced itching or antiemetics for nausea. All patients prescribed opioid therapy must also be counseled to maintain adequate fluid intake and take laxatives as needed since constipation is a ubiquitous side effect of opioid use that, left untreated, can lead to impaction/obstruction or, in severe cases, intestinal rupture. Generally, stool softeners alone are inadequate, especially if the patient is not taking fluids well; laxatives such as sennosides are preferred to ensure adequate laxation.

Table 75.17 lists common opioid side effects and AEs.

Besides the recommendations noted in Tables 75.14 and 75.15, and similarly to the 2018 FDA blueprint, the CDC guideline recommends using IR opioids when initiating therapy at the lowest possible dose for the shortest time necessary to achieve adequate analgesia. When opioids are needed for acute pain, PCPs should prescribe no more than needed. ER/LA opioids should not be prescribed for acute pain. Whenever opioids are required as treatment for pain, frequent follow up, and re-evaluation are recommended to assess the risk of harm. Suppose there are concerns for medication AEs, misuse, abuse, or suspicion for the development of OUD. In that case, clinicians are advised to carefully reduce the dose, continue to taper, and if needed, discontinue prescribing and make appropriate referrals for psychiatric/psychologic and/or medication assisted treatment.[82]

TABLE 75.17 Common Opioid Side Effects and Adverse Events

Respiratory depression: most serious
Opioid-induced constipation: most common, necessitates adequate fluid intake and co-prescribing stimulant laxatives
Sexual dysfunction and other endocrine abnormalities
Tolerance, physical dependence, hyperalgesia
Allergic reactions
Sedation, drowsiness, cognitive impairment
Risk for falls and fractures
Sweating, miosis, urinary retention
Hypogonadism
Myoclonus (twitching or jerking)
Addiction in vulnerable patients
Overdose and death

Decision to Refer Patients for Pain Management

Some PCPs decide to opt out of opioid prescribing because of the risks involved or who feel unprepared or unable to manage patients with OUD. However, every PCP will be called upon to treat patients who may truly benefit from opioid therapy. This includes but is not limited to patients with cancer-related pain and those for whom non-opioid pharmacologic options are contraindicated and/or provide inadequate analgesia, i.e. patients with multiple comorbidities such as CAD, diabetes, and chronic kidney or liver disease. It is also true that patients with OUD may require pain management for illness, surgery, or injury. If prescribing opioid therapy is beyond the PCP's level of training, knowledge, experience, and comfort, referrals to other providers with expertise in pain management or palliative medicine are most appropriate. Consultants for opioid pain management may include anesthesiologists, geriatricians (for the care of older adults with chronic pain), neurologists, physiatrists, and others. It is important not to conflate palliative care with hospice; not all patients who receive palliative pain management are hospice appropriate while, on the other hand, all patients who have enrolled in the hospice benefit will receive palliative care.[83] Palliative care focuses on symptom management (e.g. pain, fatigue, nausea, depression, anxiety, drowsiness, anorexia, constipation, dyspnea, secretions). PCPs are well-positioned to evaluate symptom complexes and to seek palliative care consultation. Referrals for palliative care are appropriate early in the course of any serious or life-limiting illness since early referrals may offer the best opportunity for favorable outcomes.

As noted in the introduction to this chapter, PCPs should develop a broad network of community resources to assist with the care of patients with pain. Several chapters discuss the role of these specialists in collaborative care for patients with pain. Also, see Chapter 44 (Geriatric Pain Management) and 82 (Pain Management at the End of Life and Home Care for the Terminally Ill Patient), which cover vital professional competencies for all PCPs.

Table 75.18 lists useful clinical resources for locating specialists for pain management and addiction treatment.

Primary Care Goals for Pain Management

PCPs strive to partner with patients to set reasonable, achievable pain management goals. This necessitates a commitment to shared decision making with the recognition that while complete elimination of pain is usually not possible, it may be minimized so that quality of life, physical function, and psychosocial function are maintained. Besides pain reduction, the plan of care should include goals such as overall level of comfort, improved physical function and activity, improved interpersonal and social interactions, and improved mood. Utilizing functional rather than numeric treatment targets will enable the clinician, patient, and caregivers to assess meaningful progress toward these goals.

A useful mnemonic (similar to the Five C's for SUD) for assessing progress toward pain management goals is the five A's: analgesia (pain relief); activity/function (measured by the performance of ADLs); AEs (drug interactions, side effects); aberrant/problematic behaviors (abuse, misuse, diversion, addiction); and affect (mood).[79] A sixth "A" may be added to signify the clinician's response: action. Action represents the steps taken by the PCP, patient, and/or patient caregivers, based upon the assessment, to modify and improve the pain treatment plan of care. Table 75.19 lists the five A's and five C's.

A balance between the benefits and risks of therapeutic interventions is sought. To this end, patients should be enlisted in their self-care by recruiting personal skills that can help sustain treatment benefits rather than expecting that the clinician will "fix" them. Thus multimodal therapy coordinated by the primary care PCMH is ideal. Multimodal care incorporates nonpharmacologic and pharmacologic treatments that engage the skills of other providers to assist the patient in achieving analgesic and functional goals.

Patient involvement in their own pain management strategy involves information sharing and collaboration to identify realistic expectations and clear, achievable goals. Numerous factors may cause under-or overtreatment of pain, such as pain expectations based on prior pain experience, lack of knowledge or misinformation about pain and its treatment, and underreporting of pain. These may be minimized through an ongoing therapeutic relationship with a trusted PCP. Involving patients in the pain management planning process allows PCPs to clarify the goals of care and increases the likelihood of treatment adherence and the most favorable outcome possible.

TABLE 75.19 Monitoring Pain and Substance Use Disorder

Pain: Five A's	SUD: Five C's
Analgesia	Control, loss of
Activity/function	Compulsive use
Aberrant behavior	Craving drug
Adverse events	Continued use
Affect	Chronic problem

Key Points

- PCPs are the first contact and provide the initial evaluation for 65% of patients presenting with pain; they often become the sole providers for these patients.
- An ongoing therapeutic relationship between patients and their PCP medical home facilitates an interdisciplinary, multimodal, and comprehensive approach for resolving pain.
- LBP is a common pain presentation in primary care, so PCPs must have a fundamental understanding of the approach to its diagnosis and management.
- When evaluating LBP, a focused History and Physical (H&P) should identify the pain as belonging to one of three categories: red flag condition needing prompt treatment or where specific treatment exists; spinal stenosis or radiculopathy; or non-specific back pain. Avoid initial imaging unless a serious condition is suspected.
- PCPs should be knowledgeable regarding psychosocial factors that might suggest a higher risk of developing chronic pain and/or long term disability.
- Nonpharmacologic and non-opioid pharmacologic treatment options are the foundation for pain management in primary care.
- As many as one in four patients receiving long term opioid therapy in primary care settings struggle with OUD.
- CDC guideline recommendations for prescribing opioids for chronic pain include:
  Nonpharmacologic therapy & nonopioid pharmacologic therapy are preferred for treating chronic pain.
  Opioid therapy should be considered ONLY if expected benefits for both pain AND function are anticipated to outweigh risks to the patient. Opioids should never be the only form of treatment.
  Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with patients, including realistic goals for pain and function, and should consider how opioid therapy will be discontinued if benefits do not outweigh risks.
- Multimodal pain management includes nonpharmacologic, complementary, and alternative medicine techniques, non-opioid and opioid pharmacologic therapy when indicated. Interdisciplinary collaboration with other providers is key to developing a comprehensive pain management strategy.
- PCPs should strive to involve patients in their own pain management strategy through clear communication and information-giving, shared decision making, and a commitment to an iterative process of reassessment and revision of the treatment plan that aims for enhanced quality of life and improved physical and psychosocial function.

Pain Management in the Emergency Department

ANDREW K. CHANG

The management and treatment of the pain in the emergency department (ED) is unique from that experienced in other medical settings. Not only is pain often acute as opposed to chronic, but it is often unexpected and sudden. In addition, the type of painful conditions seen in the ED may respond differently to different types of treatments, such as the pain from a migraine versus the pain from a kidney stone. In these and other ways, the acute pain that is seen in the ED is different from the acute pain seen postoperatively, the latter of which is both expected and planned for.

Acute pain generally lasts less than seven days but can extend up to 30 days,[1] and in some cases can become chronic. Therefore emergency physicians are challenged to provide adequate pain relief, improve quality of life, and improve function while simultaneously trying to minimize adverse effects, including mitigation of the risk of addiction from the use of opioids, both in the ED and upon ED discharge.

Prevalence and Assessment of Pain in the ED

Pain is one of the most common reasons for patients to come to the ED.[2] The prevalence of pain among ED patients is approximately 45% based on cross-sectional data from the National Hospital Ambulatory Medical Care Survey, though the percentage of patients reporting severe pain increased from 25% in 2003 to 40% in 2008.[3]

Since the ED serves as a fail-safe mechanism for our fragmented healthcare system, chronic pain patients also present to the ED with acute exacerbations of their chronic pain. Extrapolating the results of a national telephone survey of 500 patients suggests that 34 million adults with chronic or recurrent pain visit the ED at least once every two years. Of this group, 43%, or 15 million, experience recurrent pain, while 57%, or 19 million, have underlying chronic pain syndromes.[4] The number of chronic pain patients visiting the ED has likely increased because some patients have had their opioid prescriptions suddenly reduced because of physicians' responses to the opioid epidemic.

Notwithstanding the issue of providing compassionate care, pain that is not acknowledged and managed appropriately can cause anxiety, depression, sleep disturbances, increased oxygen demands with the potential for end-organ ischemia, and even decreased movement, which can lead to an increased risk of venous thrombosis.[5] Failure to recognize and treat pain may also result in dissatisfaction with medical care, hostility toward medical staff, unscheduled return visits to the ED, delayed return to full function, and an increased risk of litigation.[6]

Pain is inherently subjective and inevitably complex, with each patient experiencing pain and suffering as an individual. As physicians, we assess our patients' pain indirectly and sometimes with skepticism. The validity of patient self-reports is often questioned and attempts to "objectify" the pain experience are sought, but no such biomarkers exist. In contrast, patients themselves, especially older adults, may be reluctant to report pain presence and intensity. This may result from low expectations of obtaining pain relief, fear of analgesic side effects, and a notion that pain is to be expected as part of the underlying disease or from medical treatments. In addition, some patients have a fear of addiction when prescribed opioids or fear the stigma associated with opioid use, including from a single dose of intravenous opioids for acute severe pain in the ED.

Pain assessment can be difficult in the ED, where time frames are often compressed, and therefore simpler assessment tools are generally preferred. Although far from perfect, the two most commonly used are the 11 point verbal numeric rating scale, in which pain is rated on a scale of 0 (no pain) to 10 (worst possible pain), and the verbal descriptor scale, in which pain is categorized as none, mild, moderate, and severe. These scales are also preferred by cognitively intact elderly ED patients.[7] No matter the specific pain scale used, assessments should be repeated after therapeutic interventions. Simply asking the patient the question, "Do you want more pain medication?" may be an alternative way of judging whether adequate pain relief has been obtained since individual patients have different thresholds of acceptable pain and may balance pain severity against side effects, such as nausea and sleepiness.[8] A non-numeric yes or no question may also be easier to comprehend among mildly confused patients, older adults, and those distracted by the severity of their pain.[8]

The Problem of Balancing Undertreatment of Pain and the Risk of Addiction

In 1989, Wilson and Pendleton coined the term "oligoanalgesia" in ED patients after performing a chart review of 200 ED patients.[9] This and subsequent studies found that analgesics were underused in the treatment of pain in ED patients in a significant proportion of patients.[10–12] A few years later, pain became known as the "fifth vital sign,"[13] and relieving pain became a national priority adopted by various societies, including The Joint Commission, the Institute of Medicine, and the now defunct American

Pain Society. As a result of these and other efforts, the amount of prescription opioids prescribed and sold in the United States quadrupled from 1999–2010.[14] Not surprisingly, the number of opioid overdose deaths also quadrupled.[14] Something had to be done though in some ways the pendulum may be swinging back too far to the other side, an example of which is the abandonment of some chronic pain patients.[15]

Although some patients may decline opioid analgesics because of concerns about addiction, the ED is also frequently targeted by patients addicted to opioids. Professional discussions of pain in the ED often center on concerns of being duped by patients who fabricate symptoms to obtain opioids, so-called drug-seeking behavior. Strategies to help with chronic pain patients demanding opioids in the ED are listed in Box 76.1.

Emergency physicians frequently struggle to balance appropriate relief of acute severe pain and prevent addiction to opioids. In managing pain complaints, emergency physicians are responsible for beneficence and nonmaleficence. They must treat pain and ameliorate suffering while minimizing the extent to which their decisions enable substance abuse and increase the supply of prescription opioids available for abuse by the general public. Fortunately, certain tools, such as online state prescription monitoring programs, can aid emergency physicians in differentiating appropriate and problematic requests for opioid analgesics.[16]

Pain Treatment

Effective pain management involves both pharmacologic and nonpharmacologic modalities. A recent systematic review on acute pain was published by the Agency for Healthcare Research and Quality.[17] Simply asking about pain and validating patients' reports of pain has a potent effect on patients' satisfaction with ED pain management. In one study, patient satisfaction with pain management was predicted more strongly by the perception that ED staff asked about pain than the actual administration of an analgesic.[18] Other modalities such as reassuring the patient that pain will be addressed, immobilizing and elevating injured extremities, and providing quiet, darkened rooms for patients with migraine headaches are essential aspects of quality pain management that can result in decreased amounts and use of opioids.

Analgesics may be administered by various routes. However, most analgesics are administered in the ED either orally or parenterally. Oral therapies are most commonly used in less severe cases because they are convenient and inexpensive for patients who can tolerate oral intake. When pain is severe, analgesics need to be given more urgently and ideally titrated to effect. The intravenous (IV) rather than intramuscular (IM) route is preferred in the ED setting. IM injections are painful, do not allow for titration, have unpredictable absorption, and can result in a slow onset of analgesic effect. Unless IV access is elusive, there are few situations to recommend the IM route. More recently, alternative delivery routes for the administration of pain medications have been described in the ED setting, including nebulized[19] and intranasal[20] fentanyl.

In general, it is inappropriate to delay analgesic use until a diagnosis has been made. In the case of acute abdominal pain, a large number of studies find no deleterious effect of intravenous opioid therapy on the ability of clinicians to make appropriate diagnoses.[21]

• Box 76.1 Strategies for the Chronic Pain Patient in the Emergency Department

- Validate patient's pain and frustration/fear/other emotions: "I know that you're in pain and you're worried."
- Set clear limits when responding to requests for intravenous (IV) opioids that are not indicated: "Our standard for all patients is to not give IV medication for people who are able to take pills. Oral pain medication will give you more steady pain control, and IV pain medication will wear off sooner."
- For patients who state that only IV opioid works: "I'm really sorry you feel that way. This sounds like it is terrible for you. I understand how it must be frustrating to understand why we are saying no to more opioids, but we care about your safety. I know there are ways we can work together so that you feel better."
- Do not abandon the patient but commit to treating with non-opioid measures: "I believe that you have pain, and I want to continue to work with you to treat the pain with other approaches."
- Use risk/benefit language: "The risks of these opioids are higher than the benefits for you."
- Be empathetic when it is time to deny or stop opioids: "This must be very difficult for you. Medical research does not support this type of pain medication, and it is simply not safe for you in the long run." "It may seem in the short run that opioids help, but they are not the best approach and can make your pain and problems worse over time."

Specific Treatment Modalities

A wide variety of analgesics are used in emergency medicine practice. In a 20 ED site survey, a total of 735 doses of 24 different analgesics were administered to 506 patients receiving analgesics while in the ED. The majority of analgesics administered were opioids (59%), with morphine being the most commonly used analgesic (20%), followed by ibuprofen (17%).21 Since the publication of this study in 2007, however, policy changes have been instituted in an attempt to de-emphasize the use of opioids in response to the opioid epidemic. The rescheduling of hydrocodone from Schedule III to Schedule II, which prevented refills and required a hardcopy prescription, is just one example.[22]

Non-opioids

Non-opioids include acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and salicylates. In general, non-opioid agents exhibit an analgesic ceiling effect and cannot be titrated to effect. This limits their usefulness in the setting of severe or fluctuating pain; however, they can be considered as adjunctive therapy to opioids or combined in place of opioid therapy.[23]

Acetaminophen is indicated for mild to moderate pain and is often combined with opioid agents. Acetaminophen, unlike NSAIDs, has no antiplatelet activity or anti-inflammatory effect. Although a great deal of attention has been paid to acetaminophen hepatotoxicity, especially in the setting of chronic malnutrition, alcoholism, or liver disease, such concerns are generally not applicable in the ED setting where single or limited dosing is the general practice.

NSAIDs, including salicylates, inhibit prostaglandin synthesis by interfering with cyclooxygenase (COX) enzymes. Unlike acetaminophen, they also have an anti-inflammatory effect and are generally thought to be more potent than acetaminophen in their analgesic effect. However, they have more relevant adverse effects, including platelet dysfunction, increased risk of gastrointestinal bleeding, and increased risk of renal injury. Although NSAIDs are included in the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults,[24] most experts agree that single dose

use in the ED and/or short-term use after ED discharge is generally thought to be safe even in this population. Thus NSAIDs represent an important non-opioid analgesic in the ED setting.

Combination non-opioids, such as ibuprofen and acetaminophen, have also been studied in the ED. In one study of 416 non-elderly adult ED patients presenting with acute extremity injury requiring imaging, patients were randomized to receive one of four analgesics: oxycodone/acetaminophen, hydrocodone/acetaminophen, codeine/acetaminophen, or ibuprofen/acetaminophen. Pain scores were assessed at baseline, 1 and 2 h. There was no difference in improvement in pain scores among the four groups. There was also no difference in a subanalysis of patients who had documented fractures on radiographs and initial 10/10 pain score severity.[25] This suggests that combination non-opioids are a reasonable alternative to managing the pain from acute extremity injuries in most patients seen in the ED. However, patients should be informed that 4 grams is the daily maximum recommended amount of acetaminophen per day, with the makers of Tylenol recommending an even lower dose of 3 grams per day. Since the natural history of extremity injuries is to improve with immobilization and rest, it makes intuitive sense that the same non-opioid combination analgesics would also provide pain relief on par to opioids upon ED discharge. Since some patients who are prescribed an opioid will become addicted to an opioid, if emergency physicians can decrease the number of patients exposed to an opioid by using an alternative treatment such as that described above, then the number of people becoming addicted to prescription opioids should decrease. It is also important to remember that just because something might be generally true does not mean it applies to every patient. In other words, the lack of a difference in the four groups of the study mentioned above is on average, meaning that an individual patient might receive better pain relief with a particular analgesic, including an opioid.

Sub-Dissociative Ketamine

Several recent ED-based studies suggest a role of IV ketamine (a non-opioid) given in sub-dissociative doses (0.1–0.3 mg/kg over 10-15 min) either alone or as an adjunct to other analgesics in the management of acute pain.[26,27] However, patients can develop feelings of unreality and disorientation, although emergent reactions are rare.

IV Lidocaine

IV lidocaine has been shown to have efficacy in central pain syndromes and neuropathic pain, as well as opioid-sparing effects in the postoperative setting.[28] However, its use in the ED is not well defined primarily because of a lack of high quality studies.[29]

Opioids

Opioid combination analgesics are commonly used for moderate to severe pain in the ED. Although the opioid component in these agents does not exhibit ceiling analgesic effects, the non-opioid component dose is limited; thus one cannot titrate these analgesics. The convenience of combination therapy must be balanced against this limitation. Hydrocodone and oxycodone combination oral agents are most commonly used in the ED. Codeine is less commonly used because of the perception of less analgesic effect and concerns of variable metabolism, with some being poor metabolizers (and hence have little analgesic effect) and others hypermetabolizers (risking opioid overdose and respiratory depression).

If a patient's level of pain has been deemed severe enough to require an opioid upon ED discharge, it does not matter which one is chosen based on a series of ED studies that compared three commonly prescribed opioids (oxycodone/acetaminophen, hydrocodone/acetaminophen, and codeine/acetaminophen) against each other and found no clinically or statistically significant differences among them.[30–32]

Tramadol is also sometimes used in the ED because of its perception of having a decreased potential for abuse and respiratory depression. It is important to understand that although the risk may be less than that of traditional opioids, there remains a real risk for addiction. Its mechanism of action is unclear, with the tramadol component binding weakly to opioid receptors and inhibiting the reuptake of both norepinephrine and serotonin. One recent study using data from the Drug Abuse Warning Network concluded that tramadol combined with other drugs that depress the central nervous system (e.g. alcohol, benzodiazepines, other opioids) can enhance the sedative effects of tramadol, and caution should be exercised, especially in older adults.[33]

Opioids remain the mainstay of ED treatment for severe pain, and intravenous (IV) morphine is the standard treatment. Morphine 0.1 mg/kg as an initial bolus has been found to be safe but may not be adequate to effect pain relief.[34] If contraindicated because of allergy or other sensitivity, IV hydromorphone or IV fentanyl may be substituted for IV morphine. These opioids can be rapidly titrated to control severe pain. IV fentanyl has the advantage of being relatively short acting and is preferred in the setting of multiple trauma, head injury, and potential hemodynamic instability.

Hydromorphone is a potent opioid that has also been studied in the ED setting. The "1+1" hydromorphone rapid titration protocol administers 1 mg IV hydromorphone followed by an optional second 1 mg IV dose 15 min later based on patients' response to the question, "Do you want more pain medication?" In one study, this protocol provided adequate analgesia for 77% of patients within 15 min and 96% of ED patients within 1 h.[35] In an ED randomized clinical trial comparing the "1+1" hydromorphone protocol against usual care, in which the usual care group received an IV opioid, the "1+1" protocol was found to be statistically superior and at least as clinically efficacious and safe as traditional physician-driven treatment, with nine out of ten patients receiving satisfactory pain control within 1 h.[36] These same researchers then developed the "half and half" hydromorphone protocol for older adults (0.5 mg IV hydromorphone followed by an optional second dose of 0.5 mg IV hydromorphone based on response to the question, "Do you want more pain medication?") and demonstrated comparable pain relief to usual care but with lower mean initial doses of opioids at baseline and lower total opioids at 1 h.[37]

Most EDs have eliminated the use of meperidine because of its metabolism to normeperidine, a toxic metabolite causing central excitation and seizures, and its contraindication in patients taking monoamine oxidase inhibitors. The availability of other opioid agents of equal efficacy with fewer contraindications and fewer adverse effects argues against its continued use.

There is a current opioid epidemic in the United States, with Americans consuming 99% of the world's hydrocodone and 80% of the world's oxycodone. Therefore efforts to decrease the prescribing of opioids have become increasingly common, including the Centers for Disease Control (CDC) guidelines for Prescribing

Opioids for Chronic Pain published in 2016.[38] As the title of the publication states, the guidelines were mainly intended for patients with chronic pain; however, one of the 12 guidelines was relevant to acute pain and emergency medicine: "When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed." A recent survey of emergency physicians suggested that 12 tablets represents a 3 day supply while 28 tablets represents a 7 day supply for both younger adults and the elderly.[39]

Recent studies suggest that the contribution of emergency medicine to the opioid epidemic is limited, with emergency medicine accounting for only 4% of opioid prescriptions in 2012 in the United States.[40] Nevertheless, EDs had already begun to decrease their opioid prescribing, and various local and state guidelines were published prior to the release of the CDC guidelines. An example is the New York City ED Discharge Opioid Prescribing Guidelines that was released in early 2013.[41] This guideline gave nine recommendations for the management of patients with acute or chronic non-cancer pain discharged from an ED (Box 76.2). As of 2017, 17 states had ED opioid prescribing guidelines, with 67 recommendations around limiting prescriptions for opioids.[42]

•Box 76.2 New York City Emergency Department Discharge Opioid Prescribing Guidelines in the Management of Patients With Acute or Chronic Non-Cancer Pain (https://www1.nyc.gov/assets/doh/downloads/pdf/basas/opioid-prescribing-guidelines.pdf)

1. Short acting opioid for acute pain only when the severity of pain is reasonably assumed to warrant their use
2. Start with the lowest possible effective dose
3. Prescribe no more than a short course for acute pain. Most patients require no more than three days.
4. Assess for opioid misuse or addiction using targeted history, validated screening tools, and prescription data monitoring programs
5. Avoid initiating treatment with long-acting or extended release opioid analgesics
6. Address exacerbations of chronic or recurrent pain conditions with non-opioid analgesics, nonpharmacologic therapies, and/or referral to specialists for follow up, all as clinically appropriate
7. Avoid when possible prescribing opioids to patients currently taking benzodiazepines and/or other opioids.
8. Attempt to confirm with treating physician the validity of lost, stolen, or destroyed prescriptions. If considered appropriate, replace the prescription only with a one to two day supply.
9. Provide information on the risks of overdose and dependence/addiction, safe storage, and proper disposal of unused medications.

TABLE 76.1 Nonpharmacologic Treatments in the ED

Physical (physical therapy, osteopathic manipulation, mobilization)
Direct (heat/ice, acupuncture, transcutaneous electrical nerve stimulation, deep breathing, ultrasound)
Indirect (music therapy, aromatherapy, hypnosis, guided imagery)
Psychosocial (cognitive behavioral therapy, verbal suggestion, family support)
Education (oral advice, pamphlet, video)

Patient-Controlled Analgesia

The use of patient-controlled analgesia (PCA) has been studied in the ED, though a recent pragmatic trial of 366 patients found no advantage over usual care.[43] Nonetheless, in the setting of high demands on nursing resources, PCAs could serve to ensure adequate pain treatment.

Adjunctive Therapies and Nonpharmacologic Treatments

Given the opioid epidemic, there has been a renewed interest in the use of non-opioid analgesic adjunctive therapies and nonpharmacologic treatments of pain in the ED and after ED discharge (Table 76.1). A recent meta-analysis of 56 studies of nonpharmacologic pain interventions found that most were often effective in reducing pain in the ED though most studies were small in number.[44]

Nerve blocks have been shown to provide localized pain relief, improved door-to-analgesic times, and lowered doses of analgesics. They can be used as a stand-alone treatment or as part of a multimodal analgesic regimen. Ultrasound-guided femoral nerve blocks in particular have been shown to provide adequate pain relief in patients presenting with an acute hip fracture.[45]

Medication Assisted Therapy (MAT) in the ED

Because the ED is the only access point for care for many people, there has been a focus to start initiating MAT in the ED. A 2015 randomized clinical trial found that buprenorphine initiation in the ED is feasible.[46] In a diverse group of opioid-dependent patients, ED-initiated buprenorphine with primary care office-based follow up for ongoing treatment resulted in 78% of individuals engaged in treatment at 30 days. This compares to 37% of those referred to treatment and 45% of those who received a brief intervention who were still engaged in treatment at 30 days.[46]

MAT in the ED setting is primarily in the form of administering and prescribing buprenorphine and/or buprenorphine/naloxone, the latter of which is known by the trade names Suboxone and Zubsolv. Other MAT therapies, such as extended-release injections of naltrexone, are not currently commonly used in the ED setting.

Conclusion

The pain seen in EDs is often more acute and severe than that seen in other medical settings. Therefore emergency physicians are challenged to provide adequate pain relief for a wide variety of conditions, many of which require the use of opioids, while minimizing the extent to which their decisions enable substance abuse and increase the supply of prescription opioids available for abuse the general public. Given the current and ongoing opioid epidemic, there has been a renewed interest in the use of non-opioid analgesic adjunctive therapies and non-pharmacologic treatments of pain in the ED and after ED discharge, though many of these studies are limited by small sizes. EDs are also beginning to treat opioid use disorder with medication assisted therapies, such as combination buprenorphine and naloxone.

Key Points

- Failure to recognize and treat pain may cause unnecessary increases in anxiety and delayed return to function among ED patients.
- Consider short acting opioid analgesic for the treatment of acute pain only when the severity of the pain is reasonably assumed to warrant their use and prescribe a short course as most patients require no more than three days.
- Non-opioid and nonpharmacologic management, such as nerve blocks, should be considered whenever possible. Decreasing exposure of patients to opioids will decrease the chance of patients subsequently becoming addicted to opioids.
- NSAIDs are relatively contraindicated in older adults, though they are not likely to cause harm if used judiciously for a short time (e.g. three days or less), ideally in conjunction with a proton pump inhibitor for gastrointestinal prophylaxis and after assuring that the patient does not have acute or chronic renal failure.

Management of Pain in Sickle Cell Disease

CARLTON D. DAMPIER

Sickle hemoglobin results from a replacement of glutamine with valine at the sixth amino acid position in the β-globin subunit. Molecules of this abnormal hemoglobin polymerize upon deoxygenation into long polymers that physically deform the erythrocyte into the characteristic sickle shape and ultimately obstruct blood flow.[1] This polymerization largely ceases when adult hemoglobin is present with sickle hemoglobin, the so-called sickle trait, or with high levels of fetal hemoglobin, resulting in relatively benign conditions. In contrast, this polymer formation is promoted to varying degrees by the co-occurrence of sickle hemoglobin with other inherited abnormal hemoglobin, such as hemoglobin C, D, E, or O^{arab}, or mutations that reduce the production of normal hemoglobin (thalassemia), resulting in sickling disorders of varying degrees of hemolytic severity.[2] Given the large phenotypic variability seen in this group of hemoglobin disorders, they collectively are often referred to as sickle cell disease (SCD).

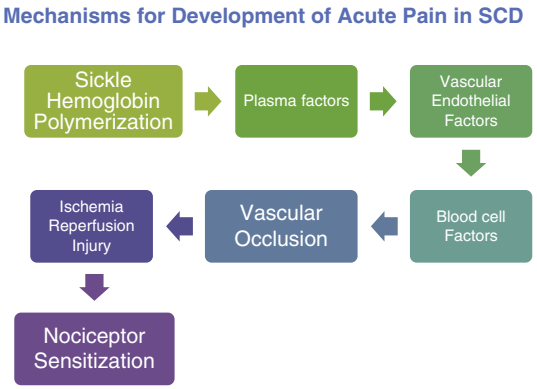
Recent whole genome sequencing suggests that the sickle mutation arose over 7,000 years ago, either in the Sahara or in west-central Africa.[3] Its prevalence was maintained and expanded in these areas by reproductive advantage as sickle trait provided some degree of protection from severe malaria.[4] Thus most of the 100,000 to 150,000 individuals with SCD in the United States trace their ethnic origins to Africa, the Middle East, or the Mediterranean where malaria was endemic; the slave trade to the Caribbean and South America also led to the spread of the sickle mutation to many individuals of Hispanic ethnicity.[5]

The pathophysiology of vaso-occlusive pain in SCD is quite complex (Fig. 77.1). Once deoxygenated, sickle hemoglobin undergoes a polymerization process that ultimately deforms the erythrocyte into the characteristic sickle shape. If the time required to complete this process, the "delay time," is longer than the time required for these erythrocytes to reach larger venous vessels, then vaso-occlusion will not occur.[6] Factors that slow the transit time of erythrocytes through the microcirculation will enhance the likelihood of vaso-occlusion, including changes in vascular tone and adhesion of erythrocytes, and other cellular elements, including leukocytes and platelets, to vascular endothelium altered by chronic hemolysis.[7] As part of this "vicious cycle" of sickling, the subsequent ischemic/reperfusion injury from initial vaso-occlusion results in the accumulation of endogenous mediators released from cells that reside within or infiltrate into the injured area (including mast cells, basophils, platelets, macrophages, neutrophils, endothelial cells, keratinocytes, and fibroblasts).[8] Collectively, these inflammatory mediators represent a wide array of signaling molecules, including neurotransmitters, peptides, eicosanoids, and related lipids, cytokines, and chemokines, which damage local nociceptive nerves leading to increased spontaneous firing that is perceived as acute pain.[9]

Although considerable further research is needed to confirm this process, the intense and repetitive nature of vaso-occlusive events and resulting chronic tissue/bone damage likely drive the development of chronic pain in adolescents and adults with SCD,[10] (Fig. 77.2) likely through a process termed *central sensitization,* which represents an activity- or use-dependent form of functional synaptic plasticity that can occur after intense, repetitive noxious stimuli.[11] Central sensitization with its augmented pain response and a symptom cluster denoting sleep difficulties, pain, affect, cognitive difficulties, and fatigue occurs by complex processes that change the response elicited by normal sensory inputs, including those that usually evoke innocuous sensations, resulting in the sensation of persistent pain.[12] Further changes in the pain experienced in chronic pain disorders occur because of anatomic and functional connectivity changes in various brain regions.[13]

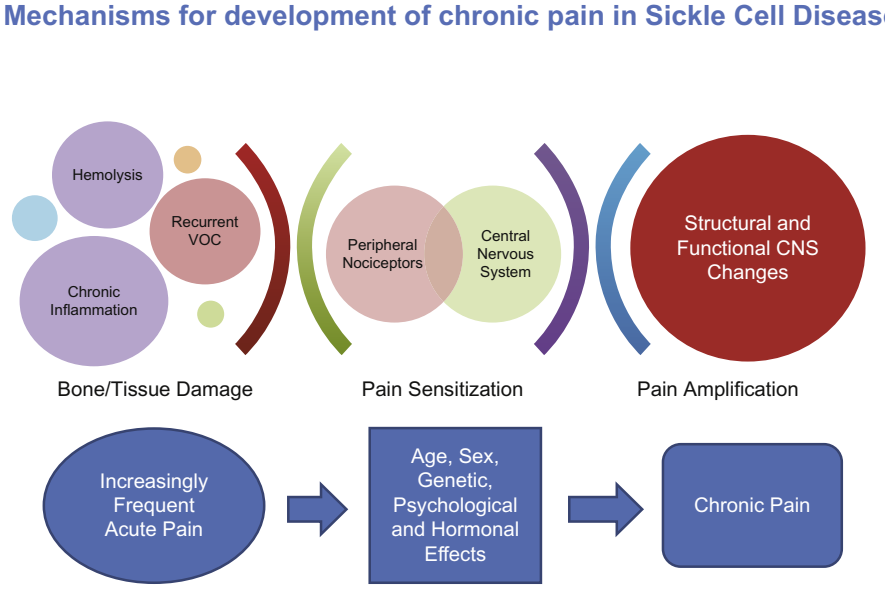
Epidemiology of Vaso-occlusive Pain

SCD is a relatively unique pain disorder, as pain can begin early in the first year of life as levels of fetal hemoglobin decline in susceptible individuals.[14] Most children reported to have pain in the first year of life have pain locations (hands/feet) and signs/symptoms (swelling or tenderness) consistent with dactylitis, often referred to as "hand-foot syndrome," which becomes progressively less prevalent in older children and rare after five to seven years of age.[15] Almost all children with SCD experience increasingly frequent pain throughout childhood and into adolescence and young adulthood.[16] However, most of these painful episodes are managed at home rather than in acute care settings.[17] Most episodes are relatively brief, typically two to three days, with the pain of moderate intensity located in a small number of body sites, usually the lower legs, back, and chest wall, with pain intensities often peaking in the late evening.[18,19] Some studies have suggested environmental triggers for these painful episodes, such as changes in weather,[20] or air quality,[21] while others have highlighted the role of stress,[22] potentially mediated by changes in vascular tone.[23]



• **Figure 77.1** Mechanisms for the development of acute pain in sickle cell disease.

young adults can experience acute left-upper-quadrant visceral pain from rapid enlargement of the splenic capsule consistent with acute splenic sequestration, an often life-threatening trapping of sickled erythrocytes and platelets in the spleen.[33] Almost all children with SCD will experience episodic right-upper-quadrant colicky abdominal pain and jaundice from cholelithiasis or bile duct obstruction and ultimately require cholecystectomy,[34] as chronic hemolysis results in bilirubin accumulation in the gallbladder and the subsequent production of pigment stones. Avascular necrosis in the vertebral column, shoulder, or hips can be a source of acute pain as well as chronic pain in adolescent and young adult patients,[35] who often respond to physical therapy for initial symptom management of hip pain; some patients, however, have progressive collapse, particularly in the head of the femur, that will ultimately require joint replacement for relief



• **Figure 77.2** Mechanisms for the development of chronic pain in SCD. *CNS*, Central nervous system; *SCD*, sickle cell disease; *VOC*, vaso-occlusive crisis.

A small number of children transition, often in their early adolescent years, from a pattern of sporadic episodes of brief acute pain to frequent, recurrent, acute pain with or without chronic pain. These individuals represent the majority of pediatric patients hospitalized for acute pain.[24] Pain is a more complex experience in adults with SCD, with features of both acute recurrent and chronic pain,[25,26] and is more often managed in an acute care setting compared to pain in children.[27] Sociodemographic, family, and disease characteristics and mental health issues are often comorbidities contributing to frequent healthcare utilization in SCD adults with hronic pain.[28,29] Detailed taxonomies describing acute pain,[30] and chronic pain in SCD have been recently published.[31]

Other Pain Etiologies in Sickle Cell Disease

Vaso-occlusive pain in SCD remains a clinical diagnosis as laboratory and imaging studies largely show non-specific increases in inflammatory markers and increased hemolysis.[32] Other pain syndromes distinct from vaso-occlusive episodes are not uncommon and always need to be considered when evaluating an individual with SCD and pain (Table 77.1). Children and, occasionally, of chronic pain or to improve physical functioning.[36] Although uncommon in the pediatric age group, leg ulcers, typically over the medial malleolus of either or both ankles, can be a source of considerable pain and disability, and are challenging to manage.[37] Headaches, as an isolated pain syndrome or as part of a vaso-occlusive event, can occur but are not well characterized.[38] Some have features characteristic of migraine headaches, others may be more typical of tension-type headaches, and a small number of individuals satisfy current diagnostic criteria for chronic daily headaches. The use of the triptan class of medications to treat migraine-like headaches in SCD individuals is contraindicated because of cardiovascular concerns.

Sickle Cell Disease Pain Management

Education Is the Foundation

A lifespan approach is most applicable for these sickling disorders, as pain will likely be experienced throughout childhood and adult life. A focus on the family is essential for children,[39,40] whereas adolescents must be encouraged and supported to accept progressively

TABLE 77.1 Pain Syndromes in Sickle Cell Disease Not Directly Involving Vaso-occlusion

Pain Syndrome	Typical Locations	Pain Characteristics
Acute splenic sequestration	Spleen	Acute visceral pain related to stretch of the splenic capsule from splenic enlargement
Splenic infarction	Spleen	Acute visceral pain from splenic infarction involving splenic tissue extending to splenic capsule
Acute bone infarction	Ribs, sternum, or long bones	Acute pain from necrosis of bone marrow
Avascular necrosis	Hips, shoulders, or vertebrae	Acute and chronic pain from progressive collapse of bone cortex related to persistent vascular compromise
Osteomyelitis	Any bone	Acute and chronic pain from bacterial infection of bone cortex or marrow, often related to chronic ischemia
Acute cholelithiasis	Gallbladder	Acute visceral pain from irritation or common bile duct obstruction by pigment gallstones
Leg ulcers	Medial or lateral ankles	Acute and chronic pain from ischemic damage to the skin and underlying soft tissue
Headache	Head	Acute or chronic headache pain with or without migrainous aura or characteristics

more responsibility for their own pain management so they can function appropriately in the adult healthcare system. Thus initial disease and pain management education involves parents and other caregivers for young children and broadens to include the school system in older children; finally, organized transition programs starting in early adolescence focus on self-management skill education.[41] Self-management skill development should include learning psychological approaches to pain management,[42] similar to other pediatric chronic pain disorders for which one meta-analysis indicated the superiority of cognitive behavioral interventions (multicomponent, relaxation, and biofeedback approaches) for pain management.[43]

Home Management: "It Takes a Village"

Several studies in children[44] and adults[25] suggest the preference to manage vaso-occlusive pain at home. The home setting is likely to be more comfortable for children and less disruptive to the families' normal activities and routines. Surprising to most healthcare providers, many SCD individuals avoid care in acute care settings, as they frequently encounter negative attitudes toward patients with SCD,[45] and a pervasive fear among healthcare providers of catering to opioid addiction, which often compromises analgesic therapy.[46] Successful home management requires a parent or other caregiver skilled in pain assessment and administration of appropriate analgesic medications. Extended family also is critical for psychological and physical support, as most pain episodes may last for several days and usually require around-the-clock medication for adequate management.[44] Support by trusted medical health professionals with experience in SCD and pain management also facilitates home management and appropriate emergency department utilization.[47]

Utilization of a biopsychosocial approach to pain management can be facilitated by engaging local complementary and alternative medicine practitioners and mental health professionals.[48] Reductions in post-procedure pain intensity scores suggest that acupuncture can be an effective adjuvant strategy for pain management in SCD.[49,50] Cognitive behavior[51,52] and mindfulness-based interventions have been evaluated in adolescents and adults.[53] In addition, guided imagery has been successfully used with younger children.[54] Clergy can also be helpful as several studies of caregivers of children with SCD have found that a large percentage of families use prayer and spiritual healing, in addition to medication to manage their child's pain at home.[55,56] Several eHealth and smartphone apps have also been developed to facilitate home pain management.[57–59]

Low potency analgesics, such as acetaminophen and ibuprofen, are recommended as initial therapy at the onset of typical vaso-occlusive pain and are often adequate for mild to moderate pain, particularly in younger children. These analgesics are often chosen out of concern for the adverse consequences of opioid analgesics and have the advantage of less sedation and subsequent disruption of age-appropriate activities. A substantial number of oral hydrocodone and oxycodone analgesics of varying potency, often in combination with acetaminophen, are available in liquid and tablet formulations for the management of more intense pain in children with SCD. Some shift away from the use of codeine containing analgesics because of pharmacogenetic issues of excessive toxicity or inadequate efficacy.[60] Although labeled dose amounts and frequency of potent oral opioid analgesics are usually prescribed, the enhanced hepatic and renal clearance of morphine in the SCD population,[61,62] and the potential impact of prevalent pharmacogenetic genotypes impacting morphine metabolism suggests that the dose and frequency of these opioids may need to be further individualized.[63] Increasing frequency of vaso-occlusive pain episodes is associated with increasing numbers of opioid prescriptions,[64,65] raising fears of opioid misuse in this population.[66] However, a review of death records shows no increase in opioid-related deaths in the sickle cell disease population during the current opioid epidemic.[67]

There have been few comparative studies of adjunctive non-opioid analgesic medications in this population. A study using pharmacy claims data suggested that pharmacologic treatments for sickle pain consisted mainly of NSAIDs and weak opioids.[68] Significantly more severe SCD patients, those with more than three yearly inpatient or emergency department (ED) visits for pain management, were prescribed more potent opioids, anti-depressants, or anti-convulsants. Prescription of both stronger opioids and anti-depressants or anti-convulsants were significantly associated with lower frequencies of acute sickle pain visits. Similarly, pregabalin provided some sustained reductions in pain intensity over a three month period in a small pilot study.[69] Further clinical trial data are needed in SCD individuals to support these observations and to establish comparative efficacy and safety data for various analgesic and anti-convulsant or anti-depressant combinations, particularly given increasing concern for neuropathic-like pain characteristics, particularly in adults.[70,71]

Management of Sickle Cell Disease Pain in the Acute Care Setting

Several studies have sought to identify characteristics of acute care utilization for sickle pain. A multicenter study across four United States cities enrolled all adults with SCD living within 60 miles (96.6 km) of a study site.[27] Twenty-one percent of participants had no acute care visits in the first 12 months of follow up, while 54% of subjects with hemoglobin SS disease and 46% with hemoglobin SC disease had three or more acute visits. Predictors of higher rates of acute care utilization included being unemployed, having chronic pain, being on chronic transfusion therapy, having a history of stroke, and being on disability or Medicaid. Similar findings have been observed in programs with day hospital/infusion centers with higher utilization associated with indicators of greater illness severity, more aggressive treatment for SCD, higher baseline opioid doses, higher socioeconomic status, greater pain related anxiety, and a history of psychiatric treatment.[29] A recent systematic review also examined risk factors for acute care utilization by pediatric patients.[72]

Comprehensive sickle pain treatment guidelines have been published by expert panels from both the National Institutes of Health[73] and the American Society of Hematology.[74] Early administration of opioid analgesics is recommended, and several ED analgesic protocols using intranasal analgesics have been developed to facilitate early analgesia.[75,76] An extensive learning collaborative model for the treatment of adults with acute sickle pain in emergency departments has been developed.[77] Implementation of this model has been shown to improve pain relief over the period of ED treatment.[78]

Intravenous doses of potent opioids, usually morphine or hydromorphone, are the typical initial treatment for vaso-occlusive pain in both adults and children, as all are assumed to have failed a course of oral analgesics at home prior to arrival in the ED. In some pediatric centers, intravenous nalbuphine is also used, as it is often associated with fewer complaints of nausea and pruritis,[79] but it is seldom used for SCD adults because it may precipitate opioid withdrawal symptoms in opioid tolerant individuals. Oral and subcutaneous routes of opioid administration are also an option for adults with limited intravenous access.[78] Administration of opioids by patient-controlled analgesia (PCA) devices is not a common practice in the ED, but where available, it allows more frequent dosing, which can be problematic in a busy ED.[80] The concurrent use of a parenteral NSAID, usually ketorolac, is a widespread clinical practice in the ED setting as an additional analgesic but are often reduced for renal insufficiency, which is not uncommon in adults with SCD.[81]

Sickle Cell Disease Pain Management in the Inpatient Setting

A snapshot of analgesic practice, across a large number of pediatric and adult hospitals that participated in an observational study of sickle pain management after hospitalization, documented the widespread use of opioid-based PCA.[82] Opioid doses varied over a wide range but appeared to be somewhat higher for individuals receiving PCA compared to scheduled opioid dosing, and for those receiving hydromorphone compared to morphine. A small clinical trial of opioid PCA dosing suggested that adult SCD individuals have a more rapid improvement in pain when using PCA largely delivered by continuous infusion rather than demand dosing, likely because individuals with severe pain had difficulty obtaining adequate pain relief with frequent demand doses early in the course of their hospitalization.[83] The importance of early analgesia is also supported by the observation that achieving an earlier maximum opioid dose was significantly associated with a shorter length of hospitalization for both frequent and infrequent pediatric sickle patients.[84]

Parenteral NSAIDs, usually ketorolac, are commonly used as an additional analgesic. Evidence of efficacy of other adjuvant analgesics for acute sickle pain is limited. Intravenous acetaminophen reduced pain intensity and provided some opioid-sparing effects in a recent single site study.[85] Refractory sickle pain that persists beyond three to five days can present a difficult management problem, particularly in adolescents and young adults. The use of concurrent low-dose ketamine infusions has been described for this situation in children,[86] and adults,[87] which were somewhat more effective in younger or males patients.[88] Use of intravenous lidocaine infusions have also been described,[89] but further research and clinical experience are needed.

Nausea, pruritus, and constipation are common opioid-related adverse effects during treatment for vaso-occlusive episodes[83] and require symptomatic management during the course of hospitalization, with constipation often being quite problematic.[90] The use of concurrent administration of low doses of an opioid antagonist (naloxone) has been shown in several small pediatric cohorts to ameliorate many central nervous systems (CNS) opioid-related symptoms without altering analgesia,[91,92] and it may be of particular importance in SCD where respiratory depression may increase the risk for symptomatic hypoxia and SCD pulmonary complications, such as acute chest syndrome. Common opioid-related adverse effects of nausea and constipation can be ameliorated by peripherally acting peripherally acting opioid antagonists,[93] but they have not been studied in SCD. Similar to its use for other critically ill patients,[94] transdermal or oral clonidine, an α2-adrenergic agonist, is often used in SCD adolescents and adults with prolonged hospitalizations and opioid exposure to reduce symptoms of opioid withdrawal after discharge, which otherwise might result in a subsequent readmission.

The use of nonpharmacologic techniques has been challenging in the inpatient setting, but a recent trial of an adapted yoga program has been piloted,[95] and approaches using virtual reality are encouraging.[96]

Management of Perioperative Pain in Sickle Cell Disease

Preoperative management of individuals with SCD relies on adequate, usually overnight, intravenous hydration and red blood cell transfusion if the hemoglobin is less than 10 grams/dL.[97] In some low-risk surgeries, transfusion may not be necessary, and in some high-risk surgeries, individuals with higher hemoglobin levels may require exchange transfusion.[98] Intraoperative management focuses on the prevention of sickling by maintaining adequate hydration, oxygenation, and ambient temperature. Effective pain control is a primary goal in the perioperative management of patients with SCD and may require additional analgesics compared to that used to treat other patients. For example, postoperative pain scores after laparoscopic cholecystectomy, one of the most common surgeries in SCD, were higher in SCD patients than in controls, and morphine consumption was more than double that compared to control children, as was the duration of PCA use.[99] SCD children also had a longer duration of postoperative hospital stay (3.4 ± 1.6 days versus 1.5 ± 0.5 days). These differences likely reflect alterations in pain perception from frequent vaso-occlusive episodes,[100] enhanced clearance of opioids,[62] and psychosocial variables.[101]

Management of Chronic Pain in Sickle Cell Disease: Largely Uncharted Territory

Chronic SCD pain has been defined as ongoing pain that was present, in one or more locations, on most days for more than six months.[31] Three subtypes of chronic SCD pain were proposed based on the presence or absence of either clinical signs or test results: (1) chronic SCD pain without contributory SCD complications, (2) chronic SCD pain with contributory SCD complications, and (3) chronic SCD pain with mixed pain types, if contributory SCD complications and pain are occurring in unrelated sites. The process for transition to chronic pain in pediatric SCD has been evaluated in a modest sized cohort follow up study.[102] Most participants who transitioned to chronic pain (80%) had episodic pain at baseline, suggesting a role for frequent and high pain intensity as suggested for several other chronic pain disorders.[103] Baseline psychosocial factors (i.e. higher functional disability, greater depressive symptoms, higher pain catastrophizing, and lower quality of life) were significantly associated with chronic pain at follow up, similar to other chronic pain syndromes.[104]

Data on the management of chronic daily sickle pain, which is likely prevalent in adolescents and young adults and associated with considerable disability,[26] is limited to a few case series or clinical trials. Currently, chronic pain management in SCD has largely relied on the use of long-acting opioid preparations,[16] or methadone,[105] sometimes using very large daily doses and putting these individuals at risk for opioid tolerance and opioid-induced hyperalgesia. Studies focusing on the U.S. population suggest that daily opioid usage is more frequent in individuals with comorbid psychological and psychiatric disorders,[106] and clinical experience suggests similar findings in the SCD population.[107] SCD chronic pain management strategies may benefit from extrapolations from other chronic pain syndromes where anti-depressants and anti-convulsants have proven track records of efficacy,[108] but further research and clinical experience are again needed before definitive treatment recommendations can be made. Adolescents and young adults with SCD who started on daily opioids should also receive concurrent psychosocial and psychiatric support, given the negative role that emotional, social, and psychiatric issues play in an individual's pain experience.[109] For example, establishing cognitive behavioral therapy care is associated with reductions in admissions for pain and length of stay for youth with chronic SCD pain, which may be partially supported by patient-reported improvements in functioning, coping, and lower pain intensity following CBT.[52]

An overview of the management of SCD is in Box 77.1.

• BOX 77.1 Management of Patients With Sickle Cell Disease

- Education
  - Self-management skill development
  - Cognitive behavioral interventions: multicomponent, relaxation, biofeedback
- Home care management
  - Parent or other caregiver trained in pain management
  - Psychological support from extended family
  - Timely emergency department utilization
- Analgesics
  - Low potency analgesics (acetaminophen, ibuprofen)
  - Oral hydrocodone
  - Non-opioids: nonsteroidal anti-inflammatory drugs (NSAIDs), pregabalin
- Acute care
  - Intravenous (IV) morphine, hydrocodone
  - IV Patient-controlled analgesia (PCA)
  - Parenteral NSAID (caution in patients with renal insufficiency)
- Inpatient setting
  - IV PCA with opioid
  - Parenteral NSAID
  - Ketamine infusion
  - Lidocaine infusion
  - Low-does naloxone (treatment of opioid adverse events)
  - Transdermal/oral clonidine
- Perioperative care
  - Preop IV hydration, blood transfusion per shared decision making of surgical team and patient
  - Intraoperative and postoperative: adequate hydration, oxygenation, ambient temperature, adequate pain control
- Chronic pain management
  - Long term opioid, e.g. methadone
  - Cognitive behavioral therapy
- Guidelines
  - National Institutes of Health[73]
  - American Society of Hematology[74]

Summary

SCD is unique as a lifelong pain disorder with features of acute recurrent pain in childhood that often transforms in adolescents or young adults into a chronic pain syndrome complicated by exacerbations of acute pain. Health providers and patients often have difficulty changing treatment goals and strategies during this transformation, which can be further complicated by transitioning from pediatric to adult healthcare systems. As with other chronic pain syndromes, mental health problems are frequent comorbidities; poverty and health disparities common in urban minority populations are additional challenges. Pain management optimally requires a multi-disciplinary team of hematologists, psychologists, physical therapists, alternative medicine practitioners, pain specialists, and addiction specialists. Further clinical collaborations are also important for expanding the evidence base for acute and chronic pain management in this population, which currently is distressingly limited. A further understanding of the pathophysiology of pain in this complex pain syndrome, likely driven by peripheral and central sensitization from repeated ischemic-reperfusion insults and chronic inflammation, could lead to the identification of new therapeutic targets and agents to ameliorate the pain and suffering currently experienced by individuals with SCD.

Key Points

- The pathophysiology of sickle vaso-occlusion in SCD involves intracellular polymer formation and related biochemical changes, a host of cellular interactions, and multiple inflammatory pathways, making the development of targeted therapeutics challenging.
- Pain from sickle vaso-occlusion likely represents acute nociceptor stimulation by inflammatory mediators from hypoxia and reperfusion injury, and peripheral and central sensitization from repeat episodes of severe pain.

- SCD is a relatively unique pain disorder, as pain can begin early in the first year of life, and almost all children with SCD experience increasingly frequent pain throughout childhood and into adolescence and young adulthood.
- Pain is a more complex experience in adults with SCD, with features of both acute recurrent and chronic pain.
- Mental health issues are often comorbidities contributing to frequent healthcare utilization in SCD adolescents and adults with chronic pain.
- Other pain syndromes distinct from vaso-occlusive episodes are not uncommon in children and adults with SCD, and they always need to be considered when evaluating an individual with SCD and pain.
- Low potency analgesics, such as acetaminophen and ibuprofen, are recommended as initial therapy at the onset of typical vaso-occlusive pain and are often adequate for mild to moderate pain, particularly in younger children. Oral hydrocodone and oxycodone analgesics, often in combination with acetaminophen, are available in liquid and tablet formulations for the management of more intense pain in children with SCD.
- Cognitive behavioral approaches—specifically deep breathing and progressive muscle relaxation, guided imagery, and calming self-talk—are effective psychological therapies for SCD pain in children and adolescents.
- Support by trusted medical health professionals with experience in SCD and pain management facilitates home management and appropriate ED utilization.
- Intravenous doses of potent opioids, usually morphine or hydromorphone, are the typical initial treatment for acute vaso-occlusive pain in both adults and children, as most have failed a course of oral analgesics at home prior to arrival in the ED.
- The concurrent use of a parenteral NSAID, usually ketorolac, is a widespread clinical practice in the ED setting as an additional analgesic, and it may have additional benefit as an anti-inflammatory agent.
- The efficacy of adjuvant analgesics for acute sickle pain has not been subjected to controlled trials, and refractory sickle pain is a difficult management problem, for which low-dose ketamine infusions are an encouraging therapeutic option for some patients.
- Chronic daily pain, which is likely prevalent in SCD adolescents and young adults, is largely managed with long-acting opioid preparations, but other analgesic and nonpharmacologic therapies are needed.
- Adolescents and young adults with SCD started on daily opioids should also receive concurrent psychosocial and psychiatric support and may benefit from anti-depressants and anti-convulsants, but further research and clinical experience are needed.

Burn Pain

JATIN JOSHI, MOHAMMAD PIRACHA, CHRISTOPHER L. WU

Introduction

The management of pain related to burns presents a clinical challenge for providers given the complex physiology of injury, chronicity of pain, and the related psychological effects. Despite the variability in etiology, pathophysiology, and severity of burn injuries, treatment options for pain remain largely uniform despite the type of injury. So called traditional analgesic agents, including opioids, have been and remain a mainstay for the treatment of different types of burn pain. However, adjuvant agents and nonpharmacologic techniques also play important roles in the management of burn pain. Ideal management of patients with burn related pain involves a comprehensive and multi-disciplinary approach that involves pain management, psychological support, and nonpharmacologic therapy.[1]

Chronic pain related to burn injury is highly relevant and is a significant challenge for burn survivors. In a survey of 336 burn patients, 52% reported ongoing pain with an average duration of 11 years after their injury. Of these respondents, 66% reported pain so severe that it interfered with rehabilitation, and 45% reported interference in their daily life.[2] Although past attempts have been made to manage the complex pain associated with burn injuries, evidence-based treatment regimens and algorithms for burn pain management remain limited.[3] Current practice standards for burn pain management are inadequate, inconsistent, and mostly unchanged in many centers for over two decades, with opioid- and benzodiazepine-based regimens as the mainstay of therapy in the acute setting. This chapter will highlight the epidemiology of burns, the pathophysiology of burn injuries and phases of recovery, and options for pain management, including pharmacologic and nonpharmacologic options.

Epidemiology

Burn injuries represent a major public health concern. They represent the fourth most common type of trauma after traffic injuries, falls, and interpersonal violence worldwide. In 2004, approximately 11 million people sought medical care for burn related injuries globally. In the United States alone, 486,000 people sought care for burn injuries in 2016. The majority of burns are minor, involving less than 10% of the total body surface area. In 2016, the American Burn Association (ABA) documented that 40,000 patients were hospitalized with a burn injury.[4]

The ABA 2019 National Burn Repository of patients admitted to burn centers in the United States (approximately 220,000 burn cases from 2009–2018) revealed that 60% of patients were Caucasian, 20.6% were Black, 9.5% were Hispanic, and 2.5% were Asian. Men constitute most burn patients, accounting for 62% of cases treated at burn centers in the United States. The distribution of burn injury is bimodal, with high prevalence in the adult (16 years of age and older) and pediatric (0 to 15.9 years old) groups. Though, the majority of burns (56%) occur between ages 20 and 60 years. The two most common causes of burns, fire/flame (37%) and scald (29%), make up 66% of all burn etiologies, followed by contact with hot objects (9.1%), electrical (3.6%), and chemical (3.5%) burns.[5] The age of the person correlates with the type of injury, with scald burns occurring more frequently in children and flame-related burns more common in adults.[6]

Significant advances have been made in public health efforts to mitigate burn related injury in high-income nations, such as smoke detector systems, flame-retardant children's sleepwear, industrial innovations to avoid fire, and improvements in clinical care. However, low- and middle-income countries have yet to fully benefit from such advances. The World Health Organization estimates that over 300,000 people die from fire-related burn injuries each year. Over 95% of fire-related burns are in low- and middle-income nations.[7] Deaths related to fire are highest in South-East Asia (11.6 per 100,000 population per year), the Eastern Mediterranean (6.4 per 100,000 population per year), and Africa (6.1 deaths per 100,000 population per year).[7] With only one death per 100,000 population per year in high-income nations, fire-related mortality represents one of the largest discrepancies for any injury etiology. Moreover, burns are a major contributor to disability and disfigurement across the world, with fire-related burns accounting for ten million disability adjusted life years lost globally each year.[8]

Pathophysiology

Based on the location and extent of the insult, burn injury is a traumatic event that may result in a systematic inflammatory response affecting all organ systems.[6] At the molecular level, there is a massive activation of inflammatory mediators, including histamine, prostaglandins, thromboxane, bradykinin, serotonin, catecholamines, platelet aggregation factor, angiotensin II, vasopressin, oxygen radicals (superoxide, hydrogen peroxide, hydroxyl ion), and corticotrophin-releasing factor. At the cellular-level protein denaturation and coagulation, surrounding tissue hypoperfusion, capillary vasoconstriction occurs, where there may be disruption to structures deep to the skin (e.g. dermal tissue, muscle). Local responses to burn trauma can develop into a systemic response that

manifests as myocardial dysfunction, increased systemic vascular resistance, increased pulmonary vascular resistance, increased pulmonary capillary wedge pressure, organ ischemia, peripheral capillary leak (causing interstitial and pulmonary edema secondary to hypoproteinemia), and temperature dysregulation (from loss of body heat and increased evaporative water loss). In severe cases, the result may be fatal as a consequence of infection, respiratory distress, shock, or multiple organ failure.[6]

Phases of Burn Recovery

The appearance, presence of pain, and healing times of the different burn depths are shown in Table 78.1. Recovery from burn injuries can be broadly divided into four phases.[9] The first phase is the initial evaluation and resuscitation that occurs over one to three days post-injury. This is when the patient often requires large volume fluid resuscitation. The second phase is when the burn wounds are excised and temporarily closed with autografting or allografting of skin to accelerate the natural healing process. This generally occurs over weeks to months, depending on the size of the burn injury. The third phase occurs with definitive wound closure and reconstruction. Finally, the final stage of recovery is rehabilitation and reconstruction, which eventually leads to discharge and reintegration into society.[10]

Types of Pain in Burn Patients

Acute post-burn injury pain can be extremely challenging to treat, often necessitating aggressive use of opioids for analgesia. Burn depth, total body surface area affected, mechanism of injury, and various patient factors play a significant role in acute burn pain. Differences in the mechanism of burn injury may also alter the severity and complexity of pain experienced. For example, pain from a partial thickness (second degree) burn results from loss of dermis and epidermis exposing raw nerve fibers. In contrast, nerves are also burned with the upper skin layers in full thickness (third degree) burns, resulting in lower levels of acute pain.[11] Pain from burns maybe both nociceptive and neuropathic in origin.[12] Pain in burn patients can be divided into four different categories, which may intensify as tissues heal:

1. *Rest pain* - constant lower grade background pain
2. *Breakthrough pain* - intermittent, short duration, rapid onset/offset, sometimes excruciating pain in those with already established baseline pain control[13]
3. *Procedural pain* - short duration, greatest intensity, occurring with certain activities (i.e. wound cleaning, debridement, dressing changes, joint range of motion exercises)
4. *Psychogenic pain* - anticipatory pain in the absence of mechanical stimulation

Pain Management Options

Current treatment of burn pain necessitates a multimodal approach to improve the likelihood of effective post-burn pain management, using both pharmacologic and nonpharmacologic methods. Many pharmacologic agents (Table 78.2) are available to manage the various types of pain related to burn injuries. Because these have been presented in greater detail elsewhere in this text, we will only provide a cursory review of the various agents in a context appropriate for burn pain management.

Pharmacologic Analgesia

Opioids

Opioids including morphine, hydromorphone, and fentanyl have been the cornerstone of effective burn pain management for decades. They are widely available, can be administered by a variety of routes (e.g. oral [PO], intravenous [IV], transdermal), are inexpensive, and have a relatively ubiquitous familiarity among healthcare providers. In experimental studies utilizing burn injury, opioids (μ-receptor agonists) have been shown to produce antinociceptive effects– although there may be reduced efficacy of morphine antinociception in chronic burn injury.[14,15] Opioid doses required by patients in the acute phase of burn injury to control pain may require adjustment based on the severity of burn injury. For example, in a study of IV-PCA usage of patients with burn injury, Lin et al. showed a positive correlation between the percentage of total body surface area burned and VAS to morphine consumption. They also showed a trend of reduced morphine use with burn injury improvement. Additionally, they cite that given the subjectivity of burn related pain, specific opiate dosing guidelines are difficult, reporting that average morphine equivalents administered to the patient can range from 55 mg to 120 mg per day, based on the severity of burn.[16]

An early negative consequence of (and possibly result from) this rapid and massive dose escalation is the development of acute opioid tolerance. A later consequence of this opioid escalation may be opioid-induced hyperalgesia. Longer acting opioids, such as methadone, may mitigate or even reverse this acute tolerance and hyperalgesia, as might using other non-opioid analgesics, including ketamine, dextromethorphan, and clonidine.

TABLE 78.1 Features of Burn Depths, an Association of Pain, and Approximate Healing Times

Burn Depth		Appearance	Blistering	Sensation	Healing Time
Epidermal		– Red	None	Painful	Seven days
Partial Thickness	Superficial	– Pink w/ wet appearance – Brisk cap-refill	(+)	Painful	14 days
	Deep	– Pale/fixed red staining – Poor cap-refill	(+/–)	Painful or painless	21 days (+/–) burn excision & skin grafting
Full Thickness		– Leathery white or brown	None	None in the burned area (+/–) Pain at edges	Usually requires burn excision & skin grafting

Adapted from Gandhi M. et al. Management of pain in children with burns. *Int J Pediatrics.* 2010.[9]

TABLE 78.2 Pharmacologic Management of Burn Pain

Agents	Examples	Mechanism of Action	Administration
Opioids	Fentanyl, morphine, hydromorphone, buprenorphine, methadone, levorphanol	μ-R agonist	IV, PO, IM, TD
NMDA antagonists	Ketamine Dextromethorphan	Non-competitive NMDA-R antagonist	IV,
NSAIDs	Ketorolac Ibuprofen Meloxicam (available IV) APAP- this is not accurate- Acetaminophen is not an NSAID, nor does it derive its action via Cox 1 and Cox 2 inhibition- please place this in a separate agent box and review the appropriate mechanism of action/ available routes of administration	Cyclooxygenase (COX-1 and 2) inhibition	IV, PO, PR; intrathecal/ local (experimental)
Gabapentinoids	Gabapentin Pregabalin	Ca^{2+} channel blockade (α2δ-1 subunit-containing channels)	PO
Local anesthetics	Lidocaine Bupivacaine Ropivacaine	Na^{+}-channel blockade	IV (lidocaine), epidural/ intrathecal, perineural, TD
α2 Adrenergic agonists	Clonidine Dexmedetomidine	Central and peripheral α2-adrenergic blockade/ sympatholysis	IV (dexmedetomidine), PO
SNRI agonists	Tapentadol, tramadol, duloxetine	Serotonin and norepinephrine reuptake inhibitor activity	

APAP, N-acetyl-p-aminophenol/acetaminophen; *IM*, intramuscular; *IV*, intravenous; *NMDA*, N-methyl-D-aspartate; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *PO*, per os; *PR*, per rectum; *TD*, transdermal.

Although opioids are an important modality for the treatment of burn pain, clinicians should be aware of the side effects (including respiratory depression, constipation, hyperalgesia) associated with their use in any patient. For burn patients, the immunosuppressant effects of opioids could theoretically lead to an increased risk of infectious complications during their acute hospital stay, although opioids should not be withheld in patients with burn related pain.[17]

Methadone is a unique opioid because of its receptor binding properties. It is both a μ-opioid and N-methyl-D-aspartate (NMDA)-receptor antagonist and also has serotonin and norepinephrine reuptake inhibitor properties. Administration can occur via oral, parenteral, and rectal routes. However, because of variable and unpredictable potency, dosing efficacy is dependent on chronicity. The long-acting analgesia provided by methadone makes this an ideal opioid for maintenance in burn pain management.[3] Further, the NMDA antagonist properties may be responsible for reducing or reversing opioid tolerance and hyperalgesia from other shorter-acting opioids, as well as modulating neuropathic pain. Methadone may be a viable option for some burn patients who are opioid-tolerant and have developed chronic neuropathic pain unrelieved by conventional pharmacotherapies.[18] An additional alternative to traditional opiate medications is levorphanol, a μ-opioid agonist. In a double-blinded trial of 81 patients, investigators compared low (0.15 mg) and high dose (0.75 mg) levorphanol for chronic neuropathic pain and noted that the high-strength levorphanol reduced pain by 36%, in contrast to a 21% reduction in the low-strength group.[19]

Fentanyl is a synthetic lipophilic opioid analog with high potency. These properties facilitate the rapid onset of action and quick redistribution from the central circulation. Lipophilicity allows for transmucosal absorption via nasal or buccal routes with rapid onset and peak effect similar to that achieved by IV administration. Although fentanyl is generally administered intravenously, it can be given orally, intranasally, and transdermally. These properties make this opioid a useful adjunct for procedural burn care activities, such as dressing changes and hydrotherapy.[20] The use of oral transmucosal fentanyl citrate and patient controlled intranasal fentanyl for procedural wound care in burns patients has been reported.[20,21]

NMDA Receptor Antagonists

NMDA antagonists such as ketamine and dextromethorphan are valuable agents for the treatment of burn pain as the NMDA receptor plays a central role in neuropathic pain processing and tolerance. In an experimental human study, ketamine significantly reduced the area of secondary hyperalgesia resulting from local first degree burn injury.[22] Similarly, dextromethorphan reduced the magnitude of secondary hyperalgesia from experimentally produced burn injuries.[23]

Ketamine is a non-competitive NMDA receptor antagonist with anti-hyperalgesia and anti-allodynia properties. It reduces

NMDA-R mediated central transmission and processing of pain, thereby inhibiting central windup. Thus there are many benefits to initiating ketamine early in the course of burn wound care. When administered with opioids, ketamine has synergistic effects with superior pain relief and reduced opioid consumption compared to placebo. When administered with opioids, ketamine appears to have a synergistic analgesic effect on experimentally induced windup-like pain in humans.[24,25] At analgesic doses, it has significantly less risk of respiratory depression and negligible psychomimetic or dissociative effects.[26] Analgesic maintenance dosing ranges from about 1 to 3 mcg/kg/min (or 0.05–0.15 mg/kg/h or 4–10 mg/h). Furthermore, there appears to be no risk of developing tolerance to the drug, even with an extended-duration infusion at analgesic doses.[27,28] A survey of 188 European burn centers noted that ketamine was preferred for analgesia in 12% and sedation in 13% of all substances used.[29] A systematic review of studies investigating intravenous ketamine as an analgesic agent for burn pain suggested that ketamine demonstrated analgesic efficacy for burn injuries with attenuation of secondary hyperalgesia and that no subjects withdrew from the studies as a result of ketamine-related side effects.[30] Delivery of ketamine via patient controlled analgesia for burn dressing changes has been reported.[31] Ketamine has been used for long term sedation and analgesia in burn patients.[27,31] Finally, ketamine may be an effective analgesic agent for painful procedures in pediatric burn patients.[32]

Dextromethorphan (DXM) is a non-competitive NMDA receptor antagonist that acts by reducing excitatory transmission of primary afferent pathways and is effective in managing challenging neuropathic/windup pain in patients who, for a variety of reasons, may be unable to receive ketamine. It has a reduced affinity for the NMDA receptor compared to ketamine and has a significant first-pass effect in the liver via CYP2D6 microsomal enzymes. Clinically, DXM has synergistic effects when administered with opioids and has superior analgesic and opioid-reducing effects when compared to placebo. The range of DXM doses used in published studies is 60 mg twice a day to 90 mg three times a day range. It is effective in 70% to 90% of patients but has been shown to have better efficacy at lower doses when coadministered with a CYP2D6-inhibitor such as quinidine. There are virtually no psychomimetic effects at the doses used clinically.[33] However, clinically, ketamine appears to be used more frequently than dextromethorphan.

Nonsteroidal Anti-inflammatory Agents (NSAIDs)

Analgesia from nonsteroidal anti-inflammatory drugs (NSAIDs) occurs by reducing inflammation and inflammatory mediators via cyclooxygenase-specific inhibition (COX-1 and COX-2). In the burn trauma population, NSAIDs may be useful adjuncts to help reduce the neurogenic inflammatory pain and fever associated with burns. However, in the acute setting, their use should be time- and dose-limited as they may present increased risks of bleeding from platelet dysfunction, gastric ulcers, and gastrointestinal bleeding from COX-1 inhibition in the setting of acute stress and renal dysfunction in the setting of reduced renal perfusion, especially in patients with larger total body surface area burns.[34] COX-2-specific inhibitors (i.e. celecoxib) may offer a better overall safety profile than non-specific COX-inhibitors like ibuprofen and ketorolac, but data in the burn patient population is lacking and needs to be better studied. NSAIDs may be especially useful for the treatment of burn pain as experimental studies suggest that intrathecal or local administration of NSAIDs may decrease post-burn hyperalgesia and reduce hypersensitivity in skin sensitized by ultraviolet burn.[35,36] Intravenous ketorolac administered to volunteers increased pressure pain tolerance threshold and attenuated secondary hyperalgesia from an experimental skin burn injury.[37] In addition, experimental animal studies suggest that NSAIDs may enhance tissue perfusion and reduce edema formation after burns.[38] There are few studies specifically examining NSAIDs or acetaminophen alone in the treatment of burn pain as the vast majority of these agents have been used as part of a multimodal approach to pain management in burn patients. A prospective, multicenter, randomized, double-blind trial evaluating intravenous ibuprofen for treatment of fever and pain in burn patients found that use of intravenous ibuprofen was associated with a significant reduction in fever and that use of the maximum daily recommended dose (800 mg every 6 h) over five days was well tolerated.[34] Finally, acetaminophen (also called paracetamol, or APAP) may be useful in the management of rest burn pain in children at doses in the 10 to 15 mg/kg/4 h range. It is available for administration via oral, rectal, and intravenous routes. In one observational study, 50% of children received only acetaminophen to control background pain.[39]

α2δ Agonists

The alpha two delta agonists (often referred to as gabapentinoids) *gabapentin* and *pregabalin* are lipophilic structural analogs of γ-aminobutyric acid (GABA) that bind to the α2δ-1 subunit of voltage gated calcium channels. In injured dorsal root ganglion neurons, gabapentin has been shown to selectively silence spontaneous discharges but failed to block the propagation of normal impulses.[40] In peripheral nerve injury, as occurs in burn trauma, gabapentin activates and enhances the efficacy and release of descending noradrenergic neuronal activity from the locus coeruleus. By using central neuronal plasticity, it induces more spinal noradrenaline release after nerve injury,[41] suppresses transmission of pain signals to the brain, and may facilitate a more natural sleep-like state in the acute setting owing to the upregulation of activity in the locus coeruleus.[42] Gabapentinoids may be potentially effective for the treatment of burn pain as experimental studies demonstrate that oral gabapentin (in humans) may decrease primary mechanical allodynia in acute inflammation following a thermal injury and that intrathecal gabapentin (in rats) may produce a dose-dependent reversal of thermal hyperalgesia evoked by mild thermal injury.[43,44]

Despite the potential benefits of gabapentinoids in the treatment of burn pain especially considering the presence of neuropathic pain in burn patients, few studies have actually been undertaken to examine the analgesic efficacy of this modality. One of the few double-blind, randomized placebo-controlled trials examining the analgesic efficacy of pregabalin found that administration of pregabalin (up to 300 mg twice a day over 28 days) significantly reduced several aspects of the neuropathic pain and pain associated with procedures.[45] A relatively small retrospective review of pregabalin noted that 69% of patients in a burn outpatient clinic experienced some reduction in pain score after treatment with pregabalin.[46] However, a prospective, randomized, double-blinded, single center, placebo-controlled trial comparing pregabalin 300 mg, 600 mg, and placebo for noncritical partial and full thickness burn injuries showed no statistically significant differences in pain scores and opiate consumption.[47]

Observational data suggest that gabapentin may be useful in reducing neuropathic burn related pain as administration of gabapentin resulted in a rapid reduction in the severity of the neuropathic burn pain and decreased opioid consumption.[48,49] Another potentially useful role for gabapentin is its use for the

treatment of post-burn pruritus in patients where pruritus is not relieved with antihistamines.[50]

Na^+-channel Blockers—Local Anesthetics

Sodium channel blockers such as local anesthetics have been shown to reduce primary and secondary hyperalgesia from experimental heat trauma in humans.[51] Human experimental studies indicate that intravenous lidocaine may attenuate longterm inflammation-induced tissue responses to thermal injury,[52] and has been shown to attenuate cytokine-induced cell injury in endothelial and vascular smooth muscle cells.[53] Local anesthetics for analgesia can be administered via nerve blocks or intravenously, in some cases.

Intravenous lidocaine has been used as an analgesic agent for postoperative pain control and the treatment of neuropathic pain. There is only one randomized controlled trial,[54] and a few observational reports describing the use of intravenous lidocaine for the treatment of burn pain.[55,56] The sole randomized controlled trial examined intravenous lidocaine (versus placebo) in 45 severe burn patients undergoing wound care procedures on two consecutive days. Subjects were randomized to either the intravenous lidocaine or control on the first dressing day and crossed over to the alternate treatment on the second dressing day. Although pain scores were significantly lower for lidocaine, there were no significant differences concerning opioid consumption or satisfaction.[54] A systematic Cochrane review was unable to recommend routine use of intravenous lidocaine in burn pain management at this time.[57]

Neuraxial and peripheral regional nerve blockade have been used as analgesic techniques in the treatment of postoperative pain. However, these techniques have not been widely used for the treatment of burn pain. Instead, a variety of single-injection regional analgesic techniques have been described in burn patients, typically for the purpose of reducing pain at skin graft donor sites.[58,59] One case report describes using double continuous peripheral nerve block catheters in a child after suffering a burn injury.[60,61] Despite the potential benefits that peripheral and neuraxial catheter blocks can offer, clinicians should be aware of the potential infectious complications associated with continuous regional analgesic techniques, especially if indwelling catheters are used for any duration.

α2-Adrenergic Agonists

Clonidine and *dexmedetomidine* are both selective central and peripheral α2-adrenergic agonists that act to decrease norepinephrine at presynaptic receptor sites thereby reducing autonomic outflow. Both drugs significantly reduce pain intensity and have a morphine-sparing effect.[62] Other potential benefits include anti-inflammatory effects, improved macrophage function, anti-apoptotic activity, reduced delirium, and reduced mortality by approximately ~70% for dexmedetomidine when compared to using benzodiazepines for sedation in critically ill patients.[63] Analgesic dosing for these agents depends on the route of administration. For clonidine, dosing regimens may include 2 to 5 mcg/kg PO, 0.1 to 0.3 mg/24 h TTD, or 30 mcg-300 mcg IV for procedural sedation in chronic opioid/chronic pain patients. It can potentially also be used in the neuraxial setting with intrathecal or epidural administration. Dexmedetomidine is given exclusively IV as an infusion at 0.2 to 1.0 mcg/kg/h. In terms of nociception, α2-adrenergic agonists may have a role in the prevention of pain. Experimental data suggest that α2-adrenoceptor-mediated mechanisms may be involved nociceptor sensitization to heat stimuli in normal skin and produce antinociceptive effects in a thermal hyperalgesia model.[64] Clinically, α2-adrenergic agonists may be used for analgesia and sedation in burn patients. A report of oral clonidine in a burn patient who had severe pain noted that administration of clonidine resulted in improved analgesia and sedation.[65] The addition of low-dose intravenous clonidine in a child with severe burns requiring large doses of morphine resulted in a significant decrease in morphine consumption with improvement in ventilatory, gastrointestinal, and psychological functions.[66] When administered to burn patients, dexmedetomidine is typically used for sedation for procedures or in critically ill mechanically ventilated patients.[67]

Serotonin and Norepinephrine Reuptake Inhibitors (SNRI)

Tramadol and *tapentadol* are examples of SNRI that also have μ-receptor agonist activity. *Duloxetine* is an SNRI that has been used in the treatment of both subacute and chronic pain. Generally, SNRI drugs seem to modulate pain circuitry at both the spinal and supratentorial levels.[68] Furthermore, SNRIs have been shown to help improve deregulation of inflammatory markers typically indicated in pain states such as tumor necrosis factor and interleukin-6.[69]

Nonpharmacologic Analgesia

Pain perception can be altered through psychological, cognitive, emotional, and environmental factors.[70] Although management of burn pain is typically achieved primarily by pharmacologic agents, nonpharmacologic techniques (Table 78.3) may be particularly helpful in the treatment of burn pain especially considering the long term nature of rehabilitation and possible development of chronic pain and stress-related disorders. Therefore various nonpharmacologic modalities (e.g. cognitive therapies, relaxation techniques) have been examined although there are significant methodologic limitations in many available studies.

Virtual Reality

Virtual reality utilizes computer-simulated environments that primarily incorporate sight to simulate physical presence in an alternate environment. By incorporating input through multiple senses, including visual, auditory, and tactile, VR can lead participants' focus away from pain and into engaging the virtual world.[70] The application of virtual reality may be most useful during painful procedures and typically used in conjunction with pharmacologic analgesic agents (rather than as a sole modality for analgesia). By distracting a patient's attention from the real world

TABLE 78.3 Nonpharmacologic Management of Burn Pain

Method	Purported Mechanism of Action
Virtual Reality	Mostly visual distraction/decrease in processing of incoming nociceptive signals
Music Therapy	Auditory distraction/attenuation of stress response to pain
Relaxation Techniques	Behavioral management of anxiety, especially immediately pre-procedure/dressing changes

painful experiences (and possibly decreasing processing of incoming nociceptive signals), virtual reality may potentially reduce pain from procedures by approximately 35% to 50% with a corresponding decrease in pain related brain activity as documented by functional magnetic resonance imaging (fMRI).[71] There has been inconsistent data, though, in the efficacy of VR's role in pain reduction for burn patients. However, a 2018 systematic review and meta-analysis of 13 randomized controlled trials with 362 patients who underwent 627 burn dressing change or physical therapy sessions did show that compared to analgesics alone, VR in addition to analgesic medication achieved a greater reduction in pain intensity.[70]

Although virtual reality can be used for patients in any age group, this technique may be especially useful for pediatric patients.[72] For example, in a randomized control trial of 54 pediatric patients who underwent physical therapy for burn injury, patients reported significant decreases in perceived pain (27%–44%, $P < 0.05$) as well as improved affect ("fun") ($P < 0.001$) during VR.[73]

Despite its potential benefits, practical challenges remain to utilizing VR in the clinical setting. Depending on the type of virtual reality system used, three may be a significant time commitment from staff for implementation of such a system and prohibitive costs.[74]

Music Therapy

There is some evidence suggesting that the use of music may be of benefit in decreasing pain, especially during dressing changes or debridement procedures.[75,76] Music may attenuate some measures of the cognitive and physiologic component of the stress response with a lower heart rate and anxiety in subjects who listened to music versus those who did not.[77] A randomized control trial of 70 burn patients comparing standard therapy versus music intervention over five consecutive days of dressing changes showed significant reduction in pain and anxiety, though not in the morphine dosage used for both groups.[78] However, not all data have demonstrated a decrease in burn pain with music therapy,[79] and reporting guidelines for music-based interventions have been proposed.[80] Music therapy may be a valuable nonpharmacologic intervention for the treatment of procedural pain after burn injury.

Relaxation Techniques

Relaxation techniques (e.g. breathing relaxation techniques) may be a useful adjunct to pharmacologic agents for the treatment of burn as these techniques, in essence, do not increase patient risk, are easily mastered and implemented, and generally do not require expensive equipment.[81] A systematic review of simple relaxation techniques for burn pain was unable to definitively determine the efficacy of simple relaxation techniques for the treatment of burn pain. However, concentration on breathing, combined with jaw relaxation, was suggested to be the most promising technique.[82] Hypnosis has also shown potential benefit in patients with burn injury associated pain.[83]

Psychological factors have an influential role in pain perception and the management of patients with chronic pain. There is growing evidence for cognitive behavior therapy (CBT) as a meaningful treatment for chronic pain. In a study of 128 patients recovering from a burn injury, comparing group CBT to usual care, there was a substantial decline of general symptom severity and post-traumatic stress in the CBT group.[84]

Future research should address some of the methodologic limitations of currently available studies in this area and alternative modalities (i.e. electronic and group therapy) to improve access to delivery.

Summary

Pain associated with burn injuries can be complex and is best treated with a multimodal approach to analgesia. Because burn injuries can cause extensive damage, one needs to be aware that nociceptive and neuropathic agents should be utilized for optimal pain control. There are few large scale randomized controlled trials to guide our analgesic management for burn patients, and we currently are guided by our pathophysiologic understanding of the nociceptive processing of burn pain. Furthermore, nonpharmacologic modalities can also offer substantial pain relief and should be incorporated to successfully treat pain in burn patients.

Key Points

- In the United States alone, 486,000 people sought care for burn injuries in 2016, with over 10 million people seeking care for burn injuries worldwide.
- Modern day clinical burn injury care requires an aggressive multimodal and multi-disciplinary approach to effective post-burn pain management, using both pharmacologic and non-pharmacologic methods.
- Acute post-burn injury pain is often very severe and extremely challenging to treat, usually necessitating extreme doses of opioids for analgesia.
- Pain from burns may be both nociceptive and neuropathic in origin.
- Pain in burn patients can be divided into four different categories: rest pain, breakthrough pain, procedural pain, psychogenic pain.
- In experimental burn injury, opioids (μ-receptor agonists) have been shown to produce antinociceptive effects.
- Consequences of rapid and massive opioid dose escalation may include acute opioid tolerance and/or opioid-induced hyperalgesia.
- Longer acting opioids, such as methadone, may be a viable option for some burn patients who are opioid-tolerant and have developed neuropathic pain.
- Fentanyl is a useful adjunct for procedural burn care activities, such as dressing changes and hydrotherapy because of rapid onset of action and quick redistribution.
- NMDA antagonists such as ketamine and dextromethorphan may be valuable agents for the treatment of burn pain as the NMDA receptor plays a central role in neuropathic pain processing and tolerance.
- NSAIDs may be useful adjuncts to help reduce the neurogenic inflammatory pain and fever associated with burns.
- Gabapentinoids may be potentially effective for the treatment of burn pain since they decrease primary mechanical allodynia in acute inflammation following a thermal injury.
- Peripheral regional nerve blockade may be useful at reducing pain at skin graft donor site but should be used with care because of potential issues of infection.
- Dexmedetomidine may reduce mortality by approximately ~70% when compared to benzodiazepines for sedation in critically ill patients.
- Nonpharmacologic techniques, including cognitive therapies, relaxation techniques, music therapy, and virtual reality, may be particularly helpful in the treatment of burn pain.

Pain Evaluation and Management in Patients With Limited Ability to Communicate Because of Dementia

THOMAS HADJISTAVROPOULOS, UNA E. MAKRIS

Pain is a subjective experience, and as such, its assessment typically relies heavily on patient self-report. However, in moderate to severe dementia, the ability to communicate verbally the subjective state of pain declines. Limited ability to communicate pain results in serious caregiver challenges in pain recognition and monitoring. It is, therefore, not surprising that despite its high prevalence in dementia,[1,2] pain is frequently undertreated in this population.[3,4] Morrison and Sui[5], for example, found that 76% of postoperative patients with dementia did not have standing orders for analgesia. Nonetheless, more recent research from Norway and Denmark suggests that the prevalence of pain undertreatment may be decreasing in those countries.[6,7]

Interestingly, researchers have failed to find significant correlations between nurses' estimates of long term care (LTC) resident pain and the administration of pain medications.[8] This is possibly because of enduring beliefs that pain is normal for frail older adults with dementia and thus should be endured. Moreover, recent research has shown that documentation of pain in LTC settings does not tend to reflect best practice standards. In an investigation involving several Australian facilities, Andrews et al.[9] showed that many pain episodes were not documented, and only a minority of episodes (22%) were associated with evidence-based assessments. Moreover, deficits in dosing patterns and appropriateness of pain medication have been identified for older adults in home care, including those with cognitive impairments.[10] Clinicians should be aware of such barriers to effective pain care and must take steps to mitigate these.

A significant concern that compounds the problem of pain undertreatment is that pain in dementia can lead to challenging responsive behaviors,[11] which, in turn, can be misattributed to psychiatric causes leading to treatment with psychotropic rather than analgesic medication.[12] Psychotropic medication may hasten death in this population[13] possibly by increasing the risk of stroke and falls.[14,15] Effective pain monitoring can reduce polypharmacy and psychotropic medication use.[16] Given potential adverse effects from pharmacologic modalities, nonpharmacologic pain management approaches (e.g. frequent repositioning, massage) also have an important role in the pain care of the dementia patient and should be considered the cornerstone of multimodal pain management in this population.

Pain Assessment Using Self-Report

Although dementia compromises linguistic and cognitive abilities in general, self-report tends to remain a valid indicator of pain in early to moderate stages of the dementia process.[17] A recent study of residents with cognitive impairment showed that less than half could self-report pain using a simple zero to ten numeric rating scale.[18] Weiner et al.[19] found that the mean Mini-Mental Status Examination (MMSE)[20] scores in two samples of older adults with cognitive impairments, who were able to self-report pain, ranged from 18.6 to 22. Those unable to self-report pain had MMSE scores with a range of 12 to 13.1, classified as having severe dementia. Chibnall and Tait[21] studied older adults with mean MMSE scores of 18 and found good support for the psychometric properties of simple self-report tools.

Interestingly, Ferrell et al.[22] demonstrated that 83% of research participants with an average MMSE score of 12 could complete at least one of four simple unidimensional pain assessment tools (i.e. The Present Pain Intensity Scale [PPI] of the McGill Pain Questionnaire [MPQ],[23] a verbal rating scale [VRS; involving four to six verbal descriptors indicative of different pain intensities], a 100 mm visual analog scale [VAS], the Rand Coop Chart[24] and the Memorial Pain Assessment Card subscale[25]; the two latter tools are not used commonly in this population), with the Pain Intensity Scale (PPI) of the MPQ[23] having the highest completion rates. The PPI is a zero to five scale that uses both numeric and verbal descriptors of pain intensity. The findings of Ferrell et al.[22] imply that it may be beneficial to attempt several different unidimensional self-report tools (e.g. a zero to ten pain intensity numeric rating scale [NRS] anchored by polar opposites such as "no pain" and "most pain," VRS, PPI) in older adults who have moderate dementia to determine which tool is the best suited for the individual patient.

Among the most commonly used pain self-report tools among younger adults is the horizontal visual analog scale (i.e. a 10 cm line anchored by the polar opposites "No Pain" and "Extreme Pain"). This scale, however, is not recommended for older adults because it has been associated with frequent unscorable responses in this population.[26] Nonetheless, better results have been demonstrated through the use of vertical analog scales.[27]

The Colored Analog Scale (CAS)[28] has also been used with some success in samples of persons with dementia. The CAS is usually presented on a rectangular piece of plastic that looks like a ruler. On one side, there is a shape that starts thin at the bottom and gradually increases in width, and deepens in color (from light pink to red) as one moves toward the top. There are "no pain" to "most pain" anchors at the top and bottom of the scale. The patient is asked to move a plastic guide to indicate the location on the scale that best describes his or her pain. The CAS was originally developed for young children with marginal self-report skills but has been used successfully in samples of older adults with mild to moderate dementia.[17] However, older adults with severe dementia are often unable to complete the tool.[29] Scherder and Bouma[27] suggested an approach that can be used to evaluate the patient's ability to comprehend the scale (e.g. asking the patient to point to the scale, point to the plastic glide, point to where the glide should be placed when there is no pain).

Although no test can determine with certainty the extent to which a patient can self-report pain effectively, a rule of thumb has been suggested based on the literature mentioned above.[17] Specifically, it would be reasonable to expect that an MMSE score of 18 or higher would indicate that a senior would likely be able to use unidimensional pain measures such as the zero to ten pain intensity NRS and the CAS. In contrast, those with MMSE scores below 12 would be more likely to have difficulty with the tools. Nonetheless, self-report should be attempted in all cases as some older adults with low MMSE scores may still be able to provide valid self-report. Based on the literature and our direct experience in clinical settings, we recommend that the NRS, PPI, and/or CAS be attempted. Where scales are presented visually (e.g. the CAS or the VRS),[30] it is important to ensure that large fonts are used to compensate for visual impairments that become more common in older age groups. While multidimensional pain assessment scales (e.g. the short version of the Geriatric Pain Measure [GPM],[31,32] which assesses disengagement because of pain and pain with ambulation in addition to pain intensity), have been shown to be useful with older adults who are cognitively intact, research is needed on the development of suitable multidimensional pain assessment tools for older adults with moderate to advanced dementia.

Pain Assessment Using Observational Assessment Tools

Given the limited ability of many older adults with moderate to severe dementia to effectively self-report pain, there has been a proliferation of observational measures designed to assess pain in this population (see Hadjistavropoulos et al.[33] for a review of various available tools). Many of these measures have limited validity evidence, but some have been studied more and have a substantial evidence base behind them. Among the most studied measures are the Pain Assessment in Advanced Dementia (PAINAD)[34] and the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC and PACSLAC-II) scales.[35,36]

The PAINAD consists of five items (Breathing, Negative Vocalization, Facial Expression, Body Language and Consolability), with each rated on a zero to two scale based on specific criteria. For example, Negative Vocalization is rated as follows: 0 = Normal; 1 = Occasional moan or groan, low-level speech with a negative or disapproving quality; 2 = Repeated troubled calling out, loud moaning or groaning, crying. The PAINAD has demonstrated good psychometric properties, including the ability to differentiate painful situations from non-pain related states,[37,38] and been translated in several languages.[39–41]

Comprehensively covering all pain assessment domains recommended by the American Geriatrics Society,[42,43] the original PACSLAC scale[36] consisted of 60 items organized into the following categories (Facial Expression, Activity Body Movement, Social Mood Personality, and Other, which includes physiologic changes, eating/sleeping changes and vocal behaviors). Each item is scored as present or absent, and the scale usually takes less than 5 min to complete. The PACSLAC has been shown to have good internal consistency and to differentiate pain related from non-pain related experiences.[36–38] When used regularly in an LTC environment, the PACSLAC was shown to result in reduced pain levels (as assessed by LTC staff), increased use of *pro re nata* analgesic medication, and reduced nurse stress. In a study of nursing staff who used the PACSLAC, the PAINAD, and the Doloplus[44,45] (which is a validated tool that has been used widely in France with English translations available from the developers' website),[46] Zwakhalen et al.[37] demonstrated that, while all three tools had good psychometric properties, nursing staff expressed a preference for the PACSLAC. Notably, the PACSLAC has been found to account for more variance in differentiating pain from non-pain related states than other commonly used observational pain assessment tools, even when several other tools were used in combination.[38] The PACSLAC has been translated into several languages.[47–49]

Despite the strong psychometric properties of the PACSLAC[36–38,50,51], a newer version, the PACSLAC-II, was developed.[35] The 31 item PACSLAC-II was intended to be a briefer scale that would maintain comprehensive coverage of the pain assessment domains recommended by the American Geriatrics Society,[43] would exclude many items that frequently overlap with delirium, and would emphasize items informed by previous investigations, including laboratory research (e.g. specific facial responses that are frequently associated with pain). The psychometric properties of the PACSLAC-II have been supported.[35,52,53] The PACSLAC-II has been found to account for more variance in differentiating pain related from non-pain related states than other commonly used tools, including the original PACSLAC, even when several other tools were used in combination.[35] Moreover, regular use of the PACSLAC-II in an LTC environment, combined with physician involvement, was shown to lead to reductions in benzodiazepines compared to a control group of patients whose caregivers did not use the PACSLAC-II regularly.[16] The reductions in benzodiazepines may have been because of a better understanding of agitated behaviors that could have resulted from pain instead of another source of distress. Other research has suggested that, under professional guidance and direction, laypersons (e.g. informal caregivers) should be able to complete the PACSLAC-II and the PAINAD in a valid fashion allowing for the provision of important pain assessment information by family members to health professionals.[54] More recently, an app version of the PACSLAC-II, with the capability of graphing patient scores over time (allowing LTC staff to observe deviations from patients' regular pattern of scores), was developed and evaluated with good results.[55] The PACSLAC-II has been translated into French, Farsi, and other languages.[52,56] A copy of the PACSLAC-II has been included as an Appendix of this chapter.

Recently, Kunz et al.[57] developed a 15 item "meta-tool" for pain assessment in "impaired cognition, especially dementia," the Pain Assessment in Impaired Cognition-15 (PAIC15) using items from preexisting scales such as the PACSLAC and the PAINAD. Tools

that were published after 2012 (e.g. the PACSLAC-II) were not considered. The selection of items and tools was based on expert consensus and studies that evaluated some of the psychometric properties of candidate items.[58] Although promising, a limitation of this work is that a direct comparison of the validity of the PAIC15 with that of other well validated tools in assessing pain in dementia was not reported. Pending such a direct comparison, the clinical value added because of the PAIC15 introduction remains to be determined through additional research.

On occasion, cutoff scores for observational pain assessment tools have been proposed in the literature.[59] However, we have explicitly argued against such practice on the following grounds: a score on an observational assessment tool would vary as a function of situational and personal factors such as duration of observation (e.g. longer observation periods would likely result in higher scores than short observation periods) and the nature of the dementing illness (e.g. dementias primarily affecting the frontal lobes would like result in more disinhibited pain responses compared to dementias primarily affecting the posterior part of the brain). Other factors, such as facial paralysis or mobility limitations, would also affect the repertoire of pain behaviors being displayed. The wide variety of factors, besides pain, that can affect scores on observational tools implies that the use of universally applicable cutoff scores would be problematic. As an alternative to the use of cutoff scores, it has been suggested that an idiographic approach be adopted wherein each patient is assessed regularly over time, and clinicians look for fluctuations in the patient's typical pattern of scores.[17] Unexpected increases or decreases from such a pattern of scores would imply changes in status.

Other Dimensions of the Pain Experience

The clinician needs to be cognizant that persistent pain affects a wide variety of quality of life dimensions, including mood and level of agitation. As such, a thorough assessment of the persistent pain would also involve consideration of such dimensions. Useful psychometric evaluation tools for mood, agitation, and quality of life, specifically designed for people with moderate to severe dementia, rely on input from knowledgeable informants and include the Cornell Depression in Dementia,[60] Alzheimer Disease Related Quality of Life-Revised tool,[61] and the Cohen-Mansfield Agitation Inventory.[62]

It is also important to acknowledge that multiple medical and psychological (particularly depressive) conditions and syndromes contribute to the pain experience (e.g. multiple pain diagnoses, sleep disturbance, musculoskeletal pain, chronic wounds, neuropathy), delirium[63,64] and that the pain itself is a result of a multifactorial pathway.[65] Assessing and addressing multimorbidity, often through careful review of the medical record, will be important for effective and safe pain management.

A Clinical Approach to Assessment of the Older Adult With Limited Ability to Communicate Because of Dementia

Several guidelines and consensus groups have described clinical approaches designed to optimize and facilitate the assessment of patients with dementia.[66,67] These approaches have much in common.[68] A general approach to the pain assessment of older adults with cognitive impairments, reflecting key points presented in various guidelines, is outlined in Table 79.1.

One of the most recent and up-to-date guidelines for pain assessment in the patient unable to self-report is the 2019 Position Statement of the American Society for Pain Management Nursing.[67] The statement emphasizes the following general recommendations: 1) be aware of potential causes of pain; 2) attempt self-report; 3) observe patient behaviors; 4) solicit proxy reporting of pain behaviors and activity changes; and 5) attempt an analgesic trial. The position statement recommends using validated assessment tools as appropriate (minimizing the emphasis on vital signs for pain assessment, regularity of pain assessment), and follow up assessments following the intervention. When soliciting proxy reports of pain, clinicians should note that proxy and patient reports of pain do not always correspond.[69] Proxy reports should be considered in the context of all other sources of information about the patient, including results of the physical examination. Moreover, in many instances, nonpharmacologic interventions may be appropriate prior to attempting an analgesic trial.

Because of concerns about limited personnel and other resources that characterize many LTC facilities, a group of geriatric pain and public policy experts recommended a feasible model of pain assessment for LTC facilities.[70] Specifically, they outlined the following recommendations:

Every LTC resident should be assessed for pain on admission and at least once a week thereafter using a validated tool. Assessments would need to be more frequent when pain is suspected and/or if symptoms appear to escalate.

A treatment plan should be documented in the chart within 24 h for patients with suspected moderate to severe pain. Depending on the circumstances, the treatment plan can be simple (e.g. administer acetaminophen) or more thorough following a medical examination.

24 h following treatment plan implementation, side effects of treatment should be evaluated and addressed.

Pain should be re-evaluated within 24 h of treatment plan implementation.

Research has demonstrated that stakeholders (e.g. front line health professionals, LTC administrators) assessed these guidelines as feasible, desirable, and appropriate.[71] Moreover, the feasibility of implementation of the aforementioned four clinical guidelines, with no significant added resources, has been demonstrated[55,72] although the sustainability of such guidelines over time would require ongoing management support. The impact of such guideline implementation on patient outcomes deserves further study.

Nonpharmacologic Pain Management

Research in nonpharmacologic pain management for patients with dementia has been extremely limited. Evidence suggests that physical therapy and physical exercise interventions are effective in this population for specific types of musculoskeletal problems.[73,74] Yet physical therapy is not always available to those who need it in LTC facilities. Sensory stimulation has also been found to be a viable option for nonpharmacologic pain management in dementia, and group psychosocial interventions have demonstrated larger effect sizes than individual approaches.[75]

A wide variety of comfort measures (e.g. soothing music, more frequent repositioning of patients with mobility limitations) can also be used, but evidence suggests that these measures are underutilized.[76] Systematic investigations of comfort measures (e.g. listening to music to help with pain management) have been very limited. Virtual reality is another modality with the potential to provide meaningful activity. Pilot testing shows virtual reality use among hospice patients living

TABLE 79.1 Guidelines for Assessing Pain With Older Adults With Cognitive Impairments

General Guidelines

1. Determine if Mini-Mental Status Examination scores are available or can be obtained. This would facilitate the determination of patient ability to provide valid self-report.
2. Always attempt self-report regardless of the level of cognitive functioning.
3. Baseline scores should be collected for each individual (ideally on a regular basis which would allow for the examination of unusual changes from the persons' typical pattern of scores).
4. Patient history and physical examination results should be taken into consideration.
5. If assessments are to be repeated over time, assessment conditions should be kept constant (e.g. use the same assessment tool, use the same assessor where possible and conduct pain assessment during similar situations).
6. Pain assessment results should be used to evaluate the efficacy of pain management interventions.
7. Knowledgeable informants (e.g. caregivers) should be asked about typical pain behaviors of the individual.
8. Other aspects of the pain experience should also be evaluated, including environmental factors, psychological functioning, and social environment.

Recommendations Specific to Self-Report Measures

1. Use of synonyms when asking about the pain experience (e.g. hurt, aching) will facilitate the self-report of some patients who have limitations in communicating verbally.
2. Self-report scales should be modified to account for any sensory deficits that occur with aging (e.g. poor vision, hearing difficulties).
3. Use self-report tools that have been found to be most valid among older adults (e.g. the Numeric Rating Scales, Verbal Rating Scales).
4. Use of horizontal visual analog scales should be avoided as some investigators have found unusually high numbers of unscorable responses among older adults.
5. Observational tools that have been shown to be reliable and valid for use in this population include the PACSLAC-II and PAINAD. Nonetheless, clinicians should always exercise caution when using these measures because they are relatively new, and research is continuing.
6. When assessing pain in acute-care settings, tools that primarily focus on evaluating change over time should be avoided.
7. Observational assessments during movement-based tasks would be more likely to lead to the identification of underlying pain problems than assessments during rest.
8. Some pain assessment tools, such as the PACSLAC scales, do not have specific cut-off scores because of recognition of tremendous individual differences among people with severe dementia. Instead, it is recommended that pain is assessed regularly (establishing baseline scores for each patient), with the clinician observing score changes over time.
9. Examination of pain assessment scores before and after the administration of analgesics is likely to facilitate pain assessment.
10. Some of the symptoms of delirium (seen frequently in LTC) overlap with certain behavioral manifestations of uncontrolled pain (e.g. behavioral disturbance). Clinicians assessing patients with delirium should be aware of this. On the positive side, delirium tends to be a transient state, and pain assessment, which can be repeated or conducted when the patient is not delirious, is more likely to lead to valid results. It is important to note also that pain can cause delirium, and clinicians should be astute to avoid missing pain problems among patients with delirium.
11. Observational pain assessment tools are screening instruments only and cannot be taken to represent definitive indicators of pain. Sometimes, they may suggest the presence of pain when pain is not present, and other times they may fail to identify pain.

Outcomes of Interest

In addition to improved scores on various assessment tools, evidence of more effective pain management can be observed in areas such as greater participation in activities, improved sleep, reduced behavioral disturbance, improved ability to ambulate, and improved social interactions.

Table Note: Many of these recommendations have been adapted from Hadjistavropoulos et al. (2007). Many of these recommendations also overlap with those of Herr et al. (2006) and Herr et al. (2019).
This table is copyrighted by Thomas Hadjistavropoulos and is reprinted here with permission.

with dementia was mostly safe and enjoyable in this population.[77] Nonetheless, the headset needed for virtual reality may be challenging to implement because many patients with advanced dementia may find it uncomfortable or be unwilling to use it.

In terms of psychological interventions, Cipher et al.[78] demonstrated that a multimodal intervention with LTC residents who had mild to moderate dementia was helpful with pain and mood management. The intervention involved the participation of caregivers/family members and behavioral interventions. More specifically, caregivers/family members assisted with rehabilitation (e.g. by facilitating patient cooperation) and social reinforcement. Participants benefited in terms of pain reduction, depression, and emotional distress as measured by validated tools that were at least partly reliant on caregiver/clinician input.

As far as older adults with moderate to severe dementia are concerned, we know that persistent pain often leads to mood deflation and depression in cognitively intact persons.[78] To the extent that this applies to people with dementia, psychological interventions designed to enhance mood management could help improve the quality of life of those who suffer from pain. Terri, Logsdon, Uomoto et al.[79] have shown that behavioral interventions (e.g. engagement in pleasant activities, caregiver involvement)

can improve mood in older individuals with dementia. Such interventions may help enhance the wellbeing of older adults with dementia who suffer from persistent pain.

Pharmacologic Pain Management

Consistent with a multimodal, collaborative approach to managing older adults with dementia and chronic pain, incorporating goals of care and expectations (from patient and caregiver) is a critical first step. The literature,[80] although not specific to patients with dementia, suggests that pain relief is one of the most commonly endorsed goals of older adults. Guidelines for the management of chronic pain recommend nonpharmacologic and behavioral interventions as first-line.[81] While there are limited studies in patients with dementia and pain, this population is particularly vulnerable to adverse events from medications, largely because of multimorbidity and polypharmacy.[82] Pharmacologic modalities for chronic pain in older adults with dementia are one component of the multimodal, interdisciplinary management of these complex conditions. Much of the summary below is derived from literature from younger adults as there is a paucity of randomized controlled trial (RCT) data on efficacy and safety, specifically in older adults with dementia.[83]

Thermal and Topical Therapies

While the etiologies for chronic pain in later life are broad, the most common and disabling are musculoskeletal pain (including osteoarthritis [OA] and chronic back pain). Recent guidelines from the American College of Rheumatology[84] (ACR) provide a conditional recommendation that thermal modalities, including trials of cold or warm compresses, applied to the painful sites (hand, knee, hip OA) may be beneficial. Caution must be used to avoid burning the skin with heating pads over long periods.

Topical medications for pain control are particularly appealing in older adult populations, given the safety profile because of limited systemic absorption. Currently available topical preparations are menthol, capsaicin, lidocaine, and diclofenac. The recent ACR guidelines do not recommend capsaicin for hand OA, although it has a conditional recommendation for knee OA. It would be important to ensure that patients avoid contact with the face/eyes since capsaicin is derived from hot peppers. Lidocaine, as a cream or patch, can be used for neuropathic pain. Since the patches require replacement at specific time intervals, this option is less ideal if the patient has dementia and is managing his or her medications. Perhaps the most commonly used topical agent is diclofenac, which is used mostly for knee and hand OA. A literature review[85] revealed that topical NSAIDs in older adults (age >60 years old) were nearly as effective and carried a lower risk of severe adverse events (gastrointestinal) compared to oral NSAIDs. While most RCT excluded older adults with renal impairment or who were anticoagulated, topical diclofenac has been used safely at a reduced frequency (twice/day instead of four times/day) in this population.

Acetaminophen

Acetaminophen (APAP) is often used as a first line analgesic for mild to moderate pain. In one systematic review[86] (including 137 studies with 33,243 participants, median age of 62 years), comparing APAP, diclofenac, ibuprofen, naproxen, celecoxib, intra-articular (IA) corticosteroids, IA hyaluronic acid, oral placebo, and IA placebo, all interventions were significantly better than oral placebo for improving pain outcomes. While APAP had the lowest effect size (0.18) of the evaluated medications, its safety profile was also superior to oral nonselective nonsteroidal anti-inflammatory drugs (NSAIDs). In a review of three RCT evaluating 140 patients with dementia, APAP was found to be well tolerated in doses up to 3 grams/day.[87] Review of medications (including those purchased over the counter) is important and should account for all sources of APAP. The long term (greater than three months) efficacy and safety of APAP in patients with dementia have not been proven.

Oral Non-steroidal Antiinflammatory Drugs

While potentially effective at treating pain and inflammation, the use of oral NSAIDs in older adults for long term use is discouraged because of known cardiovascular, gastrointestinal (GI), and renal toxicity.[88] Indomethacin may have a higher risk of adverse effects, including GI and renal effects.[87] Until additional research on the use of NSAIDs in older adults with dementia is conducted, the interdisciplinary team should weigh the risks and benefits of NSAID use and aim for the lowest effective dose for a brief duration. Patients taking NSAIDs should undergo regular monitoring of their renal and liver function.

Opioids

Opioids are not included in guidelines as first line management. If used, these medications are often trialed after other medication classes are not effective at improving pain or function. Known adverse effects in this population include falls, mental status changes, constipation, sedation, nausea, potential for increased agitation, respiratory depression, and sometimes death.[87] Tramadol, while included in the ACR guidelines, as conditionally recommended for hand, knee, and hip OA also has a concerning adverse effect profile and has not been evaluated specifically in patients with dementia. Oxycodone and morphine have been evaluated in patients with dementia and were found to reduce pain. However, the risk/benefit ratio must always be evaluated, taking individual risk factors into account. Additional research is needed as prior studies enrolled a small number of patients[89] and had a short duration (~ four weeks). Buprenorphine is a potent analgesic with mixed activity at the μ, κ, and δ receptors. Over 50% of subjects (all LTC patients with moderate to severe dementia and depression) who received buprenorphine in that study discontinued treatment because of adverse events (categorized as either neurologic or psychiatric).[90]

Adjuvant Therapies

There are very few trials that investigate the efficacy and safety of adjuvants such as anti-depressants, antiepileptic, or muscle relaxants in treating patients with pain and dementia. Many of these medications are listed on Beer's criteria as potentially inappropriate in older adults, based on a higher risk of adverse events, interaction with other medications, and impact on comorbidities. One trial evaluated a pragmatic approach to a stepwise protocol for treating pain in LTC patients with moderate to severe dementia and behavioral disturbances as compared to usual care (n = 352).[91] The protocol included an individualized approach to trialing APAP, morphine, buprenorphine, or pregabalin for eight weeks duration with a primary outcome of change in agitation. Of 12 patients who received pregabalin, 2 (16.7%) withdrew from the study because of somnolence, nausea, or drowsiness.

General Limitations

When older adults with dementia and pain are included in trials, this population is particularly prone to risks of both under- and over-reporting of adverse events. Existing trials are not designed to appropriately evaluate the cause and effect of medications on pain or other outcomes. Many questions remain to be answered regarding efficacy, safety, and improved outcomes that matter most in this population. Longitudinal and RCT designs will be integral to moving this field forward and improving outcomes for this vulnerable population.

Conclusions

There are challenges in assessing pain in people with limited ability to communicate because of dementia, but well validated observational approaches, focusing on pain behaviors, are available and are important supplements to clinical examinations and information obtained from knowledgeable informants. More research is needed on both pharmacologic and nonpharmacologic interventions, specifically focusing on people with dementia. Given the complexities involved in treating pain in this population, interdisciplinary collaborations involving physicians, psychologists, physical therapists, and other health professionals would be of the essence.[92]

Appendix A: Pain Assessment Checklist for Older Adults with Limited Ability to Communicate-II (PACSLAC-II)

Date of Assessment:Time:	Check If Present
Facial Expressions	
1. Grimacing	
2. Tighter face	
3. Pain expression	
4. Increased eye movement	
5. Wincing	
6. Opening mouth	
7. Creasing forehead	
8. Lowered eyebrows or frowning	
9. Raised cheeks, narrowing of the eyes or squinting	
10. Wrinkled nose and raised upper lip	
11. Eyes closing	
Verbalizations and Vocalizations	
12. Crying	
13. A specific sound for pain (e.g. 'ow,' 'ouch')	
14. Moaning and groaning	
15. Grunting	
16. Gasping or breathing loudly	
Body Movements	
17. Flinching or pulling away	
18. Thrashing	
19. Refusing to move	
20. Moving slow	
21. Guarding sore area	
22. Rubbing or holding sore area	
23. Limping	
24. Clenched fist	
25. Going into fetal position	
26. Stiff or rigid	
27. Shaking or trembling	
Changes in Interpersonal Interactions	
28. Not wanting to be touched	
29. Not allowing people near	
Changes in Activity Patterns or Routines	
30. Decreased activity	
Mental Status Changes	
31. Are there mental status changes that are because of pain and are not explained by another condition (e.g. delirium because of medication)?	
TOTAL SCORE (Add up checkmarks)	

COPYRIGHT: The PACSLAC-II is copyrighted by Sarah Chan, Thomas Hadjistavropoulos, and Shannon Fuchs-Lacelle. For permission to reproduce the PACSLAC, contact thomas.hadjistavropoulos@uregina.ca, who is authorized to provide permission on behalf of all copyright holders. The developers of the PACSLAC-II specifically disclaim any liability arising directly or indirectly from the use of application of the PACSLAC-II. Use of the PACSLAC-II may not be appropriate for some patients, and the PACSLAC-II is not a substitute for a thorough assessment by a qualified health professional. The PACSLAC-II (like other observational pain assessment tools) is a screening tool and not a definitive indicator of pain. As such, sometimes it may fail to identify pain, and other times it may incorrectly signal the presence of pain. The PACSALC-II should be used by qualified health care staff within the context of their broader knowledge and examination of the patient. The subscale names on the PACSLAC-II represent the pain assessment domains recommended by the American Geriatrics Society (2002).

Key Points

- Pain is challenging to assess in older adults with moderate to severe dementia because of limitations in ability to communicate pain because of cognitive and linguistic impairments.
- While older adults with mild to moderate dementia may be able to report on their pain using unidimensional scales, validated systematic observational approaches such as the PACSLAC-II or the PAINAD are needed to monitor pain levels in those with moderate to advanced dementia.
- Consensus guidelines for assessing pain in people with dementia are available.
- Research on nonpharmacologic pain management interventions is limited but does suggest that physical therapy, exercise therapy, sensory stimulation, and various comfort modalities show promise.
- Pharmacologic pain management research specifically focusing on older adults with dementia has been limited, and clinicians often extrapolate from studies based on younger persons without dementia.
- The pharmacologic modalities should be chosen based on goals of therapy, as discussed with the older adult and caregiver, and also tailored and monitored according to other medications used and concurrent comorbidities managed.
- A multimodal interdisciplinary approach of a combination of nonpharmacologic and pharmacologic modalities for pain may be particularly appropriate in older adults with dementia and should be tailored and monitored for safety according to goals of therapy, and other medications used to managed comorbidities.

Disparities in Pain Care: Descriptive Epidemiology-Potential for Primary Prevention

JANA M. MOSSEY

Background to this Chapter

This chapter is being written at an unprecedented time in the history of the United States. The coronavirus (SARS-CoV2) pandemic has swept across the country. COVID-19 case numbers, hospitalizations, and deaths show non-Hispanic Blacks, American Indians, and Hispanics to have been disproportionately affected.[1,2] The Centers for Disease Control (CDC) has reported age adjusted mortality rates for non-Hispanic Blacks and American Indians are over twice that of non-Hispanic Whites, and age adjusted hospitalization rates for Hispanic, and non-Hispanic Blacks are almost five times greater than that for non-Hispanic Whites.[3] These large disparities in COVID-19 mortality and hospitalization are attributed to the long term detrimental effects of systemic/structural racism,[4–6] manifest in persistent discrimination and unequal opportunity, poverty, segregated crowded residential neighborhoods, and current employment in "essential" low paying jobs that require the use of public transportation.[7–10]

On March 25, 2020, the horrifying death of George Floyd, an unarmed non-Hispanic Black male, was televised. Mr. Floyd's death has stimulated a widespread and continuing resurgence of and support for the "Black Lives Matter" movement.[11–13] These two events have made it virtually impossible for most individuals to continue to believe that "racism" in the United States ended in the 1960s or to deny that non-Hispanic Blacks, in particular, continue to be impacted by discriminatory racial biases. Currently, the difference between "not racism" and "antiracism" is being discussed widely, and actions necessary to be an "anti-racist" are being disseminated through news and social media.[14,15] Coincident with this, healthcare professionals are acknowledging the influence of systemic/structural racism on the healthcare system and, consequently, the health of disadvantaged minority populations.[16–19] In a recent issue of the Journal of the American Medical Association (JAMA), Hooper et al. wrote, "*The pandemic presents a window of opportunity for achieving greater equity in the healthcare of all vulnerable populations.*"[16] In mid-July, an editorial in the New England Journal of Medicine by Evans and his colleagues stated: "*Now, amid an acute public health crisis that is transforming medicine, perhaps we have an opportunity to reset our priorities to face this deeper, more chronic crisis as well.….Even if we can't change the social determinants of health for any individual patient in any given encounter, we can think more seriously about how they affect what the patient can and can't do, tailor the patient's care accordingly, and show that we are invested.*"[17] These sentiments suggest healthcare providers may be ready to accept the challenge of moving beyond a healthcare system constrained by the influences of systematic/structural racism to one in which health care is equitably delivered and universally accessible.

In addition to the above secular events, two recent developments provide additional impetus for specific change in pain management. Consequent to the opioid epidemic, the CDC[20] has issued restrictive guidelines that substantially limit opioid prescriptions for acute and chronic pain care. Practitioners and patients are faced with new challenges regarding which medication regimens and/or nonpharmacologic treatment approaches will work best.[21,22] The opportunities for doctor/patient decision making with regards to non-opioid treatment options can result in patient empowerment and increased treatment adherence. A second important change in pain management is the recognition that optimal care requires a multi-disciplinary group of pain practitioners (e.g. pain psychologists, physical therapists, and complementary medicine specialists) who join the physician and the patient in the planning and implementation of pain treatment plans.[23,24] With less reliance on opioid analgesics, this is a promising development. When fully operational, providers and patients will need to work creatively to ensure that patients who will benefit from important nonpharmacologic interventions will be able to access and pay for them.

Part I: Introduction

For most of the past 25 years, low back pain has been the number one cause of "years lived with disability" (YLD) worldwide.[25] As such, low back pain accounts for more disability burden across the globe and in the United States than any other disease or injury.[26] Acute and chronic pain are highly prevalent. Drawing on CDC data for 2016, Dalhamer et al.[27] indicate that 20.4% of the United States adult population (~50 million individuals) suffered from chronic pain. Total overall annual treatment costs associated with pain have been estimated to exceed 600 billion dollars.[28] Treatment costs represent only a small part of total pain costs. The physical and emotional suffering, loss in life quality, work

productivity, and creativity experienced by individuals in pain and that experienced by family and friends are major additional costs. Both the World Health Organization statement on health as a human right,[29] and the National Pain Strategy endorse the goals of equal access to health and health care for all individuals and reduction or prevention of the burden of pain across the life span.[30]

In 1993, Todd et al.[31] reported that Hispanics seen in the emergency department (ED) with a long bone fracture received inferior pain care compared to that received by non-Hispanic Whites. The Hispanics received no analgesic or a lower strength non-opioid analgesic, while non-Hispanic White patients received opioid analgesics. In 2000, Todd et al.[32] reported similar disparate care received by non-Hispanic Blacks treated for acute pain in the ED. Over the past 27 years, many research papers, review articles,[33–37] and government reports have documented racial/ethnic disparities in pain care,[38–40] and pain care providers and educators have been challenged to find solutions to the problem.[41,42] Despite their efforts, unequal pain care to minority groups continues as a pernicious and troubling aspect of contemporary pain management. This chapter addresses the questions: "Is the primary prevention of disparate pain care to minority groups a possibility?"; and "If thought to be possible, what can pain care practitioners do to diminish or prevent the delivery of unequal pain care?" To develop answers to these questions, Part I addresses the epidemiology of pain care disparities. An operational definition of disparate care with the selected process and outcome indicators is presented. The populations at risk of such care are identified, findings from research studies pertinent to the identified indicators are summarized, and the consequences of suboptimal pain care are discussed. Part II presents contributing causes of inadequate pain care. In Part III, the potential for the primary prevention of disparate pain care is addressed, and actions pain care practitioners may take to diminish or eliminate their contributions to disparate care and to ensure optimal pain care for ALL are identified.

Part I: Epidemiology of Disparities in Pain Care

Definition of Disparities and Indicators of "Suboptimal" Pain Care

The Oxford Dictionary defines the term *"disparities"* as "a difference especially one connected with unfair treatment."[43] While helpful, a clinical definition of "unequal or disparate treatment" is missing. From an epidemiologic perspective, an operational definition of unequal or suboptimal pain care is important. However, no comprehensive definition has been identified. Because of the privileged status of most non-Hispanic Whites, researchers have used the pain care received by them as a metric against which to compare that received by other racial, ethnic, or marginalized groups. Since most of the published studies preceded recommendations to restrict opioid prescribing, less frequent or lower dose administration of opioid analgesics was most often the study variable that indicated suboptimal or optimal care.[35,37] Selected process and outcome indicators of suboptimal pain care reported in the literature or deemed critical to evaluating pain care are presented in Table 80.1. As researchers, clinicians, and patients gain a greater understanding of the effective pain care strategies that supplement or replace those specific to a prescription of opioid analgesics, it will be important to identify new process and outcome indicators for both optimal and suboptimal pain.

TABLE 80.1 Selected Process and Outcome Indicators of Suboptimal Care for Acute and Chronic Pain

Indicators	Citation Numbers
Patient's pain level was not assessed by the treating provider	62–65,67,68,101
Provider's assessment of patient's pain level is lower than patient's self-report	70,73,74,87,88,
Provider failed to prescribe any analgesic to a patient with pain compared to a similar White patient treated for pain	63–65,75,76
Provider failed to prescribe opioid analgesic to patients with substantial pain compared to a similar White patient treated for pain	60,62–65, 77-87,91–95
Excessive time delay from emergency department (ED) arrival to administration of appropriate analgesic	104,105
At ED, hospital, primary care physician (PCP) office discharge, provider prescribed no opioid analgesic or an opioid analgesic of inadequate strength for the patient's pain level and disease status	66,84,88
At ED, hospital, PCP office discharge, provider required return visits for a patient prescribed an opioid analgesic at a shorter interval than for typical patients	96,97
Patient/provider visit is shorter than provider's average patient visit time	127
Provider diminished or dismissed patient's self-reported pain and discharged patient from ED or outpatient office without thorough evaluation	98,99,100
Acute pain patient seen in ED or surgery transitioned into post-surgical chronic pain	111–117
Acute or chronic pain patient developed post-traumatic stress disorder or post-traumatic stress syndrome following treatment	118,119
Acute or chronic pain patient developed misuse or abuse of prescribed narcotic analgesic	96,97

Indicators are drafted based on a single patient. Evidence of disparities in pain care exists if the rate of suboptimal pain delivered to race/ethnic or other marginalized groups exceeds the comparable rate of suboptimal pain delivered to the comparison group.

Population Groups at Risk of Disparities in Pain Care

Many contemporary scientists, this author included, view "race" as a socio-political construct instead of a complete biologic phenomena informed only by a group's genetic makeup.[44–46] The conclusion that "race" is predominantly contrived rather than entirely determined by genetics remains controversial given population based genome studies and the interest in the identification of gene disease markers.[47] While results of the Human Genome Project have shown that humans have 99.9% of their genetic material in common,[48,49] the differences remain unresolved between 1) the view that race is genetic and 2) the view that the effects of social and environmental exposures have contributed to the development of intergroup phenotypic differences such as skin color, hair texture, and eye color. Although no credible evidence supports the theory that non-Hispanic Whites represent a superior racial group and all other population groups are genetically

inferior, White Nationalists explicitly support this racist theory. Other non-Hispanic Whites may have implicit biases they are not consciously aware of that support the supremacy of non-Hispanic Whites. Beginning with the practice of slavery, the racist viewpoint has had a longstanding history in the United States. Currently, the population is hierarchically organized, with non-Hispanic Whites the privileged holders of wealth and power; non-Hispanic Blacks, Hispanics, and other groups are devalued and limited in their access to power, wealth, opportunity, and material goods.[44,50] Although considered arbitrary, the race/ethnic classification established by the United States Office of Management and Budget that includes[51] non-Hispanic Whites, non-Hispanic Blacks, Hispanics, American Indians or Alaska Natives, Asians, and Native Hawaiian or other Pacific Islander has become a principal classification variable used for the organization of Census Statistics and most health related research. It is used throughout this chapter. Following an informal scientific convention, non-Hispanic Whites are typically considered the "reference" or 'comparison" group. In addition to race/ethnicity, other population groups have been classified, some or all of the time, as "minority" or "marginalized." Such groups include American Indian/Native Alaskans, Asians, Native Hawaiian/other Pacific Islander, individuals who are poor, individuals with intellectual, physical, or emotional disabilities, older adults, women, persons who do not self-identify as heterosexual male or female, and those who ever have been incarcerated.[52,53] Collectively, these groups comprise the population at risk for disparate pain care.

Disparities in Pain Care: Summary of Recent Evidence

The substantive conclusions from previous research specific to the indicators listed in Table 80.1 have changed very little from the findings presented in earlier review papers published by Green et al.,[33] Anderson et al.,[36] Mossey,[34] and Meghani et al.[35] Consequently, updated findings reported in more recently published research papers are only very briefly summarized below.

Acute Pain Care: Emergency Department, Primary Care Settings

Acute pain is often treated in the ED, primary care outpatient offices or clinics, and the hospital pre- and post-surgery units. Typically, the treatment process includes 1) the identification of the patient's self-reported pain level; 2) the development of a clinical pain level assessment based on the provider's interpretation of the patient's self-reported pain and other relevant clinical information; and 3) selection and administration of an analgesic that is deemed safe for the patient and commensurate with the patient's reported pain level. Until the recent CDC guidelines in opioid prescribing for acute and chronic pain,[20] the prescription of an opioid analgesic has differentiated suboptimal pain care from optimal pain care. While some studies have reported no racial/ethnic disparities in analgesic prescribing,[54–57] the most consistent findings showed non-Hispanic Black and Hispanic pain patients, compared to non-Hispanic Whites, have received suboptimal pain care in the ED, outpatient offices, and the hospital.[58–62]

Recognized as a critical driver of the providers' analgesic prescribing, studies show self-reported pain levels of child and adult patients seen in the ED and other outpatient settings were not assessed as frequently for non-Hispanic Blacks and Hispanics as for non-Hispanic Whites. This disparity occurred during Emergency Medicine Service (EMS)[63–65] transit to the ED and after admission to the ED,[63,66,67] or attendance at primary care offices.[68] There is considerable evidence that when non-Hispanic Blacks and Hispanics self-report their pain level, their report is an underestimation of the pain they actually feel.[69,70] Researchers have speculated that such under-reporting may reflect the patients' internal pressures to maintain their self-image, cultural expectations, or fear that they will be perceived by healthcare providers as "complainers."[71,72] Strong evidence explaining their tendency to under-report pain is not available. Simultaneous to the recognition that non-Hispanic Black and Hispanic patients underestimate their pain, clinical and experimental studies report that many providers believe these patients exaggerate their pain.[73,74] As a result of the patients' and providers' misrepresentations, compared to non-Hispanic Whites, non-Hispanic Black, and Hispanic children and adults are more likely to receive no analgesic during EMS[63–65] transport to the ED and during an ED visit for a painful condition.[75,76] When analgesics are prescribed, non-Hispanic Black and Hispanic children,[62–65,77–81] and adult pain patients [60,82–86] seen in the ED consistently are less likely to be administered an opioid analgesic than non-Hispanic Whites. For example, in a study of the treatments and outcomes of children seen in the ED for a long bone fracture, non-Hispanic Blacks and Hispanics were more likely than non-Hispanic Whites to receive any analgesic [non-Hispanic Black adjusted odds ratio (aOR) 1.72 (95% confidence interval [CI] 1.51–1.95), Hispanics AOR 1.32 (1.16–1.51)]. However, they were less likely than non-Hispanic Whites to be prescribed an opioid analgesic [non-Hispanic Black AOR 0.86 (0.77–0.95) Hispanic AOR 0.86 (0.76–0.96)] or to achieve optimum pain reduction [non-Hispanic Black AOR 0.78 (0.67–0.90); Hispanic AOR 0.80 (0.67–0.95)].[80] Comparable to the experience of children, for adults with moderate to severe pain, the adjusted risk of receiving an opioid analgesic was 17% to 30% lower for non-Hispanic Blacks and Hispanics than for non-Hispanic Whites.[86]

Pre- and Post-Op and Postpartum Acute Pain Care to Ethnic/Racial Minorities

Recent studies indicate persistent ethnic/racial disparities in pre- and post-op pain care to children and adults. Compared to non-Hispanic White children, Hispanic, Pacific Islander, or Asian children were at lower odds [AOR 0.87 (95% CI 0.74–0,97); AOR 0.53 (0.33–0.84); AOR 0.83 CI 0.70–0.97], respectively, of receiving important post-op non-opioid analgesics.[87] Baldreldin et al. reported that while Hispanic and non-Hispanic Black postpartum women reported higher pain scores than non-Hispanic Whites, they received significantly fewer inpatient MMEs and were less likely to receive a prescription for an opioid analgesic [Hispanic AOR 0.80 (95% CI 0.67–0.96), non-Hispanic Blacks AOR 0.78 (0.62–0.98)].[88]

Chronic Non-cancer Pain

Chronic pain is one of the most difficult pain diagnoses for the provider and patient to manage. Suffering can be extreme, and patients often feel desperate for relief. Studies indicate the prevalence of chronic pain is lower in non-Hispanic Whites; the intensity of the pain and the level of pain interference is greater among non-Hispanic Blacks and Hispanics.[89] Recently divided into high impact chronic pain (HICP), pain with activity limitations, and low impact chronic pain (CPWL), pain without limitations,

Dahlhamer et al. reported 8.0% of the adult population in 2016 suffered from HICP, and 20.4% experienced CPWL.[90] Studies show non-Hispanic Blacks and Hispanics continue to receive suboptimal chronic pain care more frequently than non-Hispanic Whites.[82,91–95] In outpatient settings, studies indicate the percentage of non-Hispanic Blacks and Hispanics receiving opioid analgesics was smaller than for non-Hispanic Whites. Non-Hispanic Blacks were prescribed fewer opioid pills and required to return for urine testing more frequently than non-Hispanic Whites. Prescription of fewer drugs and more frequent monitoring for opioid misuse suggest pain providers are more likely to distrust non-Hispanic Black patients than non-Hispanic White patients, even though there is no evidence that non-Hispanic Blacks are more likely to misuse or divert prescribed medications for chronic pain.[96,97]

Other non-minority groups, including females and older adults, experience disparate chronic pain care. Compared to males, physicians tend to withhold giving females opioid analgesics, female pain levels are dismissed more frequently, and women are referred to pain specialists less often than males.[98,99] The experience of women whose physician diminishes their pain is particularly difficult and, very likely, demeaning to the patient. Comments of a Black female quoted in a qualitative study indicated: *"You could just tell that he just didn't believe me that I was in as much pain as I was. He was just very unsympathetic. He would literally walk away while I was in the middle of a sentence."*[100]

Ethnic/Racial Disparities in Cancer Pain Care

Non-Hispanic Blacks are at increased risk of presenting for medical care with advanced cancer than non-Hispanic Whites. They have poorer outcomes for many cancer diagnoses and are less likely than non-Hispanic Whites to receive advanced cancer treatments or, when transferred to a nursing home, to have their pain level assessed.[101] In a study of Medicaid cancer patients, Halpern et al. reported non-Hispanic Blacks and Hispanics were half as likely as non-Hispanic Whites to receive interventional pain treatments for breast cancer.[102] In a study of racial disparities in the treatment of metastatic spine disease, non-Hispanic Blacks were less likely than non-Hispanic Whites to undergo surgery; they had longer hospital lengths of stay and were more likely to experience a complication.[103]

Consequences/Outcomes of Suboptimal Pain Care

The primary objectives of acute pain treatment are to alleviate the patients' immediate suffering and to minimize the activation of pain related neurophysiologic and/or psychological processes that may lead to irreversible negative outcomes, central nervous system changes, or progression to chronic pain. Non-Hispanic Black and Hispanic patients are at increased risk of experiencing longer periods of untreated acute pain; they experience longer premedication waits in the ED,[104,105] and fewer appropriate medication prescriptions at discharge than non-Hispanic Whites.[106,107] Prolonged acute pain from long waits in the ED before receiving an effective analgesic can evoke anxiety, fear, panic, desperation, or helplessness. Other feelings that can occur include a personal sense of inadequacy, worthlessness, or invisibility. Discharge from the ED or hospital without a prescription for analgesia of sufficient strength can prolong emotional and physical suffering and increase anger and distrust.

The long-term effects of inadequately anesthetized immunization experiences of infants highlight their vulnerability to "intense pain" and the likelihood of developing negative memories about pain. Taddio et al.[108] noted that "fear of needles" developed during infancy can persist for many years and jeopardize future preventive health care. They reported that 90% of toddlers and 45% of primary school children continued to experience extreme distress during later childhood immunizations. Indicative of the lifetime implications of early unprotected immunizations or inadequately treated pain, McLennan and Rogers observed that 16% of adults still showed signs of needle phobia.[109] The limited number of longitudinal studies that track the consequences of early childhood pain exposure through adulthood makes it difficult to fully understand its impact throughout the life course.

Transition From Acute to Chronic Pain and Post Surgery Chronic Pain

The transition to chronic pain from an acute pain episode treated in the ED or an acute surgery related pain is a serious negative, disabling outcome. Researchers have observed that as many as 43% of adults seen in the ED for acute pain report persistent pain three months after the ED visit. The predictors of not fully recovering included baseline anger, sleep disturbances, low Socioeconomic Status (SES), and post traumatc stress disorder (PTSD) symptoms.[110] Post-surgical chronic pain (PSCP), defined as pain occurring at the surgery site and lasting longer than the expected healing time, is a more critical and disabling outcome of acute pain. As Glare et al. note, *"Neuropathic descriptors [of PSCP] such as hyperalgesia (heightened sensitivity to painful stimuli), dysaesthesia (an unpleasant, abnormal sense of touch), and allodynia (sensitivity to normally non-painful, often repetitive, stimulation) are frequently used."*[111] PSCP is associated with comorbid symptoms including depression, anxiety, and sleep disturbance.[112]

While the predictors of PSCP have not been fully identified, observed risk factors include severe, difficult to treat post-surgical pain, female gender, fear of surgery, perceived self-helplessness, and pain catastrophizing.[112,113] The importance of race or ethnicity as a predictor of PSCP has not yet been fully clarified.[112] Gungor et al.[114] report that non-Hispanic Blacks were at substantially higher risk for persistent post-surgical pain (PPP) following total knee arthroplasty than non-Hispanic Whites. While PPP is distinct from PSCP, they share some risk factors, including intense pre/post-surgical pain, psychological symptoms, and prolonged surgical site pain, depressive symptoms, and pain catastrophizing.[111,114] It is reasonable to conclude that, like PPP, non-Hispanic Blacks could be at increased risk for PSCP. Reported incidence rates for PSCP in adults range from 10% to over 50%,[111,113] and in children 10% to over 20%.[115,116]

Positive associations between PPP and PTSD are suggestive, but the research findings are less clear. Based on their literature review, Fishbain et al.[117] concluded that the association between chronic pain and PTSD differed according to the type of pain and the population being studied. Ravn et al. reviewed the temporal associations between post-traumatic pain and post-traumatic stress. They concluded that further study was needed to clarify the nature of these relationships.[118] The evidence of serious acute pain leading to Post Traumatic Stress Symptoms (PTSS) in children and adolescents has also been studied. After a traumatic injury about 20% of children develop PTSS, and many may re-experience the traumatic event or manifest hyperarousal, dissociation, and mood or cognitive changes.[119]

Few studies of postoperative pain trajectories have included race/ethnicity as an independent variable. Suboptimal pain care provided to minority populations increases the occurrence of

undertreated pain. As posttreatment pain is a risk factor for transition from acute to chronic pain, it is reasonable to suspect that non-Hispanic Blacks and Hispanics, compared to non-Hispanic Whites, will disproportionately experience more negative complications such as PSCP and PTSD.

Part II: Factors Contributing to the Occurrence of Disparities in Pain Care

No one factor accounts for all suboptimal pain care received by disadvantaged groups. Recently, epidemiologists, social scientists, and clinicians have recognized that systemic/structural racism is largely responsible for the designation of a population group as inferior or unequal and the creation of a healthcare system where systematic suboptimal pain care is possible.[44,120,121] A thorough presentation of the background and historical trajectory of systematic racism is beyond the scope of this chapter. Instead, important aspects of systemic/structural racism are briefly summarized here. More thorough resources pertinent to racism are identified at the end of the chapter. According to Jones,[122] there are three levels of racism: "*institutionalized, personally mediated* [explicit and implicit racism]*, and internalized* [racism]."[122] Institutionalized racism is also referred to as systemic or structural racism; the term systemic racism will be used throughout the remainder of the chapter. These levels of racism and the contributions of each to disparities in pain care are addressed below.

Societal Issues: Systemic Racism

Systemic racism has had an extensive and persistent influence on the United States social and political systems and the historical devaluation of specific groups. Jones describes systemic racism as: "*differential access to the goods, services, and opportunities of society by race…* [that]*…manifests itself in material conditions and access to power. With regard to material conditions, examples include differential access to quality education…appropriate medical facilities, and a clean environment.*"[122] Bailey et al. further define systemic racism as "*the totality of ways in which societies foster discrimination, via mutually reinforcing systems (e.g. in housing, education, employment, earnings, healthcare, criminal justice etc.) that in turn reinforce discriminatory beliefs, values, and distributions of resources.*"[44] Since the country's beginning, non-Hispanic Whites have maintained a position of power and privilege. However, non-Hispanic Blacks descendent from slaves of African origin, American Indians, and Alaska Natives actively have been demeaned, diminished as lesser, and denied equal access to opportunities including wealth, education, and health care. Their lives have been diminished, first, by the brutality of being owned slaves and, more recently, by exclusion, prejudice, and discrimination.

Systemic Racism-Contributions of the Healthcare System in the United States

Consistent with systemic racism, the United States health care reflects non-inclusive policies that hinder equitable and equal access for all citizens.[18,123] For-profit, insurance financed access to most preventive healthcare and medical services depends on an individual's eligibility for Medicare or their ability to purchase health insurance privately or through their employer. Government programs such as Medicaid may support health care for the poorest individuals, but even with changes made under the Affordable Care Act,[124] many citizens have no health insurance or are under-insured. In 2019, 7.4% of non-Hispanic Whites were uninsured compared to 27.0% of Hispanics and 13.6% of non-Hispanic Blacks.[125]

Feelings of shame for inability to pay, fear of being turned away, or worry and anxiety because of the pressures of receiving a large medical bill result in the tendency of uninsured or under-insured individuals to delay seeking medical care. When finally seeking medical attention, their health problems, including painful conditions, are likely to be more advanced and more challenging to treat. Inability to pay for prescribed medications, physical therapy, or mental health services can result in prolonged suffering and being labeled as non-adherent. Because physicians have indicated that they have difficulty trusting patients who are non-adherent, the pain care patients' who do not adhere to prescribed treatments because of inability to pay are doubly compromised. The patient does not benefit, and the provider/patient relationship is compromised.[126]

A second issue reflective of systemic racism stems from policies inherent in the United States health service payment system. Reimbursement for delivered health services is essential to the financial stability of individual providers, healthcare agencies, and insurance companies. Inevitably, some uninsured patients who are unable to pay for health services do receive medical care. To compensate for this, insurance companies may lower reimbursement amounts paid to providers and healthcare facilities. As a consequence, private healthcare providers may be forced to see more patients each day. This inevitably shortens the time a provider has to spend with each patient. This can be a special problem for non-Hispanic Blacks and Hispanics as their visit time with providers often is already shorter than that for non-Hispanic Whites.[127] Financially challenged hospital systems, including those housing an ED, may have to function with fewer professional staff than optimal. Under this scenario, all pain care providers are likely to have short patient contact time, and they become at risk of experiencing work overload. Under such circumstances, providers are at increased likelihood of making racially biased patient treatment decisions.[128] Financial constraints may also diminish the ability to hire the number of competent translators needed to assist with patients whose ability to speak English is limited. When needed, the absence of such services decreases the likelihood that optimal pain care can be delivered.

Systemic Racism-Segregated Residential Neighborhoods

As a result of systemic racism, residential segregation exists in many cities and rural towns in the United States.[129,130] Residentially segregated neighborhoods characteristically are homogenous and under-resourced with a high proportion of low income, disadvantaged families and old, rundown housing stock. A high proportion of the neighborhood residents are likely to be uninsured or under-insured.[131,132] Typically, the neighborhoods are not attractive to physicians who could establish a primary care practice office. To address the absence of neighborhood primary care offices, the local health department may establish a primary care clinic in the neighborhood with services charged on a sliding scale. The United States trained physicians often are not interested in working in these "public" clinics. As a result, International Medical Graduates (IMG) are over-represented in their medical staff.[133] As noted by Meghani et al.,[35] IMG practitioners may not have important training in cultural competency. Even when an IMG provider is fluent in English, a regional accent may be challenging to patients. Pharmacies are particularly important for those who experience pain. In their study of pharmacy availability in selected geographic

sections of Michigan, Green and her colleagues[134] reported that individuals living in residentially segregated neighborhoods were at a substantial disadvantage in their ability to obtaining pain medications because of the unavailability of pharmacies or limitations on the medications stocked by the pharmacist.

Provider Contributions to Disparities in Pain Care

Limited Education

In their seminal paper, Todd et al.[31] suggested that lack of cultural competence might have accounted for the observed lower physician opioid prescribing to Hispanic ED patients than non-Hispanic Whites. Other investigators have suggested disparate pain care may result from inadequate provider education regarding all aspects of pain care, including symptoms and diagnoses of pain conditions, treatment approaches including those that are pharmaceutical and nonpharmaceutical, approaches to address patient non-adherence, financial inability to pay for prescribed treatment modalities, prevention, and management of opioid misuse. This concern is particularly relevant given the extensive reliance on primary care physicians for a large proportion of acute and chronic pain care.[135–137] Matthias et al. highlight the difficulties primary care physicians have encountered when working with hard-to-treat chronic care patients. They have used words such as "frustrating," "ungratifying," and "overwhelming" to describe their experiences.[138] Additional pain management training would increase provider competence. As noted earlier, IMG may also have critical limitations in their education, especially regarding formal training in cultural competence.[35]

False Beliefs Held by Physicians and Other Healthcare Providers

In their provocative paper, Hoffman et al. suggest that centuries old negative beliefs such as "non-Hispanic Blacks are insensitive to pain because their skin is thick," that had originally been promoted in an attempt to justify the physical abuse of slaves still exists as either explicit or implicit biases.[139] While Hoffman suggests beliefs originated in the times of slavery, Hogarth has presented compelling and disturbing evidence that, over the past centuries, physician scientists have contributed to the racist interpretation of non-Hispanic Blacks' physical attributes.[140] Although there is no evidence to support the negative characterizations, Hoffman and her colleagues have suggested they represent persistent "false beliefs" held by some health professionals that contribute to racial disparities in pain care.[139] A list of selected contemporary "false beliefs" about non-Hispanic Blacks is presented in Table 80.2. Research has shown that medical students and residents have endorsed, as true, some of the "false beliefs." In experimental studies, researchers also have found that the more "false beliefs" about non-Hispanic Blacks that were endorsed by a study participant, the more likely the respondent recommended lower dose analgesics for non-Hispanic Blacks than for non-Hispanic Whites.[139] As discussed in the next section, many providers are not consciously aware of holding "false beliefs." Such unconscious biases can influence behaviors and clinical decisions. For example, the "false belief" that non-Hispanic Blacks are more likely than non-Hispanic Whites to misuse or become addicted to prescribed narcotics is likely to have contributed to the disproportionate withholding of prescriptions for opioid analgesics from non-Hispanic Blacks at discharge from the ED, private doctors' offices, and the hospital.[106,107]

TABLE 80.2 Selected 'False Beliefs' About non-Hispanic Blacks that Have Persisted into the Twenty-first Century and Continue To Be Believed by Individuals Including Health Professionals

Selected "false belief"
Blacks are impervious to pain
Blacks lack intelligence
Blacks have weak lungs that could be strengthened through hard work
Blacks have blood that coagulates more quickly than whites*
Blacks' nerve endings are less sensitive than Whites'*
Blacks age more slowly than Whites*
Blacks' skin is thicker than Whites'*
Black males are violent
Black women are dominant and lazy
Black males are criminals
Blacks are genetically flawed
Blacks do not follow doctor's orders
Blacks do not take medications as prescribed
Blacks are more likely than Whites to abuse opioid analgesics
Blacks are superior athletes

*'False Beliefs' included in Table 80.1: Hoffman, et al.[139]

Personally, Mediated Racism: Provider Explicit and Implicit Racial Biases

Explicit biases refer to attitudes and beliefs (e.g. stereotypes) that are known to an individual. While individuals may be reticent to reveal explicit biases that are negative, they are open to self-report. As noted above, at an individual level, the "false beliefs" shown in Table 80.2 may represent an explicit or implicit bias. Implicit biases are unconscious and outside of the individual's awareness. They are extremely difficult to identify, even if the individual strives to do so. Once identified, considerable effort is required to manage or eliminate them. Of substantial importance to pain care providers, implicit biases represent an unconscious intrusion into the provider's ability to exhibit genuine empathy, to clearly hear what the patient says, to objectively observe and evaluate the patient, to develop an understanding of what the patient is feeling, and to develop a treatment plan with the patient that meets the patients' clinical needs and expectations.[139,141,142] It is important to acknowledge that the occurrence of implicit biases experienced by pain providers is equivalent to that observed in general populations.[143] As observed in other populations, it is possible that a pain practitioner might publicly support human rights, social justice, and equal access to and receipt of optimal pain care for all yet simultaneously harbor strong unconscious negative racial biases toward minority patients. Consistent with the above, there is substantial evidence showing that implicit biases can negatively affect aspects of the provider/patient relationship and lead to poorer patient outcomes.[141,142] One explanation for the apparent inconsistency between one's conscious assertions and held implicit biases draws on a model of cognitive processing known as "dual-system models" in which social cognitions are processed

by two interconnected mental systems that are thought to meet different cognitive needs and to reside in separate memory systems.[144–146] Social scientists have developed methods to indirectly measure implicit biases using the validated Implicit Association Test.[147] Of interest, researchers have observed weak correlations between an individual's explicit and implicit biases irrespective of race.[148] From the perspective of disparate pain care, results from experimental studies of hypothetical vignettes or virtual patients show the implicit biases of both non-Hispanic Whites and non-Hispanic Blacks are reflected in their preference for non-Hispanic White patients.[149]

Patient Characteristics That Contribute to Disparities in Their Care

There is emerging evidence that differences exist between non-Hispanic Blacks and non-Hispanic Whites in terms of neurophysiologic and biochemical processing of painful stimuli and neurochemical metabolism of opioid analgesics.[150–152] Experimental studies have shown non-Hispanic Blacks and Hispanics, compared to non-Hispanic Whites, to be more sensitive to painful stimuli, to feel pain as a more unpleasant sensation, and to have lower pain tolerance.[153–155] Studies to detect pain from changes in facial expression have found that non-Hispanic White study participants had much greater difficulty distinguishing painful from non-painful expressions when looking at non-Hispanic Black faces than when looking at those of non-Hispanic White individuals.[156] In real life, non-Hispanic Whites and non-Hispanic Blacks differ in their experiences of chronic pain. Non-Hispanic Blacks feel pain more intensely than non-Hispanic Whites; they develop comorbid depression more frequently, experience greater disability and activity limitations, more frequently personally blame themselves for pain, especially when the pain is chronic, utilize more passive, less successful, coping strategies such as prayer and pain catastrophizing, and have greater concern over the addictive properties of opioid analgesics.[157,158] Similar to Hispanics, they are likely to under-report their actual pain level. Within effective provider/patient relationships, these racial and ethnic differences should not increase the risk of suboptimal pain care because providers could have learned about such differences from conversations with their patients or from the existing research papers and review articles that address racial/ethnic pain care disparities.[33–37]

Although not well studied, some non-Hispanic Black and Hispanic attitudes and behaviors could increase their risk of receipt of suboptimal care. Jones has identified "internalized racism" as one category of systemic racism.[122(P1212)] Individuals of disadvantaged groups are at risk of believing the racist insults and negative characterizations that they hear. To the extent that this occurs, non-Hispanic Blacks and Hispanics may actually self-identify as inferior, genetically impaired, and worthless. Individuals with such feelings are likely to be reluctant to volunteer information to providers irrespective of whether they fully trust them. Out of feeling inadequate, they may be unwilling to be clear about their ability to afford prescribed medications, physical therapy, and/or psychological services. Their reticence to speak freely about their health insurance or job requirements may result in non-adherence to prescribed treatments. Non-adherence has special significance since physicians have indicated they have difficulty in trusting patients who do not follow their treatment instructions.[100]

Mistrust and Miscommunication Between Provider and Patient

Pain, whether acute or chronic, remains an individual experience identified in clinic settings by self-report. The subjective nature of pain poses an immediate challenge to a treating provider, especially one whose implicit biases may evoke distrust in the patient. Even if never spoken, the question, "Is the patient's pain report accurate?" may be raised. Because provider biases often lead to the diminution or dismissal of pain reported by racial/ethnic minorities, women, and older adults, their treatment plans frequently may not meet the patients' needs. Such provider behaviors can be interpreted by the patient as: "I do not trust you" or "I do not respect you." Acute and chronic pain patients have indicated they can feel disrespected, devalued, and unheard. Chronic pain patients interviewed during several qualitative studies described experiences with their pain provider using words like demeaning, traumatic, accusing. They indicated providers appeared uncaring, disinterested, disbelieving, and dismissive.[159–161]

Loss of trust in one's healthcare provider can have serious repercussions. In her recent memoir, *Becoming*, Michele Obama highlights the distrust non-Hispanic Blacks, irrespective of their economic status, can have toward physicians. She attributes her father's long delay in seeking medical care for symptoms of lung cancer to *"his long-held view that doctors were untrustworthy."*[162]

Mutual distrust between members of a patient/provider dyad increases the probability of miscommunication. It prevents the development of the positive therapeutic relationship that many consider necessary to the provider's and patient's abilities to jointly develop an appropriate care plan the patient is willing and able to adhere to.[163,164] In her compelling article on trust and race in American medicine, Sullivan emphasizes that, in situations where trust between the patient and physician has been broken or has never been established, the physician or other pain practitioner is the party responsible for establishing the conditions under which the patient will feel safe and willing to consider trusting their pain provider.[165] According to Sullivan, *"the practical questions are how patients can know that a physician is trustworthy and how physicians can convey their competence and caring appropriately."*[165] When asked which provider characteristics evoke trust, patients have indicated 1) technical competence (necessary but not sufficient) and 2) interpersonal competence (ability to communicate, taking time to talk with the patient, non-judgmental listener, showing caring); empathy; honesty; willingness to include patient in clinical decision making. Sullivan has added a third characteristic, "comprehension."[165] She describes "comprehension" as the willingness and ability to comprehend and acknowledge the larger context within which the individual lives and to understand where the patient is coming from and what is driving his or her decisions. Sullivan and others who have addressed trust and its significance for the establishment of effective provider/patient relationships recognize the potentially disruptive effects of implicit provider biases on their abilities to establish safe environments for patients who distrust providers and the healthcare system in general.[165]

PART III: Potential for the Primary Prevention of Disparities in Pain Care

Two questions were posed in Part I: "Is the primary prevention of disparate pain care to minority groups a possibility?" and "If thought to be possible, what can pain care practitioners do to diminish or

prevent the delivery of unequal pain care?" The term "primary prevention" refers to targeted actions to avoid negative health effects/outcomes.[166] Primary prevention may be as relatively straightforward as immunization against a disease or like suboptimal pain care to disadvantaged groups. It may be more complicated and require many targeted actions. In Part II, the factors that contribute to the occurrence and persistence of disparate pain care were identified as societal, legal, and health system consequences of structural racism, the continued existence of false beliefs regarding non-Hispanic Blacks, Hispanics, and other minority groups, limits in physician education, provider explicit and implicit biases, patient characteristics, and mutual patient/provider distrust. While some of these factors are complex, have long histories, would require enormous changes in the current societal allocation of privilege and power/disadvantage and oppression, they are not immutable. Theoretically, the primary prevention of disparate pain care to minority groups should be possible. However, it is naïve to suggest that pain care providers alone can achieve this goal. The challenge to those involved in pain management is to identify the actions that are uniquely under their control, to diligently and passionately address them head on, and to persist until disparities in pain care no longer exist, and, simultaneously, to direct efforts to eliminate systemic racism beliefs, policies, and laws from the healthcare system organization and delivery of care. The following identifies positive actions designed to diminish false provider beliefs, behaviors, and explicit and implicit biases that can increase pain care disparities. The success of the actions to be taken depends on understanding and accepting:

1. Pain care providers and educators must own their explicit and implicit biases and racist beliefs,
2. While taking responsibility, they should not feel personally culpable. During a televised "Town Hall Meeting," non-Hispanic Black leaders discussed systemic racism. Dr. Paula Johnson, President of Wellesley College, stated: *"And the absolute incorrect way to take this is to take it personally, because if you personalize it, then you become defensive. Of course, you are part of it. What we should say is [that] we are part of the United States of America, and therefore, of course, there is structural racism in our institutions,"*[167]
3. Pain care providers are responsible for correcting and eliminating their contributions to racial/ethnic and other minority group disparities in pain care. In her work on patient and provider trust, Sullivan emphasizes: *"In the work to resolve mistrust, the onus surely cannot lie with the potential trustee(that is, the patient) to reevaluate their understanding of the situation….To require individuals from a group that has historically been the subject of exploitation and discrimination to resolve the issue of mistrust in American medicine is to further burden them, exacerbating injustice,"*[165] and
4. Any work to prevent disparities in pain care will require constant attention and over-time repetition of discussions, skill training, seminars, and other activities until changed attitudes and behaviors are fully integrated.[168,169] Without continuous attention and refresher sessions, immediate changes are likely to dissipate and diminish.

Actions to be Taken by Individual Pain Care Providers

- Read the existing review articles and research papers that address disparities in pain medicine to become an expert in positive and negative or dysfunctional provider beliefs and behaviors. Identify personal positive and negative beliefs and behaviors. Develop and initiate a step-by-step plan to reduce negative or false beliefs and dysfunctional behaviors and reinforce positive ones.
- Talk with patients and colleagues to identify the meanings of pain and its expression among non-Hispanic Black, Hispanic, and other disadvantaged groups. Study the important cultural histories and health related norms held by Non-Hispanic Blacks and Hispanic individuals and other minority groups such as Asian individuals and LGBTQ (Lesbian, Gay, Bisexual, Transgender, Questioning) individuals.
- Learn about the history of racism, its past and contemporary impact on non-Hispanic Black individuals, and the role of non-Hispanic Whites in its origins and persistence.
- Engage with experts, colleagues, friends and read current materials authored by non-Hispanic Blacks to understand what it means to be an anti-racist. Become an anti-racist.

It is expected that the above actions would reflect honest self-assessments, persistent efforts, and active engagement with peers, experts, and individuals from many diverse population groups. It is not expected that an individual's implicit biases will have been fully identified and addressed. To increase the likelihood of identifying and managing implicit biases, structured, multi-session educational programs are recommended.

Actions to Develop and/or Refine Structured Multi-Session Educational Programs

While promising educational approaches to develop 1) cultural competence for healthcare providers or 2) recognition, acknowledge, and management of implicit provider biases exist, no educational programs for healthcare personnel with demonstrated effectiveness in terms of provider growth, temporal stability of desired attitudinal and behavioral outcomes, translation into measurable behavioral changes, and appropriately documented improvements in patient care outcomes have been identified for use within teaching institutions or clinical practices. A comprehensive review of the literature pertinent to existing educational or systematic reviews pertinent to programs to improve cultural competence or identification of implicit biases is beyond the scope of this chapter. However, the following provides some information relative to educational programs pertinent to cultural competence and addressing implicit bias.

Educational Programs to Develop Cultural Competence

It is widely recognized that healthcare providers should have knowledge regarding the cultural customs and norms of the patients to whom they provide health services.[170–171] Programs to increase the cultural competence of healthcare providers have been developed by individual institutions and delivered for several decades to most health profession disciplines. Although initiated with positive intentions, the authors' conclusions of a 2014 Cochrane systematic review on cultural competency programs were discouraging. While they noted findings *"showed some support for cultural competence education for health professionals. These findings are tentative…the quality of the evidence was low."*[171] The findings from several more recent systematic reviews have provided equally sobering conclusions.[172,173]

Educational Programs for Addressing Implicit Bias

To strengthen abilities to personally establish conditions under which pain patients who distrust providers could experience enough personal safety to enter into a trusting provider/patient

relationship, engagement in structured exercises designed for providers to recognize, acknowledge, and manage their implicit biases are crucial. Because implicit biases are often antithetical to the individual's self-perception, substantial resistance to self-disclosure is almost always present even if the individual intellectually agrees that he or she could have such biases. Several promising theoretically driven approaches ranging from a Mindfulness[174] approach to Translational Learning Theory[175] have been proposed as the basis of programs to identify and reduce implicit bias in healthcare providers. Further developmental and evaluative research is needed before any one educational program can be solidified. Until programs shown to meet the above education program criteria become available, pain practitioners are advised to read and discuss with colleagues written materials that focus on the presence and influence of implicit bias on provider behaviors and patient outcomes.

Actions to be Undertaken in Conjunction With Professional Organizations of Pain Providers

- Support the development and evaluation of the educational programs through which providers can:
  - 1) strengthen their ability to be "caring" practitioners, and 2) recognize, acknowledge, and manage the implicit biases that may negatively influence their ability to deliver optimum pain care to all individuals.
  - Establish methods and procedures to implement continuous evaluation of pain treatment services for acute and chronic pain to ensure that suboptimal care is not being delivered. If suboptimal pain care is observed, immediate corrective actions with providers and site personnel would be implemented.
  - Refine pain care process and outcome indicators such as those identified in Table 80.1 to assess optimal or suboptimal pain care in which administration of opioid analgesics is not a primary treatment approach.
  - Advocate for health system reforms that guarantee all individuals residing in the United States have access to equitable, quality health care irrespective of income level.
  - Partner with other medical and public health personnel and professional organizations to end systemic racism in every aspect of medicine and public health and in systems of education, housing, employment, and social and legal justice.

Conclusions

This chapter began with a 'Background' statement that identified the current socio-political context pertinent to the delivery of pain care. The inclusion of a description of the current status of disparate pain care provides the reader important content information. It has been instructive, though regrettable, to recognize that the research findings suggest that, in over 25 years, only modest progress has been made toward the reduction or elimination of disparate pain care. The significance of the chapter lies in a more thorough explanation of factors that contribute to discrepant pain care, the identification of some steps to increase the likelihood that disparate pain care could be prevented, and the specification of several requirements for healthcare providers who accept the challenges of moving from delivery of disparate pain care to delivery of uniformly equal quality pain care.

The over-arching conclusion is that, with persistent effort, the primary prevention of disparate pain care can be achieved. From a societal perspective, all forms of racism must be eliminated. To do so will require the efforts of all pain care providers as well as many others. From the perspective of pain care providers, the most critical but difficult undertaking is the acceptance by providers that they are responsible for establishing the conditions under which pain patients will feel free to trust them. The presence of promising educational programs to increase sustained provider cultural competence and enable providers to identify and manage implicit biases that interfere with patient trust is encouraging. Further development and evaluative research of relevant education programs is a high priority. To further guard against disparate pain care, research is needed to develop the continuous quality of care monitoring within both acute and chronic care settings. While the elimination of disparities in pain care is a challenge, it is a challenge worthy of addressing.

Key Points

- Chronic pain remains the leading cause of Years Lived With Disabilities worldwide and in the United States.
- Despite attempts to diminish disparities in the pain care to racial/ethnic and other minority groups, women, and older adults, suboptimal pain care to such groups persists.
- The unprecedented time in the United States because of the COVID-19 pandemic and the increased recognition and support for the Black Lives Matter Movement provides a unique opportunity to recognize and make systemic changes that could diminish or eliminate disparities in pain care.
- Systemic racism characterized by differential access to power, wealth, goods, and services has targeted non-Hispanic Blacks, Hispanics, and other minority groups. Non-Hispanic Whites have maintained a position of power.
- Systemic racism perspectives have influenced almost all institutions, including health care, education, housing, neighborhood composition, and criminal justice.
- Provider implicit biases, unconscious, typically negative attitudes and beliefs about minority groups, can affect clinical decisions and add to disparate pain care.
- Healthcare providers are responsible for establishing the conditions in which pain patients will feel safe and able to participate in a clinically effective doctor/patient relationship.
- Primary prevention of disparities in pain care is possible. To achieve this, healthcare providers will be challenged to address their part in disparate care, to ensure patients can trust them, and to insist that the healthcare system make anti-racist changes.

Pain Management in the Critically Ill Patient

LIANG SHEN, JOHN E. RUBIN, JAMES LITTLEJOHN

Introduction

Pain in the critically ill has been historically poorly understood. Only recently has attention and investigation turned toward the issues of pain assessment and treatment in this patient population. The prevalence of poorly treated pain in the critically ill is considerable and greater than commonly believed among health care physicians. This chapter examines some salient issues as well as the modern, pertinent literature detailing barriers to assessing and treating pain in a critical care setting, as well as some strategies for dealing with this challenging clinical dilemma.

Prevalence of Pain in the Intensive Care Unit (ICU)

Although often unable to communicate because of the severity of their disease process or the presence of impediments such as artificial airways or endotracheal tubes (ETT), patients admitted to the ICU often experience pain and discomfort that goes unrecognized and untreated. Estimates vary based on patient populations, but large proportions of both medical and surgical patients report experiencing pain while in the ICU.[1–4]

One study of cancer patients found that between 55% and 75% of patients reported experiencing pain, discomfort, anxiety, sleep disturbance, or unsatisfied hunger or thirst.[5] Another study demonstrated that 77% of cardiac surgery ICU patients recalled experiencing pain, with 64% rating the pain as moderate or severe.[6] An often-underappreciated source of pain in the ICU is during routine procedures, such as patient turning, ETT suctioning, chest tube removal, arterial or venous line insertion, or wound care.[2] One prospective cohort study of 400 medical ICU patients found that those patients for whom analgesics were prescribed had a higher concomitant incidence of hemodynamic monitoring, greater use of neuromuscular blocking agents, more mechanical ventilation days, and more prolonged ICU and hospital lengths of stay.[7] Consistent with these findings, patients who received analgesics also had higher Trauma Injury Severity Scores and predicted mortality.

The SUPPORT investigators examined more than 4000 ICU patients over two years. Family members reported moderate to severe pain at least half the time for 50% of conscious patients who died in the hospital.[8] Similarly high rates of moderate to severe pain were found in another study of surgical ICU patients.[9]

One investigation used a questionnaire to collect data on patients' stressful experiences associated with being in an ICU and on mechanical ventilation.[10] Of those who remembered the ETT, a large proportion were significantly bothered by not being able to speak (68%), pain associated with the ETT (56%), and anxiety regarding the ETT (59%). It is not surprising that this study found that those who did not remember the ETT or ICU were on average more severely ill and subject to a longer duration of mechanical ventilation than the group who remembered these experiences. Given the severity of their disease process, the former group may have been more likely to be chemically paralyzed or heavily sedated.

Despite a high incidence of pain in ICU patients, studies find that it often goes untreated. An observational study in 128 Italian ICUs of 661 postoperative patients found that 36% of patients did not receive any analgesia in the first 48 h of their ICU stay.[11] "Pain control" was listed as the reason for administration in only 54.5% of instances in which an opioid was given.

Barriers to Pain Assessment in the ICU

Given the potential compromise of patients' physiologic stability and communication skills secondary to underlying disease processes, ICU patients present unique challenges for the assessment and treatment of pain. Indeed, critically ill patients have a much higher risk of enduring untreated pain because they often cannot communicate their level of discomfort because of altered mental status, mechanical ventilation, and sedation (Box 81.1).[12] A clinician's observation and subjective rating of ICU patient pain often underestimates that patient's pain.[13] Thus whenever possible, ICU patients should rate their own pain. Patient self-reported pain using a one to ten point numeric rating scale (NRS) has been recommended by critical care societies.[4,14]

A critically ill patient may be obtunded secondary to the underlying disease process or physiologically compromised by a process such as sepsis or shock. The question of how much pain the patient is experiencing may be difficult to answer in these settings. Many patients may not remember these experiences, and even if these experiences can be recalled, there are limitations to assessing pain retrospectively.[15] The use of proxy assessment for patient symptoms is controversial. Proxies, such as family members or bedside clinicians, may overestimate or underestimate the symptoms experienced by patients.[16,17] Therefore increased vigilance by physicians and nursing staff and the development and

• BOX 81.1 Barriers to Pain Assessment and Treatment in the Intensive Care Unit

- Severe critical illness causing altered mental status
- Endotracheal intubation or non-invasive positive pressure ventilation (BiPAP or CPAP mask)
- Failure to recognize or prioritize pain control amid hemodynamic instability, sepsis, or other organ problems

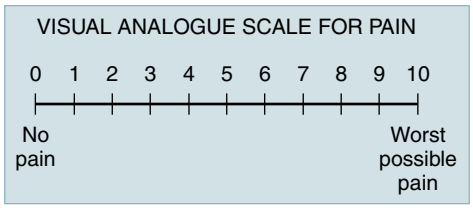
use of alternative means of pain assessment are necessary when patients cannot verbalize pain.

Indirect methods of evaluating pain are used for patients unable to communicate verbally. The behavioral pain scale (BPS) (Fig. 81.1) and the Critical Care Pain Observation Tool (CPOT) are commonly used pain scales used in adult patients, excluding those with brain injuries.[2,3] The BPS uses a patient's facial expression, upper extremity movements, and compliance with the ventilator as surrogate indicators of pain, with a score of five or greater indicating unacceptable levels of pain. Similarly, the CPOT evaluates facial expression, body movements, muscle tension, and compliance with the ventilator for intubated patients or vocalization for extubated patients. A CPOT score of three or above indicates significant pain.

Various studies to validate these tools in the critically ill have been published,[18–20] although other scales, such as the adult Nonverbal Pain Scale (NVPS), and the Faces, Legs, Activity, Cry, and Consolability scale, have also been used in different patient populations.[12]

Pain assessment and treatment can also be systematically improved in ICUs. One study examined the assessment and treatment of pain in two surgical ICUs in a university hospital setting.[21] After the investigators implemented a series of measures to introduce a modified visual analog scale (VAS) similar to an NRS (Fig. 81.2) and educated physicians and nurses on the importance of pain assessment and treatment, pain assessments improved from a rate of 42% to more than 70%. Patients whose pain was controlled (VAS less than 3/10) increased from 59% to greater than 90%. Another study showed that after standardized implementation, the CPOT resulted in a more consistent assessment of pain in critically ill patients and fewer analgesic and sedative agents being administered.[22]

The treatment of pain in critically ill and postoperative pediatric patients is also essential for their comfort, and the use of pain protocols in these regards improves patient comfort.[23] More implementation of such protocols may be helpful in the pediatric critical care population.



• Figure 81.2 Modified Visual Analog Scale for Pain.

Barriers to Pain Treatment in the ICU

The difficulty of treating pain in those hospitalized in the ICU has been documented, and there is a defined lack of high-level evidence for clinical decision making in these regards. Frequent need for rapid drug titration can contribute significantly to interpatient variability in response, which is likely more magnified in critically ill patients. Moreover, there can be significant difficulty in distinguishing adverse drug events from other comorbid medical conditions in ICU patients.[24]

A consensus guideline regarding sedation and analgesia in dying critically ill patients[25] (Box 81.2) recognized the difficulty of pain assessment in this setting as a result of several factors, including communication problems particular to the ICU environment, the severity of the critical illness, the potential presence of multisystem organ failure, the possibility of a decreased level of consciousness resulting from illness and drugs, and difficulty in the interpretation and reporting of clinical signs.

One study analyzed the adequacy of pain control for 17 trauma patients during the initial aspect of their ICU admission.[26] In contrast to the 47% of patients rating their pain as severe, 95% of house staff and 81% of nurses reported the patients had received adequate pain control. This is underscored by the fact that 53% of house staff did not ask patients if pain control was satisfactory. Presumed barriers to adequate pain control were felt to include a disparity in the perception of pain between patients and caregivers, patients refusing to request pain medicine despite the presence of moderate to severe pain, and physician and nurse concerns about patients' adverse physiologic response to further or increased doses of analgesics. It was noted that 19% of patients reported a fear of addiction to opioids. Misconceptions regarding opioid pharmacology on the part of caregivers have been reported.[26] In one report, some nursing staff felt that the use of anxiolytics negated the need for larger doses of opioids.

More recently, the opioid epidemic in the United States has increased scrutiny of iatrogenic, including ICU-acquired, opioid dependence, or opioid use disorder. Studies on the subject are still limited,[27] but in part because of concern about quantity and prevalence of opioid use in the ICU, there has been greater interest

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering) e.g.	2
	Fully tightened (e.g., eyelid closing) e.g.	3
	Grimacing	4
Upper limb movements	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
	Permanently retracted	4
Compliance with mechanical ventilation	Tolerating movement	1
	Coughing but tolerating ventilation most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

• BOX 81.2 Guidelines for Relief of Pain and Suffering in the Intensive Care Unit

Relief of Pain and Suffering

To relieve pain and suffering at the end of life, both pharmacologic and nonpharmacologic means should be used. Nonpharmacologic interventions include ensuring the presence of family, friends, and pastoral care (if desired) and changing the technologic intensive care unit (ICU) environment to a more private and peaceful one.

Initial Dosage

Most ICU patients require narcotics and sedatives to ease the pain and suffering associated with their critical illness. The amount of drugs needed varies on an individual basis. As in active disease treatment, palliative care *must* be individualized.

Titration of Analgesics and Sedatives

Once analgesics and sedatives are initiated, they are increased in response to (1) the patient's request; (2) signs of respiratory distress; (3) physiologic signs - unexplained tachycardia, hypertension, diaphoresis; (4) facial grimacing, tearing, vocalizations with movements, turns or other nursing care; and (5) restlessness.

Does a Maximum Dose Exist?

No maximum dose of narcotics or sedatives exists. The goal of palliative care is to provide relief of pain and suffering, and whatever amount of drugs accomplishes this goal is the amount needed for that individual patient.

Should Analgesics and Sedatives Be Administered in Response to Signs and Symptoms of Pain and Suffering or Before They Begin?

Support for both approaches exists among intensivists. The treatment of signs and symptoms of pain and suffering is good palliative care. When appropriate doses of narcotics and sedatives are used, and the intent of the physician is clear and well documented, pre-emptive dosing in anticipation of pain and suffering is not euthanasia or assisted suicide but good palliative care.

Summarized from: Hawryluck LA, Harvey WR, Lemieux-Charles L, et al. Consensus guidelines on analgesia and sedation in dying intensive care unit patients. *MBC Med Ethics.* 2002;3(1):3.

in the use of multimodal analgesia in these patients. In one study of 127 critically ill trauma patients, the implementation of a multimodal approach toward pain control significantly lowered average opioid use without changing average pain scores.[28]

Benefits of Assessing and Treating Pain in the ICU

Patients who are critically ill following surgery are at high risk for pulmonary complications, especially in those who require mechanical ventilation. Pulmonary complications stemming from increased pain may result in hypercarbia, hypoxia, atelectasis, retention of secretions, and pneumonia.[29] Thoracic epidural analgesia (TEA), ultrasound-guided peripheral nerve blocks, and intravenous (IV) patient-controlled analgesia (PCA) may be used in these situations. Clinical scenarios in which placement of thoracic epidurals for analgesia may be of significant benefit include patients with post-thoracotomy pain,[30,31] trauma patients suffering from rib fractures, and to facilitate weaning from mechanical ventilation.[32] PCA, either via the epidural or IV route, can be helpful in an awake and alert ICU patient by allowing the patient to receive on-demand dosing of analgesics, which may reduce the risk of undertreating pain compared to intermittent doses delivered by healthcare providers.

Some controversy exists regarding the efficacy of the administration of epidural opioids, local anesthetic infusions, intercostal nerve blocks, or IV opioids in reducing postoperative pulmonary complications. A meta-analysis of randomized, controlled trials examined postoperative analgesic therapies and their effects on pulmonary outcomes.[33] Epidural opioids decreased the incidence of atelectasis but did not have a statistically significant effect on the incidence of pulmonary infections or other pulmonary complications as compared to systemically administered opioids. Intercostal nerve blocks also did not demonstrate a statistically significant outcome toward reducing pulmonary complications after surgery. In contrast, local epidural anesthetics, compared to systemically administered opioids, were found to decrease the incidence of pulmonary infections and pulmonary complications overall. No clinically or statistically significant differences were found in other measures of pulmonary function, including forced expiratory volume in 1 s, forced vital capacity, or peak expiratory flow rate for any pain management modality. This meta-analysis suggests the value of postoperative epidural analgesia in reducing postoperative pulmonary morbidity compared to other modalities.

The mechanisms of pain's role in the body's stress response include activation of the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis, increasing the secretion of catecholamines and catabolic hormones such as glucagon and cortisol, decreasing the secretion of anabolic hormones such as insulin, and increasing antidiuretic hormone and aldosterone levels.[34] Thus one benefit of effective pain management in the critically ill may be to attenuate this stress response.

Pain management in the critically ill is especially important for patients who are dying. One group attempted to study the quality of the dying process in the ICU by retrospectively interviewing family members of 38 ICU decedents.[35] The investigation found that family members perceived that the patients experienced substantial physical symptoms during the last week of life but felt that pain was well-controlled less than half the time. A review of the hospital records showed a nearly universal absence of data regarding pain assessment and records of how sedatives and analgesics were titrated to pain and symptom relief. Of the many items measured, the perception of how well the patient's pain was under control correlated strongly with the quality of dying ratings as measured in the study. Thus optimizing pain management for end of life care supports patients and their families to achieve dignity, respect, and peace during the dying process.

Implementing a structured and scheduled approach to pain management in the ICU may also be of significant value, both to the patient and medical institution providing care.[14] ICU patients whose pain regimens were titrated based on standardized sedation, analgesia, and delirium scores attained better analgesia, received fewer opiates, and endured a shorter duration of mechanical ventilation despite comparable sedation.[36] In patients after cardiac surgery, when "as needed" analgesics were changed to scheduled, around-the-clock dosing with doses prior to procedural pain, pain relief was found to be effective in 95% of patients over the first six days postoperatively. Side effect profiles improved, and median length of stay after surgery decreased. In addition, implementation of a structured ICU pain protocol reduced the cost per patient by $10,500 by decreasing ventilator and ICU days, leading to a cost savings of nearly $2 million for the hospital over 26 months.[37]

Methods of Pain Control in the ICU

This topic is limited to a discussion of methods of pain control (Box 81.3) as pertinent to the ICU setting, given that these issues are discussed in detail in other chapters in this text.

• BOX 81.3 Multimodal Pain Control in the Intensive Care Unit

- Opioids (short and long acting)
- Narcotic Sparing Agents
  - Nonsteroidal anti-inflammatory drugs
  - Acetaminophen (paracetamol)
  - *N-methyl*-D-aspartate receptor antagonists (ketamine, methadone)
  - Gabapentinoids (pregabalin, gabapentin)
- Regional Analgesia
  - Neuraxial (epidural and intrathecal) local anesthetics and opioids
  - Peripheral nerve blocks (including sympathetic nerve blocks)
  - Myofascial plane blocks
- Pre-emptive strategies before major surgery
- Nonpharmacologic approaches (i.e. hypnosis)

Analgesia may be administered by blocking afferent impulses carried along neural pathways, affecting integration in the central nervous system (which may display plasticity and central sensitization in response to pain), and blocking efferent impulses modulated by the neuroendocrine or sympathetic nervous system.[38]

Opioids mediate analgesia by binding with central and peripheral opioid receptors, with the μ and κ receptors most important for analgesia. An "ideal" opioid would have a rapid onset, ease of titration, lack of accumulation of the drug or its metabolites, and low cost.[39] Morphine has ideal characteristics but may precipitate histamine release and theoretically cause hypotension in the ICU patient with decreased intravascular volume. In addition, active metabolites such as morphine-3- and morphine-6-Glucuronide may accumulate in the presence of renal insufficiency. Meperidine is a poor drug for use in the ICU. It is metabolized to normeperidine, the accumulation of which may lead to delirium and seizures in patients with renal compromise. Opioids are discussed in more detail in Chapter 48.

The Society of Critical Care Medicine put forth practice parameters with regard to the use of opioids in the ICU.[40] The authors suggested that morphine is the initial agent of choice and is best started at a loading dose of 0.05 mg/kg administered over 5–15 min. It was suggested that most adults require 4–6 mg/h after an adequate loading dose. This report also suggested that fentanyl (1–2 mcg/kg/h after one or more loading doses of 1–2 mcg/kg) or hydromorphone (initiated at 0.5 mg and titrated by 0.5 mg increments to a general range of 1–2 mg every 1–2 h) are acceptable alternatives to morphine. It is important to emphasize that opioid-tolerant patients often require higher doses of opioid analgesia than their opioid-naïve counterparts.

The use of opioids may lead to hypotension in patients with intravascular volume compromise or those reliant on sympathetic tone for end-organ perfusion, which may be a significant issue in the ICU population. The route of administration is important. Subcutaneous and intramuscular injections, never optimal for pain relief in any setting, are not advisable given the uncertain perfusion and absorption seen in many ICU patients.[41] Transdermal fentanyl presents similar issues and is suboptimal for acute pain management given the 12–24 h delay in both the onset and offset of analgesia.[42] Patients who can cooperate may benefit from the institution of IV PCA. IV PCA possesses an inherent safety mechanism, as the patient will become unable to use the demand feature when side effects such as sedation are more prominent. This property of IV PCA helps minimize the chance of opioid overdose and resultant respiratory depression while optimizing the timely delivery of an analgesic agent to the patient.[43]

In addition to short acting opioids, long acting opioids like methadone may be useful in critically ill patients. Methadone may be particularly helpful for patients on high doses or escalating doses of short acting opioids, though QTc duration should be carefully monitored for prolongation during therapy.[44]

Another adjunct in the multimodal approach to pain in the ICU is acetaminophen. Among older patients, those who received scheduled acetaminophen postoperatively in conjunction with either a propofol or dexmedetomidine drip were shown to have reduced in-hospital delirium when compared to a placebo.[45] Other non-opiate analgesics, such as ketamine in the form of a continuous infusion, may also be useful for critically ill patients.[14,46] Ketamine can be a versatile agent in the ICU as it can be used as both an analgesic and a sedative.

Nonsteroidal anti-inflammatory agents (NSAIDs) should not be discounted as useful adjuncts in some ICU patients. Ketorolac, an IV NSAID, has been shown to have opioid-sparing effects and therefore may limit opioid-mediated side effects. This and other nonselective inhibitors of cyclooxygenase (COX) may have adverse effects on gastric mucosal perfusion, platelet aggregation, and renal perfusion in patients with suboptimal intravascular volume status. Therefore it is recommended that ketorolac be limited to only five days' use and administered with caution in older adults.[47] Highly selective COX-2 inhibitors are not in common use in the ICU setting and may be inappropriate in older adults, given the documented increase in adverse cardiac events in this population.[48]

The preoperative use of pregabalin has been explored to reduce postoperative opioid requirements. One randomized, double-blind, placebo-controlled trial examined a pre-emptive strategy for reducing opioid consumption in elderly patients undergoing cardiac surgery by pretreating surgical candidates with pregabalin prior to surgery and then for five days after surgery. The group of patients administered pregabalin demonstrated a marked reduction of postoperative opioid consumption, to almost 50%, from the time of extubation to the fifth postoperative day, as compared to those on placebo. Patients treated with pregabalin also experienced a reduced incidence of postoperative confusion on the first postoperative day. However, the time to extubation was 138 min shorter in the placebo group.[49] It is unclear if this effect is unique to pregabalin itself or rather a class effect of the gabapentinoids, in which case gabapentin may also demonstrate similar efficacy.

Opioids may be dosed intrathecally postoperatively before a patient's transfer to the ICU. There is a concern for delayed respiratory depression in these patients, which may require monitoring and affect the timing of subsequent analgesics. Intrathecal opiate dosing was examined in a prospective, randomized, double-blind study in postoperative lumbar spinal fusion patients.[50] Patients were randomized to receive an intraoperative injection of 0.2 mg (group 1), 0.3 mg (group 2), or 0.4 mg (group 3) of morphine into the subarachnoid space under direct visualization. Pain levels at 0 h and 12 h after surgery were significantly higher in group 1 than those in groups 2 and 3. However, the patients in group 3 experienced significantly decreased respiratory rates, with higher $PaCO_2$, than those in groups 1 and 2. There was no difference in reports of pruritus or nausea among the three groups. Some intensivists have suggested that this would argue for 0.3 mg as an optimal perioperative intrathecal morphine dose.

TEA using a local anesthetic, with or without the addition of an opioid, may be helpful for patients with thoracotomy pain or traumatic rib fractures.[32] Alternative regional techniques such as myofascial plane blocks have also been utilized recently in the

setting of traumatic rib fractures. These are discussed in more detail in the subsequent section.

Another potential role for interventional pain procedures in the ICU is in patients with poor distal extremity perfusion. Sympathetic blocks may improve circulation in such situations[51] and can be achieved via a stellate ganglion block for the upper extremity or lumbar sympathetic block for the lower extremity. An indwelling axillary or femoral nerve sheath catheter can also deliver local anesthetic continually, either with or without superimposed patient-demand dosing.[52]

It is particularly important to consider the burn ICU patient population, as pain is often one of their most serious and persistent complaints. As an adjunct approach to burn patients' pain management, hypnosis was demonstrated in one study to reduce pain intensity and anxiety, improve the efficiency of administering opioids, improve wound outcome, decrease costs, and overall improve patient care of burn ICU patients without pharmacologically induced side effects.[53]

Neuraxial Analgesia and Regional Anesthesia in the ICU

Epidural infusions may consist of a local anesthetic only, an opioid only, or both. Combining both drugs allows for the synergy of two mechanisms of action: local anesthetics block sodium channels on the nerve membrane, and opioids act via opioid receptors in the substantia gelatinosa of the dorsal horn of the spinal cord. This combination also minimizes the potential toxicity or side effects from each agent, including seizures or cardiac toxicity from the local anesthetic, and sedation or respiratory depression from the opioid.[54]

Many local anesthetic-opioid combinations include fentanyl. Fentanyl is relatively lipophilic, achieves plasma levels relatively quickly, and tends to affect the neuraxis at or near the level of the spinal cord where it is infused.[55] Morphine, conversely, has relatively hydrophilic properties and tends to ascend cephalad in the neuraxis, potentially contributing to delayed respiratory depression.

The clinical situation in the ICU may dictate the choice of analgesic in the epidural. TEA may be beneficial for pain control in post-thoracotomy patients to treat incisional pain and pain from chest tube sites, which can be particularly difficult to control.[56] As many thoracic surgeries restrict the volume of IV fluids administered intraoperatively, patients may arrive in the ICU concurrently with uncontrolled pain and hypotension. Local anesthetics given via the epidural catheter may worsen hypotension because of a decrease in sympathetic tone. One solution to this problem is to provide an opioid only epidural infusion.[57] Adequate neuraxial analgesia can be achieved without the hypotension that might ensue from a local anesthetic, and a local anesthetic-opioid combination can be used once the patient becomes hemodynamically stable. Of note, while epidural opioids are effective for pain, there may not be any additional benefit for an opioid only epidural infusion over IV opioids with respect to pain scores, return of gastrointestinal function, and length of stay.[58]

A group of authors examined the effect of thoracic epidural bupivacaine-morphine versus IV PCA morphine after thoracoabdominal esophagectomy.[59] The epidural group reported better pain scores on postoperative day one and decreased opioid-mediated side effects such as sedation. There was no effect on ICU length of stay, duration of hospitalization, or mortality. The epidural group also received more IV fluid in the first 24 h, likely related to decreased sympathetic tone and hypotension.

Epidural analgesia has also been utilized for ICU patients with posttraumatic rib fractures. One study compared epidural analgesia to IV PCA in patients with rib fractures after motor vehicle accidents and found that epidurals improved patients' pain scores.[32] Although the patients who received epidural analgesia were older and sustained more rib fractures, their pain scores were significantly lower. Another study examined epidurals in patients with chronic obstructive pulmonary disease undergoing open abdominal aortic aneurysm surgery; it determined that both epidural anesthesia and postoperative epidural analgesia improved postoperative respiratory function and reduced postoperative pain compared to general anesthesia with IV analgesia.[60] Finally, one study comparing TEA to a surgeon-administered intercostal nerve block plus a postoperative IV morphine PCA demonstrated that TEA was associated with superior postoperative pain control and restoration of pulmonary function.[61]

There is evidence that despite the demonstration of efficacy for rib fractures, TEA is underutilized. A study retrospectively examined more than 64,000 patients from the National Trauma Data Bank with one or more rib fractures.[62] The authors found that mortality and pulmonary morbidity increased with the number of rib fractures. It was found that only 2% of all patients with fractured ribs received epidural analgesia. This use was increased in patients who suffered six or more rib fractures. The use of epidural analgesia was associated with a significant decrease in-hospital mortality compared to alternative forms of analgesia.

Regional anesthesia may also have an increasing role in the ICU as well. For example, truncal blocks, like serratus anterior, transverse abdominal plane, rectus sheath, quadratus lumborum, and erector spinae, can be useful tools for effective pain control in the critically ill. Peripheral nerve blocks or catheters can provide long-lasting pain control in patients for whom epidural analgesia may be undesirable or contraindicated.[63,64] Although studies related to truncal blocks in the critically ill are still sparse, an increasing number of reports suggest that they can play an important role in the multimodal pain management of the critically ill. For example, one case report demonstrated the utility of bilateral rectus sheath catheters in a patient requiring an exploratory laparotomy who refused a preoperative epidural.[65] Another randomized, controlled trial demonstrated that patients undergoing open thoracotomies receiving serratus anterior catheters with continuous infusions for 24 h postoperatively had comparable pain scores and rescue analgesic IV morphine doses compared to patients who received TEA.[66] Recently, two case reports have demonstrated the efficacy of the transversus thoracic muscle plane block for patients requiring a median sternotomy for cardiac surgery in both a single-shot and continuous infusion peripheral nerve blocks.[67,68]

Compared to other regional and neuraxial techniques, myofascial blocks have virtually no risk of hemodynamic changes, motor blockade, vascular, or intrathecal injection. Two blocks in particular, the serratus anterior plane (SAP) block, in multiple case reports, and the erector spinae plane (ESP) block, in a retrospective cohort study on patients with rib fractures, have demonstrated a reduction in opioid use (SAP and ESP), improvement in pain scores (SAP and ESP), and improvement in inspiratory volumes (ESP).[69] Although these myofascial plane blocks show promise in their efficacy and side effect profiles, additional studies are needed to elucidate further their precise applicability, safety, and dosing in patients with chest wall trauma.

One major barrier to the more widespread use of neuraxial analgesia and regional anesthesia in critically ill patients is anticoagulation. Many patients may require anticoagulation during their hospital stay. Examples include cancer patients with venous thromboembolism and post-cardiac surgery patients with valve replacements or repairs. It is important to know a patient's anticoagulation status and laboratory values prior to initiation and during the continuation of an epidural or peripheral nerve block. The American Society of Regional Anesthesia and Pain Management (ASRA) provides guidelines for the placement, maintenance, and removal of blocks and catheters for peripheral or neuraxial analgesia.[70] The salient points in the ASRA guideline are discussed in Chapter 74.

Sedation in the ICU

The main indications for sedation in an ICU setting include patient tolerance for ventilation, medical and nursing interventions, and actual patient symptoms.[71] Current practice guidelines recommend a systematic, multimodal approach to optimizing analgesia prior to treating agitation.[14] Before treating anxiety in critically ill patients, it is crucial to identify other organic abnormalities that can contribute to their symptoms. These include hypoxemia, hypoglycemia, hypotension, metabolic disturbances, and drug and alcohol withdrawal. Agitation may lead to harmful sequelae such as breathing against the ventilator, increased oxygen consumption, and removal of monitoring devices and catheters.[72] No one gold standard exists to quantify the level of sedation, and the Ramsay, Riker, Motor Activity Assessment, Richmond Agitation-Sedation Scale, and Vancouver scales all have been used for this purpose.[73–77]

Common sedatives used in the care of critically ill patients include hypnotic agents (such as propofol), opiates (including fentanyl or hydromorphone), benzodiazepines (such as midazolam and lorazepam), and centrally-acting α2 agents (most commonly dexmedetomidine). Titrating a given sedative to a defined endpoint has been recommended, with subsequent systematic tapering of the dose or protocol-based daily interruption of sedation with re-titration to minimize prolonged sedation.[14]

Analgesia-based sedation decreased the duration of mechanical ventilation compared to more traditional hypnotic-based sedation during weaning from mechanical ventilation.[78] A remifentanil-based regimen titrated to optimum levels prior to initiation of midazolam (hypnotic agent), compared with a midazolam-based regimen, resulted in a decreased duration of mechanical ventilation by more than two days. It also reduced, by one day, the time from the start of the weaning process to the time of extubation.

One study suggested that dexmedetomidine could be a viable long-term sedative in the ICU setting that may reduce the duration of mechanical ventilation and improve comfort. Two randomized, controlled trials demonstrated that dexmedetomidine was non-inferior to propofol and midazolam in maintaining target levels of sedation in ICU patients who required prolonged mechanical ventilation. Moreover, dexmedetomidine also appeared to reduce the duration of mechanical ventilation as compared to midazolam, and it reduced the time to extubation compared to both midazolam and propofol. Dexmedetomidine was also associated with decreased rates of delirium and improved patient communication with nursing staff compared to propofol. However, dexmedetomidine use did not affect the length of ICU or hospital stay and was associated with higher rates of hypotension and bradycardia compared with midazolam.[79] A more recent study found that patients who received dexmedetomidine as their sole sedative had a similar mortality rate at 90 days compared to patients sedated with propofol or benzodiazepines. However, there were more adverse events reported in the dexmedetomidine group. A significant proportion of the group also required the addition of propofol, midazolam, or both to achieve target levels of sedation, suggesting that dexmedetomidine may sometimes be inadequate as a single sedative for mechanically ventilated patients.[80]

Conclusion

The assessment and treatment of pain in the critically ill patient population are challenging tasks given the frequent lability in patients' physiologic status and the compromise in their ability to communicate. Intensivists have various therapeutic options available, including NSAIDs, acetaminophen, opioids, ketamine, and neuraxial and peripheral nerve blockades. Although undertreatment of pain in ICU patients is well documented, data suggest that organizational changes, implementation of standardized pain regimens and sedation/analgesia protocols, and appropriate use of pharmacologic therapy may improve pain control in critically ill patients. Appropriate sedation is equally important in pain control, and newer agents such as dexmedetomidine, promising shorter ventilation times and better comfort, offer more options to accomplish these goals.

Key Points

- Pain in the critically ill patient is often difficult to assess because of communication barriers and often-life-threatening, multiorgan disease.
- As part of a protocol-based approach, the use of behavioral scales should be utilized in the critically ill to quantify pain and guide analgesia and sedation.
- Pain control is an essential component of care for these patients, and several analgesic therapies are available to clinicians.
- Among opioids, morphine, fentanyl, and hydromorphone are all reasonable initial agents.
- Adjuncts in the pharmacologic management of pain include acetaminophen, NSAIDs, dexmedetomidine, and ketamine.
- Sedatives are frequently used in the ICU to increase patients' tolerance to mechanical ventilation and medical interventions. Medications for this purpose include propofol, opiates, benzodiazepines, and dexmedetomidine.
- Regional anesthesia can be utilized to reduce opioid and sedative requirements.
- TEA and intercostal nerve blocks have been employed for years in the ICU. Newer regional blocks include transversus thoracic muscle plane, rectus sheath, SAP, and ESP blocks. The benefits of these blocks include simplicity of placement, decreased risk of hemodynamic changes, and increased flexibility in the setting of anticoagulants.

Pain Management at the End of Life and Home Care for the Terminally Ill Patient

DALYA ELHADY, DIANE NOVY

Introduction

The end stages of life bring a host of challenging symptoms and causes of suffering that may have accumulated with chronic, progressive, life-limiting diseases. The symptoms of pain, dyspnea, fatigue, and loss of mobility accompany emotional states, such as depression, anxiety, and a sense of uselessness.[1] Of the many symptoms experienced by those at the end of life, pain is one of the most common and most feared.[2] Pain is often undiagnosed and undertreated and can undermine the quality of life and interfere with physical functioning and social interactions. Uncontrolled severe pain is strongly associated with heightened psychological distress and can lead to a desire for hastened death.[3–5]

Improving the quality of life and decreasing undesirable symptoms are the hallmarks of palliative, hospice, and end of life care. Although overlap exists between these models of care, there is a distinction in that palliative care aims to manage and decrease symptom burden because of disease progression of comorbid illness, whereas hospice care is focused on the care and comfort of a patient that is in imminent death or dying.[6] The American College of Physicians defines the end of life period as "a phase of life when someone is living with an illness that will worsen and eventually cause death. It is not limited to the short period when the patient is moribound."[7] This challenges providers to think about the management of pain at the end of life as a chronic symptom as many of these patients will spend significant time in this phase of their life.

Pain associated with terminal illness and end of life is an extremely stressful experience for both patient and family. The prevalence of pain is reported in up to 80% of patients and increases toward the end of life.[8] Additionally, the assessment and management of pain are made more complex by the presence of other symptoms and dynamic changes associated with disease progression. Compared to cancer patients that die in a hospital, those who die at home have a higher quality of life scores, and their bereaved family members are at less risk for developing psychiatric illness.[9] The majority of patients and families prefer to die at home, but there is a minority that prefers to die in the hospital or has no preference.[10] Vidal et al. suggest that preference for dying in the hospital may be attributed to previous failed attempts at home care, uncontrolled symptoms, or caregiver burden.[10] The experience of pain at the end of life involves the management of multiple symptoms by family and friends, which predominantly occurs as a home experience that has potential for improvement.[11]

Pain associated with the end of life and terminal illness is complex and must be viewed within a cluster of symptoms that need to be monitored and managed by the caregiver, which will also require guidance and support from the healthcare team. The successful care of a patient in the final stages of a terminal illness at home is dependent on the awareness and provision of basic and specialized interventions to ensure patient comfort and prevent prolonged grief in surviving loved ones. Careful discharge planning followed by regular assessment and reassessment can facilitate effective pain management and support for the patient at home and minimize pain "emergencies." Effective communication between the primary physician, advanced practice nurse, home care nurse, social worker, and caregiver, as well as ready access to the point person among these professionals, is essential for the success of the home care plan. Input from consulting physicians, such as pain medicine, palliative care, and psychiatry, must also be incorporated in the treatment plan (Box 82.1). A system of ongoing monitoring and support for the patient and caregiver needs to be in place to ensure the effectiveness of pain relief measures and early identification of caregiver burden and unmet needs.

Prevalence and Causes of Pain at the End of Life

It is important to acknowledge and address the prevalence of pain in the end stage conditions that affect patients with advanced medical illnesses, such as cancer, heart disease, human immunodeficiency virus (HIV) disease, neurodegenerative diseases, and end stage renal, liver, and respiratory diseases (Box 82.2).[12] The management of these patients is complicated by the potential presence of multiple comorbid disorders that may each contribute differing components of the overall pain and require separate treatments. Although pain at the end of life is often attributed to terminal illness, common chronic pain conditions are more likely to contribute to discomfort. An observational study of over 4,700 older adult decedents found the prevalence of pain in the last month of life to be 60% in those with arthritis versus 26% in those without.[13]

The prevalence of pain in the terminally ill varies by diagnosis and demographics. Approximately one-third of the people who are actively receiving treatment for cancer and two-thirds of those with advanced malignant disease experience pain.[14,15] Almost 75%

- Peripheral vascular disease
- Central or peripheral neuropathies

of patients with advanced cancer who are admitted to the hospital report pain on admission.[16] In a study of cancer patients who were very near the end of life, pain occurred in 54% and 34% at four weeks and one week prior to death, respectively.[17] In an outpatient cancer center, an evaluation of over 5,000 patient encounters where the pain intensity scores were high (7–10 on a scale of 0–10) demonstrated that 29% of these patients were hospitalized within 30 days of those visits. In another study of more than 13,000 cancer patients in United States nursing homes, an average of 30% of the patients reported daily pain. In those patients, pain varied according to age, sex, race, marital status, physical function, depression, and cognitive status.[18]

In patients admitted to palliative care units, pain is often the dominant symptom, along with fatigue and dyspnea.[12] Until recently, it was widely believed that patients dying from nonmalignant disease did not have high levels of pain. However, it is now known that patients dying from cardiac failure, chronic obstructive pulmonary disease (COPD), end stage renal disease, and other end stage diseases suffer similar levels of pain to those found in patients with malignant disease.[3] Comparing advanced cancer patients to those with symptomatic congestive heart failure (CHF), it is now clear that the symptom burden is as great or greater in the latter.[4] In a multi-center Veterans Administration (VA) study of CHF patients, it was noted that over 55% of them had pain (the majority of which rated their pain as moderate to severe), which was more common than the sensation of dyspnea.[5]

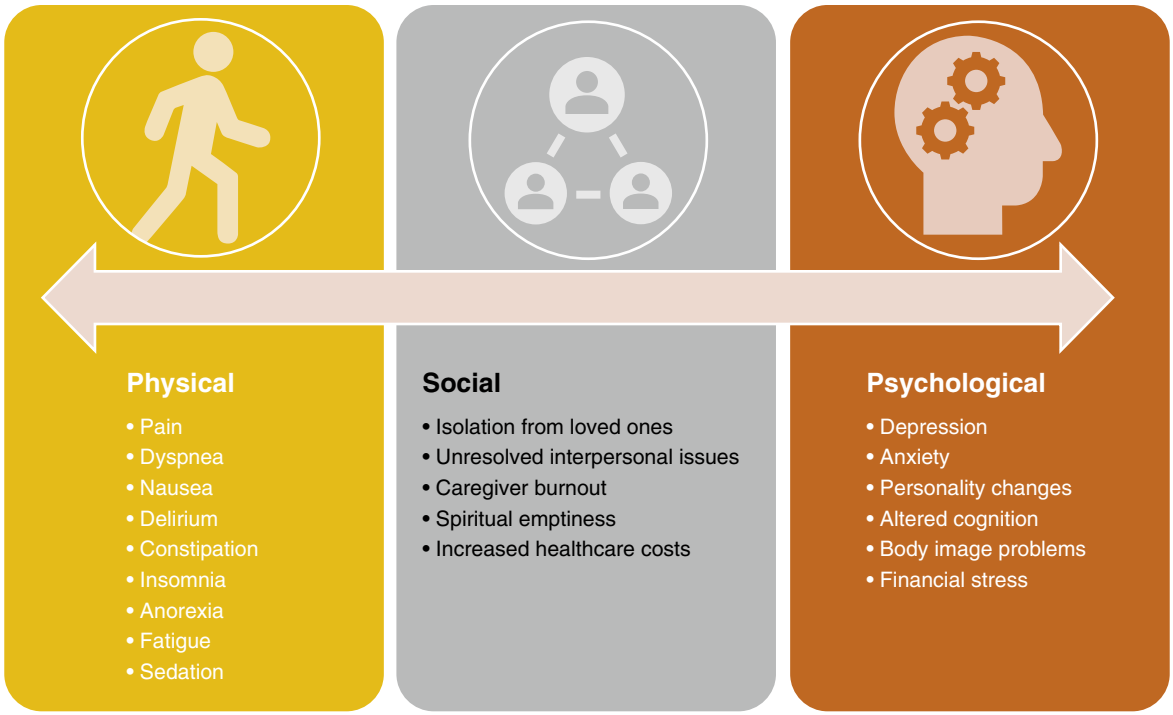
An attempt has been made to characterize the pain experience of those with HIV disease because of the frequently for this disorder to be seen in palliative care settings. More than 56% of patients with HIV disease report pain, with the most common manifestations being headache, abdominal pain, chest pain, and neuropathies.[6] There have been many reports of undertreatment of patients with HIV disease, including those patients with a history of addictive disease.[19] Other groups at particular risk for undertreatment of pain include older adults, minorities, and women.[20]

Assessing Pain and Suffering at the End of Life

Pain remains a subjective experience with physical, psychological, and social dimensions that are interdependent and intensified at the end of life. This multifaceted pain experience significantly impacts patients and families, especially when pain is not adequately controlled (Figure 82.1). Assessment of pain generally includes a thorough history, physical examination, and psychosocial assessment. This serves as a comprehensive guide in the choice of diagnostic studies and the development of a pharmacologic and nonpharmacologic treatment plan. Various assessment tools range from simple unidimensional tools, such as pain rating scales, to complex multidimensional tools that address multiple facets, including physical and psychological symptoms, functional status, mental health, and social role. A systematic review of assessment tools related to palliative care found 152 different tools that primarily identified domains such as physical, psychiatric, social, and end of life care but few existing for spiritual, cultural, and legal domains.[21]

The use of self-report is the gold standard for pain assessment.[22] Ideally, an assessment tool that is suitable for a patient's ability to self-report should be utilized to engage the patient in the evaluation. Older patients or those that are medically frail or terminally ill have a higher incidence of cognitive impairment, hearing and visual deficits, and medication side effects than those in younger or healthier populations. This may complicate the assessment of pain and requires additional time to allow for effective communication. Speech should be clear and unhurried; words and questions should be rephrased to ensure they are understood. The patient should be allowed plenty of time to ask and respond to questions. Some assessment tools such as the Verbal Descriptor Scale (pain thermometer) are validated as self-report instruments for unidimensional pain intensity in patients with mild to moderate cognitive impairment.[23] Many patients near the end of life cannot provide detailed descriptions of their pain character, intensity, or location. Particularly for patients with cognitive impairment, self-assessments may be a burden to complete and difficult to interpret. For patients who cannot self-report pain intensity and description, observational pain assessment tools have been developed to be used by healthcare providers and caregivers. Utilization of available assessment tools such as those listed in Table 82.1 may help in the appropriate assessment of pain even in patients with limited cognition and communication.

Terminally ill patients may complain of pain as a way of expressing other forms of suffering, distress, grieving, anxiety, or depression. Patient behavior suggestive of psychosocial or spiritual concerns require different interventions that will likely be more effective than analgesics. It is well established that attention and emotion influence pain processing and perception, and conversely, inadequately managed pain can lead to anxiety and depression.[15]



• **Figure 82.1** Pain at the end of life has many interactive components, including physical, psychological, and social aspects. Pain that remains inadequately controlled can significantly affect the quality of life for a patient, caregiver, and family.

TABLE 82.1 Assessment Tools for Pain and Suffering at the End of Life

Pain Assessments	Examples
Self-report	Visual Analog Scale (VAS) Verbal Rating Scale (VRS) Numeric Rating Scale (NRS) Faces Pain Scale (FPS) Verbal Descriptor Scale – Pain Thermometer Pain Drawing
Observational	Abbey Pain Scale (patients with dementia, cognition, or communication issues) Doloplus-2 (elderly with communication problems) Pain Assessment in Advanced Dementia Scale (PAINAD) Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC) Checklist of Nonverbal Pain Indicators (CNPI) Pain Assessment for Dementing Elderly (PADE) Clinical Utility of the CAN Pain Assessment Tool (CPAT)
Pain-related factors	Multidimensional Pain Inventory (MPI) Edmonton Symptom Assessment Scale (ESAS)
Reports from caregivers	Pain reports of changes in intensity, frequency, location, response to therapy Pain observations of facial grimacing, guarding, tearfulness, agitation

Therefore a comprehensive assessment is required to determine the optimal plan of care, as specific to the pain etiology as possible. The involvement of other disciplines (e.g. nursing, social work, psychology, psychiatry, and chaplaincy) can be very valuable in uncovering other sources of emotional or spiritual suffering that may be confusing the pain assessment. Another invaluable contributor to the assessment of the patient and an important part of the healthcare team will be the patient's primary caregiver.

As increasing numbers of patients are choosing to be home for their end of life, family caregivers assume the majority of patient care.[24] When the patient is being cared for at home, the physician frequently relies on second- or third-hand information supplied by the patient's caregiver on the severity of the pain, adequacy of relief, presence of side effects, and associated toxicity. The correct interpretation of the patient's and caregiver's report of pain is essential since effective pain management is dependent on an accurate assessment. Three dimensions comprise a patient's pain experience: cognitive factors (including attitudes, beliefs, and knowledge), sensory or physical input, and affective or emotional experience.[25] Although patients and families report parallel perceptions of the patient's cancer pain, family members consistently assess the patient's level of pain somewhat higher than the patient. This suggests the effect of observing rather than experiencing the pain. Studies of concordance between caregiver and patient experiences primarily exist for cancer patients only.[24] Engelberg et al. found higher concordance for observable experiences such as breathing and comfort and less concordance with subjective patient experiences such as anxiety and depression.[26]

There are important implications for evaluating the efficacy of a pain management strategy if the assessment is largely dependent on a proxy reporter for the patient. The report of poorly controlled pain may be indicative of the family member's distress and that of the patient. Areas of family distress include fatigue, lack of knowledge about pain management, concern about addiction, concern about harming the patient, and an overwhelming feeling of responsibility.[27,28] The family may interpret the patient's symptoms through their individual concerns, whereas the patient may be able to cope with their symptoms anticipating their own end of

life. Some studies have reported an inverse relationship between the health and function of the cancer patient and the amount of caregiver burden with caregiver strain, depression, and anxiety reaching its peak as the patient enters the terminal phase.[29]

Caregiver concerns and patient distress must be addressed if pain is to be adequately managed in the home as there is a close relationship between the two. Healthcare professionals who depend on caregiver reports in managing patient symptoms must keep in mind the possibility of disconcordant assessments and the trend toward overreporting by family members.[24] Disconcordance between family and patient provides a clinical opportunity for discussion to optimize wellness and understanding of the dyad. Collaboration and communication between the patient, their caregiver, and their clinician are key components of end of life care and specifically for the management of a patient's pain in the home.

Caregivers on the Front Line at the End of Life

The Role of Caregivers

The majority of patients worldwide wish to spend the end of their life at home surrounded by familiarity. The World Health Organization suggests that an increasing number of patients receiving palliative care at home is cost effective.[30] Caregivers are often family members, but friends and paid aides can also fill this role. Caregivers provide comfort and support in assisting patients with activities of daily living, symptom management, and clinical tasks. Among the responsibilities of the caregiver, pain management has been rated one of the difficult tasks that create frustration and stress for the caregiver.[31] Caregivers are expected to play a primary role in pain relief across all stages of the disease and are frequently given little or no training on how to do so.[28,32,33] In a comprehensive review of 129 quantitative research studies on caregivers and palliative care in the home setting, caregivers reported providing extensive help to dying relatives in the areas of medication and symptom management.[34]

Effective medical management of symptoms, especially pain at the end of life in the home, is a complex set of activities that becomes the responsibility of the caregiver and has the potential to decrease the patient's pain as well as ease the burden on caregivers.[31] Caregivers are responsible for ordering and filling, and paying for prescriptions. They are expected to safely store pain medications, and organize and dispense medications on a fixed dosing schedule or as needed based on their assessment of pain. They have to be skilled in administering medications in the form of injections, inhalers, and eye and ear drops. Also, they are responsible for monitoring infusions, medication quantities, medication effectiveness, and adverse events. Furthermore, they are responsible for communicating about medications and symptoms with the healthcare team. A comprehensive review of over 100 qualitative studies on caregiving at home at the end of life, the general consensus across studies was that caregivers reported a lack of preparation, knowledge, and skills in symptom, pain, and medication management, especially with the technical aspects of medication administration.[35,36] From these studies, it can be concluded that most caregivers rely on nurses or other members of the healthcare team for information related to medications.

Case 1: Caregiver's Role

Misconceptions, Challenges, and Barriers to Pain Management in the Home

Generally speaking, the home environment offers substantial benefits to the patient with a terminal illness, but home care also can result in intense burdens for caregivers resulting in compromised care.[34] Surveys of healthcare providers' perceived barriers to pain management in the home include symptom recognition, adherence to analgesic regimens, failure to report pain, and limited access to care.[37,38] Patients and nonprofessional caregivers reported fears related to addiction, analgesic side effects, and accelerating death. Additionally, religious and cultural beliefs about spiritual suffering can influence and at times contradict the foundation of hospice care, which recognizes each person's "right to die pain-free and with dignity".[39] Understanding the barriers that are faced when treating pain in home care settings can lead professionals to better educate and counsel patients and their families.[40] Because misunderstandings lead to undertreatment, all clinicians involved in the care of patients with advanced illness and pain must be able to differentiate and clearly explain to patients and their families the clinical conditions of tolerance, physical dependence, and the rarity of addiction related to opioid use at the end of life. It also is critically important to be aware that there is no established relationship between titration of opioid analgesics to affect pain relief and timing of death in palliative care or hospice settings.[41,42]

Concerns with pain management in the home have been categorized by Chi et al. into caregiver- and patient-centric issues.[31] Caregivers' functional limitations may include physical and psychological fatigue affecting their caretaking abilities. Caregivers may have misconceptions about opioid addiction or fears that pain medications cause hastening death. They also have fears associated with side effects of pain medications causing increased sedation, confusion, and constipation. This leads to under-reporting and potentially withholding treatment despite planned interventions. Physical and psychosocial demands of ongoing work, family, and financial responsibility can interfere with attention to patient care. Ineffective communication or undefined avenues of communication between the caregiver and the healthcare system have also been identified to cause delayed patient assistance. Caregivers report a lack of knowledge about prescribed medications, including a basic understanding of action, dosing, and side effects. This deficit causes confusion and difficult decisions regarding the choice and timing of medication administration for effective pain management. Some studies have estimated the incidence of non-adherence to pain medications to be as high as 24%–51%.[43] Non-adherence to pain regimen may lead to undertreatment or even potentially dangerous medication errors. Caregiver's organizational skill or the potential for multiple caregivers allows for issues in tracking, recording, and safe keeping of pain medications. Patient-centric issues that affect home pain management related to the patient's inability to verbalize pain, their personal view of the quality of life, how they consider the impact of their actions on their caretakers, and the extent of their physical deterioration.[31] The difficulties that patients and caregivers commonly encounter when trying to put a pain management regimen into place at home are summarized in Box 82.3. They illustrate that patients and caregivers need ongoing support and help with problem-solving to optimize their pain management regimen.

Martha is an 85-year-old woman whose ability to function independently has declined in the past five years. She has end stage renal disease and requires dialysis three times a week. Because of her severe fatigue and chronic non-cancer pain from debilitating osteoarthritis, she is functionally very limited. She also suffers from depression and anxiety. Her only surviving family, three adult children, all work outside of the home and cannot oversee her care during the weekday hours.

Besides her primary care physician and psychiatrist, she also sees a pain specialist and a renal specialist. In addition, she receives 20 h a week of home health care through her insurance provider. Her caregiver, Bridget, has been with her for two years and her responsibilities include taking Martha to her medical appointments, picking up Martha's prescriptions and supplies, and setting up Martha's weekly pillbox. Bridge also helps Martha with bathing and with household chores. Bridget also provides Martha

with companionship and a sense of security, knowing her needs are being addressed. Martha's adult children provide care in the evening hours and on weekends and see to it that Martha feels loved and supported.

Effects of Unrelieved Pain on the Patient and Caregiver

There is growing evidence that inadequate pain relief might hasten patient death, not only via the well-recognized morbid effects of increased physiologic stress, reduced mobility, increased proclivities toward pneumonia and thromboembolism, and increased work of breathing and myocardial oxygen requirements but also through immune suppression.[44] Pain may lead to spiritual despair and significant decrease in emotional wellbeing because the individual's quality of life is impaired. Home care is best viewed as a family experience with the recognition that every aspect of care provided to the patient will not only affect patients but also affect family caregivers. The intense demands on family caregiving at home, especially in the provision of 24 h physical caregiving, is well described.[45] Less attention has been placed on the emotional burden to the family assuming responsibility for the patient's well-being in the home.[46]

Caregiving has been identified as a risk factor for mortality.[47] This carries not only physical consequences but emotional, economic, and social implications.[48] Caregivers retain difficult memories of loved ones' uncontrolled pain and suffering. They may have enduring feelings of guilt for having given too much medication that facilitated death or frustration regarding the type of care received. These perceptions impact caregivers' satisfaction with home care of their loved ones, the quality of their bereavement, and their ability to manage pain in the future.[49]

Palliative care and hospice programs provide care for the combined unit of the patient and the caregiver. Understanding the factors that influence the adequacy of pain management in the home has become increasingly important in the face of the current trend toward shorter inpatient hospital stays, earlier hospital discharges, and the expectation that extremely sick patients will be managed at home.[50] Addressing issues with patients and caregivers regarding knowledge and attitudes about the varied etiologies of pain and its management, the stress in caregivers and community nurses, managing the technical aspects of pain in the home, and communication will serve to support families and foster trusting relationships.[51–53] When pain and other distressing symptoms are properly addressed, and advance directives are completed to guide the caregiver, quality scores for end of life care increase, costs and resource utilization decrease, and caregiver stress is diminished.[54–56] The interdisciplinary healthcare team utilizing nurses, social workers, chaplains, physicians, volunteers, and others is imperative to provide education, counseling, reframing, and spiritual care to patients and families exploring the end of life care and barriers to pain relief in the home setting. The recognition that home caregiving and community nursing have necessitated responsibility without adequate training has been an impetus for improved communication and educational programs for pain management at home.

• BOX 82.3 Home Care Challenges that Risk Poor Pain Control at the End of Life

- Complex pain syndromes from comorbidities and advanced disease
- Rapidly escalating opioid requirements and need for an alternative route of drug administration
- Polypharmacy for multiple end of life symptoms
- Impairments of memory, cognition, vision, or hearing
- Fear of opioids because of addiction or side effects
- Under-reported pain because of fear of caregiver burden or hospitalization
- Physiological, psychological, and social fatigue on patient, family, or caregiver
- Inadequacy of pain treatments, non-adherence to the regimen
- Inaccessibility to prescriptions, resources, or healthcare team for changes or emergencies
- Unfamiliarity with medication uses, administration
- Caregiver functional limitations, organizational skills
- History of drug abuse or high risk home environment

Recommendations for Positive Outcomes

Caregivers with community nursing support are on the front line of home pain management. Structured pain education programs have been shown to result in positive outcomes for patients and their caregivers.[37,38] Recommendations include teaching caregivers about the practical aspects of care at the end of life and making sure caregivers were routinely provided with general information about the nature and course of the patient's disease. Patients and caregivers should be asked whether they are concerned about addiction and tolerance (often described as becoming "used to" or "immune" to the drug). Caregivers should be educated on changes in patient behavior such as irritability or frustration that may be cues to underlying pain symptoms. They should also receive education on the symptoms of aberrant respirations, decreased food and water intake, diminished cognition, delirium, low urine output, and incontinence at the end of life phase for a patient who is actively dying.

Care providers have concerns about precipitating death with the use of opioids or benzodiazepines used aggressively during this phase of active dying. It has been established that patients have legal and ethical rights to symptom management during this time.[57] It has been observed that patients live for longer periods when symptom-driven medications are delivered as compared to those without the medications.[58,59] The reason for this is unsettled, but physiologic-based theories have been published. The provider has a duty to address the ethical, legal, and physiologic rationale for medications with patients and caregivers in this situation.

Caregiving is not uniform, and the needs of patients at the end of life and the needs of their caregivers are neither identical nor static. Incorporating a pain log or diary to improve documentation of pain, pain management strategies, and their effects on pain relief can provide concrete evidence to help individualize strategies. Accurate documentation in this manner is even more essential when multiple caregivers are involved in the care of a patient.[43] Caregiver burden and comfort with home pain management regimens must be assessed and reassessed. Essential drugs should be made available at home outside of outpatient healthcare hours to enable rapid symptom management and prevent unnecessary hospitalization. It is the professional and ethical responsibility of clinicians to focus on and attend to adequate pain relief for their patients and properly educate patients and their caregivers about analgesic therapies.

Planning for Home Pain Management

Transition From Hospital to Home

Transitioning patients with a terminal illness from the hospital to a home setting for the end of life care is a challenging task because of the complexities of coordination of care, the types of

interventions, the inadequate management of refractory symptoms, and the lack of caregiver support. Patient care that has been entirely organized by healthcare professionals during the hospital stay without caregiver involvement may cause feelings of inadequate preparation or anxiety during the discharge process as the burden of care and decision making shifts primarily to a sole caregiver. In preparing the patient and their caregivers to go home, the focus should be on security, communication, and clarification of the pain management plan. A review of efficacious home care programs found that linkages with hospital and community services, multi-disciplinary team and holistic care model, and access to the end of life care expertise (including pain and symptom management) were associated with improved outcomes.[60] The outcomes included quality of life, satisfaction with care, performance status, pain management, non-pain symptom management, supporting home deaths, and reduced healthcare costs. The components of the home care program reduced barriers within organizations, increase accountability, facilitate transitions, prevent symptom exacerbation, and avoid an unnecessary end of life hospitalization while providing overall improved quality of life and satisfaction.[60]

Hospital to home transitions should begin with a review of the guidelines and resources provided by The Joint Commission's foundations of safe and effective transitions of care to home and the National Patient's Safety goals for home care.[61] Transition to pain management in the home requires an individualized pain management plan that often benefits from early and recurring discussions of patient goals and values within family meetings with the use of "teach-back" to ensure understanding of the discharge plan. Patients and caregivers assuming responsibility for pain management may have a limited understanding of medical conditions and medications, low health literacy, and lack of confidence in self-care resulting in difficult transitions. Promotion of positive communication strategies between caregivers and staff, ensuring the adequacy of information in preparation for discharge, trying out the role of caregiver, and testing the home environment for barriers with short weekend discharges prior to definite discharges have all been some features of successful transitions to home care.[62]

Assessment of the home care environment and identification of anticipatory needs and potential scenarios for patients that are terminally ill is an integral process to achieve sustainable and satisfactory transitions to home care and to decrease the risk of readmission.[63] Repeated hospitalization and discharge episodes are notorious for interrupting the pain regimens of patients as new treatment teams become involved or new medications are added or withdrawn in light of new medical conditions or side effects.[64] The pain management plan should be appropriate, complete, and clearly written out in a language that the patient and family can understand. Pharmacists can be an invaluable resource in helping with medication reconciliation, assessing routes of administration, reviewing prescriptions for completeness, evaluating for polypharmacy, and the need for non-comfort medications or duplicate therapies.

Medication and therapeutic interventions should be financially feasible for the patient, the availability of prescribed analgesics should be verified in the community, discharge and follow up plans should be confirmed with patient and family, and the patient should not be discharged (if at all possible) within 24 h of a change in opioid drug or route of administration (Box 82.4). Availability and cost of outpatient medication can become a significant barrier for patients.[65] The community pharmacy should be contacted to ensure the availability of prescribed opioid medications or willingness to obtain them.[66] Prior to the patient's discharge home, it is important to establish the ability of a patient to both pay for and obtain their outpatient analgesic prescription. Several pharmaceutical companies have specific patient "hardship" programs for assistance. A social worker can be a helpful resource in evaluating a patient's eligibility for these programs and accessing such resources.

It is good practice for the physician or nurse to initiate contact with the patient within the first week of discharge to confirm that pain is adequately controlled. This acknowledges the central role of the family in the management of pain in the home, emphasizes that the family will be given ongoing support and back-up for their day-to-day pain management decisions, and ensures patient and caregiver confidence with the pain management approach. This initial telephone contact also confirms that pain management is a priority, and the patient's pain will continue to be monitored closely with resources readily available even though care is now on an ambulatory basis. If a patient's pain escalates once at home, it is crucial to explore with the patient or caregiver whether the pain medication is being taken as prescribed and the availability and appropriate use of rescue medications. Close follow up with the family soon after discharge is essential as they are still learning the basic principles and skills required for pain management. Once these skills have been learned and a routine established, the need is for continuing support and validation.

• BOX 82.4 Factors to Facilitate Hospital to Home Transition

Do Not Discharge a Patient

Within 24 h of a change in route of opioid administration.
Within 24 h of a change in opioid drug.
Without written instructions regarding their analgesic regimen.
Without a 24 h resource telephone number for pain management issues.
Without a bowel regimen.

If a Patient is Being Discharged on a Non-parenteral Route of Drug Administration, Make Sure

That the prescribed drugs are available in the patient's community pharmacy.

That the patient has an outpatient prescription plan and, if not, will be able to pay for the pain medication out of pocket.

That the patient is given sufficient medication at the time of discharge to continue on the pain management regimen until the patient can fill the prescription at a community pharmacy.

If a Patient is Being Discharged on a Parenteral Infusion

Avoid sending the patient home on the weekend if possible.

Give the patient a 48 h supply of oral or injectable opioids to take home if there is a mechanical problem with the pump.

Case 2: Transition From Home to Hospital

The Decision for Long Term Care Facility or Hospice Care

Some patients are unable to be cared for at home and are discharged to an extended-care facility. Such facilities include nursing homes and assisted/supportive living facilities. These patients are frequently elderly, debilitated, and receiving polypharmacy for chronic medical conditions. They are at high risk for inadequate pain assessment and consequent under medication for pain.[34] In addition, the elderly and debilitated patient's therapeutic margin

may be narrow, and the patient may be at increased risk for developing troublesome side effects, including sedation and confusion.[67] Close monitoring is required, with careful dose titration and adjustment based on ongoing assessment. This requires training, skill, and an institutional system in place that screens for the presence of pain and adequacy of relief on a regularly scheduled basis. It is essential that verbal communication be established between the physician/advanced practice nurse or pain management nurse from the discharging institution and the physician and nursing supervisor from the extended-care facility. This communication should take place prior to the patient's discharge to the facility. The two teams can then work together to ensure adequate pain relief for the patient. In recent years, some long term care facilities have established contracts with community hospice programs and have developed palliative care approaches to the care of their residents.

Hospice care, the most widely available model of home care for the dying, focuses on optimizing the quality of life in those not seeking and unlikely to benefit from life-sustaining treatment.[68] Hospice programs are run by both profit and not-for-profit organizations and have become part of the standard of care offered to patients nearing the end of life. Eligibility requirements for enrollment in a hospice program include a life expectancy of six months or less. A major advantage for patients and families followed in a hospice home care program is regular home visits by the hospice nurse and 24 h emergency support from skilled hospice nurses with back-up from the hospice medical staff. In addition, the cost of all medication related to the terminal illness is included in the hospice benefit without additional charge to the patient. Because of the variety of hospice models, levels of sophistication, and depth of services offered, the needs of the patient and the services offered through the program should be evaluated before referral. For example, although most hospice programs have changed their policy toward the use of technology in end of life care, in contrast to an earlier "no high-tech" approach, severe restrictions on the financial reimbursement for programs may limit their ability to deliver care to patients requiring the parenteral route of opioid infusion to manage their pain.

Sally is a 21-year-old woman who has suffered from neurofibromatosis and debilitating pain since her early teens. Even as she faced these challenges, she was able to finish high school and establish close friendships. However, in the past year, Sally was found to have a new tumor that is malignant and inoperable. Sally understands that her condition is terminal and now relies on her mother for assistance with activities of daily living.

Sally's pain had been treated adequately with intrathecal hydromorphone delivered by an implanted pain pump. As her disease progressed and her pain has become more severe, she was hospitalized and relied on intravenous hydromorphone in addition to her pain pump. After a three week hospital stay, Sally and her mother are eager to be discharged from the hospital and want Sally's remaining time alive to be spent at home. For this to happen, Sally would have to be off intravenous medications. This was accomplished by titrating the daily rate of intrathecal hydromorphone, transitioning intravenous hydromorphone to oral formulations, and adding adjuvant medications. Also, an assessment was made of Sally's home environment, and there was the identification of specific equipment and supplies that Sally would need. A hospital bed and bedside commode were ordered for her home. Additionally, Sally's mother had to learn techniques and skills to be Sally's primary caregiver at home. Sally's mother learned the necessary skills of how to help her daughter transfer from bed to chair and bedside commode, safe handling and delivery of medications, and communicating with Sally's healthcare team. Weekly telemedicine appointments were scheduled with Sally's pain physician. Face-to-face follow up appointments were to be scheduled as needed. Although Sally and her mother were not ready to have home hospice care at the time of discharge from the hospital, they have started to consider this option for some time in the future.

Discharge to Suspected Drug Diverting Environments

There may be patients who are going home to an environment where it is suspected that drug abuse or diversion may occur. The patients themselves may or may not have a history of illicit drug use. Patients with a history of drug abuse are at risk for having undertreated pain.[69] Three subgroups of patients can be identified: (1) patients who are actively using street drugs, (2) patients who are in methadone maintenance programs, and (3) patients who have not used illicit drugs for many years.[19] Patients with substance use disorders present a challenge in pain management at the end of life because of limited and avoidance of communication, late identification of palliative care needs, and preferences and coping strategies at the end of life that are different from those that are generally accepted.[62,63]

Patients with a history of drug abuse that require end of life pain control require strict monitoring during opioid therapy. It must be recognized that these patients, like any other patients, can experience significant pain but may require larger doses of opioids to control the pain because of the development of tolerance. If the patient is on an oral drug regimen, it may be necessary to give only a one week supply of the opioid at a time. Giving a larger amount at one time invariably results in the patient "running out of the drug" regardless of the amount given. Occasionally these patients are placed on a parenteral route of opioid administration to ensure adequate pain control and safety, maintain tighter control on the amount of drug used, and minimize the risk of drug diversion. In these situations, no extra opioid cassettes or infusion bags are left in the home, and neither the patient nor family is taught how to change the infusion. Infusion cassettes may be preferred over bags because of less risk of "siphoning off" the medication. Close coordination and communication between the prescribing physician or advanced practice nurse, the home infusion pharmacist, and the home infusion nurse is necessary for patients in this scenario.

Psychiatric symptoms and comorbidities such as anxiety, depression, and bipolar disorders are frequently seen in this population and need to be addressed.[69] A team approach with optimal cooperation is essential in the care of these patients.[70] If the patient is in an addiction maintenance program, the program must be contacted for assistance in planning the patient's overall care. One physician or advanced practice nurse should be identified as the point person to adjust analgesics and write all prescriptions, and one nurse should be identified as the person to organize and coordinate the patient's plan of care. Patients with pain who are discharged home to a high risk drug abuse environment encompass a relatively small group of individuals whose needs are more challenging and require creative solutions. However, with careful planning and close monitoring, safe pain management at home can be achieved for most people.[70]

Communication: The Cornerstone of Good Pain Management in the Home

Foundation of Communication

To ensure that the pain management plan instituted in the hospital can be maintained at home, a series of steps can be taken.[61] First, if home care nursing has been established, the home care nurse should be contacted to discuss the pain management plan. Second, the community pharmacy should be contacted to ensure that they have the prescribed opioids in stock, or if not, are willing to obtain the medication. In addition, it should be established specifically when the drugs will be available in the home pharmacy so that the patient is not left uncovered. In the event that the local pharmacy neither has nor can obtain the prescribed opioid, an alternative source for the patient must be located prior to discharge from the

hospital. Third, the physician or nurse practitioner who will be responsible for writing the opioid prescriptions and titrating the drug must be clearly identified. Fourth, the caregiver should be instructed to establish a routine where the amount of medication they have left is checked on a scheduled basis so that the medication does not "run out" (the Friday night and holiday syndrome). Some families find it helpful to keep a one week supply of the medication to the side, and when they need to go into that supply, it reminds them to call their prescribing clinician for a new prescription. These simple steps can help ease the transition from hospital to home for patients with chronic pain and the family.

It is essential that the patient and family are given specific, detailed, written instructions, in layman's language, of the pain management approach to be used, both pharmacologic and nonpharmacologic.[61] The concept that analgesics should be used to prevent pain rather than having to be "earned" through experiencing severe pain is a principle foundation of the pain management approach that should be discussed with patients and family. This principle encompasses addressing the concerns surrounding the prevalence of addiction when opioids are used to manage pain and the clinical significance of tolerance (e.g. that the opioids may no longer be effective if they are used early on in a disease process). The patient and family must have no ambiguity about whom to call on a 24 h basis if pain is not well controlled or if the patient experiences troublesome side effects. In addition, safety issues surrounding opioids in the home need to be reviewed. These include that the opioids be kept in a safe place out of reach of children; that unused opioids be flushed down the toilet or returned to the prescribing institution for disposal; that if parenteral opioids are used, a syringe and needle disposal kit be obtained; and that needles and syringes, however well wrapped, should not be disposed of in household garbage containers.

Continuity of care for patients' end stage illness or cancer with pain is particularly important. Frequently, patients receive their care in various medical settings with the involvement of numerous physicians, nurses, and healthcare professionals who may not have considered pain as a priority. In addition, effective management approaches may be changed because of the patient's or families' unfamiliarity with complicated medication administration, lack of community resources, or concern regarding opioid quantity or side effects. The hospice movement has addressed the need for continuity of care of the dying patient.[68] Similarly, the need to bridge the gap between hospital and community is recognized for the terminal patient with chronic pain who is not imminently dying.[71] A palliative care approach is seen as a valuable component to patient care that addresses the needs of the terminal patient with chronic pain earlier on in the disease process. Such a model of care is also important for dying patients who either do not have access to a hospice program or who, for a variety of reasons, choose not to be followed by the hospice system of care.

Tools of Communication

Effective communication between healthcare providers and caregivers is essential to the successful management of pain at home at the end of life. Identification of appropriate tools to facilitate communication between providers and caregivers should be established prior to or early in the transition period to home. The preferred method of communication and available technology at home should be discussed, as should the expected frequency and limitations to this mode of communication. Patients and caregivers should be encouraged to keep a daily diary to record pain level using a numerical estimate (e.g. a zero to ten scale), or a categorical scale (e.g. none, slight, moderate, severe), medication taken, other pain-relieving strategies used, extent and duration of pain relief, activity level, and interference with quality of life. Keeping a pain diary has been found to heighten patient and caregiver awareness of the pattern of pain, guide pain management behaviors, enhance a sense of control, and facilitate communication.[72]

The use of the telephone is an important aspect of monitoring and managing pain on an outpatient basis.[73] In addition, it makes expert resources available to communities where this might not otherwise be the case. Continuity of care also can be fostered through 24 h telephone availability of a pain management expert (usually an advanced practice nurse) to the patients, their families, and community professionals. Although the availability of after-hours and urgent care remains an integral resource, the utilization of these services was found to be significantly decreased with a model that employs proactive telephone-based communication. This proactive system provides a systematic call frequency and structure of one or two calls a day to each patient with standardized staff script, identification of clinical needs, and escalation of issues to a nurse for effective and efficient home care.[74]

Although the use of the telephone remains a primary mode of communication, advances in technology have made the use of telehealth an emerging option to provide clinical support in the home setting. Digital technology has become ubiquitous in both healthcare and patient homes. Most patients are regularly using computers, tablets, and smartphones with internet connections. Many patients currently use the internet as a resource for knowledge that is easily available and accessible in various formats and use calendar and alarm functions for daily organization. However, there is an opportunity to increase the use of technology for more than just appointment organization and medication reminders. Telehealth can be in the form of video or virtual consultation to facilitate support and continuity of care, digital programs to reinforce education, and the utilization of alternative communication methods such as email, web-based programs, or applications to communicate or document changes in management approach.[75] Advances in telemonitoring can enhance daily symptom management with triggers built to stimulate help seeking, help with reminders or prompts for medication management, or even initiate action by professionals. These tools can be used to personalize monitoring and augment patient-provider communication. Telehealth is regarded as an efficient and cost effective method of communication that improves equity of access to care. However, caution must be taken to utilize digital solutions in a way that adds value to patient care without adding unnecessary burden to the patient, caregiver, and provider.[76]

Case 3: Telemedicine as a Tool of Communication

Pain Management Therapies at the End of Life

How to Approach Pain Management at the End of Life

Patients in the terminal stage of an illness often experience multiple mechanisms of pain. Mechanisms of pain can be categorized into central sensitization, peripheral neuropathic, nociceptive, sympathetically mediated, and cognitive-affective.[77] It is important to differentiate among different types of pain because the type of treatment and its success is largely dictated by the pain mechanism and its original source.[77] In some conditions, especially metastatic cancer, pain is often caused by a complex mixture of nociceptive

and neuropathic factors. The etiology of the pain mechanism then forms the basis of pharmacological treatment strategy, which should be individualized and consider comorbidities, expected side effects, route of administration, and concomitant medication. An important strategy for treating patients, especially at the end of life, is using one medication that might treat more than one type of pain or multiple symptoms. For example, an opioid might be helpful for neuropathic pain as well as somatic pain. Some anti-depressants can be employed for both neuropathic pain and insomnia. This strategy is supported in the medically frail population.[78]

Besides the numerous and sometimes overwhelming responsibilities related to the pharmacologic management of pain in the home, patients and caregivers use many nonpharmacologic strategies for pain relief. Although some of these techniques are taught in the hospital setting, they are seldom reinforced by the medical team once the patient is discharged home. Non-drug interventions include both physical and cognitive approaches. Physical approaches include interventions such as heat, cold, and massage. Cognitive strategies include a variety of relaxation techniques, imagery, meditation, and prayer.[79] These nonpharmacologic therapies should be tailored to individual likes, dislikes, and effectiveness. Knowledge of the various modalities, management of expectations, and open-mindedness will help clinicians identify therapies that fit the patient's values and belief system. The use of these modalities will not only enhance pain relief but also help the patient regain a sense of control.[80] Similar to pharmacotherapy, multimodal approaches offer the potential benefit of additive and synergistic effects.

Buddy is a 75-year-old male with a diagnosis of Stage IV lung cancer. He has chronic non-cancer low back pain as well as chemotherapy induced neuropathic pain. His pain is adequately managed with tramadol and gabapentin. However, his breathing has become more labored and uncomfortable lately and has required continuous oxygen via nasal cannula. He is largely confined to his apartment that he shares with his wife. Because it is very difficult for him to come to his medical appointments, his healthcare team uses telemedicine visits to monitor his pain and health and make necessary adjustments to his medications. Buddy and his wife are reassured during these visits. When necessary, a home nurse may be sent to assess Buddy, and there will be coordination of care with his physicians.

Nonpharmacologic Approaches to Pain Management in Palliative Care

An important aspect of any management strategy is the use of nonpharmacologic treatments. Various nonpharmacologic approaches to pain are effective in alleviating pain for patients with advanced illness.[81] These include physical interventions such as positioning and active or passive mobilization, heat or cold therapy, transcutaneous electrical nerve stimulation (tens), massage; psychological therapies such as relaxation, imagery, or cognitive behavior therapy; and complementary or alternative medicine techniques such as music and acupuncture. Nonpharmacologic interventions often comfort the patient while involving and empowering family and other caregivers. The effect of these techniques on the caregiver should not be overlooked—it can have a direct effect on the experience of the patient as well as the emotional survival of the family caregiver in particular. A study by Keefe and colleagues[40] on the self-efficacy of family caregivers of cancer patients found that caregivers who rated their self-efficacy as high reported much lower levels of caregiver strain as well as lower negative mood and higher positive mood. Caregiver self-efficacy in managing the patient's pain was related to the patient's physical wellbeing. When the caregiver reported high self-efficacy, the patient reported having more energy, feeling less ill, and spending less time in bed. Aside from their objective efficacy, the use of complementary therapies can be an "emotional inoculation" that builds resiliency and an important bond between patient and caregiver.[82]

Rehabilitation and Physical Therapy

Functional rehabilitation and physical therapy techniques in appropriately selected patients can add to the quality of life even in the face of limited life expectancy. Multiple studies assessing the use of physical therapy in the palliative care setting suggest primary benefit in decreasing musculoskeletal pain levels along with improvements in mobility and completion of activities of daily living.[83,84] These studies show that patients who receive physical therapy intervention report increased quality of life and improved mood and confidence. Physical therapists seem to provide educational and physical support to patients and caregivers to maximize the patient ability and achieve meaningful care.

Massage Therapy

Therapeutic massage uses the manipulation of body tissues to affect the neuromuscular and circulatory systems to reduce muscle spasms and aid in relaxation. Massage has also been used in conjunction with aromatherapy to utilize the therapeutic properties of plant essential oils to facilitate physical, mental, and emotional wellbeing. There is good evidence that these therapies may be helpful for the reduction of pain and improvements in anxiety and peacefulness, with statistical significance shown for short periods.[79,85,86] Although studies have not demonstrated significant long term benefits in improving pain control, anxiety, or quality of life, significant improvement in sleep scores and reduction in depression scores were found in one group of patients receiving massage therapy.[87] Findings suggest that patients with high levels of psychological distress respond best to these therapies. Massage therapy is a non-invasive therapeutic tool that can reduce suffering and improve symptom management in advanced illnesses. Restricted sites or therapy may be warranted for patients with open wounds, on anticoagulation, with a recent diagnosis of deep vein thrombosis or diagnosis of multiple myeloma.[86]

Electrophysical Modalities

Transcutaneous electrical nerve stimulation (TENS) is an inexpensive and non-invasive electrical modality that can be used for patients at the end of life with or without active neoplastic disease. Alternative modalities such as therapeutic ultrasound, or interferential or pulsed shortwave diathermy may be used over normal tissue or for non-cancer patients to reduce pain and muscle spasms.[67] Overall improved quality of life, decreased pain, and improved fatigue has been associated with the short term use of TENS in hospice cancer patients.[79] Scrambler therapy is a newer modality that attempts neuromodulation by using electro-cutaneous nerve stimulation to provide cutaneous nerves with "non-pain" information thus blocking the effect of pain. Studies have shown significant, sustained pain reduction with scrambler therapy in neuropathic pain and in patients with and without cancer.[88] Awareness of implanted devices (pumps, stimulators, implantable cardioverter defibrillators, or pacemakers) and precautions to prevent malfunction must be taken with the use of therapies involving electrical stimulation.

Psychotherapy

Simple psychological interventions can have a significant impact on pain. Relaxation techniques may be effective in reducing pain in terminally ill patients. Relaxation with or without imagery can improve pain in patients with oral mucositis, which can often be

a poorly controlled symptom in this patient population.[79] Mindfulness based cognitive therapy in palliative patients resulted in improvements in anxiety, ruminative thoughts, and sleep problems and reduction in depressive symptoms.[89] These cognitive interventions can provide patients and families with support, knowledge, and skills to help cope with pain at the end of life.[67] Patients with delirium and cognitive impairment may not be appropriate candidates to benefit from these modalities of psychotherapy.

Acupuncture

Acupuncture therapy continues to be studied as a complementary therapy in symptom management of pain, dyspnea, and fatigue for palliative patients as well as cancer patients. Acupuncture has been shown to significantly reduce pain with suggested shorter analgesic onset and longer duration of action than conventional medicine.[90] Patients with dyspnea because of cancer or COPD that were treated with acupuncture/acupressure reported marked symptomatic improvement in breathlessness.[79] Although evidence has not shown the effectiveness of this modality, it remains a therapy that is relatively safe with rare complications.

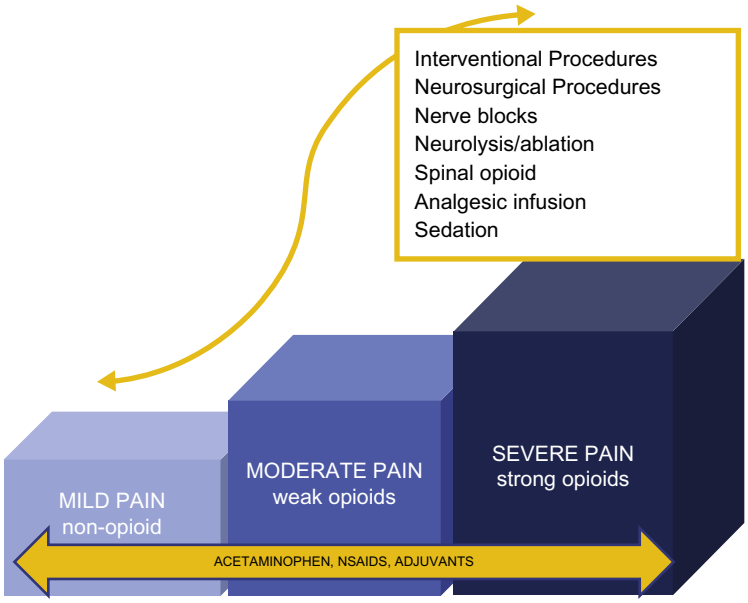
Music Therapy

The therapeutic use of music therapy as an adjunct treatment in cancer and palliative/hospice populations is increasing. Music therapy can improve quality of sleep, quality of life, and symptoms of depression and provide comfort and relaxation.[91,92] Although there is a wide variety of individual preferences, music appears to exert direct physiologic effects through the autonomic nervous system with the release of endorphin from the brain.[91]

Pharmacologic Approaches to Pain Management in Palliative Care

Pharmacologic therapies for pain include non-opioids, opioids, adjuvant analgesics, disease-modifying therapies, and interventional techniques. The World Health Organization pain ladder establishes a stepwise guideline in the approach to pain management. However, the use of this guideline for patients with a terminal illness may delay adequate pain control (Figure 82.2). Patients at the end of life may require strong opioids to achieve effective analgesia and may have contraindications to first line non-opioid therapies such as acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) because of their advanced illness.[93] Normal pharmacokinetics and pharmacodynamics may be considerably altered by patient age and end stage disease states. For example, in patients with chronic liver disease or hepatic metastases, drugs may bypass hepatic metabolism altogether, increasing bioavailability. Similarly, renal clearance is almost always diminished during the dying process, leading to the accumulation of drug metabolites, some of which may be toxic.[94]

Intractable pain and symptoms that are not responsive to basic therapeutic techniques, although not common, must be treated appropriately and aggressively.[1] In some highly selective cases, palliative sedation may be warranted.[95] Commonly, there is a need to use drugs for non-U.S. Food and Drug Administration (FDA)-approved indications or routes of administration, simply because randomized controlled clinical trials do not exist for that particular circumstance. New formulations or delivery systems are continuously under investigation and approved for market that may have a role in alleviating pain at the end of life medication. No new or renovated analgesic agents have been shown to be superior to the medications described for the patient population at the end of life. A sound understanding of pharmacotherapy for pain treatment allows the palliative care/hospice team to create a comprehensive plan of care as well as recognize and assess medication related adverse effects, understand drug-drug and drug-disease interactions, and educate patients and caregivers regarding appropriate medication usage. Rational polypharmacy (combining drugs with different mechanisms of action to produce additive or synergistic effects and minimize adverse effects) is often necessary, but there is a high potential for drug interactions that require close monitoring.



• **Figure 82.2** Modification of the World Health Organization stepwise ladder approach to pain management may be utilized to avoid delay in adequate pain control for patients at the end of life. Advanced procedures can be used for pain at any level but should be strongly considered for patients with severe pain.

Non-opioid Analgesics

Acetaminophen

Acetaminophen has been determined to be one of the safest analgesics for long term use in the primary management of mild pain or as a supplement in the management of more intense pain syndromes. It is especially useful in the management of non-specific musculoskeletal pain or pain associated with osteoarthritis but should be considered an adjunct to any chronic pain regimen. It is often forgotten or overlooked when severe pain is being treated in terminally ill patients, but it can be quite effective as an adjuvant medication. It is important to consider acetaminophen's limited anti-inflammatory effect and its risk of hepatotoxicity. Reduced doses or avoidance of acetaminophen is recommended for patients with renal insufficiency or liver failure, particularly in individuals with significant alcohol use.[96]

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

NSAIDs are useful in treating moderate to severe pain in many pain conditions mediated by inflammation. These medications are useful either alone or as adjuncts to opioid analgesic therapy and may be effective for pain of somatic origin such as bone, muscle, and skin in both cancer and non-cancer disease states.[97] These agents cause minimal nausea, constipation, sedation, or effects on mental function. However, there is evidence that their use can impair short term memory in older patients.[97] Adding NSAIDs to an opioid regimen may allow a reduced opioid dose when sedation, obtundation, confusion, dizziness, or other central nervous system effects of opioid analgesic therapy alone become problematic.[97] Extended-release formulations and alternative routes of administration of NSAIDs are available and can be used to increase compliance and adherence.[93] As with acetaminophen, decreased renal function and liver failure are relative contraindications for NSAID use. Patients with cardiovascular risk, platelet dysfunction, or other potential bleeding disorders are more definite contraindications to using NSAIDs. Gastrointestinal complications may be mitigated by the use of cyclooxygenase-2 (COX-2) selective NSAIDs such as celecoxib and low dose meloxicam or coadministration of proton pump inhibitors.[93,98] However, prolonged use of NSAID therapy should still be used with caution in high risk palliative care patients.

Naltrexone

Naltrexone is an antagonist at μ-opioid receptors that is currently approved for use in opioid and alcohol dependence but has shown potential as a non-opioid therapy for chronic pain and palliative care.[99] Low dose naltrexone exhibits pharmacologic activity against central, neuropathic, and inflammatory pain and appears to modulate or enhance endogenous opioid production without significant adverse effects. Further clinical research is required to validate efficacy.

Opioid Analgesics

Opioid analgesics are the most useful agents for the treatment of pain associated with advanced disease from chronic end stage illnesses and cancer.[100] The opioids used most commonly in palliative care are morphine, hydromorphone, fentanyl, oxycodone, and methadone. The only absolute contraindication to the use of an opioid is a history of a hypersensitivity reaction (e.g. rash, wheezing, and edema). Allergic reactions are almost exclusively limited to the morphine derivatives, and the prevalence of true allergic reactions to synthetic opioids is much lower. Opioid analgesics may accumulate toxic metabolites over time, especially when drug clearance and elimination decrease as disease progresses and organ function deteriorates.[101] Use of meperidine is specifically discouraged for repeated dosing over time because of its neurotoxic metabolite, normeperidine.[102] The mixed agonist-antagonist agents, typified by butorphanol, nalbuphine, and pentazocine, are not recommended for the treatment of pain in patients with advanced disease. They have limited efficacy, and their use may cause an acute abstinence syndrome in patients using pure agonist opioids.[103] For further information on opioids and chronic opioid therapy, see Chapter 48.

Morphine

Morphine, the prototype agonist, is considered the gold standard of opioid analgesics and is used as a measure for dose equivalence.[104] It is available in oral, rectal, intravenous, and spinal preparations. Although some patients cannot tolerate morphine because of pruritus, headache, dysphoria, or other adverse effects, common initial dosing effects, such as sedation and nausea, often resolve within a few days.[105] It is best to anticipate these adverse effects, especially constipation, nausea, and sedation, and prevent or treat appropriately. Morphine-3-glucuronide, a metabolite of morphine, may contribute to myoclonus, seizures, and hyperalgesia, particularly when patients cannot clear the metabolite because of renal impairment.[106] Side effects and metabolite effects can be differentiated over time. Side effects generally occur soon after the drug is absorbed, whereas metabolite effects are generally delayed by several days. Morphine's bitter taste may be prohibitive, especially if "immediate release" tablets are left in the mouth to dissolve. In this case, several options are available. One available type of long-acting morphine comes in a capsule that can be opened, releasing small pellets that can be mixed in applesauce or other soft food.[107] Oral morphine solution can be swallowed, or small volumes of a concentrated solution can be placed in the mouth of patients whose voluntary swallowing capabilities are significantly limited.[107]

Oxycodone

Oxycodone is a synthetic opioid that is only available as an oral formulation. Immediate-release (alone or with acetaminophen) and extended-release (OxyContin^{R}) are found in tablets and liquid forms. It is nearly as lipid soluble as morphine but has better oral absorption.[108] Side effects appear to be similar to those experienced with morphine, but one study comparing the two formulations in patients with advanced cancer found that oxycodone was less likely to cause nausea and vomiting.[109]

Hydromorphone

Hydromorphone is a synthetic opioid that can be a useful alternative to morphine in patients at the end of life. It is available in oral tablets, liquids, suppositories, parenteral, and spinal formulations. Extended-release formulation (Exalgo^{R}) is only available in oral tablet form at this time. As a synthetic opioid, hydromorphone can be useful if there is inadequate pain control or when patients experience true allergic responses to morphine or intolerable side effects occur. The metabolite hydromorphone-3-glucuronide may lead to similar opioid neurotoxicity seen with morphine metabolites: myoclonus, hyperalgesia, and seizures, especially in patients with renal dysfunction.[110]

Fentanyl

Fentanyl is a potent lipophilic opioid that can be administered via several different routes, including intravenous, spinal, transdermal, and transmucosal. Because of its potency, dosing is

conducted in micrograms. Careful fentanyl dosing is particularly important in older patients; a study of transdermal fentanyl in postoperative patients found that absorption was significantly delayed in men 64 to 82 years old compared with men 25 to 38 years old.[111] Opioid naïve patients should begin with titrated immediate-release opioids to establish the needed 24 h dose of opioid before determining that the lowest available dose, currently a 12.5 mcg/h patch, can be tolerated. Oral transmucosal fentanyl citrate is composed of fentanyl on an oral applicator to provide rapid absorption of the drug within minutes that can be effective for rapid episodic pain relief such as painful dressing changes. This formulation of fentanyl is particularly useful for breakthrough pain in patients without parenteral access, as demonstrated in the first clinical report of its use for this indication in a terminally ill patient.[111]

Methadone

Methadone has several characteristics that make it useful in the management of severe, chronic pain.[112] Methadone is available in oral and intravenous formulation and has a half-life of 24–36 h with a much longer terminal half-life, allowing for prolonged dosing intervals. However, the analgesic half-life of methadone is often much shorter. Methadone is an *N*-methyl-D-aspartate (NMDA) receptor antagonist, which may be of particular benefit in neuropathic pain.[113] Methadone is much less costly than comparable doses of proprietary continuous-release formulations, making it potentially more available for patients without sufficient financial resources for more expensive drugs.

Despite these advantages, much is unknown about the appropriate dosing ratio between methadone and morphine, as well as the safest and most effective time course for conversion from another opioid to methadone.[113] Current data suggest that the dose ratio increases as the previous dose of oral opioid equivalents increases, and although the long half-life is an advantage, it also increases the potential for drug accumulation prior to achieving steady state blood levels.[113] There may be a risk of over-sedation and respiratory depression after two to five days of treatment with methadone. Close monitoring of these potentially adverse or even life-threatening effects is required. Data suggest that methadone can also lead to life-threatening QT interval prolongation.[112] Therefore patients on methadone therapy should have interval QT screening before and during treatment.[112]

Patients currently receiving methadone as part of a maintenance program for addiction therapy often develop cross-tolerance to opioids and require higher doses than opioid naïve patients.[114] Prescribing methadone for this specific diagnosis requires a special license. In the United States, so prescriptions for methadone to treat pain must specify "for pain."

Buprenorphine

Buprenorphine is a synthetic mixed agonist-antagonist that is available in intravenous, sublingual, and transdermal formulations. Transdermal buprenorphine has been used similarly to methadone in the treatment of opioid addiction but has also been shown to provide effective analgesia for moderate to severe chronic pain as well as cancer pain.[115] Although the effectiveness of this opioid therapy has not been studied compared to other standard opioid analgesics, it has a unique pharmacologic profile that distinguishes its potential use for specific patients. Buprenorphine carries a ceiling effect for respiratory depression when used with or without other central nervous system depressants, which may provide a safer analgesic option for patients with end stage respiratory disease. Primary hepatic metabolism and elimination allow its use without dose reduction in patients with renal dysfunction. It has also been shown to have benefits in improving neuropathic pain symptoms.[116] Although buprenorphine may provide effective analgesia for opioid naïve patients, it must be used in caution with opioid tolerant patients in whom it can precipitate withdrawal symptoms.

Tapentadol

Tapentadol is a newer opioid that acts as a weak opioid agonist and a noradrenaline reuptake inhibitor. This drug is available in the immediate- and extended-release formulation and has no significant active metabolites. The gastrointestinal related side effect profile is decreased compared to strong opioids, and reviews have shown similar effective analgesia.[117] Therefore this may be an alternative option for patients that have failed standard opioid therapy because of inadequate pain control or intolerable side effects.

Routes of Administration of Opioids

The oral route is generally preferred when patients are capable and enteral absorption is not problematic. Enteral feeding tubes can also be used when patients can no longer swallow. In the palliative care setting, alternative routes of administration must be available for patients who can no longer swallow or when other comorbidities preclude the oral route.[118] These include transdermal, transmucosal, rectal, vaginal, topical, and neuraxial (epidural, intrathecal). In a study of cancer patients at four weeks, one week, and 24 h before death, more than half of the patients required more than one route of opioid administration. As patients approached death and oral use diminished, the use of intermittent subcutaneous injections and intravenous or subcutaneous infusions increased.[17] Therefore in caring for patients near the end of life, it is essential to identify alternatives to oral administration that can be used if necessary.

Some opioids have available commercial preparations in the form of suppositories, compounded suppositories, or microenemas that can be used to deliver the drug directly to the rectum or stoma. Sustained-release morphine tablets have been used rectally, with documented efficacy and safety as compared to oral administration.[119] The rectum, stoma, or vagina can also be used to deliver medication. However, the use of these routes may be hindered by the presence of fecal contents, mucosal dryness, thrombocytopenia, or painful lesions. Vaginal administration may require a tampon covered with a condom or an inflated urinary catheter balloon to prevent early discharge of the drug since the vagina has no sphincter. Although useful, the rectal or vaginal routes may be unacceptable to many patients and their caregivers, especially when the patient is obtunded or unable to assist. Nebulization is an alternative route for opioid administration that has been utilized for the relief of dyspnea but continues to be studied for analgesic efficacy. Nebulized morphine, fentanyl, and hydromorphone have been found to decrease respiratory and heart rate and increase oxygen saturation with only mild or moderate adverse effects of drowsiness, cough, bitter taste, or claustrophobia because of nebulizer mask.[120]

Transdermal fentanyl or buprenorphine are available in adhesive patch form. This route of administration is particularly useful when patients cannot swallow, do not remember to take medications or experience adverse effects from other opioids. Patients should be monitored by a responsible caregiver for the first 24–48 h of therapy until steady state blood levels are reached. The transdermal route of administration may not be appropriate

for patients with fever, diaphoresis, cachexia, morbid obesity, and ascites, all of which may significantly affect the absorption, blood levels, and clinical effects of the drug.[111] Some patients experience reduced analgesic effects within 48 h of applying a new patch. The option of more frequent (every 48 h) patch changes must be weighed against whether a higher dose can be tolerated with increased duration of effect. Patches are not suitable for severe uncontrolled pain because of the inability of rapid titration. Under most circumstances, breakthrough pain medications should be available to patients using any continuous-release opioids, such as transdermal patches.

Although most patients do well on the oral or transdermal route of opioid administration, some may require temporary or ongoing administration through a parenteral route.[57,58] Parenteral administration in palliative care is usually limited to subcutaneous and intravenous delivery because repeated intramuscular opioid delivery is excessively noxious. The most common indications for a parenteral infusion are bowel obstruction or malabsorption, severe stomatitis, intractable nausea and vomiting, and dysphagia.[57,58] A parenteral opioid infusion also is considered for patients with rapidly escalating and unstable pain or those with frequent and severe episodes of breakthrough pain. In these situations, the use of patient-controlled analgesia in combination with the continuous parenteral infusion helps ensure more effective pain relief.

The intravenous route provides rapid and continuous drug delivery but requires vascular access that is costly and may not be easily obtained or maintained in a home or long term care setting. Continuous infusions are usually only considered in patients who have an indwelling central venous port or other long term central venous device. However, in most cases, a continuous subcutaneous infusion can accomplish the goals of therapy without the need for intravenous access. Subcutaneous bolus administration of opioids has a slower onset and lower peak effect when compared with intravenous bolus. However, the subcutaneous route of administration is an inexpensive and effective method to achieve adequate pain control with minimal side effects and requiring minimal training for use in the home setting.[121]

Neuraxial routes, including epidural or intrathecal delivery, may allow administration of drugs, such as opioids, local anesthetics, and α-adrenergic agonists. However, this method for medication delivery requires complex placement and equipment by healthcare professionals with potentially greater caregiver burden. The risk of infection and other complications, along with higher initiation and maintenance costs, are significant concerns when considering intraspinal delivery systems. Patient selection should be based on greater than six months' life expectancy for implanted programmable pumps and adequate organizational infrastructure to manage these devices.

Discharge planning for patients receiving parenteral therapy is more complex and requires a team approach, with good communication between the hospital and community. A discharge planner can facilitate referral to home care agencies such as a home infusion company and identify constraints with insurance or drug availability. Operation of the infusion device may be accomplished by a home infusion care nurse or families that have been trained. All patients and their families who are receiving a parenteral infusion at home must have a 24 h resource person available to them to troubleshoot the system. The most common error encountered in a continuous infusion at home using a computerized pump is incorrect programming, leading to an inadvertent overdosing or under-dosing of the patient. Patients receiving parenteral therapy should be adequately monitored for signs of increasing pain or the occurrence of side effects such as increasing sedation, nausea, or vomiting.

Adjuvant Therapies

The term *adjuvant analgesics* is often used synonymously with *co-analgesics* and *pain-modifying drugs*. A wide variety of non-opioid medications from several pharmacologic classes have been demonstrated to reduce pain caused by various pathologic conditions or modify the ongoing disease process in a way that specifically reduces pain. Under most circumstances, these drugs are indicated for the treatment of severe neuropathic pain or bone pain, and opioid analgesics are used concurrently to provide adequate pain relief. Typical adjuvants include tricyclic anti-depressants, serotonin-norepinephrine reuptake inhibitor anti-depressants, anti-convulsants, corticosteroids, and other disease-modifying drugs, such as bisphosphonates for metastatic bone pain. For more information on adjuvant analgesics, see Chapters 53–57.

Anti-depressants

The analgesic effect of tricyclic anti-depressants appears to be related to inhibition of norepinephrine and serotonin reuptake, making these neurotransmitters more available within central nervous system pain inhibitory pathways. There are many significant, controlled clinical trials for several pain conditions, and guidelines list tricyclic anti-depressants as one of the first line therapies for neuropathic pain.[122] Analgesic doses of anti-depressants are generally much lower than the effective dose for the treatment of depression. Although the significant side effects of tricyclic anti-depressants require careful titration and monitoring in elderly and palliative care populations, their sleep-enhancing and mood-elevating effects may be beneficial enough to outweigh their disadvantages.[123] The newer mixed selective serotonin-norepinephrine reuptake inhibitors such as venlafaxine and duloxetine may offer some of the advantages of tricyclic anti-depressants without the anticholinergic side effects.[124]

Anti-convulsants

The older anti-convulsants, such as carbamazepine and clonazepam, are recognized to relieve pain by blocking sodium channels.[123] These compounds are very useful in the treatment of certain types of neuropathic pain, especially pain with episodic, lancinating qualities such as trigeminal neuralgia. The mechanism of analgesic action of gabapentin and pregabalin is thought to result from calcium ion channel blockade.[125] Gabapentin has shown efficacy in the treatment of non-malignant neuropathic pain such as painful diabetic neuropathy, whereas pregabalin has been shown to be superior in managing neuropathic cancer and cancer treatment related pain.[126] Additional evidence supports the use of gabapentin in neuropathic pain syndromes seen in palliative care, such as thalamic pain, pain because of spinal cord injury, cancer pain, and restless legs syndrome, and HIV-associated sensory neuropathies.[127] Withdrawal from anti-convulsant medications, if indicated because of ineffectiveness or adverse effects, should be gradual to prevent possible seizures.[128]

Corticosteroids

Corticosteroids are particularly useful for neuropathic, visceral, and bone pain syndromes in patients with far advanced disease, including plexopathies and pain associated with stretching of the liver capsule as a result of metastases.[129,130] Dexamethasone

produces the least amount of mineralocorticoid effect, making it the least toxic choice. Dexamethasone is available in oral, intravenous, subcutaneous, and epidural formulations that can be administered once daily because of the long half-life of this drug. Usually, divided doses are used to mitigate high dose toxic effects, such as psychosis and severe blood sugar abnormalities in diabetic patients. High dose corticosteroids may be given with severe pain crises, similar to the doses used in acute neurologic emergencies. Intravenous bolus doses should be administered over several minutes to reduce untoward reactions, such as burning sensations. Intravenous doses should also be considered for patients on maintenance corticosteroid therapy that cannot maintain oral therapy as abrupt discontinuation can induce withdrawal symptoms.

Local Anesthetics

Local anesthetics are helpful in relieving neuropathic pain. They can be given orally, topically, intravenously, subcutaneously, or neuraxially.[131] Mexiletine (oral) has been reported to be useful when anti-convulsants and other adjuvant therapies have failed.[132] Electrocardiogram evaluation prior to initiation of therapy is recommended to assess for conduction blocks that can be exacerbated by local oral anesthetics. Local anesthetic gels and patches have been used to prevent pain associated with needlesticks, minor procedures and reduce the pain of postherpetic neuralgia.[133] Intravenous lidocaine in a continuous infusion has been reported to reduce intractable neuropathic pain in inpatient palliative care and home hospice settings.[134] Epidural or intrathecal lidocaine or bupivacaine delivered in combination with an opioid can provide a superior reduction of neuropathic pain.[135]

Bisphosphonates

Bisphosphonates inhibit osteoclast-mediated bone resorption and alleviate pain related to metastatic bone disease and multiple myeloma. Bisphosphonates can be used to reduce the incidence of pathologic fractures and to treat tumor-related hypercalcemia.[136] Zoledronic acid has demonstrated improved safety and efficacy than pamidronate, specifically in patients with breast cancer and multiple myeloma.[137] Similarly, there appears to be more sustained pain relief with zoledronic acid compared with other bisphosphonates in patients with metastatic prostate cancer.[138] Clinical trials in patients with lung and renal cell carcinoma have also shown therapeutic benefit from regular infusions of zoledronic acid.[139]

Palliative Chemotherapy and Radiation Therapy

Palliative chemotherapy is the use of antitumor therapy to relieve the symptoms that are associated with malignancy. Considering patient goals, performance status, tumor sensitivity, and potential toxicities, chemotherapy can be utilized to optimize symptom control and quality of life even though it may not improve survival.[118] Radiation therapy is also a highly useful adjunct to control pain from bone metastasis and pressure-inducing and ulcerative malignancies. Single-fraction and hypofractionated regimens are proving to be effective in very sick patients and those with limited life expectancy in whom the costs of multiple treatment sessions are untenable.[140] These therapies are often underused in hospice or palliative care and should be considered for any patient with a life expectancy of more than a few weeks.[141]

Therapy for Intractable Pain

The use of ketamine and dexmedetomidine has gradually increased in the management of intractable pain in cancer patients and terminally ill patients. Ketamine is a potent NMDA-receptor-channel blocker available for administration in oral, sublingual, intranasal, topical, subcutaneous, and intravenous formulations. It is used in subanesthetic doses for both pain and mood disorders without causing respiratory or cardiovascular depression.[142] Ketamine may also be helpful in the reduction of opioid consumption and tolerance. It has been found to be more effective in neuropathic pain, ischemic pain, and regional pain syndromes.[143] Dexmedetomidine is a selective alpha-2 adrenergic agonist that is administered intravenously that can produce sedation and analgesia but does not cause respiratory depression. Dexmedetomidine has also been shown to be potentially useful for severe or refractory pain, delirium, and opioid induced hyperalgesia.[144] The use of ketamine or dexmedetomidine infusions in a non-intensive care hospital care setting may allow for a window of time to achieve optimal pain control with primary regimen escalation or to allow patients to achieve other goals in their terminal phase. Ultimately if pain cannot be controlled, there is an option for palliative sedation. Palliative sedation is the infusion of medication to lower the level of consciousness of a patient to limit the awareness of suffering that a patient finds intolerable and intractable. Though this modality has met resistance in the past, it has been through the scrutiny of both ethicists and judges coming out as an acceptable practice for the properly selected patients. Studies have demonstrated that patients undergoing palliative sedation experience no life-shortening effect.[145]

Cannabis for End of Life Therapy

Cannabis in plant-based products has multiple components creating a synergistic entourage compared to synthetic cannabis products primarily used for medicinal formulations. Patients with advanced cancer using cannabis have reported improvements in pain, appetite, nausea, and overall general wellbeing.[146] Many providers have changing attitudes of cannabinoid use that appear to be in part related to legalization efforts. However, this acceptance has not translated into actual recommendation and prescription.[147] There remains a paucity of high quality evidence on using cannabinoids to treat cancer-related and terminal illness pain. Most studies clearly document potential adverse effects of dizziness, nausea, fatigue, somnolence, disorientation, drowsiness, and confusion.[126] These may be particularly important when considering the frailty, baseline symptoms, and other comorbidities of this patient population.

Beginning Therapy, Adding or Changing Drugs, and Breakthrough Pain

Initial analgesic therapy and dosing will depend on patient-specific medical, psychological, and social considerations and sound knowledge of pharmacotherapy. Frail patients and those with pain crises may require observation in a monitored setting to provide safe and effective relief within an acceptable time frame. Opioids should be initiated in immediate-release form in lower doses for opioid naïve patients because of significant inter- and intraindividual variation in clinical responses. Idiosyncratic responses may require trials of different agents to determine the most effective drug and route of delivery for any given patient.

Prompt reassessment within one or two days is essential so that adjustments can be made as soon as possible. Poor pain control after initiation of therapy may be because of inadequate dosing or end of dose failure. Titration and combination of drugs that may provide additive or synergistic effects should proceed along rational lines, based on the pharmacokinetics and monitored pharmacodynamics of the drugs. Patients continuing to take increasing doses of immediate-release medications as needed more than four times daily with inadequate pain control should be considered for additional extended-release opioid. This dose is determined by calculating the total daily dose of immediate-release medication used in a 24 h period and dividing it in half to approximate the extended-release dose to be administered twice daily. Transitory flares of pain, or breakthrough pain, may still occur both at rest and during movement. If breakthrough pain lasts longer than a few minutes, the patient may continue to take immediate-release opioid to provide relief.

For safety, a patient should reach a steady state on the current regimen before titration. Medications generally require four to five half-lives to reach a steady state, approximately 24 h for immediate-release opioids and two to three days for extended-release opioids. If adverse effects exceed the analgesic benefit of the drug, it may be converted to an equianalgesic dose of a different opioid. However, opioid rotation should not be the first option for patients experiencing mild side effects, as most of these will be time limited.[126] For patients with intolerable side effects, poor pain despite adequate titration, changes in the route of administration, change in end organ function, or unsafe drug interactions, rotation in opioids should be addressed. Because of incomplete cross-tolerance in transitioning opioid classes, consider reduction of the calculated dose by one-third to one-half and titrate upward based on pain scores.[118]

Minimizing and Managing Adverse Effects

There are a variety of adverse effects that drugs for pain can cause patients in palliative care. The normal side effects of pain relief medications are often exacerbated by changes in metabolism caused by end stage disease, polypharmacy associated with advanced age, and other factors. Following are some of the more common adverse effects and an overview of possible approaches to preventing or alleviating them.

Constipation

Opioid induced constipation is any change from baseline bowel habits when initiating opioid therapy.[126] A prophylactic bowel regimen with stool softeners and/or bowel stimulants should always be started when commencing opioid analgesic therapy. Bulking agents, such as psyllium, should be avoided because these tend to increase desiccation time in the large bowel, and debilitated patients can rarely take in sufficient fluid to facilitate their action. If over-the-counter medications are ineffective at creating regular laxation, prescription therapies are indicated. When traditional regimens have failed to bring about the desired effect, using a peripherally acting μ-opioid receptor antagonist such as methylnaltrexone can be useful. Multiple drugs in this class have been formulated to target opioid induced constipation, and because they do not enter the central nervous system, there are no symptoms of opioid withdrawal or increased pain. Pure opioid antagonists, which are generally used to treat acute overdose, can be used in selected cases to prevent opioid induced bowel dysfunction.[148]

Sedation

Opioid induced neurotoxicity can include symptoms of delirium, tremor, myoclonus, and hallucinations that are associated with opioid therapy. In addition, sedation serves as a warning sign that occurs before respiratory depression. Excessive sedation may occur with initial doses of opioids, but if sedation continues to persist after the first few days and other correctable causes have been identified and treated, then dose reduction may be warranted. However, some studies have shown the use of psychostimulants to be beneficial in counteracting opioid induced sedation in cancer patients.[149] These medications include dextroamphetamine, methylphenidate, and modafinil.

Respiratory Depression

Respiratory depression is rarely a clinically significant problem for opioid tolerant patients who are in pain.[94] When respiratory depression occurs in a patient with advanced disease, the cause is usually multifactorial.[150,151] When depressed consciousness occurs along with decreased respiratory rate or hypoxemia and is associated with opioid use, slow, cautious titration of diluted naloxone can be administered every few minutes while providing respiratory support and supplemental oxygen. Excessive administration of naloxone may cause abrupt opioid reversal with pain and autonomic crisis.

Nausea and Vomiting

Nausea and, less commonly, vomiting may be adverse effects associated with opioids because of activation of the chemoreceptor trigger zone in the medulla, vestibular sensitivity, and delayed gastric emptying. Habituation usually occurs in most cases within several days.[118] In severe or persistent cases without other identifiable causes, antiemetic pharmacotherapy or consideration of transdermal route is indicated.[97]

Myoclonus

Myoclonic jerking can occur with high dose opioid therapy, particularly with morphine in the face of renal dysfunction because of metabolite accumulation.[118] Opioid rotation is warranted with additional consideration of benzodiazepines such as clonazepam, lorazepam, or Valium to treat distressing myoclonus.[94] High dose opioid infusions should be requested in preservative free solutions because of reported associated grand mal seizures.[152]

Pruritus

Pruritus because of histamine release can occur with most opioids, although it appears to be most common with morphine. Most antipruritic therapies cause sedation, which should be confirmed as an acceptable alternative by the patient. Antihistamines (such as diphenhydramine) are the most common first line approach to this opioid induced symptom. Ondansetron and pentazocine have also been reported to be effective in relieving opioid induced pruritus. However, both have some risk of recurrent opioid induced pruritis.[153]

Hyperalgesia

Opioid induced hyperalgesia is a paradoxical increase in sensitivity to painful stimuli with increasing doses of opioids. The escalation of pain or failure of analgesia following opioid titration may be because of high or rapidly increasing doses. Patients may experience pain in a different location or of a different quality. Managing opioid induced hyperalgesia entails opioid rotation or reduction and supplementation of non-opioid analgesics.[117]

Conclusion

Effective pain management in advanced medical illness and at the end of life is a critical component of quality medical care to ensure dignified, safe, and comfortable dying. To quote Sir William Osler, the "father of modern medicine," "The study of morbid anatomy combined with careful clinical observations has taught us to recognize our limitations and to accept the fact that a disease itself may be incurable and that the best we can do is to relieve symptoms and make the patient comfortable." A personalized and multifaceted approach to pain management to include nonpharmacologic and pharmacologic interventions for the patient continues to be warranted even at the end of life. Although the basic principles of pain management are the same whether the patient is being cared for in an acute care setting, their home, or a long term care facility, there is a major shift in responsibility for day-to-day pain management when the patient is cared for at home. Pain management in the home becomes a family experience with every aspect of care provided to the patient affecting the family system as a whole. Successful pain management at home depends on an informed and confident patient and caregiver with collaboration and effective communication between the family and designated primary individuals in their healthcare team. A system of continual assessment of patient and caregiver must be in place to ensure the effectiveness of pain relief measures and early identification of undue stress on the part of the caregiver.

Key Points

- Pain is a prevalent symptom at the end of life that is increasingly managed in the home environment.
- Assessment and management of pain becomes more complex at the end of life, becoming a family experience.
- Transitions and challenges to home pain management must be addressed to ensure adherence to a pain management plan, adequate analgesia, and decreased burden for caregivers.
- Tailoring a pain management regimen that fits the patient's and family caregiver's values, goals, and capabilities is important to maintain successful home care.
- Family and patient education in pain and symptom management, as well as ongoing support from competent pain practitioners, is essential.
- Clear, straightforward communication is a critical component of this education and support.
- Continuity of care and minimization of emergencies can be fostered through various tools of communication.
- Match the mechanism of pain with the class of drug whenever possible; initiate therapy and adjust the dose according to therapeutic response, side effects, and known pharmacokinetics of the drug.
- Nonpharmacologic approaches are effective pain management techniques at the end of life that can have positive impacts on the patient and their caregiver.
- Non-opioids should be considered in the treatment of mild to moderate pain of musculoskeletal origin.
- Opioid analgesic drugs are often necessary to relieve moderate to severe pain, and long-acting or sustained-release analgesic preparations should be used for continuous pain.
- Adjunctive drug therapies should be considered independently or concurrently with opioids, especially for neuropathic and bone pain.
- Anticipate, monitor, and treat breakthrough pain, changes nearing the end of life, and adverse effects of medications.
- Last, and perhaps most important, know your limitations. When a patient is not responding to therapy, be prepared to consult with someone who has more training, expertise, and experience. A team approach is often needed.

Clinical Trial Design Methodology and Data Analytic Strategies for Pain Outcome Studies

NEBOJSA NICK KNEZEVIC, PATRICK SCHOBER, ROGER CHOU, THOMAS R. VETTER

It is traditionally held that the first comparative clinical trial was performed in 1747 by Dr. James Lind of the British Royal Navy to identify a treatment for scurvy. Lind evenly assigned 12 scurvy-afflicted sailors to receive cider, vitriol (a weak acid), vinegar, sea water, oranges, lemons, or nutmeg paste.[1] After six days, only the two sailors who had received oranges and lemons (and thus adequate amounts of vitamin C) had sufficiently recovered to return to duty. Two centuries later the advent of the pharmaceutical industry and the evolution of methodologic concepts led to the first controlled clinical trial in which patients were randomly assigned to different treatments. Performed in 1947–48, it was observed that the effects of streptomycin on pulmonary tuberculosis were significantly better than those of a placebo.[2,3]

Evidence-Based Medicine

In contrast to the previous common acceptance of the merit of individual medical or surgical practice—the proverbial "in my experience" (N of one), "in case after case, I have seen" (N of two), and "in my series" (N of three or more)—evidence-based medicine (EBM) acknowledges that simple intuition, unsystematic clinical experience, and a pathophysiologic rationale are inadequate bases for clinical decision making.[4] EBM stresses the critical examination of evidence from clinical research. EBM likewise offers a formal set of steps to complement medical training and "common sense" for clinicians to effectively interpret the results of clinical research ("how to read a paper") and to apply them in their practice. Lastly, EBM places a lower value on expert authority than does the traditional medical paradigm.[5–8]

EBM provides a process for evaluating evidence to inform clinical practice, which can be divided into five key steps. The first step is to **define a focused, clinically relevant question** with the goal of translating uncertainty into an answerable question. A useful structure for formulating an answerable clinical question is the mnemonic PICO:

P – Patient, Population, or Problem
I – Intervention
C – Comparison or Control
O – Outcome

The second step is to **search for evidence** by systematically retrieving the highest-quality information available to address the clinical question. The third step is to **critically appraise evidence** in terms of validity, clinical relevance, and applicability. The fourth step is to **apply the evidence in practice** to extrapolate scientific evidence and make a case-specific decision. The final step is an **evaluation of the clinical outcomes** and performance of the EBM-guided decision. EBM is not a linear process but rather an iterative, perpetually improving process made possible by continuous re-evaluation of the available evidence.[8,9]

Many systems for grading the level or quality of evidence and the strength of recommendations have been developed. Unfortunately, guideline developers worldwide have historically been inconsistent in how they rate the quality of evidence and grade the strength of recommendations, resulting in confusion among guideline users.[10]

While the GRADE system is not without limitations,[11] it has improved the standardization of EBM methods. GRADE defines and clearly delineates all the major domains that affect the reliability of research evidence, including the quantity, quality, consistency, and types of studies of the published evidence. This assessment results in one of four grades of evidence (high, moderate, low, or very low), which describes confidence in the estimated effect.[12,13] This certainty estimate may be rated down if there is a risk of bias, imprecision, inconsistency, indirectness, or publication bias.[14–18] Recommendations may also be assigned based on the evidence grade, an estimate of net benefit relative to harm, and other factors, including costs and burdens.[10,19,20] In GRADE, recommendations are graded as strong or weak, although groups implementing GRADE have used other categories (e.g. conditional instead of weak or an additional moderate category).

In some situations with GRADE, a moderate or strong recommendation might be justified, even when the evidence is of a low or very low quality. For example, a guideline found evidence for pulsed radiofrequency treatment of the dorsal root ganglion in the treatment of postherpetic neuralgia to be very low. However, the recommendation was graded moderately strong based on potential benefit relative to harm, as well as other considerations, including that the intervention is considered easy to perform and safe.[21] The terminology and development of practice recommendations are discussed later in this chapter.

Since the term was coined about 30 years ago,[22] EBM has progressed from a novel concept to a buzzword to a mantra.[23]

EBM is often misconstrued as being only about randomized clinical trials (RCTs). However, this is an oversimplification. In reality, EBM has always emphasized the importance of considering the best available evidence, which can include observational studies.[24]

The Spectrum of Outcomes Research

The appraisal of a new or existing treatment modality, including pain management, involves three steps.[25–29] These steps are ideally, but not always, undertaken sequentially.

1. **Efficacy**, or whether a treatment achieves its intended clinical benefits ("Can it work?"), is demonstrated under "optimal" circumstances in highly controlled settings with carefully selected patients, typically in an RCT.
2. The **effectiveness**, or whether these benefits are also seen under more ordinary or "naturalistic" circumstances, is assessed ("Does it work?"), often by way of an analytic cohort study, although RCTs can also be designed to evaluate effectiveness.
3. The **efficiency or cost effectiveness** (the health status improvement realized for a given amount of resources expended) can be determined via a healthcare economic evaluation ("Is it worth it?"). An economic evaluation can also provide crucial insight into the value of providing a healthcare intervention to a specific population (Figure 83.1).[30]

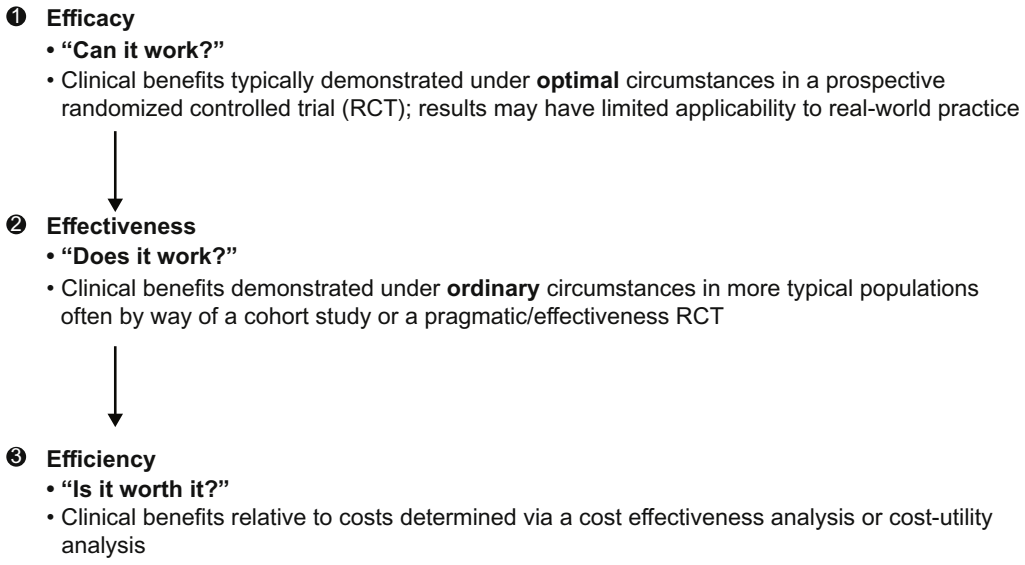
Importantly, for an intervention to be cost effective, it must first be shown to be effective. For example, routine imaging for low back pain (LBP) in the absence of "red flags" is associated with no benefit in pain or function compared to the usual care without routine imaging.[31] Therefore even though lumbar x-rays are relatively inexpensive, routine imaging cannot be cost effective. On the contrary, interventions associated with relatively high up-front costs can still be cost effective if the clinical benefits are substantial or the up-front costs are offset by decreased downstream costs. An example of such an intervention is the STarT Back screening tool, which stratifies patients based on the prognosis of LBP (low, medium, or high risk). At 12 months, compared with the non-stratified current best practice, STarT Back screening and treatment targeting was associated with a mean increase in general health benefits (0.039 additional QALYs) achieved with cost savings (£240.01–274,40), as well as fewer days off work.[32]

Experimental Versus Observational Study Designs

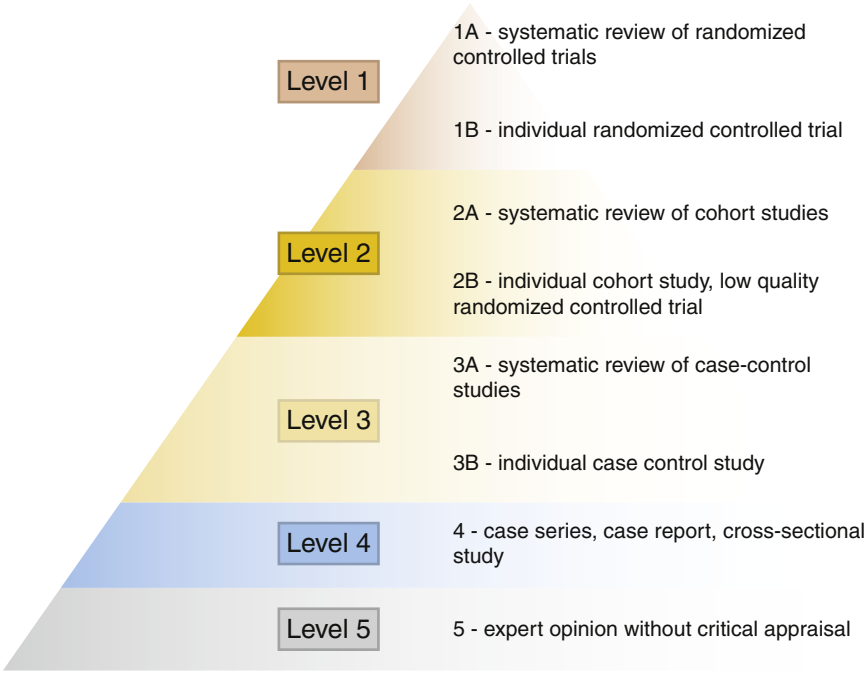
An RCT has been viewed by many clinician scientists (not to mention journal editors and reviewers) as the de facto "gold standard" of clinical trial design for evaluating the *efficacy* and safety of a treatment or intervention.[33] However, while a well-conducted RCT generally provides more valid (true) results than other study designs, there are several other study designs, which may on a situational basis, be more appropriate to apply in conducting human research.[34] For example, for evaluating harms, it may be unethical to randomize patients, or for rare or long-term harms, adequately powered RCTs may not be feasible.[35] The hypothesis posed dictates the study design that is the most appropriate. Different study designs were associated with ascending levels of strength (Figure83.2). Key characteristics that increase the strength of evidence are randomization, the presence of a control group, patient and investigator/provider blinding, low attrition, and control for known confounders.[36–39]

The array of quantitative study designs was classified as either experimental or observational. In an experimental trial, also called an interventional or controlled trial, the allocation of clinical interventions was determined by the investigators. This is not the case for observational studies, which are further divided into descriptive and analytic categories (Figure 83.3). A descriptive study focuses on describing a population, whereas an analytic study is characterized by the performance of the analysis involving a comparison group. Different study types are also distinguished by the timing of the data collection, which can be described as prospective or retrospective.[33,40–47]

Another distinction between the different study types lies in the tension and trade-offs between internal and external validity. Internal validity concerns include incomplete identification of and adjustment for confounders, misclassified variables, and selection bias, and require tight controls. External validity concerns include



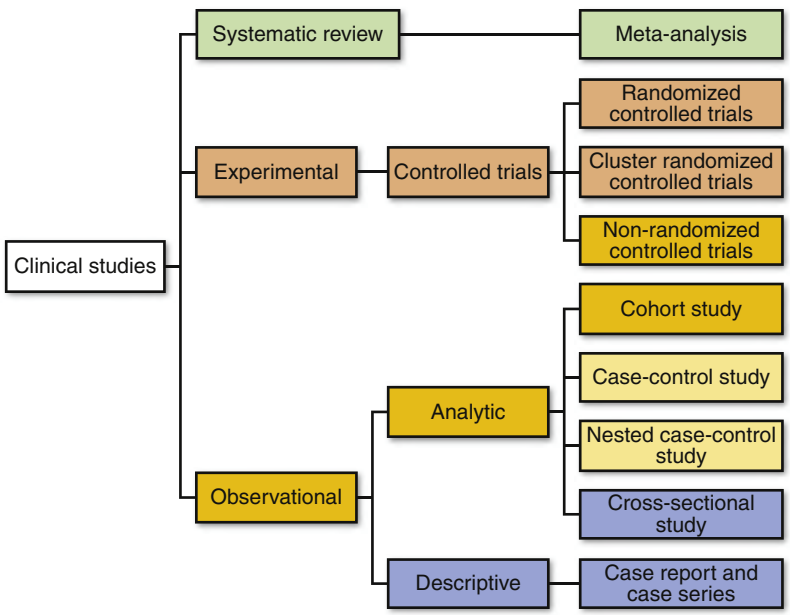
• **Figure 83.1** The appraisal of a new or existing treatment modality, including for pain management, involves three steps.



• **Figure 83.2** Levels of evidence based medicine.

the evaluation of selected populations, data handling, and timeliness.[48] External validity (generalizability or applicability) is separate from risk of bias but is also critical for interpreting research evidence. Studies may be at a low risk of bias and therefore valid (i.e. give true results) but only apply to very specific situations (i.e. have limited external validity). Therefore it is important to consider whether the study evaluates effectiveness or the extent to which a treatment works on average patients in everyday settings, as compared to efficacy, that is, the extent to which a treatment works in highly selected patients in tightly controlled settings.[49]

Observational studies can complement findings from often smaller scale RCTs by assessing treatment *effectiveness* in patients in a more realistic, natural clinical practice.[50] However, it is important to note that a randomized trial is not necessarily an efficacy study, nor is an observational study necessarily an effectiveness study. Rather, the aspects that determine whether a study is an efficacy or effectiveness study include the methods used to ensure that a study evaluates more representative populations, interventions, and comparisons; evaluation of patient-centered outcomes; and being conducted in settings typically encountered in clinical practice.[49]



• **Figure 83.3** Classification of clinical study designs.

Case Report and Case Series

A case report is useful, for sharing with the medical community, novel, rare, or atypical features identified in medical practice in an individual patient. It has historical significance as a type of clinical study that dates back by millennia.[51] However, since the mid-20th century, it has waned in terms of importance, in favor of more rigorous, statistically, methodologically relevant study designs.[52] Nonetheless, publication guidelines such as Consensus-based Clinical Case Reporting Guideline Development have been developed by international groups of experts to promote the accuracy, transparency, and usefulness of case reports.[53]

Currently, the case report remains a useful educational tool to generate new investigational questions and support learning methods rooted in critical thinking and problem solving. Case reports are also useful in pharmacovigilance because they facilitate sharing rare, unexpected, or long term adverse effects that may have gone undetected during clinical trials. Case reports contributed to the evidence that led to 18 of 22 drugs being withdrawn from the Spanish market between 1990 and 1999.[54,55] Important limitations remain, namely the lack of controls, uncertainty of a follow up, and the fact that it is difficult to generalize findings from a single patient.[56]

A case series can help address some of these concerns by increasing the sample size. A case series describes the medical outcomes of a group of patients with a particular disease or disease-related outcome, often over time. As with a case report, a case series comes with the primary limitation of the lack of a control group and potential sampling bias. Risk ratios cannot be calculated based on such evidence.[57]

An example of a case report, which represented the first reported occurrence of such an event, describes a patient who experienced an extremely rare and unpredictable thalamic stroke resulting in the disappearance of a pre-existing chronic pain condition,[58] following which the patient's chronic LBP completely disappeared. Such unique cases may provide insight into neuromodulation, neuroplasticity, and brain stimulation.[58]

Cross-Sectional Study

A cross-sectional study determines the prevalence (i.e. the existing presence) of a disease at a given point or period in time. If a sample is randomly chosen, such a frequency survey provides a valid "snapshot" of the characteristics of the source population. It can provide an estimate of the magnitude of a problem and thus the significance and rationale for further investigation. Of note, a cross-sectional study's measurements are taken at a single point in time, whereas longitudinal studies conduct several observations over time.[59] A cross-sectional study cannot assess possible causality between a predictor variable (e.g. sex and socioeconomic status) and an outcome variable (e.g. pain intensity). While a cross-sectional study cannot assess the comparative outcomes (benefits and risks) of an intervention, the findings of a cross-sectional study can generate hypotheses for further studies.[40–44,60,61]

For instance, a cross-sectional study aiming to investigate the frequency and features of painful diabetic polyneuropathy enrolled 816 patients attending hospital diabetic outpatient clinics.[62] Diabetic polyneuropathy was diagnosed in 36% of patients, strongly correlating with male sex, age, and severity of diabetes. A subset of these patients, 2.5% of the study population, with pure small-fiber polyneuropathy, was found to be unrelated to either the demographic variables or the severity of diabetes. On the contrary, painful polyneuropathy was correlated with the female sex and was diagnosed in 13% of the study population.[62] As discussed, cross-sectional studies cannot determine causality. However, demonstrating that this form of neuropathic pain correlates with sex offers insights that may contribute to improving pain management. Cross-sectional studies can be used to observe or compare individuals and groups. For example, a cross-sectional study examining social health determinants in patients following total knee arthroplasty divided their participants into two groups based on whether they had chronic postsurgical pain. This allowed them the investigators to see that patients with a lower educational level had a three-fold higher association with chronic post-surgical pain.[63]

Case-Control Study

A case-control study aimed to determine the relationship between a single outcome (disease) and one or more previous possible contributing factors (exposures). Case-control studies look or work backward, starting with the identified outcome or disease (exposure ß disease). Case-control studies are retrospective, relying upon existing data or recall of exposures, and are therefore generally less time consuming and less costly to perform than studies using a prospective design. This study design is particularly suited to outcomes that are rare or have a protracted onset. Cases are patients with the outcome of interest, whereas controls are patients without the outcome of interest. The controls must be drawn from the same source population (study base) as the cases, such that the controls are comparable to the cases in all important respects except for the outcome of interest.[64] Thus controls must also be chosen independently of their exposure status.

Primary validity threats with a case-control study include selection bias (non-comparable controls without the disease) and recall bias (differential recollection of exposure among cases with the disease). Overmatching can also occur if the cases and controls are matched on a variable that is also associated with the exposure of interest. Thus if someone matches a factor that is affected by both exposure and a cause of disease, this will obscure disease association.[65]

Because cases and controls are selected for analysis based on the presence or absence of outcomes, there is no true denominator in a case-control study. Therefore the event rate, relative risk, and risk ratio cannot be calculated. Instead, the odds ratio (the ratio of the odds of exposure in the cases and the odds of exposure in the controls OR) is conventionally generated as a measure of the association between exposure and disease in a case-control study. When the outcomes occur at an infrequent rate, the odds ratio should approximate the relative risk.[40–44,66]

A case-control study was performed to quantify the degree of overlap between facial pain and pain experienced in other parts of the body.[67] Data were collected from participants in a large prospective study, including 424 cases of chronic facial pain and 912 controls. They reported pain at other locations in the body using a mailed questionnaire. The findings were that facial pain had the greatest overlap with headaches (OR = 14.2, 95% CI = 9.7–20.8), followed by neck pain (OR = 8.5, 95% CI = 6.5–11.0). For locations below the neck, the overlap decreased substantially (OR ≤ 4.4).[67] A limitation of this study was its reliance on self-reported symptoms.

Nested Case-Control Study

A nested case-control study is a case-control study in which the cases and controls are selected from members of an existing cohort.[68] The members of the base cohort are followed for a certain period until the specific outcome or end-point occurs.[42,69] The nested case-control design differs from the non-nested case-control design in that patients are selected from a well-defined cohort, for which data on all members can be obtained.[70] This design makes it easier to satisfy the fundamental assumption of the case-control study: cases and controls represent unselected samples from the same study base.[70] In addition, a nested case-control study can be designed to prevent attrition bias. If all data are collected prospectively before the outcome occurs, a nested case-control study is also unlikely to be affected by recall bias, even though the cohort does not need to be prospective.[41]

The following is an example of a nested case-control study designed as a follow up to a 5-year cohort study, aiming to determine how headache types and patterns over time can be associated with the risk of developing temporomandibular disorder (TMD).[71] The cohort study followed 2410 patients who were TMD-free at the beginning of the study. The ensuing nested case-control study matched the cohort of 248 incident TMD cases with 191 TMD-free controls. The findings showed that both headache prevalence and frequency increased among patients who developed TMD compared to controls. In particular, in terms of headache frequency, definite migraines among TMD cases increased tenfold,[71] suggesting the usefulness of future studies in investigating whether the treatment of migraines may reduce the risk of developing TMD.

Cohort Study

A cohort study aims to determine the relationship between a single contributing factor (exposure) and one or more possible outcomes (diseases). Cohort studies look forward starting with the identified exposure (exposure à diseases). Cohort studies are, by definition, longitudinal. However, data collection can be prospective, retrospective, or ambispective (utilizing both retrospective and prospective data from the same study population). The key design element is that all participants in a cohort study are outcome or disease-free prior to exposure (intervention) and at the outset of data collection. The outcome data are then sequentially collected.

Prospective and retrospective cohort studies may be less prone to recall bias than case-control studies but are subject to differential attrition bias, whereby participants in one group exit the study at a disproportionate rate. Cohort studies are also vulnerable to confounding by indication, a form of selection bias in which a variable is a risk factor for a disease among the non-exposed individuals and is associated with the exposure of interest in the population from which the cases are derived, without being an intermediate step in the causal pathway between the exposure and the disease (e.g. a marked increase in gastrointestinal bleeding in patients prescribed a nonsteroidal anti-inflammatory drug [NSAID] plus a proton-pump inhibitor versus only an NSAID).[72,73]

Prospective cohort studies are also typically more time consuming and costlier than case-control or other observational studies, especially for rare outcomes (diseases) and those with a protracted onset. The cohort study allows for direct estimation of the incidence (new event) rate, relative risk, and relative risk ratio.[40–44,74] Of note, an RCT is a type of prospective cohort study with random assignment to exposures (interventions).[33]

A prospective cohort study was undertaken to identify predictors of moderate to severe persistent postoperative pain (PPP) 6–12 months after total knee arthroplasty (TKA).[75] The study population consisted of 300 patients undergoing primary unilateral TKA. Prior to surgery, a wide array of data was collected from the patients, including clinical information, psychological variables, quantitative sensory testing, and blood samples for genotyping, in addition to information on surgical factors related to the operation and measurements of acute postoperative pain. Thereafter, 6–12 months after surgery, the patients completed follow up questionnaires with minimal loss of participation, keeping the attrition bias low. All of this information was then analyzed using multivariate logistic regression to identify the predictors of PPP. The prevalence of moderate to severe PPP, 6 and 12 months after surgery, was 21% and 16%, respectively. At six months, 66% of patients were correctly classified as having moderate to severe PPP using a combination of the following predictive variables: preoperative pain intensity, expected pain, trait anxiety, and temporal summation. At 12 months, the same first three predictors correctly classified 66% of the patients.[75]

Non-Randomized Controlled Trial

In a non-randomized controlled trial (NCT), assignment to treatment and control groups is performed by the investigators but not through a randomized process. In contrast to RCTs, an NCT lacks the critical component or randomization, making them more susceptible to biases and confounding factors.[47] An inherent shortcoming of NCT is that it is difficult to determine whether differences in outcomes between interventions are because of the interventions themselves or other confounding variables.

Despite this important shortcoming, an NCT may be helpful in some situations in which RCTs are not feasible because of high cost, ethical considerations, lack of participants willing to be randomized, or other factors.[76] NCTs can be useful for identifying potentially effective interventions that warrant an evaluation in RCTs. NCTs are sometimes included in meta-analyses and used to inform medical decision making, but research is needed to understand when NCTs are more likely to be reliable and when they are likely to be misleading.

One such experimental controlled trial that relied on a non-randomized design aimed to determine the benefit of a 10-week shoulder home-based exercise program (SHEP) in a group of elite wheelchair athletes. The participants were assigned to either the exercise or control group in a non-random, mixed-pair design, where each participant was matched to a control in terms of two variables: whether they used the wheelchair for daily activities or only for sports, and whether they experienced shoulder pain or not. This design allowed the researchers to compare the baseline and post-intervention changes more accurately, both in terms of shoulder pain and range of motion. The 10-week SHEP did not provide significantly different changes in either outcome between the experimental and control groups. The limitations relating to non-randomized allocation and small sample size apply when it comes to the interpretation of this study's results in the context of similar studies.[77]

Randomized Controlled Trial

An RCT is a type of controlled clinical trial based on participants being assigned to the possible exposures or interventions purely by play of chance ("flip of a coin") using tools such as

computer-generated randomization sequences.[33] When successfully implemented, random allocation produces two or more treatment groups that are free of selection and confounding bias by both known and unknown factors, assuming that the sample size is sufficiently large and randomization is carried out successfully.[78] When those involved in an RCT are blinded (masked) to the intervention each participant receives, allocation, treatment, and assessment biases are also reduced.[79] Thus when properly designed and performed, an RCT is more likely to have internal validity. It accurately and reliably measures what it is intended to be measured, that is, the relative benefits and harms of two or more interventions.

Patient blinding is a critical factor contributing to the high quality and internal validity of a well-designed experimental trial. Moreover, double-blinding is achieved when both the patient and the investigator (if it is impossible to blind the investigator, the outcome assessor, data collectors, or data analyst may be blinded) are blinded to the treatment allocation. Successful double-blinding helps prevent response bias, such as observer bias and confirmation bias, which can be caused by the experimenters or the participants being influenced by their expectations of the results. In the case of either pharmacologic or non-pharmacologic interventions for chronic pain, blinding is rarely reported and has often been found to fail, primarily because of the large treatment effect sizes and high rates of adverse effects.[80]

An example of an RCT trial on chronic LBP investigated whether adding an open-label placebo (OLP) to treatment as usual (TAU) could benefit patients.[81] There are ethical concerns surrounding the study of placebo effects because of the widespread belief that deception is required in order for the placebo effect to take place. In this study, 97 participants consented to take OLP for three weeks following TAU treatment. The consenting participants were randomized to TAU or OLP, and the treatment assignment was revealed to both the participants and investigators. Only registered nurses who completed the assessments were blinded. The findings showed that OLP enhanced pain reduction by approximately 30% of the baseline pain and disability ratings. More specifically, OLP provided a pain reduction of 1.49 points on a 0–10 scale of pain intensity, compared to a 0.24-point change provided by TAU alone.[81] This study has some important limitations, primarily in terms of reporting bias, because of the utilization of self-appraised outcomes combined with an open-label design. Additionally, the highly positive response to OLP may be explained by the encouraging educational information the participants were provided with placebo effects, combined with unconscious processes associated with physically opening pill bottles and taking pills. Expectations of pain relief may have encouraged participants to differentially interpret normal spontaneous fluctuations in pain. A double-blinded study design is important for reducing unwanted placebo effects related to expectations of benefits or harm (nocebo effects). An alternative strategy is the use of an active placebo, which produces side effects intended to persuade the patient that they are receiving the active compound.[82]

An enriched enrollment randomized withdrawal (EERW) trial is a variation of the traditional RCT that has been introduced for studying chronic pain, particularly pharmacologic therapies. The first step of an EERW is the enrichment phase, where only the patients who respond to the drug and tolerate the side effects will progress to the next phase. In the withdrawal phase, these patients are then assigned, in a double-blind, randomized manner, into a group that will continue taking the study drug, and the control group will be switched, through titration, to a placebo or another comparator.[83,84] The EERW design may be considered an extreme form of efficacy study since it is intentionally designed to evaluate a highly selected patient population known to respond to and tolerate the treatment of interest. Furthermore, EERW studies reflect a highly selected population and are not representative of clinical practice, as the response to the drug cannot be predicted, and treatment would not normally be interrupted in patients who respond well. Additionally, patients withdrawn from treatment following randomization may be aware that they are no longer receiving the study drug, which may cause performance bias by influencing their response to the placebo.[83] Therefore the interpretation and utility of EERW studies have been controversial.[85]

Cluster Randomized Controlled Trial

A cluster randomized trial (CRT) is a study design in which individuals are randomized into groups; the group as a whole is randomized, and not the individual. Physicians, group practices, health plans, or even geographic regions (counties or states) can be defined as clusters. In a CRT, all individuals within a given cluster are assigned to the same study arm.[86] The methodology of CRTs has been widely discussed.[87–89] In evaluating a therapy, unlike a standard (individually randomized) RCT, a CRT may be better suited at replicating conditions of actual use in clinical practice to produce more generalizable findings.[90]

CRT is often performed when individual randomization is not feasible. For example, if a clinician is implementing a new LBP evaluation and treatment study protocol, it would be challenging to randomize some patients in a clinic to one protocol and other patients to another protocol because there is a substantial amount of shared knowledge of the different protocols and overlap among clinic personnel. CRT can also offer cost and time efficiencies over individually randomized trials.[86]

However, compared with individually randomized trials, CRTs are more complex to design, require more participants to obtain equivalent statistical power, and require more complex analyses (e.g. adjustment for the intracluster correlation coefficient of the cluster randomization).[91–93] A CRT is also typically not blinded. Thus not surprisingly, the use of this trial design creates challenges that may undermine the validity of some findings.[92,94]

For example, a CRT investigated the benefits of a digital health psychological intervention (WebMAP) in comparison to usual care alone in children and adolescents with chronic pain.[95] The 143 participants were patients selected from eight different clinics. The clustered randomization design that stems from the clinics determines whether they would initiate the WebMAP intervention two, four, six, or eight months after study commencement. The findings showed that neither WebMAP nor usual care showed significant changes in pain related disability and pain intensity over time. However, youths in the WebMAP group perceived a significantly higher global improvement both post-treatment and at follow up ($p \leq 0.01$). Additionally, greater engagement with the WebMAP modules was associated with a significant reduction in both pain related disability and pain intensity.[95] The clustered design of this study was used to implement the intervention. However, possible limitations are the potential differences in the amount or type of care provided at each clinic under usual care control. Nonetheless, the WebMAP intervention was provided through mobile access and was consistent among the groups.

Meta-Analysis

A systematic review involves a detailed and comprehensive search strategy to identify and appraise all relevant studies on a particular topic. A meta-analysis may then be performed to combine and compare the results of multiple scientific studies using statistical techniques to synthesize data into a single estimate or summary effect size.[96] Moreover, when conducted rigorously, it may provide the strongest synthesis or summary of evidence. Meta-analyses typically feature data from published RCTs. However, they can also include non-randomized, observational, and even unpublished studies.

A conventional meta-analysis makes direct comparisons between trials in a pairwise manner. More recently, network meta-analysis has emerged, which incorporates evidence from indirect comparisons using logical inference (i.e. comparing A to C using studies that compare A to B and B to C). The first step of a systematic review is a specific and well-formulated hypothesis, followed by a thorough and extensive literature review. The inter-judge reliability of those involved in the review and selection of studies for inclusion is an important component of meta-analytic reports. The next step is to evaluate the quality and strength of evidence for each study, based on the robustness of the study design and minimization of bias. Pooling of studies in meta-analyses can be performed using a variety of statistical methods. This is discussed in the statistical section of this chapter.

Several forms of bias could arise in a meta-analysis. One of the most important is publication bias because studies with positive, statistically significant results are more likely to be published, promoted, and thus identified in literature searches. However, meta-analyses are also one of the ways that enable us to detect publication bias, which is not possible when looking at individual studies. The principal methods for detecting publication bias are typically based on the detection of small sample effects. This refers to the fact that the findings of larger studies are more precise and tend to cluster closer to the "true" point estimate, whereas smaller studies are less precise, with more variability in point estimates. "Small sample effects" refers to unbalanced estimates from studies with small sample sizes that can be a marker of publication bias. Small sample effects can be detected through graphical methods (funnel plots) or statistical methods (e.g. Egger test). Clinical heterogeneity is common among meta-analyses because confounding factors, uneven blinding, and other effect modifiers are inconsistent among studies.[97–100] This reinforces the importance of stringent inclusion criteria and quality assessment using available guidelines.[101]

Healthcare Economic Evaluation

Healthcare economic evaluation has matured considerably in the last three decades. However, despite its widespread promotion, many physicians and researchers remain reluctant to apply economic evaluation methods in their clinical decision making and clinical trials, including chronic pain treatment modalities.[102,103] Much of this reluctance has been attributed to physicians and their innate propensity to think more in terms of clinical effectiveness and advocacy at the individual patient level rather than on cost effectiveness at the population or policy level.[25,104]

Furthermore, as witnessed by the ongoing, intense United States healthcare reform debate, there is a strong unwillingness among Americans and their elected officials to consider whether an intervention may be cost effective, often because of fears of government-mandated rationing of care and geriatric discrimination. A provision of the American Recovery and Reinvestment Act of 2009 created and funded the Patient-Centered Outcomes Research Institute (PCORI) to undertake rigorous comparative effectiveness research. The Patient Protection and Affordable Care Act of 2010 specifically prohibited PCORI from undertaking any comparative cost effective analyses using cost per quality-adjusted life year (QALY) as a common metric.[105–107] Nevertheless, given the aging United States population, the associated increasing healthcare utilization but decreasing active workforce, and the unsustainable growing percentage of the United States gross domestic product devoted to healthcare, there is a clear and imminent need for valid healthcare economic evaluation data to establish healthcare funding priorities, including those for chronic pain treatment modalities.[25,108] Different countries develop their own guidelines. For example, in the United Kingdom, economic analysis is part of the National Institute for Health and Care Excellence (NICE) guidelines.[109]

Efforts to provide optimal care while controlling unnecessary or wasteful healthcare expenditures should focus on delivering "high value, cost-conscious healthcare."[110] Whether an intervention provides such a high value depends on assessing whether its health benefits justify its costs. There are three key concepts for understanding how to assess the value of healthcare interventions. First, assessing the benefits, harms, and costs of an intervention is essential to understand whether it provides good value. Second, assessing the cost of an intervention should include the cost of the intervention and any downstream costs that occur because the intervention was performed. Third, the incremental cost effectiveness ratio estimates the additional cost required to obtain additional health benefits and provides a key measure of the value of a healthcare intervention. In the United States, most decision makers consider interventions that cost less than $50,000 per QALY gained as highly cost effective.[110,111] The point at which an intervention is not cost effective varies, although many decision makers consider up to US$100,000 per QALY gained as reasonably cost effective.

Conventional economic evaluation techniques include cost-minimization analysis, cost-benefit analysis, and cost-utility analysis (including cost effectiveness analysis).[103,112–115] A cost-utility analysis is a type of cost effectiveness analysis that measures outcomes using quality-adjusted life years or other similar measures. Such full economic evaluations require that two or more therapeutic interventions be compared concerning both their costs and effects.[112,116] The six fundamental steps in undertaking a full economic evaluation include 1) identifying the perspective of the study, 2) identifying the alternatives that will be compared, 3) identifying the relevant costs and effects, 4) determining how to collect the cost and effect data, 5) determining how to perform calculations for cost and effect data, and 6) determining how to depict the results, draw comparisons, and make conclusions.[112,116,117]

With proper planning, a healthcare economic evaluation can be validated and reported alongside a clinical RCT.[25,118–122] However, given the logistical challenges of such a conjoint study,[121] researchers often combine previously published cost and clinical outcome data to create a decision analysis model.[25,123] The validity of such studies depends on how well the model simulates the key clinical issues and the reliability of the assumptions and parameters used to estimate the costs, outcomes, and utilities. Therefore sensitivity analyses are critical for understanding how conclusions

might change depending on the variability or uncertainty of the key parameters.

For example, decision analysis modeling demonstrated the cost effectiveness of adding non-pharmacologic interventions for chronic LBP to usual care.[124] The study population was divided into four groups depending on their pain impact: high, moderate, low, and none. A typical baseline mix of patients was constructed with 25% low impact, 35% moderate impact, and 40% high impact chronic pain. To calculate QALY gains, societal costs were measured based on non-pharmacologic intervention, back-related healthcare costs, and productivity losses caused by absenteeism. The most cost effective intervention to add to usual care was yoga, with a societal cost savings of $1773 associated with QALY gains of 0.048. Based on the generally accepted willingness-to-pay of $50,000/QALY, only traditional Chinese acupuncture was found to not be cost effective in complement with usual care, as it carried a societal cost of $302 and only gave QALY gains of 0.004.[124]

Methods for considering cost effectiveness when evaluating evidence are evolving. GRADE recommends that resource considerations, though not necessarily cost effectiveness analyses, be included in the evidence profiles and summary of findings tables. Because of variation across countries and over time, it is recommended that resource use (costs) be measured in natural units, such as the duration of inpatient hospital stay or the number of outpatient visits. The key considerations for making GRADE recommendations on economic evaluation are as follows: 1) identifying specific items of resource use that may differ between alternative interventions, which may be important to patients and decision makers; 2) finding evidence for the differences in resource use between the interventions being compared; 3) rating the confidence and quality of effect estimates using the same criteria as for the health outcomes; and 4) valuing the resource use for the specific interventions for which the recommendations are being made.[125]

Standards for Reporting Study Design and Findings

In 1858 Pasteur introduced the methods section of the scientific report, creating what is now known as the IMRAD format (Introduction, Materials and Methods, Results, and Discussion).[126,127] Not surprisingly, in the subsequent 150 years, as investigators have applied the above various basic study designs, there has been wide variability in their application and the content and organization of their published reports. In response, standards for reporting of study design and findings have been promulgated, several of which are applicable to acute and chronic pain management (Table 83.1). The Enhancing the Quality and Transparency of Health Research (EQUATOR) network was created to monitor and propagate the proper use of these guidelines,[128] and thus "to improve the quality of scientific publications by promoting transparent and accurate reporting of health research."[129] Furthermore, an increasing number of major (high impact) clinical and healthcare journals require or recommend adherence to the applicable set of such guidelines for submitted manuscripts.

TABLE 83.1 The Various Publication Guidelines

Acronym	Full Title of Guideline	Notes
EQUATOR	Enhancing the quality of and transparency of health research	http://www.equator-network.org/
CONSORT[a]	Consolidated standards of reporting trials[130]	http://www.consort-statement.org/
STROBE	Strengthening the reporting of observational studies in epidemiology[131]	http://www.strobe-statement.org/
PRISMA	Preferred reporting items for systematic reviews and meta-analyses[132]	http://www.prisma-statement.org/
SQUIRE	Standards for quality improvement reporting excellence[133]	http://squire-statement.org/
MOOSE	Meta-analysis of observational studies in epidemiology[134]	
COREQ	Consolidated criteria for reporting qualitative research[135]	
STARD	Standards for accurate reporting of diagnostic tests[136]	
TREND	Transparent reporting of evaluations with non-randomized designs[137]	http://www.cdc.gov/trendstatement/
SPIRIT	Defining standard protocol items for clinical trials[138]	https://www.spirit-statement.org/
CARE	Consensus-based clinical case reporting guideline development for CAse REports[53]	https://www.care-statement.org/
AGREE	A tool to improve reporting of clinical practice guidelines[139]	http://www.agreetrust.org/resource-centre/agree-reporting-checklist/
SRQR	Standards for reporting qualitative research: a synthesis of recommendations[140]	
CHEERS	Consolidated health economic evaluation reporting standards[141]	

[a]The main CONSORT Statement is based on the "standard" two-group parallel design. However, there are several different types of randomized trials, some of which have different designs (e.g. cluster, non-inferiority, and equivalence, or pragmatic trials), interventions (e.g. herbal medicinal, non-pharmacologic, or acupuncture), and data (e.g. harms), for which specific CONSORT Extensions exist. There are many extensions of PRISMA for different types of systematic reviews and meta-analyses.

Standardization of Pain-Related Outcome Measures

Regardless of the study design used, pain related research should assess and report valid, reproducible, and clinically meaningful outcomes to patients. Unfortunately, even though measures, such as joint range of motion, dynamometer measures of muscle strength, or radiologic evidence of successful spinal fusion, are often considered objective outcomes, they may not correlate well with pain, function, or health-related quality of life. On the other hand, pain, function, and health-related quality of life are more clinically relevant but are inherently subjective outcomes. Research suggests that pain can be measured in a reliable fashion, using measures such as numeric rating scale or visual analog scale. However, the meaning of these ratings has generated considerable debate.[142]

Importantly, although pain may reflect a patient's subjective experience, it is insufficient by itself, as self-reported pain scores often do not correlate well with the actual functional ability or status. Therefore pain related studies need to go beyond self-reports of pain and routinely examine outcomes that measure patients' behavior and function in their daily lives.

Since its inception in 2002, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) has enlisted a broad array of experts in its efforts to improve the design, execution, and interpretation of clinical trials of treatments for pain.[143] IMMPACT recommends that trials routinely measure outcomes in multiple core domains, including pain, physical functioning, emotional functioning, global improvement, satisfaction with treatment, and adverse events, and includes a list of suggested measurement tools for each of these domains. In addition to addressing clinical trial outcomes, IMMPACT has developed a series of consensus reviews and recommendations regarding the conduct, interpretation, and reporting of trials for acute and chronic pain in adults, trials for acute pain in adults, and trials for pediatric acute and chronic pain.[144–153]

Assessing and Addressing Bias and Confounding in Clinical Research

Bias refers to any systematic process, effect, or error in the design or conduct of a study that favors one outcome over others.[154] Therefore studies at greater risk of bias are more likely to be misleading. Important types of bias include 1) *selection bias*, resulting in differences between groups other than the intervention of interest; 2) *performance bias* because of the effects of knowledge of patient assignment to different therapies; 3) *attrition bias* because of differences between those persons who do versus those who do not complete a study, and the level of participant compliance may remain a source of bias even among those who complete the study; 4) *detection bias* resulting in the differential interpretation of outcomes based on knowledge of assigned interventions; 5) *reporting bias* from the selective presentation results, typically those that are more favorable or statistically significant; and (6) *publication bias* from the preferential publication of studies reporting positive findings.

Methods to reduce the risk of bias in randomized trials include 1) use of adequate randomization and allocation concealment to prevent selection bias; 2) assessment of similarity of groups at baseline to detect important imbalances and failure of randomization to control for known confounders; 3) blinding of patients, caregivers, and research staff to avoid performance and detection bias; 4) low loss to follow up and use of intention-to-treat analysis to avoid attrition bias; 5) full reporting of pre-specified primary and secondary outcomes to avoid reporting bias and bias; and 6) for meta-analyses, efforts to locate unpublished studies and performance of graphical or statistical tests to determine whether publication bias and its potential magnitude may be present.

Given a randomized trial with a large enough sample and successful implementation of randomization, the problem of selection bias is eliminated mainly because all confounders, including those that are unmeasured or unknown, are equally distributed between groups, assuming successful randomization and a large enough sample size. Successful blinding of patients and research staff should largely eliminate performance and detection bias.[155]

As noted earlier, by their very nature, observational studies are susceptible to selection bias and confounding by indication, and they cannot blind patients and treating clinicians to the interventions received. Confounding refers to a situation in which the association between an intervention (I) and an outcome (O) is distorted by another factor (C).[156] This occurs when I is associated with C and when C is also an independent risk factor for O. For example, patients with back pain may have poorer outcomes when prescribed opioids compared to those not prescribed opioids if opioids are preferentially prescribed based on the presence of psychological comorbidities.[157] In fact, if back pain is also associated with psychological comorbidities, and if these are independently associated with poorer outcomes, a study that does not address this confounder will provide misleading results about the effects of opioid use on back pain. In addition, depressive symptoms and race were associated with increased healthcare utilization for chronic pain conditions.[157]

To address this during the assembly of the cohort, a study could match patients with key confounders such as psychological comorbidities or restrict enrollment to patients without psychological comorbidities. After a cohort is assembled, a study could evaluate baseline differences between groups in psychological comorbidities to assess the likely impact of this confounder and perform statistical adjustment through regression or other methods (e.g. propensity score matching) to control for its effects or stratification to evaluate how effects vary in defined subgroups.

Different types of evidence-focused studies differ in their susceptibility to bias. Therefore when evaluating the validity of a study, it is important to consider any design-specific methodologic shortcomings and their place in the study design hierarchy. For example, a well-conducted RCT will generally be less susceptible to bias than a well-conducted cohort study. When it comes to large-scale studies, key resources have become available with the emergence of big data science, access to large healthcare databases, modern epidemiologic methods, and large-scale computing power.[48] However, attention to the validity of data and analytic methods is still needed to determine the reliability of studies based on big data sources.

Statistical Concepts and Methods for Pain Outcome Studies

Basic Statistical Concepts and Terminology

Statistical methods are the cornerstone for analyzing and interpreting research data and form the basis for clinical decision making in pain medicine. Statistical methods can be divided into descriptive

and inferential methods. Descriptive statistics provide a concise summary of sample data,[158] whereas inferential statistics are used to draw conclusions about the larger population from which the data have been sampled.[159] For both the appropriate description of data and their analysis, it is important to consider the scale that has been applied to measure or collect the data and how the data are distributed. The following data types and measurement scales are distinguished[160]:

- Nominal data are characterized by discrete and mutually exclusive categories and are thus also referred to as categorical data. Such data have no natural or logical order. Examples include surgery type (e.g. with the categories general, orthopedic, cardiac, and other) and blood groups. A special case of nominal data is binary or dichotomous data in which there are only two categories, such as mortality (dead/alive).
- Ordinal data are similar to nominal data, but they do have a meaningful order and can be ranked. However, the distance between the ranks cannot be determined objectively, and it may not be the same across different ranks. A Likert-type scale to assess patient perception of a certain statement in terms of "strongly agree, agree, neutral, disagree, or strongly disagree" is a typical example. While there is a natural order, the distance between strongly agree and agree has no intrinsic meaning and may not necessarily be the same as that between "agree" and "neutral."
- Interval data are numeric, and equal distances or intervals have the same interpretable meaning. For example, the difference between 5° and 10° temperature on the Celsius scale is the same well-defined 5° difference as that between 20° and 25°. Interval scales such as the Celsius scale have an arbitrary rather than a natural zero point, precluding the calculation of ratios.
- Ratio data share the same characteristics as interval data and have an absolute zero point, which allows for the description of the data in terms of ratios. The difference in systolic blood pressure between 60 and 120 mm Hg is the same as that between 120 and 180 mm Hg, and a systolic blood pressure of 120 mm Hg can be said to be twice as high as 60 mm Hg.

Descriptive Statistics

The first step in converting raw data into useful information is to explore and describe the characteristics of the collected data. While it is theoretically possible, especially for small datasets, to show every single data point, this approach is usually tedious and may not provide a comprehensive overall impression of the data. Descriptive statistics are often used to reduce a large amount of data into a few characteristic numbers that provide a simple but informative overview of the typical values in the dataset and how the values vary.[161]

Nominal and ordinal data are typically summarized by the absolute frequencies (counts) combined with the relative frequencies (proportions or percentages) of observations within each category.

Interval and ratio data can also be shown as absolute or relative frequencies within specific bins or intervals of the range of values, as typically displayed with a histogram. Numerical data have two key characteristics that should typically be reported: the central tendency (the average value of the data) and the variability (the extent to which data spread around this average value). Data that approximately display a normal, bell-shaped distribution are appropriately described by their mean and standard deviation, whereas the median and quartiles are usually more informative for skewed data. Some ordinal data, such as numeric rating scale data, can also be meaningfully summarized by medians and quartiles.

Inferential Statistics

As studying an entire population of patients (e.g. all patients with complex regional pain syndrome type I) is usually not possible or feasible, clinical researchers commonly study a sample of patients to make inferences about the population of interest.[159] To draw meaningful conclusions, the sample should ideally be a random sample or must at least be representative of the population. However, samples are inherently affected by random sampling errors, and the estimates obtained from a sample generally differ from the underlying population parameters. For example, one would always expect to observe some between-group differences in the outcomes in a study comparing the effect of two treatments, even if the treatment effects are identical in the population. Moreover, when repeating the same study multiple times, using a different sample of the same population each time, one generally expects to observe different treatment effects in each study. It is thus inappropriate to base the conclusions of a research study on what has been observed in a particular study sample. Instead, statistical methods are needed (1) to determine whether the data provide sufficient evidence to claim an effect of the treatment or intervention in the population (or more generally, to claim a difference or association) and (2) to estimate what the "true" treatment effect (or any other estimate obtained from a sample) could plausibly be in the population from which the data were sampled.[159]

These two aims of inferential statistics are addressed by (1) hypothesis testing[162] and (2) effect size estimates and their confidence intervals.[159] Hypothesis tests and effect size measures with confidence intervals provide important and complementary information by showing two aspects of the same data set. Of note, the focus here is on the most commonly used approach to statistical inference, the so-called frequentist approach. Other approaches, such as Bayesian inference, are beyond the scope of this chapter.

Hypothesis Testing

An empirical scientific hypothesis can generally be proven false according to the principle of falsifiability. However, this cannot be proven true. An illustrative example is given by Karl Popper[163]: *"… no matter how many instances of white swans we may have observed, this does not justify the conclusion that all swans are white."* In contrast, the single observation of a black swan disproves the hypothesis that all swans are white.

In this context, a statistical hypothesis test does not test the actual research hypothesis that there is a treatment effect or difference between groups; instead, it tests the null hypothesis of no effect or no difference. In the standard superiority testing framework, the *p*-value obtained from a hypothesis test is the probability of observing an effect or difference as large as (or even larger than) the one that may be observed if the null hypothesis is actually true.[159]

Thus a small *p*-value raises doubt on the plausibility of the null hypothesis. If the *p*-value is below a pre-specified threshold (commonly 0.05), the null hypothesis is rejected in favor of the alternative hypothesis, and researchers conclude that there is an effect or difference.[162] However, note that a hypothesis test can only quantify the evidence against the null hypothesis but cannot actually disprove it. There is always a chance of reaching a wrong conclusion by either rejecting the null hypothesis when it is, in fact, true (type I error) or by not rejecting the null hypothesis when it is, in fact, false (type II error).[164]

Effect Sizes

Effect sizes quantify the magnitude of a relationship between variables, for example, between a variable that defines the treatment group and some outcome variable.[165] More than 70 different effect sizes have been described in the literature, including standardized or unstandardized mean differences, relative risks, odds ratios, or correlation coefficients. The effect size estimate should generally be accompanied by a confidence interval, which indicates the precision of the estimate and provides a range of values of what the effect (or any other estimate obtained in a sample) could plausibly be in the population from which the data were sampled.[166] Most commonly, a 95% confidence level is used, which indicates that approximately 95% of confidence intervals would be expected to contain the "true" population parameter on repeated sampling from the same population.

Effect sizes address the important question of whether the observed effect or relationship is clinically relevant instead of simply statistically significant.[159] Whenever the confidence interval contains a clinically important effect, a relevant effect cannot be ruled out even when it is not statistically significant. Conversely, a confidence interval that does not contain an important effect questions the clinical relevance, even when the result is statistically significant. Note that there is a close conceptual and mathematical relationship between confidence intervals and hypothesis testing. When a 95% confidence interval includes the null hypothesis value indicating no difference or no effect (e.g. 1 for a relative risk or 0 for a mean difference), the result is compatible with "no effect," and a corresponding hypothesis test would be nonsignificant at the 0.05 significance level.[159]

Standardized effect sizes allow the assessment of results across studies that report similar outcomes (e.g. pain relief) using different measures (e.g. 0–6 verbal rating scale, 0–10 numeric rating scale, and 0–100 visual analog scale). The standardized mean difference (also referred to as Cohen's d) is a unitless measure that standardizes results across studies by dividing the difference in the mean scores between groups by the pooled standard deviation. Each point in the effect size is equivalent to a difference of one standard deviation. Although the clinical interpretation of effect sizes can vary depending on the outcome being measured, the population assessed, and other factors, a general rule of thumb is that an effect size of 0.2–0.5 indicates a small effect; >0.5–0.8, a moderate effect; and >0.8, a large effect.[167]

Commonly Used Inferential Statistical Methods in Pain Research

This section describes some common hypothesis tests, methods to quantify relationships, techniques to assess agreement, and methods to pool data across studies. This section is by no means comprehensive, and a detailed description of how to use these methods in practice is beyond the scope of this chapter.

Importantly, each statistical method (test) has particular assumptions, for example, relating to the distribution of the data in the population from which the data were sampled. Statistical methods that are based on the assumption of a specific data distribution are referred to as parametric methods.[168] The assumed distribution is most often a normal distribution, but parametric methods are specifically designed for other distributions, some of which are also introduced below. Notably, the assumption of a specific distribution does not necessarily refer to the outcome variable itself, as often erroneously assumed by researchers, but, for example, to a normal distribution of the residuals (difference between observed and predicted values) in a linear regression model. In contrast to parametric methods, non-parametric methods do not assume a specific distribution.[168] However, both parametric and non-parametric methods also rely on other assumptions, for example, relating to the independence of observations. Assumptions are only somewhat covered here. Researchers should familiarize themselves with a particular method that they wish to use in more detail.

Statistical Methods for Continuous Outcomes

Continuous outcomes are often compared between two groups using two-sample t-tests,[169] and one-way analysis of variance (ANOVA) is used for more than two groups.[170] Test assumptions include normally distributed data and an equal variance in each group. Welch's t-test and Welch's ANOVA are alternatives when the assumption of equal variances is violated. The non-parametric equivalents, which can be used irrespective of the data distribution, are the Mann-Whitney *U* test (also known as the Wilcoxon rank-sum test or Wilcoxon-Mann-Whitney test) for two groups and the Kruskal-Wallis test for more than two groups.[171] For non-independent data (e.g. repetitive measurements in the same subjects at different time points), a paired t-test or repeated measures ANOVA, or their non-parametric counterparts, the Wilcoxon signed-rank test and the Friedman test, can be used.

When the analysis aims not to compare groups on a continuous outcome but to assess the strength of the relationship between two continuous variables, a correlation analysis is typically performed.[172] The correlation coefficient ranges from −1 to +1, with a value of 0 indicating no relationship and with absolute values increasingly closer to 1 indicating an increasingly stronger relationship. A positive coefficient indicates that the value of one variable tends to increase while the other increases, and a negative coefficient indicates an inverse relationship. Pearson's correlation coefficient is used to quantify a linear relationship between two normally distributed outcomes, whereas the non-parametric Spearman's rank correlation coefficient describes a monotonic relationship (i.e. one variable tends to consistently, but not necessarily linearly, increase or decrease while the other increases).[173]

Linear regression is used to test and quantify relationships between one or more independent variables (also termed predictor, covariate, or explanatory variables) and a continuous (dependent) outcome variable.[174] Two-sample t-tests and ANOVA are essentially special cases of linear regression with categorical independent variables. Linear regression with only one continuous independent variable provides a coefficient of determination that is identical to the squared Pearson's correlation coefficient.

However, linear regression is much more flexible than the techniques mentioned above and allows the simultaneous estimation of the relationship of several continuous or categorical variables with the outcome variable and determines whether the effect of one variable on the outcome depends on the value or level of another variable. It can be used to estimate how the outcome is expected to change for a particular change in each independent variable or predict the outcome value based on a set of predictor variables. Moreover, linear regression controls for the effects of other variables; for example, it can control for confounders in observational research or adjust for baseline imbalances in randomized controlled trials.[175] Extensions of linear regression, such as linear mixed effects models, are available for non-independent data.[176]

Statistical Methods for Count Data and Ordinal Data

Counts (e.g. hospital length of stay in days) are discrete rather than continuous, are often severely skewed, and may not satisfy the assumptions of linear models. Ordinal data are organized into discrete, ordered categories and can usually not be appropriately analyzed using methods that assume a normal distribution. Both count data and ordinal data can be compared between groups using the non-parametric tests listed in the above section, "Statistical Methods for Continuous Outcomes." However, flexible parametric regression-based approaches are also available to analyze count data (e.g. Poisson regression or negative binomial regression) and ordinal data (e.g. ordinal logistic regression).[174]

Statistical Methods for Categorical Outcomes

Pearson's chi-square tests can be used to test for an association between two nominal variables, for example, between treatment groups and a categorical outcome.[177] Fisher's exact test is an alternative to the Pearson's chi-square test when its assumptions regarding a minimum number of expected counts are violated. Pearson's chi-square tests and Fisher's exact tests rely on the assumption that the observations are independent of each other (e.g. no repeated measurements on the same subjects). McNemar's test can be used for paired data.[177]

Logistic regression was used to analyze relationships between one or more continuous or categorical independent variables and a binary outcome and estimate the probability that a binary outcome will occur, given the values of the independent variable(s).[174] As with linear regression and other regression models, logistic regression can be used to control for other variables (e.g. confounders). An extension of logistic regression and multinomial logistic regression is used for categorical outcomes with more than two levels.

Statistical Methods for Time-to-Event (Survival) Data

Researchers are often interested in analyzing the time until an event of interest occurs, which is typically an event such as the death of a patient. Therefore the term "survival analysis" is often used. However, any other well-defined event that has not occurred in all patients by the time the study ends can be analyzed as well.[178] The research interest is thus typically a combination of a binary outcome (has the event occurred?) and a continuous outcome (how long did it take until the event occurred?).

Another unique feature of time-to-event data and a key distinction from other continuous outcomes is that the actual survival time is unknown for patients who do not experience the event before the study ends or before they drop out of the study. Such patients are said to be censored, and all that is known is that the survival time is greater than the time until censoring. Statistical methods that can appropriately account for censored data are subsumed under the term time-to-event analysis or survival analysis and comprise a broad spectrum of techniques.[178]

A Kaplan-Meier curve is commonly used to plot the estimated probability of survival beyond a certain time point. Kaplan-Meier curves of different treatment groups plotted in one graph allow for a visual comparison, and the survival curves can be more formally compared with a log-rank test. Cox proportional hazards regression is particularly useful when the relationship between several independent variables and survival time is of interest or when the analysis needs to control for confounders. Results are commonly reported as hazard ratios, which are not the same as relative risks but can often be conveniently interpreted in a similar way.

Statistical Methods to Assess for Agreement

Agreement analyses are required to determine the degree to which multiple measurements of the same quantity produce the same result.[179] This can refer to measurements obtained by two different measurement techniques at the same time, measurements simultaneously performed by two different operators or raters using the same measurement instruments or rating scales, or measurements performed by the same person at two time points.

A Bland-Altman analysis is commonly performed to assess the agreement of two clinical measurement techniques that measure the same continuous outcome and determine whether the techniques can be used interchangeably. The Bland-Altman technique estimates the mean difference (representing the systematic bias) and how far apart the measurements are expected to be for the vast majority of measurement pairs (95% limits of agreement).[179]

The intraclass correlation coefficient (ICC) is frequently used to assess the inter- and intra-rater reliabilities of the measurement scales. There are several variants of the ICC, and the choice depends on factors, including whether the interest lies in absolute agreement or consistency and whether the same or different raters rate the subjects. For categorical data, Cohen's kappa quantifies the agreement between two observers beyond what would be expected by chance, and Fleiss kappa is used for more than two observers. For ordinal data, weighted Cohen's kappa is particularly useful as disagreements can be differentially weighted, depending on whether they refer to adjacent categories or distant categories (e.g. weighted kappa can account for the fact that there is less disagreement when one rater says "very poor" and the other "poor" than when one rates "very poor" and the other "excellent").[179]

Meta-Analysis

When researchers aim to summarize the current evidence on a particular research question, a systematic review methodology provides a rigorous approach to identifying relevant studies and extracting data in a structured and reproducible way.[180] Quantitative data of studies that are sufficiently similar in terms of patient population, treatments, and outcome measures are often pooled in a meta-analysis to obtain an overall summary estimate of the treatment effect (or any other effect) of interest. This summary effect is a weighted average of the effect size estimates from the individual studies, and weights are assigned based on how precisely a study estimates the effect size. As precision is primarily driven by sample size, larger studies generally receive more weight in a meta-analysis than do smaller studies.

Two main classes of meta-analyses were identified. A fixed-effect meta-analysis assumes that all variability in effect sizes between studies represents sampling error (i.e. that there is one common "true" effect size that all studies estimate).[181] The summary effect in a fixed-effect meta-analysis estimates this common effect size. In contrast, the random-effects meta-analysis allows for the true treatment effect to vary between studies. This is often a more realistic assumption, and thus it is usually recommended to perform a random effect meta-analysis because the setting,

patient population, disease characteristics, and how the treatment is administered tend to vary between studies. Under the random-effects assumption, the pooled effect size represents the mean of the distribution of true effect sizes.[181] The variation in true effect sizes between studies is referred to as statistical heterogeneity and provides important information on the extent to which a treatment effect would be expected to vary under different study conditions.

Important Statistical Considerations and Common Pitfalls

The Visual Analog Scale Controversy: Ordinal or Ratio Scale?

Pain intensity is commonly assessed using a visual analog scale (VAS). There is an ongoing debate about whether VAS scores should be considered ordinal or ratio data and whether parametric statistical methods can be appropriately used to analyze these data.[182–186] In fact, VAS scores have properties of both scales, and we advocate a pragmatic "it depends" approach.

First, several variants of the VAS score are used. A VAS score measured as a distance on a 100 mm line between the two extremes "no pain" and "worst imaginable pain" may essentially come quite close to a continuous measure with a natural zero point. However, some may question whether a score of 60 represents twice as much pain as 30. When the VAS score is rounded to or recorded as an integer between 0 and 10, similar to a discrete 11-point (0–10) Numeric Rating Scale (NRS) score, it loses some of its granularity and might be more like an ordinal scale. Second, not only the scale but also the distribution of data must be considered. VAS scores can be approximately normally distributed but also severely skewed, depending on whether they are concentrated around the center or around either extreme of the scale.[187] Third, the chosen statistical test may depend on the aim of the analysis. For simple between-group comparisons of VAS scores, irrespective of their measurement scale or distribution, there is little cost of using non-parametric tests.[187] On the other hand, corresponding parametric tests for between-group comparisons such as t-tests and ANOVA are quite robust against violations of the distributional assumptions, particularly for larger sample sizes,[169] and have been shown to generate valid results unless many patients report VAS scores at either extreme of the scale.[188] Moreover, parametric methods are more flexible and possible when more complex analyses are needed. When required, these techniques can be used when their assumptions are satisfied, and as stated earlier, these assumptions do not necessarily refer to the VAS score itself but to the residuals.

Of note, parametric models specifically designed for ordinal data, such as ordinal logistic regression, are also available[174] and can be useful for NRS-like data. A continuous ordinal regression modeling approach for ordinal data, with many ordered categories such as a 0–100-point VAS scale, has been suggested for VAS data that are extremely skewed.[187] Given the numerous possibilities, it is not very helpful (or prudent) to follow a dogmatic approach in which VAS scores must always be considered as either ordinal or interval data. It must always be analyzed using a specific parametric or non-parametric analysis technique. Instead, factors such as data distribution, the purpose of the analysis, and the sample size should also be considered when choosing a statistical method to analyze VAS data.

Sample Size Calculation

A key feature of any research study is an informed estimate of how many participants will be necessary to meet the study aims while avoiding an excessive number of patients. As outlined earlier in this chapter, two types of errors can occur when rejecting or not rejecting the null hypothesis based on a hypothesis test result, and the probability of making such errors decreases with increasing sample size. Thus the sample size should be chosen such that the probabilities of type I error (denoted as α) and type II error (denoted as β) are reasonably low.[164] The "power" of a study (also often referred to in the context of sample size calculations) is the probability of detecting a difference or effect when it is actually present in the population and corresponds to $1-\beta$.[162]

Common choices for the calculation of a sample size include an α of 0.05 and power of 0.8 (80%) or 0.9 (90%). The required sample size is also a function of the effect size that researchers want to be able to detect and the assumed variability of the data. While it is common to base the calculation on an expected difference or effect (e.g. based on pilot data or previously published literature), researchers are well advised to use the minimally important clinical difference (MICD) approach instead. Otherwise, the study may be underpowered to detect smaller yet clinically important effects.[164] Additional assumptions are required for more complex study designs, such as studies involving correlated data. When the aim of the study is not to test a specific hypothesis but rather to estimate some population parameters, the sample size should be chosen such that the parameter can be estimated with sufficient precision (with a confidence interval that is sufficiently narrow for the respective study aim).

Multiplicity Adjustments

When researchers test multiple hypotheses, each at a "standard" 0.05 significance level, the risk of a type I error markedly increases and can end up being much higher than the initially targeted α-level.[189] This situation commonly occurs when 1) several outcome variables are measured, 2) when the same outcome is repetitively studied at several time points, 3) when several groups are compared with each other in multiple pairwise comparisons, 4) when multiple subgroups are studied, or 5) when interim-analyses are performed.

When at least one significant test result from a set of tests would lead to a relatively strong inference, multiplicity adjustments are necessary.[189] For example, concluding that a particular treatment works because it is significantly superior to placebo in one out of four studied outcomes carries a considerable risk of being a false-positive result unless an appropriate adjustment is made. Similarly, comparing four treatment groups with each other and concluding that "treatment A" works better than "treatment D" because this difference happened to be significant can be severely misleading when the analysis was not adjusted for multiple comparisons. In contrast, no rigorous adjustment may be needed when the analyses are only exploratory or hypothesis-generating.[189]

The Bonferroni technique is probably the best known and definitely the simplest technique to adjust for multiple comparisons. With the Bonferroni technique, the significance criterion was set at α divided by the number of hypothesis tests (e.g. for $\alpha = 0.05$ and four tests, the significance threshold would be $0.05 \div 4 = 0.0125$), and only p-values smaller than the adjusted significance threshold were considered statistically significant.[189] Equivalently, the p-value can be adjusted by multiplying it by the total number of tests, and the adjusted p-value is then compared

against α. Notably, the Bonferroni adjustment was rather conservative. A variety of other adjustments are available and can often be automatically requested from the statistical software when performing tests involving multiple comparisons (e.g. for pairwise between-group comparisons after ANOVA).[190,191]

Distinguishing Between Statistical and Clinical Significance

As noted earlier in this chapter, inferences of a study generally refer to the population from which the data were sampled, not to the sample itself. In this context, it is incorrect to claim that something was "greater" or "better" (or something similar) based on observations in the sample in the absence of formal statistical analyses.

Even after statistical testing, results are often misinterpreted; for example, when clinically irrelevant between-group differences are highlighted as an important finding, the difference is statistically significant. It is important to realize that statistical significance and clinical importance are distinct concepts, and it is distinctly possible that irrelevant effects are statistically significant, whereas important effects may fail to reach the significance threshold.[159,192] Therefore the results of hypothesis tests should not be viewed in isolation but instead should be reported along with effect size measures and their confidence intervals. Ideally, researchers should define *a priori* what they consider a clinically important effect.

For example, with a large enough sample size, a study may report a difference in pain scores between the treatment and no treatment groups with an average of three points (95% CI: 0.7–5.3) on a 0–100 scale, with a *p*-value of 0.01. Although such a difference is statistically significant, the clinical significance and relevance of such differences are very small or negligible.

Another challenge in interpreting the results of studies that report means or differences in outcomes related to pain or function is that such data do not indicate whether they reflect a situation in which some patients experienced a very good outcome and others experienced no benefit or a situation in which patients generally experienced a small, similar average result.[193]

Studies commonly investigate a global approach for pain improvement by seeking a statistically significant decrease in the mean level of pain among their population. Among the most common outcomes measured is the effect on pain intensity and opioid consumption, outcomes that rely strongly on large sample sizes to achieve stronger and adequate statistical power. The clinical profile of a new intervention should include outcomes and parameters such as the delay and duration of the effect and the number of patients who report satisfactory pain control and tolerance of side effects.[194]

The MICD is defined as the smallest change in an outcome that a patient would perceive as clinically meaningful.[195] The IMMPACT group proposed defining the MICD as a 30% or greater improvement in self-reported pain and function.[196] The IMMPACT group also recommended that studies report the proportion of patients in each group who meet the MICD threshold. Based on the absolute difference between groups in the proportion of patients who experienced MICD, the number needed to treat to achieve one clinically meaningful outcome can be calculated [100 ÷ (the percentage of individuals with MICD in group A minus the percentage of individuals with the MICD in group B)].[197] Therefore in a study in which 40% of patients in group A experienced MICD for pain relief compared with 20% in group B, the number needed to treat is 100/20, or five. In contrast, in a study in which 40% of patients in group A experienced MICD compared with 37% in group B, the number needed to treat is 100/3, or 33.

Equivalence and Non-Inferiority Trials

In the conventional hypothesis testing framework (commonly termed superiority testing), a significant test result provides evidence against the null hypothesis. However, a non-significant test result means that there is insufficient evidence to reject the null hypothesis and thus does not provide evidence for the null hypothesis.[198] Therefore the interpretation that treatments are equally effective (or similar claims) when the difference is not statistically significant is flawed because there is no evidence for the null hypothesis.

Therefore superiority testing is not appropriate when the study aim is to demonstrate that a certain treatment (a new, alternative treatment) is as good as (equivalent to) or at least not worse than (non-inferior to) some other treatment (a standard treatment). An equivalence or non-inferiority study design and analysis are required instead.[199] As two treatments would likely never have identical effects (and if so, this would be impossible to prove), an equivalence study aims to show that the treatment effect differs by no more than a clinically acceptable margin. Similarly, a non-inferiority trial aims to show that one treatment is no worse than the other treatment by more than an acceptable amount. Because the results of equivalence and non-inferiority trials are sensitive to the definition of a clinically acceptable margin, it is considered essential that the equivalence or non-inferiority margin is defined *a priori* to avoid post hoc decision making.[199]

Multiple Related Outcomes and Joint Hypothesis Testing

Researchers often study the effects of a particular treatment on several related primary outcomes, such as pain scores and analgesic consumption in pain research. However, when the results are discordant, for example, if the treatment decreases pain but increases analgesic consumption, it can be challenging to reach a clear conclusion and invite *post hoc decision making*.[200] A further drawback of testing multiple primary outcomes in isolation is that a multiplicity adjustment is needed, as described above, which reduces the power of the analysis. Alternatively, researchers may declare one outcome as primary and the other as secondary and base their conclusions on the primary outcome. However, this approach can also be problematic when the outcomes are equally important.

It is often best to declare both (or more) related and equally important outcomes as primary outcomes and analyze them jointly in such situations.[200] An important feature of this joint hypothesis testing framework is that clear *a priori* decision rules are specified to decide whether an experimental intervention is superior to the comparison treatment or not. Commonly, the experimental treatment is only declared superior when it is superior to the comparison treatment for at least one of the outcomes and non-inferior for all other outcomes. Note that joint hypothesis testing does not require multiplicity adjustments, and at the same time, it ensures that a clear conclusion can be reached based on *a priori* decision rules.

Association Versus Causation—Confounding in Observational Research

A common mistake in observational research is to claim the effect of exposure on the outcome or to use other terminology suggesting a causal relationship. In contrast to a randomized trial, patients exposed to some factor of interest in an observational research usually systematically differ from patients who are not exposed.[175] For example, when studying a particular treatment observationally,

the treatment is not randomly assigned but may depend on several factors such as patient and disease characteristics. This leads to systematic differences between patients who have been versus those who have not been treated with the treatment of interest. Such differences, in turn, could themselves be related to the outcome and could thus explain some or perhaps even all of the observed differences in the outcome. It is thus inappropriate to conclude that the treatment leads to lower pain (or whatever the outcome may be); all that can be claimed is an association or relationship.

Factors that are causally related to the exposure and the outcome are referred to as confounders.[201] Statistical methods to control for confounding factors, such as multivariable regression or propensity score-based approaches, are available,[175,202] and they should be used when analyzing observational data. However, residual confounding, for example those caused by unobserved factors, is nevertheless possible; thus causal inferences based on observational data should generally be avoided.

Concluding Statements

EBM offers a formal set of steps for clinicians to effectively interpret the results of a clinical research ("how to read a paper") and apply them in their practice. The GRADE system is widely used to grade the quality of published evidence and the strength of recommendations. This chapter has discussed different types of clinical studies that focus on pain outcomes and have different levels of evidence (from case reports and case series to complex randomized controlled trials, systematic reviews, and meta-analyses). Furthermore, we discussed key statistical methods used when planning these studies or analyzing the data.

Key Points

- A case report shares with the medical community, novel, rare, or atypical features identified in a patient.
- A cross-sectional study determines the prevalence of a disease at a given point or period in time.
- A case-control study determines the relationship between the absence or presence of a single outcome (disease) and one or more previous possible contributing factors (exposures).
- A nested case-control study is a case-control study in which cases and controls are selected from members of an existing longitudinal cohort.
- A cohort study determines the relationship between a single contributing factor (exposure) and one or more possible outcomes (diseases).
- A randomized controlled trial is a type of controlled clinical trial predicated on participants being assigned to possible exposures or interventions purely by play of chance.
- A CRT is a trial in which individuals are randomized into groups; the group as a whole is randomized, and not the individual.
- A meta-analysis combines and compares the results of multiple scientific studies that are sufficiently similar to obtain an overall summary estimate of the effect of interest. This summary effect is the weighted average of the effect size estimates from the individual studies.
- Healthcare economic evaluation techniques promote efforts to provide optimal care while controlling unnecessary or wasteful healthcare expenditures to focus on delivering high value, cost-conscious healthcare.
- Bias refers to any systematic process, effect, or error in the design or conduct of a study that favors one outcome over others, whereas confounding refers to a situation in which the association between an intervention and an outcome is distorted by another factor.
- The *p*-value obtained from a hypothesis test is the probability of observing an effect or difference as large as (or larger than) the one that may be observed if the null hypothesis (that there is no effect or no difference) is true.
- Effect sizes quantify the magnitude of a relationship between variables, for example, between a variable that defines the treatment group and some outcome variables.
- Statistical methods have been developed to analyze data, including continuous outcomes, count data, ordinal data, categorical outcomes, time-to-event (survival) data, agreement, and diagnostic accuracy.
- Sample size calculation provides an informed estimate of how many subjects will be necessary to meet the study aims while avoiding an excessive number of patients. It is a key feature of studies to minimize the probability of type I and II errors.
- Testing multiple hypotheses increases the probability of type I errors. This may be avoided by joint hypothesis testing when the outcomes are equally important. Another solution is multiplicity adjustment, such as the Bonferroni technique, which consists of dividing the significance criterion by the number of hypothesis tests.
- When interpreting clinical research results, a key concept is that statistically significant results are not always clinically meaningful. Calculation of the MICD, effect size, and confidence intervals may help distinguish between the two.
- A non-significant test result does not allow the conclusion that the two treatments work equally well. Instead, an equivalence study can show that the treatment effect differs by no more than a clinically acceptable margin. A non-inferiority trial shows that one treatment is no worse than the other treatment by more than an acceptable amount.
- Statistical methods are available to control for confounding factors, such as multivariable regression and propensity score-based approaches.

Outcome Domains and Measures in Acute and Chronic Pain Clinical Trials

HONORIO T. BENZON, HUBERT A. BENZON, DENNIS C. TURK

An important feature in the planning of any clinical trial regards the decisions made as to the outcome criteria that will be used to evaluate treatment efficacy. Traditionally, the outcomes used in both acute and chronic pain research have been a reduction in pain intensity and presence of adverse effects (AEs). However, more recently, other important factors have been identified that should be included as outcome measures.

Several groups have reviewed and suggested outcomes to be considered in clinical trials, both general and well as disease specific (e.g. the Initiative on Methods, Measures, and Pain Assessment in Clinical Trials; IMMPACT),[1–3] Core Outcome Measures in Effectiveness Trials (COMET),[4] outcomes measures in rheumatology,[5–7] NIH task force,[8] and Veterans Health Administration Workgroup.[9] The objective of COMET is the development and application of agreed standardized sets of outcomes, known as "Core Outcome Sets" (COS). They noted that the sets represent the minimum that should be measured and reported in all clinical trials of a specific condition and that COS are also suitable for use in routine care, clinical audit, and research, other than randomized trials. They stated that the existence or use of a COS does not imply that outcomes in a particular study should be restricted to those in the relevant core outcome set. COMET "aims to collate and stimulate relevant resources, both applied and methodological, to facilitate the exchange of ideas and information, and to foster methodological research in this area."[4] A representative example of the group's publications to accomplish this primary aim is a COS on effectiveness trials.[10]

This chapter will discuss the outcome domains and measures advocated by several groups, namely, IMMPACT,[1,2] pedIMMPACT,[3] and APS-POQ-R[11] as they provide comprehensive recommendations. The domains enumerated by IMMPACT, pediatric IMMPACT (pedIMMPACT), and American Pain Society-Post-operative Questionnaire-Revised (APS-POQ-R), (i.e. pain; physical functioning; emotional functioning; participant ratings of improvement and satisfaction with treatment, symptoms and adverse events; and participant disposition [adherence to the treatment regimen and reasons for premature withdrawal from the trial]) were developed by a set of individuals with experience in conducting clinical research, quality improvement, providing clinical care, and several lay advocates. It is important to acknowledge that patients may have different ideas regarding the most important outcomes for them. For example, when adults with chronic pain were surveyed, they affirmed that the set of domains recommended by these groups were important to them. However, they also described the importance of improving sleep quality, reducing fatigue, and improving the enjoyment of life following treatments.[12] We will review domains and measures for acute and chronic pain for adult and pediatric populations specifically proposed by IMMPACT, pedIMMPACT, and APS-POQ-R. Moreover, patient satisfaction, a reflection of the interaction of the different domains, will be discussed in detail as a complement to the others proposed.

Besides considering important outcome domains, we will discuss general issues in selecting appropriate outcome measures to address the research questions of interest and to describe some of the most frequently used instruments in clinical trials conducted in anesthesiology and pain medicine. We do not intend to present an exhaustive list or provide a comprehensive critique of the psychometric properties and the strengths and weaknesses of all measurement tools enumerated. Instead, we will discuss several measures that have been selected by knowledgeable investigators of clinical trials in anesthesiology and pain medicine. We have included an extensive set of references to accompany this chapter and that are electronically available that readers can consult depending on their particular interests. Note, that although we focused on measures that can be considered for use in clinical trials, many of the measures described should be considered appropriate for use in clinical practice.

Selecting Outcome Measures for Use in Clinical Trials

Although the outcome domains for acute and chronic pain trials in both adults and children overlap, the measures selected will vary to some extent based on the age of the patients and their ability to comprehend the concepts entailed in the measures, the amount of patient burden required to respond, and the experimental context (e.g. developmental stage; cognitive limitations, postoperative vs. chronic pain state). There are instances where the same measures can be used across different ages, type of pain, and treatment contexts (e.g. perioperative vs. chronic). For example, a single question regarding pain severity or several questions regarding mood, ability to engage in functional activities, and the presence of AEs may be acceptable in both acute and chronic pain trials.[11] Similarly, simple ratings of pain intensity may be used across certain ages (eight to 18) but not for all (e.g. neonates) or those with the inability to communicate (unconscious or otherwise cognitively

TABLE 84.1 Factors to Consider in Selecting Pain Reported Outcome Measures

- The clarity of the instructions and items contained in a scale (Can the population for whom it is intended understand the instructions and the meaning of the individual items?)
- Respondent demands (i.e. Does the measure have acceptable *patient burden*?)
- The *validity* of the measure (Does an instrument measure what it is designed to measure?)
- The *reliability* of the measure (Does the instrument demonstrate that it consistently measures the construct intended?)
- The items contained in the instrument all measure the construct of interest and the context of use, and the items in the scale demonstrate reasonably high correlations with each other - sometimes referred to as *internalconsistency*, Cronbach's alpha, or *coefficient alpha*
- Will the same results occur if the instrument is completed at two points in time without any intervention - sometimes referred to as *test-retest reliability or consistency* over time?
- The measure is *responsive* to change (Are treatments capable of demonstrating change on this measure?)
- Are there appropriate *normative data* to which the current sample is to be compared available?
- Does the measure place excessive demands/burden on the person responsible for scoring it (Are there lengthy and complex scoring algorithms required?)?

compromised patients). The availability of appropriate normative data for the sample to be included in a trial becomes an essential consideration in selecting from available measures.

Throughout this chapter, we will describe a wide range of measures, particularly patient reported outcome measures (PROMs). These measures are essential in assessing a subjective state such as pain and the impact that pain has on all domains of an individual's life—physical functioning, emotional, and broadly conceptualized as health-related quality of life (HR-QoL) as emphasized by IMMPACT, pedIMMPACT, and APS-POQ-R. In selecting from the vast array of general, disease specific, and treatment specific PROMs available, investigators, as well as clinicians, need to pay attention to a host of factors outlined in Table 84.1. The set of concepts outlined are typically referred to as the psychometric or clinometric characteristics of the measure or procedure.[13]

For measures dependent on physical assessment (1) the *inter-rater reliability* (Would the same result be obtained from two or more raters of the same patient?) and (2) *intra-rater reliability* (Would the same rater obtain comparable results if the procedure is performed on the same patient at two points in time?) need to be considered. For physical assessment, it is important to acknowledge the importance of training for examiners to maximize agreement.[14]

Clinical Significance vs. Statistical Significance

Once an outcome measure is selected, it is important to consider the amount of change that would have to occur following treatment for the results to be meaningful. Traditionally, the emphasis has been on statistically significant differences. For example, a 30% reduction in pain on an 11-point numeric rating scale (NRS) has been accepted as demonstrating a statistically significant result.[15] However, a statistically significant outcome can be affected by the sample size included in the study. A small but statistically significant result in a study with a very large sample may have little clinical importance and, therefore, may be trivial.[16] More recently, attention has been given to the concept of clinical meaningfulness as an important complement to statistical significance. Several studies have been conducted to identify the amount of change on any scale that would be required for the change to be clinically significant (i.e. meaningful, important to patients and providers).[17] There are several ways to determine clinical significance, with an anchor-based approach being most appropriate. Many anchor-based approaches for establishing criteria for identifying important change rely on a global item completed by the patient as the anchor for within person changes indicating that the change is meaningful. For example, to determine whether there were important changes in pain over the course of treatment, patients' pain could be assessed at baseline and again at the end of the trial, at which point they would also be asked if they were "better," "about the same," or "worse," compared with the beginning of the trial. These improvement ratings would then serve as the standard with which to evaluate the importance to the patient of whatever changes in pain had occurred during the course of the trial.

Whenever an anchor-based approach has been conducted to identify a meaningful clinically important difference (MCID) has been established in should be used[18] to determine whether the results obtained are clinically important. However, when an MCID has not been formally determined, a reasonable rule of thumb is to use distribution-based criteria, either the effect size or change, based on the standard error of measurement (SEM). An effect size of 0.50 (i.e. one-half the standard deviation) may be a practical criterion to use when beginning to investigate important changes in PROM.[19,20] SEM provides a measure of within person change that is less dependent on a specific sample because it incorporates both the standard deviation and the reliability as a proxy for the MCID.[18] In several studies, 1 SEM approximated the MCID threshold.[21]

Outcome Domains and Measures in Adult Acute Pain Trials

For acute pain trials, both IMMPACT[22] and APS-POQ-R[11] recommend that intensity and pain relief should be the primary outcome domains for and clinical trials and quality improvement (QI). IMMPACT suggested that an NRS be used. Verbal rating scales (VRS) for pain intensity ("no pain," "mild pain," "moderate pain," "severe pain") and amount of pain relief ("no relief," "little relief," "some relief," "moderate relief," "complete relief") have also been frequently used. APS-POQ-R recommended using an 11-point NRS (zero, no pain, to ten, worst pain imaginable) for two questions—pain at its *least* and at its *worst* over the past 24 h (note that the interval could be shorter depending on the patient's ability to respond and the research question, for example, 6 h). In addition, APS-POQ-R recommended a third question, the percentage of time the patient experienced severe pain in the past 24 h. An additional outcome of potential interest noted was time to first analgesic intake. Consideration should also be given to the timing of pain assessment during recovery. Pain ratings should also pain at rest (e.g. lying down) and when appropriate on specific movements (e.g. coughing, repositioning, ambulating).

The occurrence of AEs is an important outcome domain. The usual side effects should be observed and when patients are able directly reported by them. APS-POQ-R specifically suggests assessing the severity of four common postoperative side effects, nausea, drowsiness, itching, and dizziness, with each rated on an 11-point NRS when patients are capable of making such ratings. A caution regarding solicitation reports of side effects from patients is noteworthy. Asking about the presence of specific side effects may

prompt patients to report the occurrence of these and increase the number, whereas an open-end question asking patients if they have experienced or are experiencing "any" side effects may lead to missing some that the patients do not consider reporting. Thus there are some trade-offs with either approach.

The impact of pain and treatments on other AEs have also been assessed. For example, studies have focused on the degree of the patient's sedation (e.g. observer's assessment of alertness/sedation scale,[23] Ramsey sedation scale),[24] sleep quality or interference (Pittsburgh Sleep Quality Index,[25] Epworth Sleepiness Scale),[26] or the presence of delirium.[27] The Mini-Mental Status Examination (MINI) has been used to measure sedation as well as the cognitive ability of the patient.[28] The Opioid-Related Symptoms Distress Scale has been employed to look specifically at symptoms related to opioid intake; these include difficulty passing urine, headache, feeling of lightheadedness, fatigue, or weakness.[29] It should be noted that there is no single assessment tool designed to assess all the side effects, mostly the focus is on a specific one.

Both IMMPACT and APS-POQ-R suggest that physical functioning is an important outcome domain for acute pain clinical trials. APS-POQ-R suggests asking four questions related to the inference of pain with physical functioning, specifically, sedentary activities (i.e. turning, sitting up, repositioning), activities out of bed (i.e. walking, sitting in a chair, standing at the sink), and falling asleep and staying asleep. They suggest that each of these questions should be rated on an 11-point NRS. For perioperative studies, it was suggested that time to first bowel movement, length of intensive care unit (ICU) and/or hospital stay, and patient satisfaction be considered as appropriate. For longer duration acute pain studies as in the recovery room, intensive care, or emergency department, IMMPACT and APS-POQ-R recommended additional outcomes domains for physical function such as the timing of ambulation. Assessment of other functional activities to consider will depend on the context and duration of pain. Some of the measures used for assessing physical functioning in chronic pain discussed below may be appropriate to consider depending on the time interval.

Emotional functioning is the least studied outcome domain in postoperative pain studies, although it is important as it may influence the rate of recovery, length of hospital stay, and patient satisfaction with the treatment. APS-POQ-R recommends four questions rating emotional functioning, each on an 11-point NRS scale, namely how anxious, depressed, frightened, and hopeless patients felt. In the immediate postoperative period, these simple measures of emotional distress may be most reasonable to decrease patient burden. However, in longer duration acute pain trials (e.g. days, weeks), more comprehensive tools for assessing anxiety may be considered, such as the Yale Preoperative Anxiety Scale,[30] the Hospital Anxiety and Depression Scale (HADS),[31] and the Generalized Anxiety Disorder-7 (GAD-7).[32] There are multidimensional tools used in chronic pain investigations (discussed below) that have been utilized in acute pain studies, when reasonable given the context of acute pain (e.g. emergency department, ambulatory care clinic), that assess several outcome domains (Table 84.2). These include the Brief Pain Inventory (BPI), Medical Outcomes Study Short Form Health Survey SF-36 and its modifications (SF-12 and SF-8), and EuroQoL 5-D.[33–39] These instruments have been shown to have very good psychometric properties when used with chronic pain samples. However, they should be cautiously used as they were not specifically designed or validated for use in the immediate postoperative period.

Another multi-domain measurement tool is the International Pain Outcomes Questionnaire (IPO),[40] developed by the European Commission-funded PAIN OUT project. IPO includes domains of pain intensity, physical and emotional, functional interference, side effects, and perceptions of care. The questionnaire was finalized after two modifications: (1) phase one to five questions were added to the 14 item APS-QoR-R, (2) phase two to eight questions were removed from the questionnaire. As a result, the final version had high internal consistency reliability. However, although promising, to date, not many publications have reported results using the IPO.

Perhaps the comprehensive measure and one that has received the greatest amount of research is the set of quality of recovery (QoR) instruments.[41–43] These were initially developed and validated for use in the perioperative period. The QoR is the most commonly used instrument in postoperative pain studies, and it appears that a shortened version, the QoR (QoR 9, QoR 15), may be a reasonable alternative, and thus we describe it in some detail.

Myles group formulated a comprehensive QoR40, simpler nine item QoR questionnaire, and more recently, a QoR15.[41–43] The set of QoR tools measure five dimensions of health: pain, physical comfort, emotional state, psychological support, and physical independence. All of the QoR instruments have very good validity and reliability and excellent completion and return rates. The MCID, i.e. minimal change in score that indicates a meaningful change in a patient status —improvement or deterioration—was noted to be 0.92, 6.3, and 8.0 for the QoR, QoR40, and QoR15, respectively.[44]

The QoR 15, which has fewer items than the QoR 40 and with similar psychometric properties, has fewer items and takes 3 min to complete (Figure 84.1). Utilization of the QoR15 (or the QoR40), the IPO, or the APS-POQ-R includes most of the outcome domains recommended by the IMMPACT group.

QoR-15 Patient Survey

Date: _ _ /_ _ / _ _ Study #: __ __ ___ ___

Preoperative ☐ Postoperative ☐

PART A

How have you benn feeling in the last 24 hours?

(0 to 10. where: 0 = none of the time [poor] and 10 = all of the time [excellent])

1.	Able to breathe easily	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
2.	Been able to enjoy food	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
3.	Feeling rested	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
4.	Have had a good sleep	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
5.	Able to look after personal toilet and hygiene unaided	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
6.	Able to communicate with family or friends	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
7.	Getting support from hospital doctors and nurses	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
8.	Able to return to work or usual home activities	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
9.	feeling comfortable and in control	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time
10.	Having a feeling of general well-being	None of the time	0	1	2	3	4	5	6	7	8	9	10	All of the time

PART B

Have you had any of the following in the last 24 hours?

(10 to 0. where: 10 = none of the time [excellent] and 0 = all of the time [poor])

11.	Moderate pain	None of the time	10	9	8	7	6	5	4	3	2	1	0	All of the time
12.	Severe pain	None of the time	10	9	8	7	6	5	4	3	2	1	0	All of the time
13.	Nausea or vomiting	None of the time	10	9	8	7	6	5	4	3	2	1	0	All of the time
14.	Feeling worried or anxious	None of the time	10	9	8	7	6	5	4	3	2	1	0	All of the time
15.	Feeling sad or depressed	None of the time	10	9	8	7	6	5	4	3	2	1	0	All of the time

• **Figure 84.1** Q0R 15 Patient Survey.

While patient satisfaction is not directly addressed in the QoR instrument (Table 84.2), the authors noted that quality of recovery is directly related to patient satisfaction.[45] In one study, the investigators noted a strong association between the original nine item QoR and patient satisfaction. Since the QoR does not specifically assess patient satisfaction, investigators should consider including a measure of patient satisfaction when using the QoR.

Outcome Domains for Adult Chronic Pain Clinical Trials

As noted, based on a review of the literature, IMMPACT recommended that six core domains should be considered in *chronic pain* clinical trials: (1) pain; (2) physical functioning; (3) emotional functioning; (4) participant ratings of improvement and satisfaction with treatment; (5) symptoms and adverse events; and (6) participant disposition (adherence to the treatment regimen and reasons for premature withdrawal from the trial) (Table 84.3).[2] Moreover, IMMPACT indicated that other domains might be considered depending on specific research questions addressed in the trial (e.g. clinician or surrogate ratings of improvement, interpersonal functioning). The group emphasized that there are exceptions to using all the domains but the rationale for not including a domain should be explained. Additionally, the group acknowledged that statistically significant effects for all the domains were important to establish the efficacy of the intervention, however, investigators should indicate the primary outcome(s) of interest.

The IMMPACT domains depend primarily on patient self-report (PROMs). Self-reports assess experience and behavior at a single point in time or evaluate an experience averaged over a recalled period (e.g. last seven days).[46] However, pain can fluctuate over time depending on the activity and mood of the patient and on environmental factors that can impact emotional or physical function. Thus more frequent ratings using daily diaries and real-time data acquired electronically may be useful ways to evaluate the impact of treatments as related to circumstances that are influenced by a variety of factors (e.g. pain intensity at rest versus during movement, time of day as symptoms may vary).

TABLE 84.3 Core Outcome Domains and Measures for Chronic Pain Clinical Trials

Outcome Domain	Outcome Measurement Measures
Pain	11 point (zero to ten) numeric rating scale of pain intensity Usage of rescue analgesics Categorical rating of pain intensity (none, mild, moderate, severe)[a]
Physical functioning[b]	Multidimensional Pain Inventory interference items Brief Pain Inventory interference items
Emotional functioning[b]	Beck Depression Inventory Profile of Mood States
Participant ratings of global improvement and satisfaction with treatment	Patient Global Impression of Change
Symptoms and adverse events	Spontaneously reported adverse events and symptoms and use of open-ended prompts
Participant disposition	Information on patient recruitment, and progress through the trial (CONSORT diagram)

[a]Recommended when numeric ratings not feasible.
[b]Use one of the two recommended tools.

Pain

The assessment of pain often involves determining the extent of the patient's disease or injury and whether the patient's behavior is "appropriate" or "reasonable" for the disease or injury.[47] These questions are evaluated by taking the patient's history and physical examination, both of which require interpretation by a clinician and his or her experience and through assessment measures. NRS, VRS, and visual analog scales (VAS) are reliable, and all consistently show greater ability to detect improvement after treatment. However, IMMPACT recommended the 11-point NRS because of concerns raised about the ability of older populations to understand the use of VASs, and they can be difficult to use during telephone interviews and on electronic devices such as smart telephones. The VRSs tend to be limited by the number of categories (e.g. three, five, seven) used and thereby restrict the range of the scale. Therefore the ability to detect small but potentially meaningful change maybe limited.

A caution about self-reporting pain intensity. Although it seems deceptively simple to ask patients how much they hurt, several factors can influence the rating. For example, how much they hurt now, on average (usual), or when pain is at its worst? Over what period, last hour, days, week? Compared to what—"worst pain imaginable," "worst pain ever had," "pain before starting treatment," "during the last surgery I had"? Thus although a patient will readily respond to the question, patients may interpret the question differently, and the wording of the question can influence the responses obtained. Nevertheless, the gold standard for pain assessment depends on the patient who responds to the questions at the current time.

In addition to assessing the intensity of pain, measures such as the short form of the McGill Pain Questionnaire-2-Revised,[34,48] have been developed to assess descriptors characterizing pain (e.g. dull, aching, stabbing). These descriptors may differentiate nociceptive pain from neuropathic pain, and treatments may affect some of the characteristics but not others. Several measures have been developed to assess characteristics specifically associated with neuropathic pain, and these are described below.

Neuropathic Pain Measures

There are two sets of neuropathic pain measures, those that determine the qualities and progress of the neuropathic pain syndrome and questionnaires that determine whether a pain syndrome consists mostly of neuropathic features.[49] The former tools include the Neuropathic Pain Scale (NPS) and Neuropathic Pain Symptom Inventory (NPSI).[50–52] These measures assess the distinct pain qualities associated with neuropathic pain, determine the efficacy of different treatments, and help elucidate the mechanism(s) of

the effect of such treatments. However, the NPS and NPSI do not differentiate patients with neuropathic pain from patients with non-neuropathic pain

Four questionnaires determine whether a pain syndrome are mostly neuropathic or not: the Leeds Assessment of Neuropathic Symptoms and Signs (LANSS),[53] the Neuropathic Pain Questionnaire (NPQ),[54,55] the neuropathic pain diagnostic questionnaire, Douleur Neuropathique called the DN4,[56] a Neuropathic Pain Screening Questionnaire (NPSQ) designed for use in a primary care setting,[57,58] and the Short-Form McGill Pain Questionnaire-2 (SF-MPQ-2).[59] The LANSS is a seven item pain scale that consists of a grouped sensory description and sensory examination with a simple scoring system. The first five questions ask for the presence of unpleasant skin sensation, appearance of the skin, increased sensitivity of the skin to touch, sudden bursts of electric shock-like sensations, and hot or burning skin sensations. The last two questions involve sensory testing for the presence of allodynia and altered pinprick threshold. A different number of points, relative to their significance to neuropathic pain, are given positive answers for a maximum of 24 points. A score of <12 makes it unlikely that the patient's symptoms are neuropathic in nature, whereas a score >12 makes neuropathic mechanisms likely to be contributing to the patient's pain. The NPQ contains 12 items to help differentiate neuropathic pain patients from non-neuropathic pain patients. A stepwise discriminant analysis of the 12 NPQ items identified three items as significant predictors. These included tingling pain, numbness, and increased pain because of touch. From these three items, the authors offered a short form of the NPQ.[55] The French neuropathic pain group developed the DN4. Although there are four main questions, the DN4 is a ten item questionnaire of sensory descriptors and signs related to bedside sensory examination. A cutoff score of four predicts a neuropathic pain syndrome. The NPSQ has six questions, "higher scores suggested a neuropathic component."[58] The LANSS and DN4 have similar predictive values, sensitivities, and specificities. The short form NPQ and the NPSQ have lower values.

The SF-MPQ-2[59,60] includes descriptors commonly reported by patients with neuropathic pain and descriptors that are most commonly reported by patients with various nociceptive pain conditions (e.g. osteoarthritis). The SF-MPQ-2 consists of 21 descriptors, each rated on an 11 point NRS from "no pain" to "worst possible pain." Based on a factor analysis, the SF-MPQ-2 comprises four factors, namely, four readily interpretable subscales—continuous pain, intermittent pain, predominantly neuropathic pain, and affective descriptors. The reliability, validity, and subscale structure of the revised SF-MPQ-2 were examined in responses from individuals with diverse chronic pain syndromes and in a sample of patients with painful diabetic peripheral neuropathy who participated in a randomized clinical trial. This measure has been shown to reliably and validly distinguish between these two groups of patients and has been reported to be reliable when assessing patients with chronic pain. It has also shown to be both reliable and valid when assessing acute back pain patients.[59]

Physical Functioning

Physical functioning can be assessed in three primary ways: validated performance-based outcome measures of pain-related physical functioning (e.g. 6-min walk test [6MWT], timed sit-to-stand test),[61,62] patient self-report (PROMs), and recording of activity taking place in real-time (e.g. ambulatory measures of activity such as using accelerometry).[63] Each of these approaches has strengths and limitations, and as a set, they may provide complementary information, but they are not interchangeable. For example, clinical assessment of physical functioning provides an objective indication of functional capacity but may not reflect patients' perspectives on the impact of pain on their functional activities in their daily lives. In addition, electronic measures of performance acquired during routine daily activities may vary from what is observed in a constrained clinical setting where patients know they are being observed and have different levels of motivation. Thus as noted, they provide complementary information, and the one(s) selected will depend to some extent on the research question.

IMMPACT, in conjunction with outcomes measures in rheumatology (OMERACT), published an extensive list of PROM of physical functioning clinical, observer, and laboratory measures of physical functioning, and naturalistic assessment in the patient's lived environment.[64] Selected measures are listed in Table 84.4. These include tools for pain-related and general physical functioning/activity measures,[33,65–68] activities of daily living,[35,69–71] disease,[72–76] and site-specific physical functioning.[77–84] Additionally, IMMPACT-OMERACT enumerated several clinical, observer, and laboratory tools available and grouped them by sub-domain, including mobility or activity measures,[85–87] general physical functioning,[62, 88–92] multi-activity tests,[93,94] and site-specific domains[95–98] (Table 84.4). The set of measures and procedures that we included in our table is illustrative but not exhaustive. IMMPACT/OMERACT recommended the timed up and go (TUG),[85] the 6MWT,[61,86] and the Short Physical Performance Battery (SPPB)[93] for performance measures of physical conditioning. Interestingly, the 6MWT has been used in studies in regional anesthesia and acute pain.[99] The reliability of electronic recording (e.g. accelerometry, actigraphy) has been established.[63,87,100]

Employment status has been used to reflect physical conditioning, usually in the form of a binary question. Other questions include sick leave, short-term disability, and absenteeism from work. While there are validated measures that assess the patient's work activities,[101–104] these tools are not commonly used at the present time but may be used depending on the research question being addressed.

For interference with function and, as noted previously, psychometrically validated HR-QoL include the SF-36 and variants[35] while the Pain Disability Index (PDI)[66,105] is a general measure of physical functioning**.** Other comprehensive measures that evaluate physical functioning include the West Haven-Yale Multidimensional Pain Inventory (MPI),[67] and SW Sickness Impact Profile (SIP),[69,106,107] the EuroQoL, and the Nottingham health profile.[108,109] Several disease specific measures have been developed. Some examples of disease specific measures include the WOMAC for osteoarthritis,[75,110] and Roland Morris back pain Disability Questionnaire (RMDQ) for back pain,[72,73] the Neck Disability Index (NDI);[80,111] and the Fibromyalgia Impact Questionnaire Revised (FIQ-R)[74,112,113] (see Table 84.4).

Emotional Functioning

Psychological variables are involved in the initiation, maintenance, and prolongation of chronic pain.[114] These variables include beliefs, appraisals,[115,116] and thought processes, catastrophizing (assuming the worst possible outcome),[117] sense of control/helplessness,[118,119] self-efficacy,[120,121] coping,[122,123] moods and behaviors,[124] depression,[125,126] and fear, and anxiety.[116,127] These psychological determinants are extensively discussed in Chapters 14 and 22.

There are two ways to assess emotional functioning. When a specific psychiatric diagnosis is required, interview-based methods

TABLE 84.4 Selected Measures on Physical Functioning for Use in Chronic Pain Studies

Patient Reported Measures	Measurement Tools
Pain-related physical functioning/activity	Pain Disability Questionnaire (PDQ)
	Pain Disability Index (PDI)
	Multidimensional Pain Inventory (MPI)
	Brief Pain Inventory (BPI)
General physical functioning/activity	MOS 36 Item Short Form Health Survey (SF-36)
	Sickness Impact Profile (SIP)
	PROMIS Physical Functioning Item Bank
Activities of Daily Living	Center for Disease Control and Preventions' Healthy Days Measures (CDC HR-QoL-14)

can be used. There is an important distinction between PROMs to assess emotional functioning compared to interview-based assessment designed to determine psychiatric diagnoses. The former depends on the patients' perception and reporting on their thinking and mood, whereas clinical interviews have a different purpose and require interpretation to arrive at a diagnosis.

For most clinical trials, PROs are used to assess emotional function as an outcome, a response induced by the treatment. As for physical functioning, emotional functioning and distress can be assessed by general measures or disease specific or population-specific measures. In the assessment of patients experiencing pain, the most frequent psychological constructs include anxiety and depression. General measure for anxiety include the anxiety subscale of the Hospital Anxiety and Depression Scale (HADS),[31] State-Trait Anxiety Inventory (STAI),[128] and Generalized Anxiety Disorder (GAD-7),[32] and for depression, the Beck Depression Inventory (BDI),[129] and Public Health Questionnaires PHQ-9[130] and PHQ-4.[131,132] The emotional components of pain can also be assessed using the mental health component of the SF-36.[35] More specific measures include the Pain Anxiety Symptoms Scale (PASS-20),[133] Tampa Scale of Kinesio-Phobia (fear of movement),[134] fear-avoidance beliefs questionnaire (FABQ),[135] and Geriatric Depression Scale (GDS) (Table 84.5).[136]

Patients' Beliefs, Expectations, and Coping

Although not specifically recommended as core outcome measures of emotional functioning and patients cognitions (e.g. attitudes, beliefs, and expectations) are important in understanding patients/experience of pain and may mediate or moderate treatment outcomes. Some Instruments that measure attitudes and beliefs include the Pain Beliefs Questionnaire[137] Pain Beliefs and Perceptions Inventory (PBPI),[138] and Survey of Pain Attitudes (SOPA).[139] The chronic pain coping inventory (CPCI),[140] Coping Strategies Questionnaire (CSQ),[141] and Vanderbilt Pain Management Inventory (VPMI)[142]

are measures that evaluate coping strategies while the Catastrophizing Scale[143] and Pain Catastrophizing Scale[144] assess patients' catastrophizing. Finally, the Pain Locus of Control[145] focuses on patients' perceptions of control (i.e. self, powerful others, chance), while the Pain Self-Efficacy Scale[146] and the Chronic Pain Self-Efficacy Scale[147] assess the patients' perception of self-efficacy for controlling pain and their lives more generally. Several short-forms of these questionnaires have been developed and may be useful to reduce patient burden, e.g. pain catastrophizing,[148] pain self-efficacy,[146] and coping.[149]

Several general comprehensive measures evaluate pain, and physical and emotional functioning.[114] These include the BPI short form,[150] and MPI[67] for pain. For general health and interference of pain with functional activities and to some extent, SF-36,[36] SIP,[106] Nottingham Health Profile,[151] and PROMIS-29.[152] A very brief measure based on the BPI includes three questions, designed to cover key outcomes is the PEG.[153] The domains covered, each with a single item in the PEG, include average Pain, interference with Enjoyment of life, and interference with General activity, have the advantage of efficiency. It has been used in primary care settings. In addition to these general measures, there are a large number of comprehensive disease specific measures have been published, e.g. FIQ-R,[113] NDI,[111] and WOMAC (see Table 84.4).[75]

Measures in the Elderly and Patients With Cognitive Impairment

PROMs depend on the ability of the patient to respond to verbal questions. This creates unique problems for those patients who cannot respond to such inquiries. Assessment tools have been developed for the elderly and adults with cognitive impairment. Geriatric Pain Measure,[154] Pain Assessment in Advanced Dementia (PAINAD),[155] Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC),[156,157] and DOLOPLUS-2,[158] and the Pain Assessment in Impaired Cognition Scale (PAIC15).[159] These measures are discussed in Chapter 43 (Pediatric Chronic Pain Management) and 79 (Pain Evaluation and Management in Patients With Limited Ability to Communicate Because of Dementia). Similarly, measures are needed for neonates, infants, and young children. These are discussed later in this chapter. Complete psychological assessment is discussed in Chapter 22.

Domains and Measures in Acute and Chronic Pediatric Pain Clinical Trials

We combined the core domains for acute and chronic pain clinical trials for use in pediatrics for easier discussion and referral to the outcome measures. We will address acute pain first since, in contrast to adult studies, many of the pediatric recommended measures that have been used in acute pain trials have also been included in chronic pain trials.

It is important to acknowledge that selection of specific outcome measures in pediatrics is a daunting task that involves complex decision making and the selection of measures that are appropriate for the age and developmental status of the patients included in the study. We describe a wide range of assessment tools (i.e. PROMs, surrogate, physiologic) for the set of outcome domains recommended, each with advantages and disadvantages, that have been developed and used to assess the important outcome domains across developmental stages in this section. Many of the measures discussed are applicable across types of pain and various contexts. However, we also note several that are disease specific (e.g. migraine, juvenile rheumatoid arthritis) and context specific (e.g. postoperative, procedural, home, emergency department).

One of the most challenging concerns with pediatric pain assessment is that because many children are too young or developmentally immature to communicate their level of pain verbally,[160] we rely on the observer (e.g. parent, nurse) as a proxy to make an assessment. However, observers can over or underestimate children's pain[161,162] and can be influenced by their own beliefs, concerns, emotions, and contextual factors.[163] Ideally, a patient's own personal assessment of his or her pain is the gold standard, but validated observation and surrogate-reported scales can assist in both clinical decision making and research when self-report is limited (see below). Note that similar concerns apply when adults have limited or impaired ability to communicate.

For pediatric postoperative pain management, pedIMMPACT was developed.[3] Specifically, pedIMMPACT recommended pain intensity, physical functioning, emotional functioning, symptoms and AEs, and global judgment of satisfaction with treatment as preferred outcomes domains. These domains are slightly different from IMMPACT in that they did not incorporate satisfaction in the domain of patients' ratings of global improvement. According to pedIMMPACT, for chronic and recurrent pain, pediatric clinical trials, investigators should consider adding three additional outcomes to those recommended for acute pain trials, namely, role functioning, sleep, and economic factors. IMMPACT recommended that role functioning and sleep should be considered secondary outcomes and did not consider economic factors as a relevant outcome domain in adult clinical outcome studies.

For children, developmental stage and age are essential considerations in selecting measures to assess the outcome domains. Thus pedIMMPACT suggests measures that would be appropriate for different age cohorts.

For *self-report measures* of acute pain intensity in clinical trials and adolescents, pedIMMPACT recommended the Poker Chip Tool[164] for children aged three to four years of age for procedure-related and postoperative pain; the Faces Pain Scale Revised (FPS-R)[165] for ages four to 12 years for procedure-related, postoperative, and disease-related pain; and the VAS[166] for ages eight and above for procedure-related and postoperative pain. There are no validated self-reported pain scales for children under the age of three as many will not accurately self-report their pain. Thus for neonates and infants, assessment must be based on observation and estimation by surrogates.

The Poker Chip Tool consists of a set of four red plastic poker chips, each representing a "piece of hurt." In this scale, "hurt" is included as a proxy for "pain." The child chooses "how many pieces of hurt" they have. Children without pain have no pieces of hurt. The first chip represents "a little hurt," the second indicates "a little more hurt," and the fourth chip equals the "most hurt you could ever have." As such, scoring is from zero to four.[164] The FPS-R consists of six gender-neutral line drawings of faces that are scored from zero to ten.[165] The faces from left to right show no pain, increasing to more pain, and finally ends at very much pain. The patient then points to a face on the scale to represent their level of pain. The faces are meant to represent how a child feels inside, not how their actual face looks to the providers. The Wong-Baker FACES pain scale consists of six hand-drawn faces that range from smiling to crying.[167] The faces represent "no hurt" to "hurts worst," and the scale is scored from zero to five. The Oucher combines two separate scales: the photographic faces scale and a 0-100 mm vertical NRS. The photographic faces scale consists of six photographs of culturally sensitive faces (i.e. Caucasian, Afro-American, and Hispanic) that are scored from zero to five. The adjacent vertical NRS is scored from zero to 100.[168,169]

There is not complete agreement as to the types of pain assessment scales to use in pediatrics. PedIMMPACT recommended the use of the VAS and not the NRS because of the paucity of psychometric studies with NRS in pediatrics. The color analog scale (CAS) used gradations of color, area, and length to enable children to concretely identify variations in pain intensity.[169,170] The measure is pocket sized (10 cm in length) with gradations from small and white to wider and deep red reflecting increases in pain intensity. In the original CAS, children were asked to move a slider along the length of the CAS to indicate how much pain they have. The back of the measure has a corresponding zero to ten NRS to determine a number representing the child's pain.

A group of other investigators advocated for the use of self-report measures for the evaluation of pain when possible.[168,169] They noted that observer reports or behavioral observations are limited and may not be in agreement with the child's self-report as parents tend to underestimate or overestimate their child's pain. The group reviewed the psychometric properties, interpretability, and feasibility of self-report pain intensity measures. They noted that several self-report measures fulfilled the criteria of "well-established assessment."[171] These include the NRS (NRS-11), VAS, CAS, FPS-R, and original FPS, FACES, pieces of hurt/poker chip tool, Oucher photographic and numeric scales.[168,169] In contrast to pedIMMPACT, these investigators recommended the NRS-11 and the VAS across all types of pain for children six years and older.[169] Similar to pedIMMPACT,[3] they recommended the pieces of hurt tool for acute procedure-related postoperative pain in children between three and four years of age (with a behavioral observational measures as a secondary outcome); the FPS-R for acute procedure-related postoperative and disease-related pain in children four and 12 years of age; and the VAS for acute procedure-related postoperative and disease-related pain in children over eight years of age and adolescents, with the FPS-R as a secondary measure with the VAS for children between eight and 12 years.[168]

For *observational measures* of acute pain intensity from procedural and postoperative pain, pedIMMPACT recommended several tools for children one year and above. These include the Face, Legs, Arms, Cry, Consolability (FLACC),[172] the Children's Hospital of Eastern Ontario Pain scale (CHEOPS),[173] the Parents' Postoperative Measure (PPM)[174] for postoperative pain measure at home, and the COMFORT Scale[175] for children on a ventilator or in critical care. The Toddler-Preschooler Postoperative Pain Scale (TPPPS)[176] is recommended for postoperative pain in children aged one to five years.

The FLACC scale is a five item scale scoring the face (F), legs (L), activity (A), cry (C), and consolability (C), each with a range of zero to two.[172] The scale is scored in a range of zero to ten, with zero representing no pain. The revised FLACC scale incorporates additional observable behaviors to improve validity in children with cognitive impairment. Given its validation in a wide range of patients and its ease of use, it is a helpful tool for patients who cannot self-report.

The CHEOPS scale rates six behaviors: cry, facial expression, verbal responses, torso position, touch, and leg position.[173] The scale is anywhere from zero to three, depending on the specific behavior. The minimum score is four (no pain), and the maximum score is 13 (worst pain).

The PPM is a 15-item observation scale where parents report on changes from their children's usual behavior. The number of items parents have circled "Yes" are summed for a total score out of 15. A score of at least six out of 15 signifies clinically significant pain.[174]

The COMFORT scale combines observation and physiologic signs. It measures alertness, calmness/agitation, respiration, physical movement, blood pressure changes, heart rate changes, muscle tone, and facial tension. Total scores can range between eight and 40. A score of 17-26 generally indicates adequate sedation and pain control.[175] Because of the complexity of measuring blood pressure and heart rate, this scale is used primarily for patients in a critical care setting.

The TPPPS is an observational scale specifically only for children aged one to five years old.[176] The TPPPS consists of seven items divided among three pain behavior categories: (1) vocal pain expression, (2) facial pain expression, and (3) bodily pain expression. The seven pain behavior items were scored as "one" if the behavior(s) is present during a five rain observation interval and as "zero" if the behavior(s) is not present. Scores on the scale range from zero to seven. A modified TPPPS was noted to be a suitable assessment tool of pain in children who presented in an accident and emergency department.[177]

For children with intellectual disabilities, there is the Non-Communicating Children's Pain Checklist-Postoperative Version (NCCPC-PV).[178] It included vocal, social, facial, activity, body and limbs, and physiologic signs on a range of zero to three. A total score of seven or more indicates a child has pain. A total score of six or less indicates a child does not have pain. The tools mentioned above are discussed in Chapter 28.

For pediatric chronic pain trials, pedIMMPACT recommends the same self-report measures employed in acute pain studies. The number of pain-free days or days when pain reaches a certain level (e.g. three on a five point scale may also be noted).[3] The same tools

for assessing patient satisfaction and symptoms and AEs in acute pain are recommended.

There are no validated measures for physical recovery for acute pain in children.[3] Instead, the time to ambulation, time to resumption of swallowing, oral intake, time out of bed, time to ambulation, and time to normal spirometry have been recommended by the group. In addition, the IMMPACT group recommended the adolescent, pediatric pain tool[179] for emotional response; the facial affective scale for measuring the affective component of pain in patients eight years or older;[3] the Procedure Behavior Check List (PBCL);[180] or the Procedure Behavioral Rating Scale Revised (PBRS-R)[181] for evaluation of behavioral distress during procedures. The different presentations of global ratings of satisfaction do not appear to affect the response. For children below eight, proxy ratings by parents are advised. Evaluation of economic factors involves the assessment of both direct and indirect costs of the treatment.

For pediatric chronic pain studies, school age children and adolescents' assessment of physical functioning can be evaluated by the Functional Disability Inventory,[13,182] while PedsQL is utilized in children less than seven years, although it can be deployed in children two to 18 years old.[183] In addition to physical functioning, the PedsQL also determines emotional, social, and school functioning. As emotional functioning refers to depression and anxiety, these domains can be appraised by the Children's Depression Inventory for ages seven to 17 years and the revised Child Anxiety and Depression.[184]

For role functioning, the following measures can be evaluated: PedMIDAS for headache in children six to 18 years old;[185] school attendance for school age children; and the PedsQL across the pediatric and adolescent age-span. While sleep disruption is common in children with pain, the pedIMMPACT group does not recommend a specific tool. Finally, the group acknowledged the difficulty in assessing economic factors in children.

Additional measures not discussed by the pedIMMPACT group include the Children's Comprehensive Pain Questionnaire for school age and adolescent children,[186] and the pain behavior observation method for children with juvenile rheumatoid arthritis.[187] To evaluate anxiety, tools include the Children's Anxiety Sensitivity Index (CASI),[188] Multidimensional Anxiety Scale for Children (MASC),[189] and the revised children's manifest anxiety scale.[190] Self-report questionnaires for anxiety include the Self-report for Child Anxiety Related Disorders (SCARED)[191] and the Spence Children's Anxiety Scale.[192] The child's Coping abilities can be assessed by the Pain Coping Questionnaire (PCS),[193] Pain Response Inventory (PRI),[194] or the Pain Catastrophizing Scale for Children (PCS-C).[195] These measures are discussed in Chapter 43.

Patient Satisfaction

Although not traditionally considered an outcome in pain clinical trials, more recently, patient satisfaction with treatment has received growing attention and deserves to be included as an important outcome. Patient satisfaction is a barometer used by many hospitals to measure success and drives infrastructural changes.[196] The determinants of patient satisfaction are either patient-, provider-, and process-related.[197,198] Patient-related factors include physical and psychological health, expectations, and sociodemographic factors. The social and personal characteristics encompass age, race, gender, culture, social class, education, marital status, occupation, and income. Satisfaction is increased when the healthcare matches up to the patient's expectations. Provider-associated considerations include competence (perceived versus observed) and verbal and non-verbal interactions with the patient. Empathy, length of the provider's visit, and the amount of information given influence patient satisfaction. In addition, ancillary services, accessibility and convenience, cost, and bureaucratic and environmental factors, and organization of health care are process-related features.[197] Increased accessibility, shorter waiting times, and availability of the provider naturally improve patient satisfaction.

Patient satisfaction in acute pain management encompasses satisfaction with the process itself (i.e. the collective effort to achieve analgesia) and the outcome (i.e. the success of the pain regimen).[199] Although overlap exists, the two components should be viewed as separate entities.[196] Although a patient could receive inadequate pain control, he or she may be thankful for all information provided, and the providers attempt to ensure optimal analgesia. Conversely, a patient with minimal postoperative pain could be dissatisfied because of preconceived expectations and to his or her lack of involvement in the decision making process. For example, published studies noted that satisfaction was dependent not only on anesthetic outcome but also on how patients were approached and how the information was relayed.[200,201] The results showed that process-related factors (e.g. participation in decisional process) are just as important as outcome-based parameters (i.e. pain intensity) in ensuring patient satisfaction.

The type of treatment can also affect patient satisfaction. After total joint surgery, joint function, hip instability, leg length equality, and self-care are major determinants.[202,203] Range of motion, improvement in strength, and ability to perform activities of daily living are important after hand surgery.[204] Appearance after cosmetic surgery following a breast cancer operation determines patient satisfaction.[205] In these surgical publications, patient education, shared decision making, length of follow up, duration of waiting time, state of the facility, and quality of food also significantly affect patient satisfaction.[202–204] The surgeon's empathy, rather than duration of visit, positively influenced the patients' satisfaction.[206]

Satisfaction also depends on patient-related factors that can escape medical control.[197] In a recent observational study, patient-related sociodemographic variables such as male gender, older age, and higher education level were associated with increased satisfaction scores after anesthesia.[207] A cross-sectional analysis of patients undergoing non-obstetric surgery in the United Kingdom identified younger age, female sex, obesity, history of stroke, neuropathic pain, and long-term opioid use constituted non-modifiable parameters associated with severe discomfort after surgery.[208]

Tools to measure patient satisfaction include user-friendly questionnaires to validated measurement tools. Simple measurement methods include satisfaction scores presented in the NRS or verbal descriptor scales. However, the reliability of these scales is questionable since they cannot capture the manifold nature of satisfaction.[199] The patient global impression of change (PGIC),[209] a very popular tool and recommended by IMMPACT, has been utilized to represent patient satisfaction. However, it does not assess satisfaction *per se.* Patients simply comment on their overall status and whether the latter has changed, worsened, or remained status quo. This scale does not capture the multidimensional and complex nature of satisfaction.[196]

Reliable setting-specific and procedure-related tools have been devised and validated to assess patient satisfaction and related to anesthetic management. These include the Iowa Satisfaction with Anesthesia Scale for monitored anesthesia care,[210] and the Scale of Patients' Perceptions of cardiac anesthesia services.[211] Sophisticated questionnaires developed for general non-cardiac anesthesia include the evaluation du vécu de l'anesthésie générale (EVAN-G)

questionnaire,[212] Leiden Perioperative Care Patient Satisfaction questionnaire (LPPSq),[200] patient satisfaction questionnaire for Anesthesia Care,[213] Patient Satisfaction with Perioperative Anesthetic Care questionnaire (PSPACq),[214] Anesthesiological Questionnaire (ANP),[215] and the Bauer questionnaire.[216] The EVAN-G questionnaire is designed for patients who had general anesthesia, whether inpatient or ambulatory. It consists of 26 questions pertaining to attention, privacy, information, pain, discomfort, waiting, and global impression.[212] The EVAN group recently developed a psychometrically sound satisfaction questionnaire for regional anesthesia.[217] The patient satisfaction questionnaire for anesthesia care, developed by investigators from Switzerland and Austria, contains items on information (and involvement in decision making) on care in the recovery room and pain management.[213] In contrast, the Bauer questionnaire includes ten anesthesia-related questions pertaining to discomfort (e.g. pain at surgical or injection site, sore throat, hoarseness, thirst, cold, shivering) and five questions pertaining to satisfaction with preoperative information, emergence from anesthesia, pain, and overall anesthesia care.[216] The five straightforward questions related to patient satisfaction explain the use of the Bauer questionnaire in a large cross-sectional study investigating the outcome of perioperative anesthesia in the United Kingdom.[208] The time required to complete the questionnaires usually ranges from 3 to 12 min.[218] Most tools are linguistically specific to the population for whom they were originally developed. While the EVAN questionnaires have English translations, the ANP and the perioperative anesthetic care questionnaire have not been translated in English and are specific to German and Taiwanese patients, respectively.

The previous questionnaires target patient satisfaction. In addition, there are validated multidimensional tools that include patient satisfaction as part of the overall assessment of pain management. These include the APS-POQ-R)[11] and the IPO questionnaire.[40] The APS-POQ-R was developed for QI audits of pain management, while the IPO, a modification of the APS-POQ-R, was designed for postoperative application. Both questionnaires include a question on patient participation in the therapeutic decisional process. We suggest that a tool to evaluate patient satisfaction should be included if these general measures are utilized in acute and chronic pain outcome studies.[39]

Summary and Conclusions

Pain is a biopsychosocial construct, and clinical trials on pain should reflect its multidimensional nature. It includes not only the intensity of the pain but also physical and emotional aspects. AEs are consequences of any treatment. Patient satisfaction reflects the interaction of all these domains. Measures that determine these domains and possess valid psychometric/clinometric properties have been identified in acute, postoperative, and chronic pain in adult and pediatric populations. Published clinical studies on chronic pain have utilized these measures and recommendations proposed by IMMPACT, while investigations in acute and postoperative pain have started to embrace the domains recommended by IMMPACT and APS-POQ-R. Outcome domains for acute and chronic pain in children, as proposed by pedIMMPaCT, are largely similar to those proposed for adults. In pediatric research, the age and developmental stage must be considered when selecting specific measures for the outcomes of interest. A large and growing list of both general and specific measures has been developed for adults and children. Investigators need to be cognizant of the basic psychometric/clinometric characteristics of all measures they consider. They also need to attend to the responsiveness of the measures to change and the normative samples on which the measures were developed to assure that the measure is appropriate for the sample to be included in the trial. Although we focused on measures that can be considered for use in clinical trials, many of the measures should be considered appropriate for use in clinical practice.

Key Points

- Pain is multidimensional and clinical trials on acute and chronic pain should reflect its multifaceted nature in the outcomes used to evaluate various interventions.
- IMMPACT recommended that six core domains should be considered in chronic pain clinical trials; (1) pain; (2) physical functioning; (3) emotional functioning; (4) participant ratings of improvement and satisfaction with treatment; (5) symptoms and adverse events; and (6) participant disposition (adherence to the treatment regimen and reasons for premature withdrawal from the trial).
- The selection of measures to assess the important outcomes in clinical trials should attend to the (1) reliability, (2) validity, (3) responsiveness, (4) availability of appropriate comparison groups and generalizability to the study sample, (5) patient burden, (6) appropriateness for the sample included in the study, and (7) the criteria for clinical significance.
- IMMPACT recommended measures appropriate for each of the above domains. Generic or disease specific measures with valid psychometric properties are available for low back pain, fibromyalgia, musculoskeletal and joint pain, neuropathic pain, and other chronic pain syndromes.
- NRS, VRS, and VAS are reliable, and all consistently show greater ability to detect improvement after treatment. However, IMMPACT recommended the 11-point NRS because of concerns raised about the ability of older populations to understand the use of VASs, and they can be difficult to use during telephone interviews and with handheld devices.
- The neuropathic pain measures determine the qualities and progress of the neuropathic pain syndrome and questionnaires that determine whether a pain syndrome consists mostly of neuropathic features.
- Most clinical trials on chronic pain included the domains recommended by IMMPACT, but studies on acute or postoperative pain have been less consistent in making use of IMMPACT and APS-POQ-R recommendations. Emotional functioning is the least studied domain in postoperative pain trials.
- The QoR tool for postoperative pain is the most commonly used multidimensional tool in perioperative pain studies. However, patient satisfaction should be investigated when using the QoR since it does not measure such outcomes.
- Clinical trials on pediatric acute and chronic pain should strive to include the same domains as in adult studies. The choice of measures for each domain should consider the age appropriateness and limitations posed by those whose ability to communicate are impaired.

Ethical Issues in Pain Research

KATHERINE GENTRY, GARY A. WALCO

There are numerous ethical considerations when conducting pain research with humans. In this chapter, we will briefly review the genesis and growth of research ethics as a field, often in response to historical examples of research misconduct. We then discuss ethical issues specific to the study of pain, including (1) how pain can affect an individual's ability to act autonomously, (2) unique risks of study participation for patients with pain, (3) justice concerns regarding participant selection and distributing the benefits and burdens of research, (4) the ethics of inducing pain for research purposes, (5) controversies over the use of placebos, (6) issues specific to studying pain in children, and (7) burgeoning considerations in the study of genetic and epigenetic phenomena related to pain. We recognize that any one of these issues may warrant an entire chapter, and as a result, our effort is to summarize issues rather than address them exhaustively.

Brief Historical Overview

The field of research ethics with human participants was borne out of numerous instances of research misconduct and scandal that have marred the legacy of medicine and science. During the Nazi regime, harmful and deadly experiments were conducted on concentration camp inmates to determine the conditions (and limits) under which military personnel could survive, testing medications and treatments, and carrying out eugenic ideals.[1] The Nuremberg Code was authored in 1947 by judges who presided over the trial of Nazi physicians, and this code laid the foundation for all subsequent research ethics declarations. It emphasized the protection of human research participants' rights through informed consent and the right to withdraw from research, as well as the duty of the investigator to act in participants' best interests.[2] Other research scandals that have informed the field of research ethics include the intentional infection of disabled children with Hepatitis A at the Willowbrook Institute in the 1950s,[3] the propagation and widespread distribution of an immortal cell line obtained without permission from Henrietta Lacks—a black woman dying of cervical cancer,[4] and the United States Public Health Service's "Tuskegee Study of Untreated Syphilis in the Negro Male," a forty-year observation during which men were not told the truth about the study's purpose, nor were they offered treatment when it became readily available.[5]

In 1964, the World Medical Association developed the Declaration of Helsinki, which outlines proper conduct for physicians who perform research. It has been revised multiple times and remains a key resource guiding the ethical conduct of research worldwide. The 1975 revision defined the need for oversight by an institutional review board (IRB) to protect human subjects, paralleling a similar requirement instituted in 1974 by the Commission for the Protection of Human Subjects of Biomedical and Behavioral Research in the United States.[6]

That same commission authored the Belmont Report, published in 1979, which establishes respect for persons, beneficence, and justice as the ethical principles that must be considered and balanced in the research context.[7] Respect for persons encompasses two "convictions": that individuals should be allowed to act autonomously and that those with diminished autonomy are deserving of extra protection. Respect for persons underlies the requirement for informed consent in research participation. To act beneficently is to promote a person's wellbeing. In research, this duty requires that investigators thoroughly assess the potential benefits and harms of their study and try to maximize benefits and minimize harms to participants. Justice, in the words of the Belmont Report, focuses on "who ought to receive the benefits of research and bear its burdens?" Ethically conducted research must have a process for participant selection that does not take advantage of vulnerable or captive populations, and the findings from publicly funded research must benefit everyone, not a privileged minority. Freedman writes that ethical research should also be scientifically valid (thereby producing reliable and generalizable data) and be of use to society.[8]

The 2018 update to the United States Code of Federal Regulations governing human subjects research considers children, prisoners, individuals with impaired decision making capacity, and economically or educationally disadvantaged persons to be vulnerable populations. That is, these populations have constrained or limited autonomy and may be susceptible to coercion or undue influence.[9] IRBs are obligated to scrutinize research involving these populations to ensure that the benefits of research participation are not outweighed by potential harms. When research involving children does not hold the prospect of direct benefit, it may still be approved if it is considered to present "minimal risk" or a "minor increase over minimal risk" of harm to the child. For a study to be deemed "minimal risk," the probability and magnitude of harm or discomfort anticipated in the research "are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations or tests." This standard has been criticized because of its lack of specificity and potential for variable interpretation by individual IRBs; nonetheless, it remains the standard criterion employed to categorize research risks.[10,11]

Ethical Issues Specific to Pain Research

The experience of having pain may compromise a participant's ability to act autonomously and provide valid informed consent. Pain is noxious, and individuals' judgment may be ill-affected

by the immediate desire to make it stop. Included here is that pain may impair cognition,[12] and the ability to reason beyond the immediate goal of relief. Especially patients for whom pain has been poorly controlled, there may be a tendency to overestimate the potential benefits of an experimental therapy resulting in a biased assessment of the harm to benefit ratio.[13] Thus investigators have a heightened obligation to ensure that prospective participants can understand and reason with information pertinent to risks and benefits of study participation.

A crucial component of autonomous action is voluntariness; the potential research participant must be free to enroll in a study without experiencing overt or implicit coercion. The pain research context may threaten voluntariness in a few ways. For example, there is a risk that some individuals will feel compelled to enroll in a study that is presented by their healthcare provider to maintain the therapeutic relationship and be seen as a "good patient." Also, incentives offered by the research program may overtly exert influence on potential research participants. Incentives are intended to attract participants and compensate them for the time, effort, and discomfort that research may entail. However, when an incentive is disproportionate to the study burdens and is so enticing that the participant feels there is really no choice to be made, this is termed "undue influence" and is considered unethical. On a more subtle level, improved access to healthcare services only while "on study" could serve to unduly influence some potential participants to enroll. This issue is especially problematic in developing economies.

Investigators must minimize harm to research participants. Investigational pain therapies pose risks of an altogether different type than that typically experienced in other pharmacologic trials. Analgesic trials for short-term acute or post-procedural pain involve very limited administration of the study drug. However, for chronic pain, participants may receive the study drug over several days to weeks. If that medication is superior to contemporary therapies, it may be difficult for the participant to revert back. This issue is highlighted even more when the study drug promotes physical dependence (as in the case of opioids). There is an obligation to ensure ongoing followup beyond the scope of the trial.

Last, investigators must consider if the participants they plan to enroll are representative of the population to whom they ultimately hope to provide benefit. Clinical trials are often relatively narrow in defining inclusion criteria, and biases based on age, language, and sociocultural factors are far too common.[14] For example, vaso-occlusive episodes characteristic of sickle cell disease may be exceedingly painful and require potent analgesics for treatment. However, even fundamental research on analgesic medications (e.g. pharmacokinetic and pharmacodynamic studies) in this patient population was rare for many years.[15,16] The pediatric population has also been omitted from most analgesic trials, which will be discussed further below.

Ethics of Placebos

The long-standing method by which analgesics have been tested is by randomly assigning participants to receive the test drug or a placebo and then comparing mean pain scores (typically, a rating of pain intensity). The ethical concern is that those assigned to the control group are likely to experience pain until they receive rescue medications. This may be justified if there is true equipoise – that is, the researcher truly does not know if the test drug is superior to placebo. However, this is rarely the case with analgesics, and thus alternative study designs have been pursued.

Nagasako and Kalauokalani explicated these concerns drawing on lessons learned in psychiatry to make recommendations for the field of pain medicine.[17] Whether the use of placebo controls may be judged as ethical depends partly on the state of existing treatment (i.e. if existing treatments have been rigorously studied and shown to be effective, then new drugs may be compared against existing treatment, not placebo). However, if the best available therapy has not been rigorously established or the treatment effects vary significantly across a population, then for some participants, treatment with placebo would be no better than treatment with the "best available" therapy.

Another consideration is whether the condition under study can allow for the potential harms of placebos.[17] An individual exposed to a cold pressor stimulus (experimentally induced pain) would not experience significant harm if given a placebo. In contrast, a person who had undergone abdominal surgery could experience significant harm if given a sham epidural or a placebo instead of a parenteral analgesic.

It is also worth noting that placebo-controlled studies have merit. "Placebo concurrent control" is one of five study designs recommended in the United States federal regulations regarding controls in drug studies.[18] Randomized, double-blind, placebo-controlled trials minimize bias (both on the part of the investigator and the participant), provide an internal standard against which efficacy of the study drug can be measured, and provide the cleanest conditions for distinguishing adverse drug effects from effects of underlying disease.[19] Scientific validity can be considered an ethical principle, which lends support to the use of placebos.[8,17] Furthermore, one cannot ignore the profound clinical effects of a placebo. A review is well beyond the scope of this (see Chapter 17). However, any time one administers a drug, the clinical effect is the combined impact of the therapeutic effects of the drug and placebo, and often the latter is far greater than the former.[20] The placebo effect is so strong that it remains intact, even when patients know they are receiving a placebo.[21,22] How could one measure this profound effect without including a placebo control?

The Ethics of Laboratory Induced Pain in Humans

One may potentially learn a great deal about pain and its impact by inducing nociception experimentally and studying various correlates. Research involving experimentally induced pain enables us to study and manipulate different variables to understand relationships in ways not feasible in a naturalistic setting. We may better comprehend the trajectory of pain syndromes, the contributions of genetic, biologic, and psychological factors, and, ultimately, pain prevention, coping, and treatment. Despite the potential wealth of information that this type of research can produce, when one is intentionally inflicting pain on another human, ethical considerations, focused on how pain may be evoked in the laboratory, and the range of outcomes of interest to investigators, are paramount.

Pain may be induced through various means, including mechanical, temperature (heat and cold), ischemic, vibration, and electrical stimulation. Within experimentally induced pain studies, outcomes of interest may include (1) *pain threshold*, the lowest level of nociceptive stimulation the participant labels as painful; (2) *pain tolerance*, the maximum level of nociceptive stimulation the participant is willing to withstand; and (3) *pain responsiveness*, the participant's subjective, behavioral, or physiologic response to a defined or standardized nociceptive stimulus.

The risk-benefit ratio used to evaluate the ethical status of a given study in this arena depends on the nature of the pain being inflicted (including the specific stimulus itself, its intensity, and duration) and the presumed gains from obtaining the data. A thorough review of various means of inducing pain and the methodologies used in laboratory studies is beyond the scope of this chapter.[23,24] However, to meet ethical standards, certain common elements are universally important. For example, painful stimuli should be of the lowest intensity and the shortest duration needed to answer the research question. In addition, full informed consent is imperative, including the participants' right to withdraw from the study at any time without penalty.

In research involving laboratory-induced pain, attention to external validity is essential. Participants selected for research trials should be representative of the population to whom the results are to be generalized. For example, imagine the differences in pain tolerance that might be ascertained in a study conducted on military recruits versus college undergraduates versus a community sample of middle-aged adults. Without ensuring that a study's results will be generalizable to a target population, the benefit of the study is not obvious and potentially inherently unethical.

There is a long history and continues to be a growing body of literature supporting the clinical relevance and application of laboratory induced pain.[25,26] For example, by studying conditioned pain-modulation (formerly called diffuse noxious inhibitory controls, DNIC) using Quantitative Sensory Testing (QST), one can predict elements of patients' acute, postoperative, and chronic pain responses.[27] As clinical applications of experimentally induced pain expand, it is still important to maintain the same ethical framework of gaining the needed information while minimizing patients' exposure to noxious stimuli.

In conducting laboratory pain studies with minors who are incapable of providing informed consent, even more rigorous standards must apply. As study participation is of no immediate benefit to the child participant, the value of the research must be apparent, the child's informed *assent* is essential, and the right to withdraw should be made clear to the child participant and the child's parents or guardians. This field has clearly evolved. In 1986, a study involving pain thresholds in pediatric patients led to an initial uproar within the IRB, and they demanded a personal appearance by the investigators. Once the IRB learned that the methods included nothing more than inflating a blood pressure cuff until the child or guardians first labeled the circumferential pressure as pain, and using a simple pressure algometer on the index finger until the child first labeled the stimulus as pain, they approved the study with no further ado.[28] Since then, many studies with children have gone on to include pain tolerance, principally through a cold pressor paradigm,[24,29] and pain responses, and their correlates through QST methodology.[30]

The majority of early trials involving experimentally induced pain were with healthy children. However, much may be learned about individual differences, sociocultural elements, and contextual factors that influence clinical pain syndromes, by including participants with chronic pain or other comorbidities. In a recent review of emerging trends in pediatric and adolescent pain research, Wilson and colleagues discussed studies focused on aspects of conditioned pain modulation, temporal summation, neurophysiologic measures, condition-specific protocols, and psychological factors. They then turned an eye to future research, specifically on those at risk for or presenting with chronic pain problems.[30] They bring up ethical issues, as described below, regarding the cold pressor test. However, these considerations would be relevant for other methods of inducing pain in the laboratory with minors and adult volunteers.

von Baeyer and colleagues defined some key elements to pursuing this cold pressor research in children.[29] They posited that while generally one should avoid inflicting pain on children, there may be a great deal to be learned about pain processing by conducting such studies. Ethical concerns with minors as well as adults may be addressed if the paradigm (1) is demonstrated to be a valid means of gaining the needed information, (2) is the only means by which the information could be obtained, (3) involves no tissue damage or significant psychological distress, and (4) uses the least possible amount of stimulation to answer the study question. Risk may be minimized by providing participants control over the situation, such as discontinuing participation and controlling the stimulus to have it withdrawn to minimize exposure to high levels of discomfort. They then go on to provide specific methodologic recommendations to minimize risk.[29]

Birnie et al. examined Although this paper was specifically focused on children,these same ethical and methodological considerations may be applied to adults as well. ethical concerns and acceptability of the cold pressor paradigm from the perspective of researchers, parents, and children.[24] Using a survey of research professionals and questionnaires directed to children who participated in cold pressor studies and their parents, the authors found that for most such studies, full IRB processes were required. In these studies, adverse events are extremely rare, and overall experiences by all were positive. Thus with mindfulness of risk and appropriate safeguards in place, ethical concerns about laboratory -induced pain in children may be addressed.

Clinical Trials in Minors

The traditional analgesic trial for acute pain is a double-blind, randomized, placebo-controlled trial. A relatively straightforward pain model, such as third molar extraction or bunionectomy post-procedure pain, is used to test a drug against a placebo, typically relying on pain intensity scores as the dependent variable. Thus individuals agree to participate for the benefit of payment, recognizing that there may be a period of under- or untreated pain before they receive rescue. However, it is unethical to seek such consent from a minor as they are deemed incapable of conducting such a risk-benefit analysis for themselves.[31] Several organizations have weighed in to protect the rights of children participating in such clinical trials.[32]

Few drugs are adequately studied and labeled for use in children. Prior to recent innovation, only about 20% of drugs that were approved by the United States Food and Drug Administration (FDA) included labeling for pediatric use.[33] Therefore pediatric providers have had to face an unfortunate choice with regard to treating pain: They either prescribe a drug "off label" with inadequate data on safety and efficacy or leave pain untreated, causing significant suffering and potential for long-term deleterious effects. Through federal legislation that incentivized (Best Pharmaceuticals for Children's Act; BPCA) or required (Pediatric Research Equity Act; PREA) pediatric drug trials, the situation has improved over the past two decades. As of March 2020, 791 new pediatric studies resulted in various labeling changes, either supporting or not supporting specific medication use in pediatric age groups.[34] However, only six moieties were shown to be safe and effective, specifically for pain indications in children under age 11 years.

Given the changing landscape of pediatric research, the FDA convened an expert panel in 2009 to address the methodologic and ethical concerns inherent to pursuing analgesic trials in children

and to give explicit consideration to the practice of extrapolating from adult trials to predict drug efficacy in children.[35] Using the "not greater than minimal risk" standard described above, it was clear that it would be unethical to enroll infants and children in placebo-controlled trials, as there was the potential for them to experience un- or under-treated pain. The panel discussed other methodologies, especially immediate rescue paradigms, where nurses or parents provided analgesia, and the principal outcome is shifted from pain scores to analgesic usage. Similarly, rather than relying only on placebo-controlled trials, non-inferiority trials using various analgesic medications have shown validity.[36]

Studying pain and analgesia in neonates is particularly challenging. Until the mid-1980s, many believed that newborns—especially premature newborns—did not experience significant pain, and if they did, it would have no lasting effects. With this mindset, there was no need for analgesic trials. However, research has shown that even the youngest premature infants demonstrate hormonal and metabolic changes in response to nociception, and there are significant short and long term sequelae of pain experiences in this age group.[37] Fortunately, perspectives on the need for analgesic trials involving neonates and infants have begun to shift, and various issues for consideration and methods to conduct such research have been espoused.[38]

The use of control groups in studies of infants remains an outstanding issue. As the field recognized that infants experience pain and that methods to relieve pain exist, questions arose about whether it is ethical to include a "no treatment" condition in a neonatal study when evidence of effective treatments was available.[39] Pain researchers should know enough about the field to recognize the unacceptability of exposing an infant to untreated pain. However, evidence indicates that this concern has not been shared universally among the research community; a review published in 2016 found that in clinical trials of analgesics for painful procedures, 64 percent of babies in the control groups received either placebo or no treatment.[40] Regardless of whether researchers are from within or outside of the pain medicine field, outdated local standards of care should not be tolerated as a control group for studies of pain in children, as those standards are often inadequate.[41]

As children mature, they develop the capacity to understand medical information and become increasingly able to provide meaningful assent or dissent for medical interventions and research. The United States Code of Federal Regulations defines assent as "a child's affirmative agreement to participate in research. Mere failure to object should not, absent affirmative agreement, be construed as assent." Each potentially approvable category of research involving children includes the stipulation that "adequate provisions are made for soliciting the assent of the children and permission of their parents or guardians." Precisely when and how investigators should seek assent, however, remains vague.

Sterling and Walco have discussed the complicated interactions of child development and notions of what is necessary for valid consent/assent, and they question the soundness of stipulations in the federal guidelines that suggest that some research may be deemed so important that child dissent may be ignored.[42] They argue that investigators and IRBs must take responsibility for a customized approach to assent for the children who may become research participants. They also call for a formal study to establish the elements that define assent, as has been defined for informed consent, and empirical investigations of how best to address these elements in children of various ages and developmental stages.

Ethical Issues in Genomic Approaches to Understanding Pain

As is the case in so many areas of medicine, genomics research has the potential to improve our understanding of certain pain conditions. Many genes have been identified that have a role in the experience of pain and its treatment, such as genes responsible for neurotransmitter signaling, drug metabolism, and pain perception and modulation.[43]

However, with this potential come additional ethical concerns. Inherent to genome sequencing is the generation of large amounts of data for which researchers need to have a specific plan for protection and usage. Tissue samples and genomic information may be saved in a central repository for subsequent study. Researchers are obligated to ensure the data are secure, given the highly sensitive nature of genomic data and potential for re-identifying individuals through their genetic information. Several provocative questions emerge when considering genomic studies: What (if any) results will be returned to the research participant? Will researchers report only on the genomic region of interest for the study, or will they report more broadly? What will be the plan for disclosing pathologic genes or mutations found incidentally? What if the findings have implications for family members? For these questions, eliciting the participants' and families' preferences in advance of sample collection is crucial. Clearly, not all participants are comfortable with biobanking or broad data sharing. For a more detailed discussion of ethical issues arising in pediatric genomic research, see Rotz and Kodish.[44]

A major focus of the 2018 revisions to the United States CFR "Common Rule" was the handling of consent for genomic research. The common rule allows for "broad consent," in which a participant provides prospective consent for the unspecified future use of identifiable biospecimens and private data.

Last, equity and inclusion are important considerations when banking specimens and genomic information. Is there over-or under-representations of particular ethnic groups? What harms could come from the use of these data in the future? A helpful framework when considering genomic research involving minority communities has been presented by Claw et al. previously.[45] Moreover, all of these questions are of great significance, and the field is progressing so rapidly that new ethical challenges continue to emerge before we have clarity on some of those already posed.

Conclusion

Researchers in the field of pain must adhere to the same ethical standards as any other medical researcher and attend to a series of elements unique to the study of pain. Participants with pain may be uniquely vulnerable. Trial designs need to be evaluated for the potential harm to both individuals and populations. As technology advances, new questions of what is "ethical" will continue to emerge. Our ultimate aim is to relieve suffering, and studies must be designed to answer the research question while exposing participants to as minimal discomfort as possible. While designing ethically sound research protocols takes careful consideration, investigations that have been conducted with the help of voluntary participants, that have employed fair selection processes, and that have respected the wellbeing of participants will produce valid results and promote trust in the scientific enterprise.

Key Points

- Essential principles of research ethics include respect for persons, beneficence, and justice. In addition, research methods must be valid and produce results of scientific value to justify the risks to which research participants are exposed.
- Ethical challenges particular to research in the field of pain medicine include:
  - Pain may compromise participants' ability to act autonomously.
  - Potential participants' willingness to volunteer may be compromised by situations in which their healthcare provider is also a study investigator or if participants' actual or perceived access to health care and pain relief is contingent upon study participation.
  - Unique risks of participation in analgesic trials include uncontrolled pain during the trial (especially if assigned to a placebo arm), uncontrolled pain when coming off of study medications, and the development of tolerance and the experience of withdrawal, for certain classes of medications.
- There are ethical arguments for and against the use of placebos in pain research. Placebo designs can minimize bias, provide a standard against which treatment efficacy can be measured, and establish conditions for distinguishing adverse treatment drug effects from effects of underlying disease; these features are consistent with the principle of scientific validity. However, the use of placebos may violate principles of beneficence and justice when the research involves participants with compromised autonomy or is conducted in an area for which a broadly available and efficacious standard of care already exists.
- Studies involving laboratory-induced pain must attend to the following issues:
  - The study design and participant population must ensure external validity and generalizability of the results.
  - The study's methods must be a valid and necessary means of gaining the needed information.
  - The process of inducing pain must not cause tissue damage or significant psychological distress.
  - The least possible amount of stimulation should be used to answer the study question.
- Although it is widely understood that infants experience pain, and there is much to be learned about the safest and most effective ways of providing comfort and analgesia in this population, studies continue to appear in the literature that have not adequately provided rescue analgesia or comfort measures for infants in placebo or control groups.
- Genomic approaches to the study of pain introduce several ethical concerns surrounding the immense amount of data that can be generated, the potential to re-identify participants based upon genomic information, and the implications that population-level genomic information can have on cultural narratives, biases, and access to healthcare services.

Treatment Development: Directions and Areas in Need of Investigation

STEVEN P. COHEN, NEBOJSA NICK KNEZEVIC, DAVID A. WILLIAMS, CHRISTOPHER L. WU

Introduction

Over the past decades, numerous advances have been made in pain medicine. Despite these advances, there are many gaps in our knowledge of the treatments currently available. We describe potential areas for investigation, including perioperative pain management, pharmacologic, interventional, and non-interventional chronic pain management.

Perioperative Pain Management

Significant progress in the management of perioperative pain has been made over the past two decades. Increased awareness of the treatment of postoperative pain, improved analgesic techniques, and new analgesic agents have contributed to improvements in its management. Despite these advances, many challenges remain to improve the quality of pain control.

Enhanced Recovery Pathways

Enhanced recovery programs (ERPs) for surgical patients may reduce variation in care and improve perioperative outcomes through the development and implementation of standardized, evidence-based perioperative pathways.[1,2] Multimodal analgesia incorporating primarily non-opioid agents and techniques (e.g. regional anesthesia/analgesia, nonsteroidal anti-inflammatory agents, acetaminophen, gabapentinoids, and local anesthetics) to minimize perioperative opioid use and side effects is a central tenet of ERP programs.[3] Although initial ERP programs focused on colorectal surgery, they have been increasingly adopted for a broad range of complex surgical procedures. The available literature indicates that implementing ERP pathways will result in decreases in hospital length of stay (LOS)/costs and perioperative morbidity, including lower risk of pulmonary, infectious, and gastrointestinal complications.[4–6] ERPs have received increased interest in the United States over the past decade, in part because of the increased emphasis by payers on quality-based reimbursement and bundled payments.

As ERP programs become a more routine part of surgical care, several areas require further investigation. For example, the optimal analgesic combination for ERP programs is uncertain. There has been increased scrutiny regarding the use of analgesics commonly used in most ERP pathways. Gabapentinoids are an integral part of most multimodal analgesic regimens postoperatively, and when administered as a single dose preoperatively, they have been shown to decrease pain and nausea/vomiting. However, recent literature raises concerns about the efficacy and perioperative respiratory depressant effects of gabapentinoids.[7,8] The United States Food & Drug Administration (FDA) officially released new warnings for gabapentinoids regarding the risk of respiratory depression.[9] However, the precise role of gabapentinoids in perioperative multimodal analgesia needs to be elucidated.

The use of regional anesthesia/analgesic techniques is an integral part of most ERP pathways because the benefits of its use (minimization of opioids, superior analgesia) facilitate the ERP goals of promoting earlier patient recovery. However, there is a paucity of literature examining the precise contributions of regional anesthesia/analgesia (vs. none) within the context of an ERP pathway.

Increased compliance with process measures directly influenced by the anesthesiologists, including the use of multimodal analgesia, and in conjunction with a formal anesthesia protocol, such as an ERP pathway, is associated with reduced LOS. In one study, patients who received high compliance (vs. low compliance) in ERP pathways had a significantly lower LOS, and multivariable regression indicated that utilization of multimodal analgesia and strict adherence to a postoperative opioid administration protocol for breakthrough pain were independently associated with reduced LOS.[4]

Although the use of ERP pathways can minimize postoperative opioid use, perioperative opioid minimization does not routinely translate into decreased prescriptions for opioids upon discharge. For example, in one study, implementation of an ERP colorectal pathway did not result in significantly lower opioid prescriptions at discharge even though these patients had a combination of low discharge pain scores, no preoperative opioid use, and low morphine milligram equivalent consumption before discharge.[10] Further studies are needed to determine how to modify opioid prescription practices on discharge after surgery in an attempt to continue opioid minimization after hospital discharge.

Chronic Post-surgical Pain

Chronic post-surgical pain (CPSP) is a potentially debilitating postoperative complication that may have a significant impact on activities of daily living and decrease the quality of life in adults[11]

and pediatric surgical patients.[12] Large observational trials suggest that CPSP may occur in 10% of patients postoperatively and may be severe in 1 of 100 patients.[13,14] A neuropathic component that predicts more severe CPSP is present in a significant portion of patients with CPSP as a systematic review of CPSP noted the presence in 6% of patients after total hip/knee arthroplasty and 68% of patients after thoracic and breast surgeries.[15]

There are many risk factors for the development of CPSP. Preoperative pain and psychological vulnerability (i.e. anxiety and catastrophizing) are two of the most important preoperative risk factors for the development of CPSP.[14] Intraoperatively, surgical technique has also been shown to be an important risk factor for the development of CPSP, primarily because of intraoperative nerve damage.[16] In addition, the intensity of acute pain postoperatively has been shown to be associated with the development of CPSP.[14] Although these risk factors are strongly associated with the development of CPSP, there is no causal relationship between any individual risk factor and the development of CPSP, such that decreasing/attenuating the severity of risk factors would automatically result in a decrease in the incidence or severity of CPSP.

Although we have improved our understanding of CPSP over the past decades, we still lack solid evidence for the prevention and treatment of CPSP in part because many studies have significant methodologic issues.[17] Well-designed prospective trials for various modalities for the prevention and treatment of CPSP are needed as most available studies on CPSP are based on retrospective observational data. Moreover, meta-analyses of treatment modalities for either the prevention or treatment of CPSP rarely have sufficient meaningful data to perform a subgroup analysis for individual CPSP syndromes. One interesting future area of investigation is the trajectory of acute postoperative pain (i.e. the slope or resolution of pain) that may be important in predicting the development of CPSP.[14,18]

Treatment strategies for CPSP can be grouped into pre-, intra-, and postoperative interventions. These strategies are described below.

Preoperative Considerations

Preoperative Opioid Optimization

The incidence of chronic opioid use by patients prior to surgery has been estimated to be approximately 9%.[19,20] The presence of opioid use prior to surgery has been associated with worse economic outcomes, including longer length of hospital stay, increased incidence of hospital readmission, increased financial costs, and lower incidence of return to work.[20,21] In addition, observational studies suggest that the preoperative use of opioids is correlated with an increase in postoperative patient mortality and morbidity, including higher surgical site infection rates, higher rates of reoperations, constipation, neurologic complications, acute renal failure, venous thromboembolism, and subsequent opioid abuse.[22–24]

There is relatively little high quality data in preoperative opioid optimization despite the increased interest in weaning opioids prior to surgery. Future studies should attempt to confirm the correlation between preoperative opioid use and increased perioperative mortality and morbidity. In addition, substantially more data are needed to determine whether decreasing preoperative opioid use will lead to a decrease in perioperative mortality, morbidity, and other outcomes, including length of hospital stay and incidence of hospital readmission. Finally, investigators should attempt to determine the threshold at which any potential benefits may occur (i.e. what percentage decrease in preoperative opioid use is needed to affect postoperative outcomes).

Intraoperative Considerations

Analgesia in Patients With Obstructive Sleep Apnea

Surgical patients with obstructive sleep apnea (OSA) pose significant challenges in the management of postoperative pain. This issue is complicated by the fact that a large percentage of patients with OSA (e.g. 26% of adults in the United States) are not diagnosed at the time of surgery.[25] Unrecognized severe OSA has been associated with an increased risk of postoperative mortality and morbidity, including an increase in 30-day postoperative cardiovascular complications.[26]

Although the standard tool to diagnose OSA is polysomnography (i.e. sleep study), it may not be completed prior to surgery or even feasible for large numbers of patients. The STOP-Bang questionnaire was specifically developed to meet the need for a reliable and easy-to-use screening tool for OSA.[27] The STOP-Bang consists of eight dichotomous (yes/no) items related to the clinical features of sleep apnea, and patients can be classified for OSA risk based on their scores. Published guidelines recommend minimizing opioids and sedatives postoperatively for the perioperative management of patients with OSA.[26]

Intraoperatively, the use of regional rather than general anesthesia is associated with a reduced incidence of major perioperative complications such as the need for mechanical ventilation, reintubation, and pulmonary/cardiac complications.[28] Postoperatively, the use of regional analgesic techniques with only a local anesthetic-based regimen (when possible) and multimodal analgesia is preferred as a study in which OSA patients who received more than two additional non-opioid analgesia modes showed significantly lower odds of gastrointestinal complications, need for mechanical ventilation, and critical care admission.[29]

Well-designed and well-executed prospective randomized controlled trials (RCTs) would help determine the optimal postoperative and post-discharge analgesic regimen for OSA patients. Although non-opioid analgesics are recommended for patients with OSA, some non-opioid analgesics are associated with sedation, which may not be ideal for OSA patients. A study on the acute effects of gabapentin on sleep breathing in older men noted that gabapentin worsened sleep breathing acutely compared with placebo.[30] Finally, the "safety" of undertaking surgical procedures in an outpatient setting for those patients needs to be explored further. However, more recent data support the notion that moderate-risk, high-risk, or diagnosed OSA can safely undergo outpatient and advanced ambulatory surgery without extended stay or hospital admission and avoiding adverse postoperative outcomes.[31]

Pharmacologic Chronic Pain Management

Pharmacologic treatment of chronic pain starts with the use of acetaminophen and/or nonsteroidal anti-inflammatory drugs (NSAIDs). However, other drugs, such as tricyclic anti-depressants or anti-convulsants, are usually added in case of an associated neuropathic or nociplastic component. Opioids have been over-utilized in chronic non-cancer pain patients in the last few decades, which has contributed to the opioid epidemic and a significant increase in opioid addiction in this patient population.[32] However, opioids are still considered the most effective analgesic for patients with cancer pain.[33]

Acetaminophen

Acetaminophen (paracetamol) was considered as the "analgesic of first choice" for many years, even though it is viewed as a weak analgesic.[33] Besides its well-known hepatotoxicity with higher doses, cardiovascular (CV) and gastrointestinal (GI) effects have also been noted.[34] Acetaminophen has not been shown to be superior to NSAIDs in the treatment of post-surgical pain[35] or for the treatment of hip and knee osteoarthritis (OA).[36] It was less effective than celecoxib (a selective COX-2 inhibitor) for the treatment of chronic low back pain (CLBP).[37] In the United Kingdom, recent National Institute for Health and Care Excellence (NICE) guidelines do not recommend the use of acetaminophen for patients with LBP. Several ongoing clinical trials are testing the efficacy of acetaminophen compared to opioids for various forms of acute, chronic, and postoperative pain. There have also been investigations into different formulations combining an opioid pain reliever with acetaminophen (i.e. Percocet). One such study (NCT03088826 on clinicaltrials.gov) hypothesized that Percocet containing morphine immediate release (MSIR) would provide greater analgesic efficacy than Percocet containing oxycodone at 30 min and 1 h after administration for acute painful conditions. Research is needed to determine the optimal role of intravenous versus oral acetaminophen in perioperative analgesia and oral acetaminophen combinations with other analgesics for long-term pain management.

Nonsteroidal Anti-inflammatory Drugs

NSAIDs represent a large and invaluable group of therapeutic agents used in pain management and are the first choice medications for inflammatory pain, as well as postoperative pain, traumatic pain, osteoarthritis, and rheumatic disorders. A cross-sectional study assessing the prevalence of NSAIDs reported a growing prescription trend, particularly in patients older than 60 years, female sex, and those with underlying heart conditions. However, long-term use of NSAIDs is not recommended because of serious adverse effects (AEs).[38]

The concept behind selective COX-1 and COX-2 inhibitors is not absolute, and at high doses, numerous NSAIDs antagonize both COX isoenzymes, although caution is required when using NSAIDs because of potential AEs, including CV side effects.[39–42] A newer form of ketoprofen (L-Lysine salt) showed gastro-protective effects.[43] The use of NSAIDs has been associated with GI inflammation, bleeding, ulceration, and/or perforation (impaired prostaglandin-mediated mucosal protection with COX-1 inhibition) as well as increased thromboembolic risk, myocardial infarction (MI), and stroke (increased thromboxane/prostacyclin ratio because of COX-2 inhibition).[44] The statements about the CV side-effect profile of NSAIDs were further reinforced by the FDA in 2015,[45] and even individuals without underlying heart conditions or related risk factors are susceptible to heart attacks and strokes with the use of NSAIDs.

The important decision of whether to use COX-2 selective (c2s) or nonselective (ns) NSAIDs in pain management must be made after first estimating the patient's odds of developing GI and CV AEs. This was explored by two RCT trials (PRECISION and CONCERN studies) and a meta-analysis.[46] In comparison to naproxen and ibuprofen (ns NSAIDs), celecoxib (c2s) had a comparable CV safety profile and was advantageous with respect to GI and renal AEs (PRECISION study). Similarly, in the high-risk GI population, celecoxib was found to be superior to a combination of naproxen and proton pump inhibitors (CONCERN study). Ongoing clinical trials are investigating the effect of NSAIDs use on opioid consumption. Another phase four clinical trial is currently attempting to optimize NSAID use by determining whether naproxen taken twice daily before the start of menses has a better effect on dysmenorrhea and bladder pain than naproxen taken on the first three days of menses (NCT03697720 on clinicaltrials.gov). Studies are needed to determine the incidence of CV and bleeding AE for the short-term use of NSAIDs during the perioperative period.

Opioids

A recent systematic review and meta-analysis showed a statistically significant, but small, improvement in physical functioning and pain but with a much greater risk of side effects when opioids were compared to placebo and similar benefits of non-opioid alternatives used in different types of chronic pain (neuropathic, nociceptive, central sensitization, or mixed types of pain).[47]

Opioids cause many AEs such as vomiting, constipation, drowsiness, nausea, and dry mouth in addition to misuse. The FDA has been mandating and encouraging the development of new "druggable" molecules to decrease the current opioid crisis. A potential pharmacologic approach could be evaluated in the future using tissue-targeted selective opioids. It was found that μ opioid receptors displayed pH-sensitive binding. Therefore the activity of its agonist NFEPP ([{±}-N-{3-fluoro-1-phenethylpiperidin-4-y1}-N-phenylpropionamide]) is achieved in an acidic environment, which is expressed in inflamed tissue and can be limited to peripheral action only.[48]

Tramadol and Tapentadol

Besides their μ opioid receptor agonist activity, these drugs are also norepinephrine (tramadol and tapentadol) and serotonin (tramadol) reuptake inhibitors. Tapentadol has minimal effects on serotonin. With this dual pain management approach, practitioners can go "half" up the "ladder" and still achieve substantial pain control very early in the pain development process.[49] Tramadol provides relief of moderate to severe pain, such as LBP, OA, soft tissue surgeries, and total hip arthroplasty surgery. Physical function and social wellbeing were sufficiently improved when tramadol was used to control pain in patients with postherpetic neuralgia (PHN) and painful diabetic neuropathy (PDN).[50,51] Several studies evaluating tramadol, tramadol/acetaminophen, and tapentadol deemed them superior to placebo[52] or an active compound, such as oxycodone, pregabalin, codeine/acetaminophen, or NSAIDs, in people with CLBP.[53,54] They expressed low to moderate AEs such as dizziness, nausea and vomiting, a low incidence of GI bleeding, and lower AEs such as dizziness, nausea, vomiting, low incidence of GI bleeding, and lower withdrawal rate compared with morphine or fentanyl. Multimodal analgesic combinations provide complementary and synergistic mechanisms of action and are promising avenues for pain relief. For instance, there is ongoing research into the use of fixed-dose combinations of weak opioids such as tramadol with NSAIDs such as diclofenac. This particular combination has shown a safe, effective, and to be well tolerated.[55]

Anti-depressants (Tricyclic Anti-depressant, Selective Serotonin Reuptake Inhibitor, and Serotonin and Norepinephrine Reuptake Inhibitor)

Tricyclic anti-depressants (TCA) have been used for a long time in the treatment of neuropathic pain conditions (PDN, PHN, painful polyneuropathy, post-mastectomy pain, post-stroke central

neuropathic pain).[56] TCAs express analgesic effects in much lower doses than the ones used for depression management.[57,58] Besides inhibiting the reuptake of norepinephrine and serotonin, TCAs can have significant AEs when they interact with histamine, cholinergic receptors, and cause blockade of ion channels.[59] Duloxetine, a selective serotonin and norepinephrine reuptake inhibitor (SNRI), is approved by the FDA for the treatment of PDN, fibromyalgia (FM), and chronic musculoskeletal pain.[60] Patients with CLBP and neuropathic components had better outcomes when receiving duloxetine than placebo and with a similar AE rate.[61] Milnacipran (SNRI) was approved by the FDA for FM associated pain.[62] The two selective serotonin reuptake inhibitors, fluoxetine and paroxetine, have been shown to alleviate pain and improve the quality of life better than placebo in patients with FM.[63,64] Both duloxetine and paroxetine improved quality of life and reduced pain intensity in patients with PDN.[65,66] TCAs, such as amitriptyline, are routinely administered as co-analgesics in pain management. However, they only provide relief for approximately one in three patients. Clinical trials of genetic determinants of anti-depressant efficacy for pain treatment (such as NCT02256943 on clinicaltrial.gov) hypothesize that more knowledge on how cytochrome variants influence experimental pain and side effects will help better predict the response of patients.[67]

Anti-convulsants

Carbamazepine acts by decreasing the excitability of A-δ and C neuronal fibers through the stabilization of voltage-gated sodium channels. The FDA approved it for neuropathy treatment in patients with trigeminal neuralgia but not in other neuropathic disorders.[68] Dizziness, somnolence, and altered gait are the most commonly reported AEs with Stevens-Johnson syndrome, blood dyscrasias, and toxic epidermal necrolysis noted as serious AEs.[69] A decrease in neurotransmitter release by calcium influx modification can be achieved by gabapentin, thus regulating neuropathic pain safely. A crossover study found that gabapentin was associated with mild effects on pain but with significant reversal of sensory loss in patients with complex regional pain syndrome (CRPS).[70]

Both gabapentin and pregabalin are effective for painful PDN, PHN, painful polyneuropathy, spinal cord-, and cancer-related pain. Some AEs were recorded with gabapentin use, such as dizziness, somnolence, and ataxia, which led researchers to the efforts of pregabalin development.[71] Pregabalin has been shown to exhibit a stronger analgesic potential and better effect on sleep and quality of life improvement compared to gabapentin in patients with PHN and PDN, while the nature of its AE profile remains open for further investigation.[72–74] In CLBP patients, pregabalin had similar efficacy as celecoxib. However, the combination of the two drugs was more effective than either monotherapy.[75] In patients with FM taking anti-depressants for concomitant depression, the use of pregabalin significantly improved their pain.[76] Despite the well-defined molecular targets of gabapentinoids, more research is needed into its mechanism of action, particularly in the brain. There is also a need for more studies to correlate patient responses with genetic, epigenetic, and phenotypic characteristics.[67]

Topical Treatments

Topical NSAIDs (diclofenac, ibuprofen, and ketoprofen) have been developed to decrease systemic administration and associated AEs and are widely studied and used. They provide short-term anti-inflammatory effects in addition to pain relief in chronic pain patients.[77] In a study assessing diclofenac sodium patch versus control patch in chronic myofascial pain of upper trapezius muscle, statistically significant pain relief was recorded.[78]

Lidocaine blocks the activity of sodium channels in peripheral neurons when used appropriately and does not result in significant plasma drug levels.[60] In patients with peripheral neuropathic conditions, topical lidocaine 5% patch was proven to decrease pain. However, it was no more effective than placebo in patients with CLBP.[79] For myofascial pain syndrome (MPS) patients, treatments with lidocaine 5% patch alone and in combination with 0.5% bupivacaine over one painful area were both superior over placebo.[80,81]

Topical capsaicin has been found to have stronger analgesic potential than placebo in patients with chronic non-specific LBP.[82] Either topical or spinal delivery of capsaicin or its analog (resiniferatoxin) can desensitize the TRPV-1 receptor, which leads to analgesia. This analog has been used in a cancer-induced dog model to achieve persistent anti-hyperalgesia.[83] As a TRPV-1 receptor activator, capsaicin at a topical high dose increases calcium influx, resulting in the disruption of neuronal fiber nociception. When a capsaicin patch was used in MPS, no significant pain reduction was noted over placebo or NSAID patches.[84] A high dose of capsaicin (8%) was found to be effective in providing pain relief for patients with PHN, sustainable for 12 weeks.[85]

In recent reports, treatment of CLBP with botulinum toxin type A (BoNT) showed superior pain relief compared to placebo.[86] Injections of BoNT exhibit their effects by inhibiting inflammatory mediators and neurotransmitter release, thus decreasing pain in PHN, trigeminal neuralgia, PDN, and intractable neuropathic pain condition.[87] Pain was found to be significantly decreased within a week after a single intradermal injection of BoNT-A in PHN patients, lasting for 12–16 weeks.[88] However a trial evaluating BoNT-A intradermal injection in patients with CRPS with allodynia found it be ineffective and poorly tolerated.[89] In general, BoNTs were proven as a good therapeutic approach for persistent pain states with long-lasting irreversible effects. Studies assessing the effects of BoNT on cervical MPS patients showed a positive outcome in pain reduction. However, when lumbar MPS efficacy over placebo was evaluated, negative findings were noted for BoNT application. The inconsistencies among BoNT studies come from poor study design.[90] In a study where a light chain of BoNT-A neurotoxin was conjugated with substance P, chronic pain patients were successfully treated for nociception upon intrathecal delivery.[91] Bupivacaine, a long-lasting local anesthetic, may be applied topically with the use of a film-forming spray, providing an easy and durable application.[92] More research into the efficacy of this delivery method would be of interest.

Monoclonal Antibodies

Monoclonal antibodies are derived from large B-cell glycoproteins, with long half-life immunoglobulin isotopes chosen to provide an extended pharmacologic response with less frequent applications. A recent review analyzed studies involving the use of monoclonal antibodies in chronic pain[93] and found that specific signaling pathways involved in peripheral neuronal inflammation (nerve growth factor [NGF], calcitonin gene-related peptide [CGRP], epidermal growth factor receptor [EGFR], tumor necrosis factor-alpha [TNFα], and ion channels) can be targeted by monoclonal antibodies in several chronic pain states such as migraine, neuropathic pain, OA, CLBP, and cancer pain. This type of therapy can cause mild AEs, but it is rarely prescribed because of high production costs. The pharmacokinetic properties, safety, and tolerability of many monoclonal antibodies are areas of interest for investigation.

Tanezumab is one of the most commonly used nerve growth factor inhibitors designed to modulate pain, stiffness, and physical function in chronic pain related to OA.[94] In general, anti-NGFs are well tolerated with mild AEs such as arthralgia, myalgia, headache, and burning sensations. In a study of CLBP patients, tanezumab was superior to placebo and naproxen sustained even in a long-term extension study.[95] Anti-CGRP monoclonal antibodies were first used in migraine-related pain conditions. However, they have recently shown potential in reducing somatic, inflammatory, and neuropathic pain as well. More severe AEs were noted in phase II clinical trials with monoclonal antibodies against CGRP, such as abdominal and back pain, fatigue, coronary vasoconstriction, and liver toxicity.[96]

Newer Pharmacologic Options

Cannabinoids

The use of cannabinoid compounds relies on the activation of CB1 (spinal neurons, dorsal root ganglia, brain, primary sensory nerves) and CB2 (spinal ganglia, microglia, monocytes, macrophages, B and T lymphocytes) receptors. CB1 receptor activation can reduce pain peripherally and centrally, while CB2 receptor activation decreases the release of inflammatory cell mediators.[97] CB1 receptor alterations are responsible for nociceptive processing when agents that block endogenous CB1 metabolism increase its concentration and activate receptor function. Spinal and peripheral sites of action have been identified in animal neuropathic pain models.[98] CBD receptor agonists modify the cytokine profile by blocking peripheral immune tissue receptors and could be a potential treatment for chronic pain diseases.[99] In the review by Fitzcharles, RCTs were assessed after exploring the efficacy, tolerability, and safety of cannabinoids in chronic pain from FM, back pain, OA, and rheumatoid arthritis.[101] Insufficient evidence was collected to recommend the use of cannabinoids in chronic pain management as the slight superiority of cannabinoids over placebo or amitriptyline was not sustainable. Nabilone (cannabinoid 1 agonist) was shown to improve pain and quality of life in patients with FM[102] and DPN.[103] Newer combinations of cannabinoid CB1μ opioid receptor agonists expressed strong anti-nociceptive effects in several experimental models.[104]

Many states have or are in the process of approving the use of cannabis for medical purposes. However, we still have a long way to go until cannabis is integrated into medical practice. It is difficult to derive the exact dosage for specific conditions while balancing the effectiveness and abuse potential.[100]

Nectar 181 (NKTR181) or Oxycodegol

This agent is a selective μ-opioid agonist. The results of a clinical trial found that NKTR-181 was a safe and effective alternative for patients with CLBP.[105] Despite its advantages, such as low blood–brain barrier permeability and lower abuse and addiction potential over oxycodone,[106] the FDA denied the approval of this drug in January 2020 because of potential misuse because snorting or injecting the drug would increase its rate of crossing the blood–brain barrier. The company has decided to withdraw the nondisclosure agreement for oxycodegol and to stop further program investments.[107] Nonetheless, selective μ opioid agonists remain a promising avenue for the development of analgesic drugs, and future research may be warranted.

Oliceridine (TRV130)

Oliceridine is a novel dual signaling molecule with opioid efficacy. However, it has better tolerability and greater safety than morphine.[108] TRV130 is called a biased ligand because it acts on GPCR μ receptors via G-α protein with weak effects on the β-arrestin pathway, thus producing analgesia with limited side effects such as respiratory depression.[109] In contrast to morphine, the specific nature of the dual pathway of oliceridine allows for comparable or better therapeutic efficacy and a more favorable risk-benefit ratio for moderate to severe acute pain following abdominoplasty.[110] After a denial from the FDA in November 2018, a new drug application was resubmitted in February 2020, and the fate of this pain treatment is yet unknown. Future research is needed to determine its potential role in pain management.

Kapa (kKOR) Opioid Family of Agonists

These agonists have peripherally restricted action, minimal abuse potential, and a low number of AEs, yet possess a significant pain control component which make them promising candidates for future.[111]

Bisphosphates

Bisphosphates (BPs) have been shown to be effective in the treatment of CRPS with improvements in both pain and quality of life when IV alendronate,[112] clodronate,[113] pamidronate,[114] or neridronate[115] were used over placebo. The mechanism of action of BPs in CRPS patients is not well characterized because their ability to reduce bone reabsorption by osteoclastic inhibition is not believed to be important in these patients. The evidence for the therapeutic efficacy of oral and intravenous BP formulations in CRPS is promising. However, there is an unmet need for large, well-conducted RCTs to validate these results.[116]

Immune Signaling

The anti-inflammatory cascade releases interleukin (IL)-4 and IL-10 cytokines, which play a significant role in several animal neuropathic models. IL-10 was effective in the management of chronic peripheral[117] and PDN models.[118] A double-blind, placebo-controlled trial showed that immune globulin intravenous (IGIV) resulted in significant pain reduction in patients with refractory CRPS.[119] Toll-like receptor (TLR-4) antagonists showed significant results relating to inflammatory mediators and neuropathic pain states, and prospective therapies could include spinal delivery of TLR antagonists (lipopolysaccharide-RS) for acute to chronic pain prevention.[120,121]

Lipid Mediators

Several lipid mediators have been found to have anti-hyperpathogenic and anti-inflammatory effects. For example, prostaglandins derived from omega-6 fatty acids have peripheral anti-inflammatory and central effects on spinal excitability.[122] Mediators derived from omega-3 long-chain fatty acids have been metabolized by soluble epoxide hydrolases in their signaling cascade. Therefore enzyme inhibitors have proven to have statistically significant anti-hyperpathic effects in preclinical studies.[123] One of the mediators of the self-healing properties of inflammatory pathways is endogenous proresolvins. In inflammatory and polyneuropathic

models, these molecules possess significant antihyperpathic.[124] Currently, at the preclinical stage of drug development, a newly discovered pro-resolving lipid mediator termed maresin 1 (MaR1) was found to relieve neuropathic pain via a novel mechanism for inhibiting pyroptosis.[125]

Sodium Channel Blockers

For many years, sodium channel blockers (mostly studied NA_V 1.7, 1.8, and 1.9 channel isoforms) have been used in trigeminal neuralgia treatment, specifically carbamazepine and oxcarbazepine. Oxcarbazepine was shown to be significantly better in pain reduction for patients with PDN than placebo.[126] BIIB074 is a relatively new, selective Na_v 1.7 antagonist, capable of inhibiting the firing of trigeminal neurons, with no serious AEs observed.[127] Studies on VX-150, a Na_v 1.8 inhibitor, in acute pain after bunionectomy (NCT03206749) showed promising results; studies on knee osteoarthritis (NCT026660424) and small fiber neuropathy (NCT03304522) have also been completed. Tetrodotoxin (TTX) is another sodium channel antagonist, isolated as a toxin from puffer fish, and has been shown to have long nerve blockade effects in animal and human studies.[128] The future directions of sodium channel blocking drug development will be on small bioavailable molecules as selective antagonists expressing only nociceptive properties.

N-Methyl-D-aspartate Antagonists

Since nociception in FM patients depends on excitatory glutamate activity on N-Methyl-D-aspartate (NMDA) receptors, the significance of NMDA antagonists in the management of this condition may be very useful. In FM and CRPS, ketamine is widely used as a non-competitive NMDA antagonist, in addition to acting on opioid muscarinic, GABA, and non-NMDA glutamate receptors. Ifenprodil is another NMDA inhibitor recently tested in clinical phase 1/2 studies for posttraumatic stress disorder (PTSD) pain.[129] Memantine and dextromethorphan are also used, but with great caution because of the side effects of dizziness, nausea, and sedation.[130] Ketamine[131] and memantine[132] both showed statistically significant differences in pain scores in FM patients, but only memantine was superior to the placebo group. In PHN treatment, topical ketamine was not effective for pain score reduction.[133] Evidence shows that ketamine may be an effective analgesic among select patient populations. Future studies would help determine the efficiency of ketamine among other populations, such as pediatric patients, and investigate alternative routes of administration.[134]

Calcium plays a significant role in cell homeostasis, and the largest groups of receptors within calcium channels are TRPV1 and TRPA1. Inflammatory, neuropathic, visceral, and cancer pain, as well as migraines, are highly dependent on TRP channel activity. This channel alone is associated with diabetes and cancer neuropathies, as well as chronic pain. Thus genetic or pharmacologic blockers have great potential to control these types of pain.[129]

Neurokinin

This type of therapeutic approach was developed to target the neurokinin (NK) receptor as part of the dorsal horn of the spinal cord and is involved in anti-nociceptive tolerance and opioid-induced hyperalgesia. Studies have shown that NK1 receptor inhibition leads to the control of hyperalgesia and conduction in chronic neuropathic pain cases.[135] Ongoing research is investigating the structure affinity/activity of hybrid peptides acting as opioid agonists and NK receptor antagonists. Future experiments, including conformational analyses and molecular docking studies, would promote drug development at this target.[136]

Gene Therapy

Gene expression can be modified by using viral vectors. A multicenter, dose-dependent, phase I clinical trial in patients with cancer showed that intradermal injection of intermediate and high doses of NP2 resulted in significant pain relief.[137] Adeno-associated virus vector transfection of genes that regulate voltage-gated potassium (Kv) channels can contribute to the relief of neuropathic pain.[138] Gene therapy by herpes simplex viral vector delivery of effectors to interleukin 4, 6, 10, or tumor necrosis factor-alpha (TNFα) can be used to decrease morphine intolerance and withdrawal symptoms. In animal models, intrathecal or viral, vector delivered interleukin 4/10 demonstrated efficacy in chronic neuropathic pain models.[139] TNFα inhibitor (infliximab) was discontinued in a double-blind, randomized, placebo-controlled CRPS study as it failed to improve impairment level scores and the overall outcome.[140] Overall, these types of treatments could be beneficial over multiple daily medication dosing regimens while being highly specific for the target. Such treatments would attenuate significant AEs of traditional pain relief methods. However, study designs must be carefully designed. One of the spinal function modifications could be achieved by intrathecal delivery of transfection systems where transcription factors are altered and protein synthesis is affected. The same could be achieved through intraganglionic injections, from which pathologic protein expression in pain patterns can be altered.[141,142]

Non-pharmacologic Chronic Pain Management

Interventional Pain Management

The past two decades have witnessed a dramatic rise in the number of interventional pain procedures performed,[143,144] which has led to increased scrutiny from payers, regulatory bodies, and the lay press. The reasons for the increased scrutiny include an absence of evidence for more procedures to reduce the prevalence of chronic pain or the rate of surgery, and the conflicting evidence, based on predominantly small, low-quality studies, to support their use.[145,146] In one review, the perspective of the provider(s) performing a randomized trial or an evidence-based review had a marked effect on the findings, with interventional pain providers being more likely to experience positive outcomes in clinical trials and reach positive conclusions in review articles, which suggests both the importance of patient selection and technique as well as the possibility of bias.[147]

Obstacles

There are numerous obstacles involved in performing placebo-controlled trials for pain interventions, including the ethical considerations of performing invasive sham procedures, recruitment, high costs to conduct interventional trials, lower return on investment for funding sources (unlike drugs, a company that sponsored a positive trial on intervention would not be the sole financial beneficiary), and unique issues surrounding patient selection and

technique.[148] For example, many patients with LBP have multiple pain generators that can be difficult to identify and isolate, with significant overlap between presentations. Regarding the procedures themselves, technical aspects can also affect the probability of success (e.g. transforaminal versus interlaminar epidural steroid injections [ESI], particulate versus non-particulate steroids, size and orientation of electrode for radiofrequency ablation, intra- versus extra-articular injections for sacroiliac joint blocks).[149,150]

Given the obstacles enumerated, there has been a paucity of placebo-controlled studies evaluating pain interventions, with most containing small numbers, short follow up periods, and serious methodologic shortcomings. For facet radiofrequency ablation and sacroiliac joint injection studies, the controlled trials with the largest numbers of patients enrolled 81 and 24 participants, respectively, with the sacroiliac joint study following patients for only one month.[151,152] This has led to questions about efficacy from payers and referral sources and, in some cases, has resulted in methodologically suspect comparative-effectiveness studies being misinterpreted as demonstrating a lack of efficacy.[153] For ESI, there is widespread agreement that the procedures are more effective than no treatment, but disagreement on the duration of benefit, the magnitude of effect, and even what constitutes a true placebo, as a systematic review found that epidural non-steroid injections afford greater benefit than non-epidural control injections.[154,155] Conventional spinal cord stimulation (SCS) is impossible to evaluate in placebo-controlled trials because of the inability to mask sensations, although high-frequency and burst stimulation are amenable to sham comparisons. However, to date, studies comparing verum to sham stimulation have all been characterized by small numbers (≤40 patients) and short follow up periods (<4 weeks).[156]

Comparative and Cost Effectiveness

Comparative and cost effectiveness studies are of increasing importance in the evaluation of high-cost, high-risk interventional pain procedures, particularly in those that need to be repeated, such as ESI and radiofrequency ablation. Cost effectiveness analyses have been performed for various chronic pain interventions,[157,158] but many are characterized by a lack of equipoise and unrealistic or speculative assumptions. Cost-utility analyses address the question of whether or not a procedure should be undertaken, which presupposes efficacy. Both cost effectiveness and cost-utility analyses are heavily contingent on factors such as whether interventions enable pain patients to work, reduce the need for surgery, and reduce the need for high-risk interventions such as chronic opioid therapy, which in turn reflects patient selection and myriad other factors.[159,160]

Comparative-effectiveness research involves the direct comparison of existing healthcare interventions to determine which works best for which patients and which poses the greatest benefits and harms. There are few high quality comparative-effectiveness studies for interventional pain treatments; one large, multicenter, randomized study found that ESI plus conservative therapy was superior to either ESI or conservative therapy as stand-alone treatments.[161] Many studies, particularly those on SCS, have included a treatment arm in which individuals receive conventional medical management that most have already failed.[162] An implicit form of bias in these studies is that they were recruited by physicians who provide the service(s) being compared to non-interventional therapies and are usually offered the opportunity to crossover to the intervention arm if they fail to derive benefits. In addition, multiple studies have shown that procedural interventions are associated with a higher placebo response rate than medications.[163,164] Given the growing number, utilization, and costs of procedural interventions and the accompanying scrutiny that has ensued, large-scale, prospective comparative and cost effectiveness studies are urgently needed.

Predictive Modeling

Identifying individuals likely to respond to pain treatments has been identified as a top priority by the National Institute of Health (NIH) Federal Pain Research Strategy Task Force.[165] Phenotyping, as it pertains to pain medicine, involves predicting treatment responses based on observable characteristics. Although factors such as technique can affect outcomes, patient selection is by far the most critical factor. In accordance with the biopsychosocial model of pain, factors that could affect interventional treatment outcomes might include the type and degree of pathology (e.g. individuals with a herniated disc respond better to ESI than those with spondylosis without nerve root compression), concomitant psychopathology (e.g. depression), concomitant medical conditions (e.g. sleep disorders, inflammatory arthritis), and social factors (e.g. job satisfaction and secondary gain).

Phenotyping has been advocated by the IMMPACT group in clinical trials,[166] but has not been widely used in clinical practice. One avenue by which this may be facilitated is the development of predictive models based on large-scale registries. For example, it is generally appreciated that individuals with axial low back pain, who are on opioids, with ongoing secondary gain, and who have failed multiple treatments may be less likely to respond to ESI and SCS, but quantifying the probability of success is nearly impossible. Genotyping is more commonly used to predict the response to analgesic medications (e.g. pharmacogenetics for opioids) and may also play a role in procedural interventions, especially those involving drug delivery (e.g. intrathecal delivery systems, ESI, and joint blocks). Identifying likely responders can profoundly impact the results of efficacy studies and cost effectiveness analyses.

Biomarkers

Pain is inherently subjective, and studies have generally demonstrated a poor correlation between imaging findings and pain perception.[167] The lack of any objective means to identify and quantify pain and to measure the response to treatment has led to widespread calls to explore the use of biomarkers, which may include diverse tools such as imaging (e.g. functional MRI and positron emission tomography), molecular (e.g. genomic, proteomic, metabolomic), psychophysical (e.g. conditioned pain modulation, quantitative sensory testing), and behavioral (e.g. facial expressions, fear-avoidance) indices. Biomarkers can be divided into various categories, including risk assessment, diagnostic, prognostic, predictive, and evaluative biomarkers. Discovering new biomarkers and evaluating existing candidates was identified as a key research priority by the NIH Federal Pain Research Strategy.[165]

Regenerative Medicine

Most of the leading causes of chronic pain, including spinal pain and arthralgia, result from degenerative processes that are a consequence of repetitive stress or acute traumatic events. Regenerative medicine involves the process of replacing, engineering, or regenerating human tissue to restore or establish normal functions. It can involve the use of autologous or homologous stem cells, platelet-rich plasma, and placental derivatives, among others. At the molecular level, regenerative medicine may involve stimulating the body's intrinsic repair

mechanisms and/or supplementing these pathways by using autologous or homologous biologic agents when the body is incapable of healing itself. The conceptual advantage of regenerative medicine is that it employs natural substances, thereby reducing the likelihood of adverse reactions, including infection, when autologous tissue is involved. However, regenerative medicine is not devoid of risks, depending on the cell source and location, including localized inflammation, immunologic rejection, and abnormal tissue growth, including tumor formation.[168] Widespread complaints of unsubstantiated claims of effectiveness, inappropriate use, and unanticipated complications led the FDA in November 2017 to issue a comprehensive policy framework to guide the development and oversight of regenerative medicine products. Areas ripe for investigation in this area include identifying patients and conditions most likely to benefit, optimizing treatment protocols (e.g. tissue types and cell numbers), and evaluating long-term effectiveness.

Non-interventional Chronic Pain Management

As we learn more about chronic pain being a perceptual phenomenon, we need to refocus our thinking away from pathologic tissues and onto aberrant perceptions originating in the brain.[169,170] How does one "fix" a perception, and what tools are needed? The answers to these questions represent gaps in our knowledge as well as opportunities for future research. There are likely to be at least three complex processes that can manifest as the perception of pain.[171,172] Each process appears to respond differentially to different classes of treatments,[173] yet currently, we lack efficient methods of detecting which processes and mechanisms are active within a given patient. One type of pain that we are learning a great deal about through large NIH-funded research networks such as the Orofacial Pain Prospective Evaluation and Risk Assessment study (OPPERA; NIDCR/NIH)[174] and the Multidisciplinary Approach to the Study of Pelvic Pain (MAPP; NIDDK/NIH)[175,176] is the concept of central sensitization. This mechanism is thought to be responsible for up to half of all chronic pain cases, which are labeled collectively as the "chronic overlapping pain conditions" (COPCs). Currently, there is a lack of standardized means of assessing COPCs in a given individual. The lack of such a classification tool has hampered the ability to study the overlap of these conditions in a large number of cases. Psychologically based therapies are likely to play increasingly important roles in pain management, as these types of interventions directly impact cognitive and affective neurocortical processes involved in pain perception.[177] However, a challenge to clinicians is how to make these psychological therapies available to patients at low cost and with little burden. Pain self-management, which uses many aspects of these psychological therapies, can be delivered to patients digitally, which is more convenient for patients and clinical practice. While going digital seems to be an attractive clinical option, it is still a young and emerging field with many pros and cons needing consideration before application. Symptom tracking is a component of self-management, and its role in self-management has recently expanded to facilitate shared decision making within the patient-provider dyad.

The use of symptom tracking in combination with digital technology facilitating N-of-1 study designs allows the patient and provider to directly compare the impact of two potential interventions on symptoms for a given patient. This technology brings us closer to personalized pain management.

The following sections provide more details about gaps and future considerations for identifying pain types, identifying COPCs, and using digital self-management approaches and about the future potential of using N-of-1 trials for personalized pain self-management.

The Value of Identifying Types of Pain and Underlying Processes

The International Association for the Study of Pain (IASP) has defined three types of pain.[171,172] The first is called nociceptive pain, which arises from the activation of nociceptors associated with actual or potential tissue damage. It can be inflammatory in nature and usually represents the mechanics of a functioning protective system for the organism. This form of pain is typically not associated with somatosensory nervous system dysfunction. The second type of pain is referred to as is neuropathic pain, which results from lesions to the somatosensory nervous system (either peripheral or central).[178] This form of pain is clearly associated with a dysfunction in the processing of pain. The final mechanism is type of pain is called nociplastic pain. This form of pain arises from functional changes in how the central nervous system processes nociceptive information.[171,178,179] Minimal nociceptive information is augmented by the central nervous system processes resulting in pain. This type of pain may also be thought to be a disordered process.

In any given individual, one or more pain types may be active to varying degrees. For example, it is possible for an individual with OA, a primary nociceptive pain condition, to have comorbid features of a nociplastic condition (e.g. FM) as well. In studies of OA hip and knee replacement, patients with features of nociplastic pain had a 20%–25% greater risk of failure and had greater opioid requirements for pain relief than those without nociplastic features.[180,181] Similar findings have been reported for medial branch blocks[182] and hysterectomy.[183] We also know that medications that tend to work well for nociceptive forms of pain (e.g. NSAIDs) may work less well in the context of nociplastic pain; the latter responds better to centrally acting compounds (e.g. gabapentinoids, NSRIs).[184]

Future clinical practice would ideally be able to match medications with underlying pain type(s). To conduct studies that match medications to pain types, we need better assessment tools to identify the active mechanisms within a given patient (i.e. biomarkers as discussed previously). High quality assessment of pain mechanisms can in part be accomplished using quantitative sensory testing (QST) and neuroimaging modalities.[185–198] While such approaches have revealed useful research about the composition of the various types of pain, these methods remain primarily impractical in the clinical setting. Ideally, QST could be engineered for delivery in the clinical environment, and valid patient-reported outcome measures for indexing neuroimaging findings could be validated for use in clinical settings. Efforts aligned with these suggestions are currently in progress in several studies in the United States and United Kingdom and represent an exciting future direction that could support broader and more efficient attempts to target treatments to the underlying mechanisms of pain.

The Value of Identifying the Chronic Overlapping Pain Conditions

Currently, it is estimated that 100 million individuals experience pain in the United States.[199] In Europe, the estimate is 150 million across 37 countries.[200] Of these, it is estimated that nearly half

may have one or more of the 10 conditions currently identified as COPCs.[201,202] COPCs are generally more prevalent in females than in males and consume billions of healthcare dollars annually.[201,202] The conditions comprising COPCs include, but should not be limited to, temporomandibular disorders (TMD), FM, irritable bowel syndrome (IBS), vulvodynia (VVD), myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS), interstitial cystitis/painful bladder syndrome (IC/PBS), endometriosis (ENDO), chronic tension-type headache (cTTH), migraine headache (MI), and non-specific CLBP.

Historically, most of these conditions have been studied as single conditions without considering their overlap with other conditions. Future research will explore common mechanisms across these conditions and study the degree of overlap among the conditions. Early studies exploring the degree of overlap in such conditions generally support the idea that with greater numbers of overlapping conditions, however the clinical course becomes more challenging.[203]

One barrier to studying COPCs is the lack of a simple method for assessing all 10 conditions within the same individual. It would not be clinically feasible to administer the diagnostic criteria for all 10 conditions to the same person. A potential solution to this problem has been to use ICD10 codes to develop computable phenotypes for each of the 10 conditions, followed by a search for overlapping diagnoses within administrative databases.[220] One study using this approach found that the top three COPCs were CLBP, MI, and IBS. The least common were VVD, ENDO, and urologic chronic pelvic pain syndrome (UCPPS). Some COPCs appeared to have a greater likelihood of comorbidity than others. FM, for example, showed a strong likelihood (odds ratio >5) of co-occurring with seven of the other conditions (e.g. IBS, UCPPS, CLBP, and MI). In contrast, cTTH had substantially lower odds ratios of co-occurring with any of the other COPCs. Still, they had greater odds of co-occurring with any COPC than with other medical conditions.[220] Future studies will want to explore why some conditions co-aggregate more than others and whether there may be temporal influences on when each condition emerges over time.

The Value of Understanding Central Sensitization

It has been suggested that the dominant underlying pain type for many chronic pain conditions (including COPCs) may be nociplastic and therefore would differ mechanistically as well as in treatment response from nociceptive or even neuropathic forms of chronic pain.[173,205–207] A key component of nociplastic pain is the concept of central sensitization. First described by Woolf[208,209] and later translated into clinical assessment criteria,[169] central sensitivity manifests with the following features: (1) pain not because of neuropathic pain; (2) pain not because of nociceptive or inflammatory processes; (3) pain following a widespread distribution (i.e. not localized); (4) the presence of sensory hypersensitivity (e.g. sensitivity to light, sounds, tastes, touch, odors), and (5) the presence of symptoms associated with increased "mental load" (e.g. problems with mood, sleep, cognition, and fatigue).

Sensory hypersensitivity is often assessed using QST and has been found to play a role in many of the COPCs (e.g. TMD,[210] MI,[211] ENDO, pelvic pain,[212,213] cLBP,[214] and FM[215]). "Mental load" can be associated with the concept of increased symptom burden or a diminished state of "wellness." A symptom cluster involving problems with sleep, pain, affect, cognition, and energy (SPACE; see Chapter 61 on self-management) has been identified as an indicator of unwellness in both animal and human models.[216–219] The assessment of each symptom within the SPACE symptom cluster can provide clinicians with a way to prioritize pharmacologic and non-pharmacologic treatment options. Targeting any one symptom within the cluster is likely to confer benefits to pain and overall "mental load" (e.g. treating sleep can help pain).[204] Future research will focus on assessing sensory hypersensitivity and symptom clusters conferring increased mental load. Such phenotypes are likely to inform both the course of treatment and serve as meaningful outcome endpoints for treatment improvement.

Digital Pain Management Resources

Digital pain management resources take many forms, including telephone-based coaching,[221] interactive voice response self-management (IVR),[222] digital devices combined with artificial intelligence,[223] digital versions of cognitive and behavioral self-management,[224–226] digital versions of acceptance and commitment therapy (ACT),[227,228] self-management on websites or for smartphones,[229,230] and virtual reality programs for pain control.[231] Digital pain management resources have the advantage of being available to patients 24/7, tend to be less costly than in-person office visits, and are more convenient as they do not require driving long distances to obtain care.[232] Given the current demands on time for office visits, digital pain management resources also help to broaden care beyond what can be offered in a relatively brief office visit.

Online pain management resources are plentiful and widely accessible, ranging from free to relatively costly subscription services. Recent work in this area has focused on key components of what should be included in such programs to make them effective.[232] Such components include techniques that enhance self-efficacy (e.g. relaxation, exercise, sleep hygiene), social support, monitoring (e.g. symptoms and behaviors), and a means of structuring the intervention such as goal setting, action planning, and shared decision making with a healthcare provider. The latter category, a means of structuring the interventions, is often missing from most digital programs, with the majority of online or smartphone programs offering a more limited set of resources (e.g. relaxation techniques or pain symptom monitoring). More challenging and more rarely encountered are programs that automate goal setting, problem solving, action planning, or shared decision making. In the 900 plus smartphone apps claiming to offer pain management, the majority included only a few of the easiest modules to digitize.[230] To enhance the effectiveness of digital pain management resources, it is important to include more of the components that have historically made traditional face-to-face interventions effective.

Another challenge facing digital pain management interventions is that most programs have been developed without any pain expertise,[233] and most programs available to the public have not been subjected to clinical trials.[230,233,234] The few programs that have been developed by pain experts and that have been studied clinically usually come from academia with grant funding rather than a sustainable business plan. Thus unfortunately, once the grant ends, support for the digital program expires. Most evidence-based digital self-management programs are not available to the public.[235] A challenge for the pain treatment community going forward will be to construct business models that support the development, testing, and sustainability of such resources.

Expanding the Value of Symptom Tracking: Personalized Medicine Using N-of-1 Trials

Informed clinicians try to apply evidence based medicine in their practice. The evidence often comes from large RCTs or even meta-analytic studies of multiple RCTs.[236] The problem with blanket recommendations from evidence based sources is that RCTs and meta-analytic studies aggregate large amounts of data to describe the outcomes for a statistically averaged individual. Thus an individual with the characteristics of the "average" patient in these large trials may not exist in the real world. As individuals deviate from this average because of clinical history, demographics, or other factors, their heterogeneity can diminish expected outcomes.[237] An alternative to clinical recommendations based on big data is the use of little data, or N-of-1 trials.[238]

Part of self-management is monitoring symptoms and behavioral changes over time (see Chapter 61, Patient Education and Self-Management). Such longitudinal monitoring has the advantage of revealing patterns in symptoms for the individual (e.g. pain tends to worsen on weekends compared to during the week, or fatigue is worse in the mornings compared to later in the day). Identification of such patterns provides data for the individual with which they can generate hypotheses about why the pattern exists and what can be done about it. Historically, there has not been any standardized approach to using symptom monitoring data, and patients were largely on their own to interpret and find benefits from the revealed patterns. Recently, symptom monitoring has been performed at the next level in terms of its potential utility. Patients can be their own scientists and discover what works best for them using a structured N-of-1 experimental design combined with symptom monitoring.

N-of-1 trials are single-patient crossover trials that can leverage the patient-provider relationship by studying whether two or more treatments work well in a given individual. N-of-1 trials can be conducted in "real world" settings and work best in chronic conditions such as pain and for treatments with rapid onset and washout (e.g. NSAIDs, massage, acupressure, meditation, exercise, sleep hygiene methods). Such trials benefit from the use of a smartphone app or wearable technology to capture daily ratings of symptoms and AEs and weekly adherence data. Patients also need to decide which symptom (or set of symptoms) is being targeted by the interventions (e.g. sleep, pain, mood).

The provider and patient work together to develop an N-of-1 trial design in which two treatments are selected and the order of treatment use is randomly determined (e.g. treatment A [two weeks], treatment B [two weeks], treatment A [two weeks], treatment B [two weeks]). After the trial is completed, the patient and provider evaluate which intervention had the best impact on the selected symptom(s) chosen as the outcome. Depending upon the results, the patient has proof of something working or knows which treatment options should be reconsidered.

"Trialist" is a smartphone app that facilitates N-of-1 trials.[239] Analytics of patient end-user experiences with N-of-1 methodology found that patients were generally enthusiastic about recording their information and accessing their own data. Despite highly informative reporting and graphing functionality, patients tended to prefer simpler/minimalist graphs of data. Providers, on the other hand, may find more complex data more informative. Patients also valued the ability of the data to provide insights into their condition of which they had forgotten or were unaware. The partnership between the patient and provider trying different options together and allowing patients to participate in informed decision making was also identified as a benefit of this approach.[240] The broader use of the N-of-1 methodology is a likely future direction for facilitating personalized pain self-management.

Exciting directions for future work include improving our ability to assess for the types of pain so as to improve our ability to match treatment to the hypothesized processes involved. One type of pain, nociplastic pain, is the newest classification and is thought to be driven by central sensitization. Central sensitization is a relatively new phenomenon in need of additional studies given its association with hyper-sensory sensitivity and symptom clusters that overlap with pain processing. Clinically, there has been an expansion of digital options for receiving pain care, but the quality of these offerings is often untested. While digital options typically offer specific skills, they often lack much of the goal setting and treatment planning that is essential to the provider-patient relationship. Future studies will aim to better integrate these elements of care into digital offerings. Personalized pain medicine represents a broad field in need of additional studies, much of which will involve non-interventional approaches.

Conclusions

Despite numerous advances in the investigation of pain medicine over the past decades, there are many gaps in our knowledge of treatments in the areas of perioperative pain management, pharmacologic, interventional, and non-interventional chronic pain management. In the area of perioperative pain management, the development of ERPs, elucidation of mechanisms, and effective treatment for CPSP are needed. In the area of pharmacologic chronic pain medicine, the development and role of newer analgesic agents need to be researched further. Additional studies using placebo-controlled trials for pain interventions and comparative/cost effectiveness studies are needed for interventional pain management, along with more research in predictive modeling, biomarkers, and regenerative medicine. Finally, in the area of non-interventional chronic pain, additional research is needed to identify COPCs and utilize digital pain management resources.

Key Points

- Advances in perioperative pain management will revolve around patient-centered outcomes and recovery (enhanced recovery after surgery).
- Optimization of perioperative opioid management is paramount.
- High quality placebo-controlled trials for interventional pain medicine are needed.
- The ability to identify underlying pain mechanisms will facilitate personalized pain medicine.
- COPCs likely share a common underlying mechanism of central sensitization.
- Studying how and why COPCs overlap will broaden our knowledge of central sensitization.
- Digital self-management resources can extend clinical practice but currently are limited in what components of self-management are offered and with variable quality.
- Shared decision making between patients and providers can be informed by the use of N-of-1 trials comparing two treatment options for an individual patient.
