Once a patient has failed medical and conservative management, it is reasonable to consider more invasive options. Epidural treatments for PMPH include the use of saline, colloids, fibrin glue, and blood. The gold standard treatment is EBP, which entails

injecting a small amount of autologous blood into the epidural space. EBP offers a promising and immediate resolution of symptoms in approximately 61%–98% of patients.[85] Contraindications to a blood patch are similar to those of any neuraxial procedure. The first contraindication was patient refusal. If a patient has religious concerns about blood transfusion, alternative patching materials can be offered. The coagulation status of the patient must be reviewed to minimize the risk of epidural hematoma. An EBP should not be performed on patients who are septic, āre bacteremic, or have a localized infection at the injection site to prevent the introduction of bacteria into the epidural space. It is safe to perform an EBP in patients who are HIV positive because HIV naturally crosses the blood–brain barrier; thus there is no increased risk of introduction centrally during the procedure.[86]

The technique of EBP was first described by Gormley in 1960 and is based on the placement of a single shot epidural.[85] The procedure typically requires two people: one to locate the epidural space and the other to draw the blood. Sterility is of utmost importance during both epidural placement and blood collection. The patient can either be supine or in the lateral decubitus position, depending on the patient's tolerance. It is wise to select a site that is caudal to the suspected dural tear since 15 cc of epidural blood will spread roughly six segments cephalad and three segments caudad.[87] Additionally, more caudal levels are associated with less cord compression. After EBP, the patient remained supine with his legs slightly elevated. Martin et al. found that 2 h in the supine position after EBP provided the patient with 100% relief versus 60% in a group that remained supine for only 30 min.[88]

The mechanism of action of EBP is not fully understood, but appears to be due to two separate mechanisms. The first and initial effects can occur within minutes and are likely due to compression of the dura toward the spinal cord and the reduction of intradural volume. MRI analysis of five patients following EBP placement showed large extradural collectures with an anterior displacement of the thecal sac and a mean spread of 4.6 vertebral spaces.[89] This epidural spread following an EBP is longitudinal and circumferential, helping to envelop the entire dural sac. The reduction in the intradural volume shifts the CSF more cephalad, re-suspending the brain, and reducing traction. In accordance with the Monro-Kellie rule, an increase in intracranial CSF helps to reduce cerebral vasodilation and intracranial blood volume.

While patients often report instant relief in their symptoms because of these effects, post-blood patch MRI studies have shown that these compressive mass effects disappear by 7 h after the procedure.[90] A second and more long-lasting effect is likely due to the sealing of the dural or arachnoid tear with a gelatinous plug, preventing further loss of CSF. The blood patch acts as a temporary plug until permanent repair of the meningeal puncture can occur. Failure of self-closure of the dural or arachnoid tear can result in EBP failure despite initial relief. Optic nerve sheet diameter (ONSD) is a surrogate marker of intracranial pressure and has been studied in patients undergoing EBP procedures. Dubost et al. found that the ONSD increased in patients who had a successful EBP but not in patients who had EBP failures.[91] This suggests that a sustained increase in intracranial pressure is associated with a successful EBP.

The ideal volume of blood to draw and inject during an EBP is ~20 mL, stopping on injection if the patient complains of back, buttocks, or neck pain. There appears to be no relation to the volume of blood injected and EBP success rate.[92] In a multinational, multicenter, randomized, blinded trial to determine the optimum volume of autologous blood for an EBP, 121 patients experiencing symptoms after an ADP were allocated to receive 15, 20, or 30 mL of blood.[93] Only 54% of patients in the 30 mL group were able to receive the entire volume because of pain on injection, while 81% in the 20 mL and 98% in the 15 mL group were able to tolerate receiving the allocated volume.[93] Interestingly, the 20 mL group had the highest incidence of permanent or partial relief, at 73%, while the 15 mL and 30 mL groups had an incidence of 61% and 67% relief, respectively.[93] This study confirms that 20 mL of autologous blood appears to be the optimal volume for placement of an EBP. Chen et al. found that 7.5 mL of autologous blood was comparable to 15 mL of blood in its analgesic effect but with less nerve root irritation during injection.[94] Further studies on optimal blood volume in the nonobstetric population are warranted.

Alternative patching materials include epidural fibrin glue and epidural dextran-40. Although these materials have been successfully employed, they are not widely used owing to their cost and safety concerns. Dextran-40 appears to be a safe alternative for Jehovah's Witnesses. Epidural saline blouses or infusions are ineffective alternatives and often result in more interventions with a lower success rate because saline is quickly absorbed from the epidural space. As a last resort, surgical repair of the dural tear may be considered and is typically reserved for severe cases of chronic PMPH that have failed management with an EBP.

The optimal timing of EBP remains controversial. Placement of EBP too early in PMPH symptomatology is thought to be associated with an increased risk of EBP failure. In a 13-year retrospective review of 129 patients, the success rate for permanent relief of PMPH from an EBP was 86% in patients receiving it 48 h after a neuraxial procedure, 65% in patients receiving it at 24–28 h, and only 50% in patients receiving it within 24 h.[95] This may be confounded because patients with worse symptoms and CSF leakage may require an EBP earlier, and subsequent patches may be necessary to help with closure of the dural puncture.

EBP is typically considered a safe treatment option. The most common side effects of EBP are low back and radicular pain because of an inflammatory response and nerve root compression, which tends to resolve spontaneously or with nonsteroidal anti-inflammatory drugs.[96] Rare but possible complications include epidural hematoma, infection, and arachnoiditis because of unintentional subdural or subarachnoid injection of the blood. Two cases of facial nerve paralysis following EBP have been reported, both of which resolved spontaneously.[97]

While EBP is considered the gold standard for the treatment of PMPH, sphenopalatine ganglion block (SPGB) has been suggested as a simple and minimally invasive alternative to an epidural blood patch. The mechanism of SPGB, which was first described in 1909, is thought to be related to cerebral vasoconstriction.[98] The sphenopalatine ganglion is a collection of parasympathetic fibers located bilaterally in each pterygopalatine fossa. With the loss of CSF, this ganglion is activated, releasing acetylcholine, nitric oxide, and vasoactive peptide, causing vasodilation of dural blood vessels.[98] Blocking these ganglions with intranasal lidocaine decreases nociceptor signaling and blocks cerebral dural vasodilation, relieving the PMPH.[99] The traditional approach to an SPGB involves introducing a cotton-tipped applicator soaked in a local anesthetic solution into the nares. The SPGB can be repeated at 20 min intervals, usually up to two times, if the resolution of headache symptoms is not achieved. In a 17-year retrospective chart review, more patients received relief from their headache symptoms at 30 min and 1 h in the SPGB group than in the EBP group with equal recovery at 24 h, 48 h, and one week.[99] Patients who received an EBP required more return visits

to the emergency department than the SPGB group.[99] A clinical trial comparing the use of saline versus lidocaine for an SPGB did not show any significant difference in pain intensity at 30 min, with similar pain reduction and avoidance in an EBP, suggesting that the major effect of the SPGB may not necessarily be because of the local anesthetic used.[100] SPGB appears to be a safe and useful alternative for patients who have contraindications or may be reluctant to undergo an EBP.

PMPH Summary

PMPH and its management are well-known and widely accepted entities in anesthesia entities. With better awareness of the risk factors related to PMPH, clinicians need to be vigilant when performing neuraxial techniques. Although nonfatal, it can cause significant morbidity and should be treated seriously. In the setting of a dural puncture or inadvertent puncture with pathognomonic symptoms, the diagnosis of PMPH is straightforward. Treatment should start with conservative therapy as the headache is generally self-limiting within 7–10 days. EBP is the gold standard and the most effective treatment modality for PMPH. Surgical repair may be required in patients with chronic PMPH. Newer treatment modalities are available, but high-level evidence supporting their efficacy is still needed.

SPONTANEOUS INTRACRANIAL HYPOTENSION

Dost Khan

SIH was initially described by Schaltenbrand in 1938 and is characterized by symptoms similar to dural puncture headache, but in the absence of dural puncture. The incidence is approximately five per 100,000 person-years. Women are affected twice as often as men, and the peak incidence is in the fourth or fifth decade of life.[101]

Clinical Symptoms of SIH

This syndrome is usually suspected in patients with postural headaches after a fall, trauma, whiplash, exercise, or violent coughing. Although classically postural, the headache can be nonpositional or even paradoxical (worse when lying down).[102] The headache can be gradual or thunderclap in onset and has also been described as exertional, intermittent, or mainly occurring at the end of the day. Headache results from the downward displacement of the brain from the loss of buoyancy with traction on pain-sensitive structures, including the dura. Another mechanism is the compensatory dilation of the pain-sensitive intracranial venous structures. Additional symptoms include neck pain, stiffness, nausea, vomiting, blurred vision, tinnitus, vertigo, and photophobia. Tinnitus is secondary to the transmission of the abnormal CSF pressure to the perilymph,[103] while vision and balance abnormalities are because of stretching of the optic and vestibulocochlear nerves. Cranial nerve (CN) palsies leading to ophthalmoplegia can involve the oculomotor (CN III), trochlear (CN IV), or abducens nerve (CN VI), with CN VI being the most commonly affected.[104] Hyperprolactinemia and galactorrhea can result from distortion of the pituitary stalk.[105] Symptoms referable to the spine include back pain and radiculopathy, presumably due to compression of the nerve roots or spinal cord by the leaked CSF. The International Classification of Headache Disorders has published diagnostic criteria for SIH (Table 39.4),[106] although some experts consider the criteria too restrictive.[107] The differential diagnoses of SIH include primary (new daily persistent headache) and secondary headache disorders. Secondary headaches to be considered are subarachnoid hemorrhage, subdural hematoma, carotid/vertebral artery dissection, cerebral venous sinus thrombosis, benign intracranial hypotension, posttraumatic headache, meningitis, and postural orthostatic tachycardia syndrome.[101]

TABLE 39.4 Diagnostic Criteria for Headache Attributed to Low Cerebrospinal Fluid (CSF) Pressure

A. Any headache fulfilling criterion C
B. Either or both of the following:
   a. Low cerebrospinal fluid (CSF) pressure (<60 mm CSF)
   b. Evidence of CSF leakage on imaging
C. Headache has developed in a temporal relation to low CSF pressure or CSF leakage or led to its discovery.
D. Not better accounted for by another ICHD-3 diagnosis.

Criterion C
Evidence of causation was demonstrated by at least two of the following: 1. Headache has developed in temporal relation to the onset of non-vascular intracranial disorder or has led to its discovery; 2. Either or both of the following: a) headache has significantly worsened in parallel with worsening of the non-vascular intracranial disorder, b) headache has significantly improved in parallel with the improvement in the non-vascular intracranial disorder; 3. Headache has characteristics typical of non-vascular intracranial disorder; 4. There is also evidence of causation.

From: Headache Classification Committee of the International Headache Society. The International Classification of Headache Disorders, third edition. *Cephalalgia.* 2018;38(1):1–211.

The most common cause of SIH is leakage of the CSF through an incompetent dura, either because of an overt dural tear, presence of a meningeal diverticulum, through dural defects along nerve root sleeves, or perineural cysts (Tarlov cysts). In an observational study of 568 patients with SIH, Schievink et al. classified the cause of spinal CSF leaks into four categories: Type 1 (dural tear) occurred in 26.6% of patients; Type 2 (meningeal diverticula) occurred in 42.3%; Type 3 (CSF-venous fistula) occurred in 2.5%; and Type 4 (indeterminate type) occurred in 28.7% of patients.[108] Secondary dural injuries have been reported because of vertebral osteophytic spurs[109,110] and herniated or calcified degenerative discs piercing the dura.[111] The onset of symptoms can be precipitated by a fall, trauma, or exercise. SIH appears to be associated with generalized connective tissue disorders, ascribed to compromised elastic fiber integrity and spatial disorganization of dural tissue, as seen in mouse models.[101,112,113] These include Marfan syndrome, Ehlers-Danlos syndrome type II, Loeys-Dietz syndrome, autosomal dominant polycystic kidney disease, isolated joint hypermobility, joint hypermobility with fascial thinning, and spontaneous retinal detachment.

Diagnosis of SIH

The diagnosis of SIH is suspected with low CSF pressure on diagnostic lumbar puncture and meningeal enhancement on MRI of the cranium. Diagnostic lumbar puncture usually shows a low CSF pressure (<60 mm H_2O; reference range, 65–195 mm H_2O). However, normal to high CSF opening pressure has been reported with lumbar puncture, suggesting that low CSF volume, rather than pressure, may be the principal pathophysiologic driver.[114] CSF protein, red cell, and white cell counts are usually increased, postulated to decrease CSF flow in the setting

of increased permeability of dilated meningeal vessels. Brain MRI shows meningeal enhancement, subdural fluid collection, caudal displacement of the cerebellar tonsils, and pituitary abnormalities (enlargement or hyperemia) (Fig. 39.6).[101,109] Scheivink noted five characteristic features of SIH: (a) subdural fluid collections, (b) enhancement of the pachymeninges, (c) engorgement of venous structures, (d) pituitary hyperemia, and (e) sagging of the brain (mnemonic: SEEPS).[101] Meningeal enhancement is usually thickest in patients with low intracranial pressure and subdural fluid collections. A relationship between SIH, subdural fluid collection, and subdural hematoma has been noted.[115,116,117] Spine MRI of patients with SIH usually shows epidural or paraspinal fluid collections and collapse of the dural sac.[118] It is interesting to note that meningeal enhancement slowly decreases, even after the patient improves with treatment, and may take three–five months to resolve the meningeal changes.

Radionuclide cisternography (RC) was once considered the confirmatory test in the diagnosis of SIH. The presence of SIH is indirectly proven by the lack of ascent of the injected dye, rapid disappearance of the radioisotope from the CSF (within 4 h), and the early appearance of the radioisotope in the urinary bladder. However, leak sites have often not been demonstrated using cisternography. This is because the patient was brought back to the radiology department after injection of the radioisotope, and images were taken at several time intervals. Hence, leakage of the radioisotope may have occurred between the images. Other disadvantages of RC include poor spatial resolution, invasiveness, and possible radioisotope extravasation through the needle tract, resulting in inaccurate interpretation. For these reasons, RC is now considered to have limited usefulness in the diagnosis of SIH.[119,120]

CT myelography (CTM) and intrathecal gadolinium magnetic resonance myelography (Gd-MRM) can localize spinal CSF leaks.

• **Figure 39.6** Brain magnetic resonance findings consistent with intracranial hypotension. CTM is now considered the diagnostic procedure of choice to show the location and extent of CSF leak in SIH.[101] It has better localizing power and provides finer details compared to RC. Standard CTM is used to localize slow CSF leaks wherein the CSF is confined to one or two vertebral levels, while dynamic CTM (D-CTM), whereby the contrast is injected intermittently followed by immediate scanning after each injection, is utilized when the leak is suspected to be rapid and spread over several vertebral levels.[121] D-CTM involves placement of the patient on a tilt table, thereby facilitating contrast flow over the dependent segment of the thecal sac where the suspected leak is located (i.e. prone positioning for the ventral leak). Because patients are positioned on a tilt table, D-CTM requires considerable patient cooperation and limits the scope of imaging, precluding visualization of the entire spine.[122,123] Gd-MRM has higher sensitivity than CTM for small, slow leaks but is more complex to perform.[120,124] Intrathecal gadolinium administration is considered off-label, and doses should not exceed 0.3–0.5 mL because of increased risk of acute neurotoxicity and potential fatal encephalopathy.[125] In cases of rapid CSF leaks or recalcitrant SIH symptoms with negative imaging, digital subtraction myelography can be employed as an adjunctive test.[126]

The location of the CSF leak can be anywhere throughout the spine, with the cervicothoracic and thoracolumbar junctions serving as the most common sites.

Treatment of SIH

Many patients respond to conservative measures alone, including bed rest, oral hydration, steroids, oral or intravenous caffeine, and the application of an abdominal binder. An EBP is considered when conservative treatment fails because it can induce an inflammatory reaction to seal the leak. It is the treatment of choice for SIH, although it is less effective in SIH than in postdural puncture headaches. The lower success rate may be related to the injection of the blood away from the site of CSF leak, the presence of multiple CSF leaks, and the rare occurrence of CSF leaks at the anterior aspect of the spinal cord or nerve root sleeves.

In the absence of CTM demonstrating the exact location of CSF leak, most pain medicine practitioners inject the blood at the thoracolumbar area to cover the upper and lower thoracic levels. If not effective, a second injection can be considered in the lumbar region. Ferrante et al.[127] reported excellent results with blind lumbar EBPs in 42 patients by strictly maintaining the Trendelenburg position immediately before and 24 h after EBP, premedicating with acetazolamide, and activity modification for two weeks post-procedure. The prolonged Trendelenburg position promotes the rostral spread of the EBP; maintaining this position for 24 h after the procedure is probably not necessary. Debate exists over the superiority of targeted EBP. In 56 patients with SIH, 87% of patients exhibited benefit after just one targeted EBP vs. 52% of patients in the blind EBP group.[128] However, in a retrospective review of 116 patients who underwent EBP for SIH, no clinical difference was observed between the targeted vs. two-site blind EBP groups.[129] Factors associated with greater first blood patch efficacy included volume of blood, number of levels injected, and targeted injections.[130] Performing more than two EBPs is probably not necessary. If one or two EBPs are not effective, then a CTM should be performed before another EBP is attempted to delineate the vertebral level and the site of CSF leak.[131] The use of a transforaminal epidural blood patch, although reported to be successful,[132] should be done as a last resort. This is because of possible compression/occlusion of the radicular artery accompanying the nerve root, leading to segmental ischemia of the spinal cord and possible paralysis.[133]

Epidural patches performed with fibrin glue alone[34] or autologous blood have been described.[135] It should be noted that fibrin glue has been associated with allergic reactions and viral infections. Surgical intervention is warranted if multiple EBPs are ineffective,[136,137] and the patient's condition deteriorates.[101,109] Surgery for SIH is challenging, and close follow up is recommended because some patients may develop recurrent CSF leaks.

The recurrence of headaches after successful treatment may be due to leak recurrence. If the character of the headache changes, rebound transient intracranial hypertension[138] and dural venous sinus thrombosis are possible.[139]

SIH Summary

SIH is characterized by the same symptoms as PDPH, although the patient had no history of meningeal puncture. CSF pressure is usually low on diagnostic lumbar puncture, and there is meningeal enhancement on MRI. CTM confirms the diagnosis and helps determine the exact site of CSF leak. If conservative measures are ineffective, several EBPs may be required to treat the headache.

Key Points

Cervicogenic Headache

- Cervicogenic headache pain refers to pain referred to the cervical spine from the neck.
- The pathogenesis can be explained by the overlap between the first three cervical nerves, the trigeminal nucleus, and the cervical plexus.
- Cervicogenic headaches can be diagnosed based on clinical symptoms that meet the criteria or diagnostic block.
- It is very important to distinguish cervicogenic headaches from internal carotid or vertebral artery dissection, tumors in the posterior fossa, Arnold Chiari formation, migraines, and tension-type headaches.
- A full history and physical examination are necessary for diagnosis. History may include a history of whiplash injury or cervical disease. Physical examination should include the range of motion of the neck.
- Imaging can be used to determine the presence of cervical disease. However, a temporal relationship is required to prove causation.
- Treatment can be non-pharmacologic, including massage, physical therapy, transcutaneous electrical nerve stimulation therapy, and psychotherapy.
- Interventional treatments such as radiofrequency ablation can be curative in patients who have complete pain relief after a diagnostic block.
- Surgical intervention, such as neurectomy and dorsal rhizotomy, requires weighing the risk of worsening pain post-intervention with the possible benefits of the procedure.

Post-meningeal Puncture Headache

- The crucial components of PMPH are a history of dural/arachnoid puncture and bilateral postural headaches.
- Headache after dural/arachnoid puncture is not directly related to the amount of CSF leakage or subarachnoid pressure. Headache may be secondary to a sudden alteration in CSF volume and subsequent cerebral vasodilatation.
- Concomitant intracranial pathologies may be present in patients with PMPH. The signs and symptoms of alternative pathology include the presence of a significant nonpostural component of the headache, a changing pattern of the headache, and severe nausea and vomiting.
- Prevention of PMPH depends mainly on needle size and needle tip design. The smallest practical needle diameter with a non-cutting tip was associated with the lowest risk of PMPH.
- Initial therapy for PMPH, in the first 24 h, should be conservative, relying mainly on medications. Approximately 85% of PMPHs resolve spontaneously within five days.
- The initial and rapid relief from an EBP is secondary to the circumferential compression of the dura and reduction of the intradural volume. This shifting of the vertebral subarachnoid CSF cephalad causes re-suspension of the cerebral structures, reduction of traction on pain-sensitive intracranial structures, and decreased cerebral vasodilatation. The lasting relief from an EBP is related to the sealing of the dural/arachnoid hole.
- Caffeine and theophylline block the brain adenosine receptors, causing cerebral vasoconstriction. The acute increase in subarachnoid pressure after EBP may deactivate adenosine receptors and relieve headaches.
- Prevention of PMPH with pharmacologic agents or prophylactic EBP after ADP has not been proven effective.
- Sphenopalatine ganglion blocks may be considered a safe and effective alternative to EBP.

SIH

- SIH is characterized by symptoms similar to meningeal puncture headache in a patient with no history of meningeal puncture.
- The cause of SIH is leakage of the CSF due to weakness of the spinal meninges, such as meningeal diverticulum, or small tears in the root sleeves or cysts. Other associated anatomical abnormalities include herniated discs and vertebral spurs.
- The hallmarks of SIH include postural headache (without a previous history of dural puncture), low CSF pressure on diagnostic lumbar puncture, and meningeal enhancement on MRI.
- The symptoms include postural headaches, neck stiffness, visual, hearing, balance disturbances, back pain, and radiculopathy.
- Although the headache is classically postural, it can be nonpositional or intermittent. It can be gradual or sudden at the onset.
- CT myelography (CTM) is the diagnostic procedure of choice in SIH because it has a better chance of showing the location of the CSF leak and provides finer details than RC.
- Gadolinium magnetic resonance myelography (Gd-MRM) is more sensitive than CTM but is also more complex to perform. However, intrathecal injection of gadolinium is contraindicated because of recent reports of encephalopathy and death from unintentional intrathecal injection of gadolinium.
- EBP is the treatment of choice for SIH, and several EBPs may be required if there are multiple sites of leakage.
- Although fibrin glue can be injected into the epidural space, there are not enough publications or experience to support its routine use.
- If conservative measures and EBPs are ineffective, surgical repair can be employed if structural abnormalities or focal CSF leaks are identified.

Orofacial Pain

AURELIO ALONSO, MASSIMILIANO DIGIOSIA, DANIELA VIVALDI

Introduction

Orofacial pain (OFP) refers to pain associated with the face, head, and neck and can be associated with the masticatory and cervical muscles, temporomandibular joint, intraoral tissues, salivary glands, and others.[1,2] It can be classified into the following categories: musculoskeletal, neurovascular, and neuropathic orofacial pain conditions.

Orofacial pain disorders have complex anatomy and specialized sensory innervations of the head and neck. Many orofacial pain disorders are unique and represent a clinical diagnostic challenge. Patients may present with one entity to multiple types of orofacial pain. This chapter presents an introduction to practical issues regarding assessment, diagnosis, and management of common orofacial pain disorders.

Other forms of orofacial pain, such as odontogenic pain, will not be discussed in this chapter since these conditions are usually already ruled out by a general dentist or other dental specialist.

The specialized structures of the head and face have a rich sensory innervation supplied by the trigeminal system, lower cranial nerves, and upper cervical roots. Pain is one of the most prominent symptoms of disease in this area. Usually, the acute pain symptoms closely correlate with other signs and symptoms of the disease. However, the correlation between pain and other symptoms may not be evident in several more complex, chronic pain problems, particularly those involving the masticatory system.[3]

Epidemiology of Orofacial Pain

Chronic pain affects approximately 100 million adults in the United States, with an economic burden of over 600 billion.[4] OFP is one of the most common pain conditions; its prevalence is estimated to be between 17%–26% in the general population, and 22% of the population suffered at least one orofacial pain in the length of six months.[2,5] Similar to other pain conditions, OFP is more prevalent in females than males.[6,7] After toothache, temporomandibular disorder (TMD) is the most common orofacial pain.[5] In a large prospective multi-site study, the incidence of TMD was 3.9% annually, and females had only slightly higher incidence than males.[8] The onset and chronification of TMD are associated with other comorbid pain conditions like chronic wide spread pain, lower back pain, and headaches (Fig. 40.1).[9–14] The prevalence of TMD depends on the illness in question, the diagnostic criteria used to identify the disease, and the study population. For example, in a review study that used the Research Diagnostic Criteria for Temporomandibular Disorder (RDC/TMD) as the diagnostic criteria for TMD, the general population prevalence of temporomandibular joint (TMJ) pain was 2.6%, muscle disorders had a prevalence of 9.7%, in comparison, the prevalence of these conditions in the patient population was 45.3% and 30.1%, respectively.[15,16] Unlike TMD that has a recognized and validated diagnostic criteria in the RDC/TMD and Diagnostic Criteria for Temporomandibular Disorder (DC/TMD),[15,17] the prevalence and incidence of several OFP conditions, for example, neurovascular orofacial pain, are unknown because until recently they were not defined in a comprehensive, internationally acceptable comprehensive classification.[18,19]

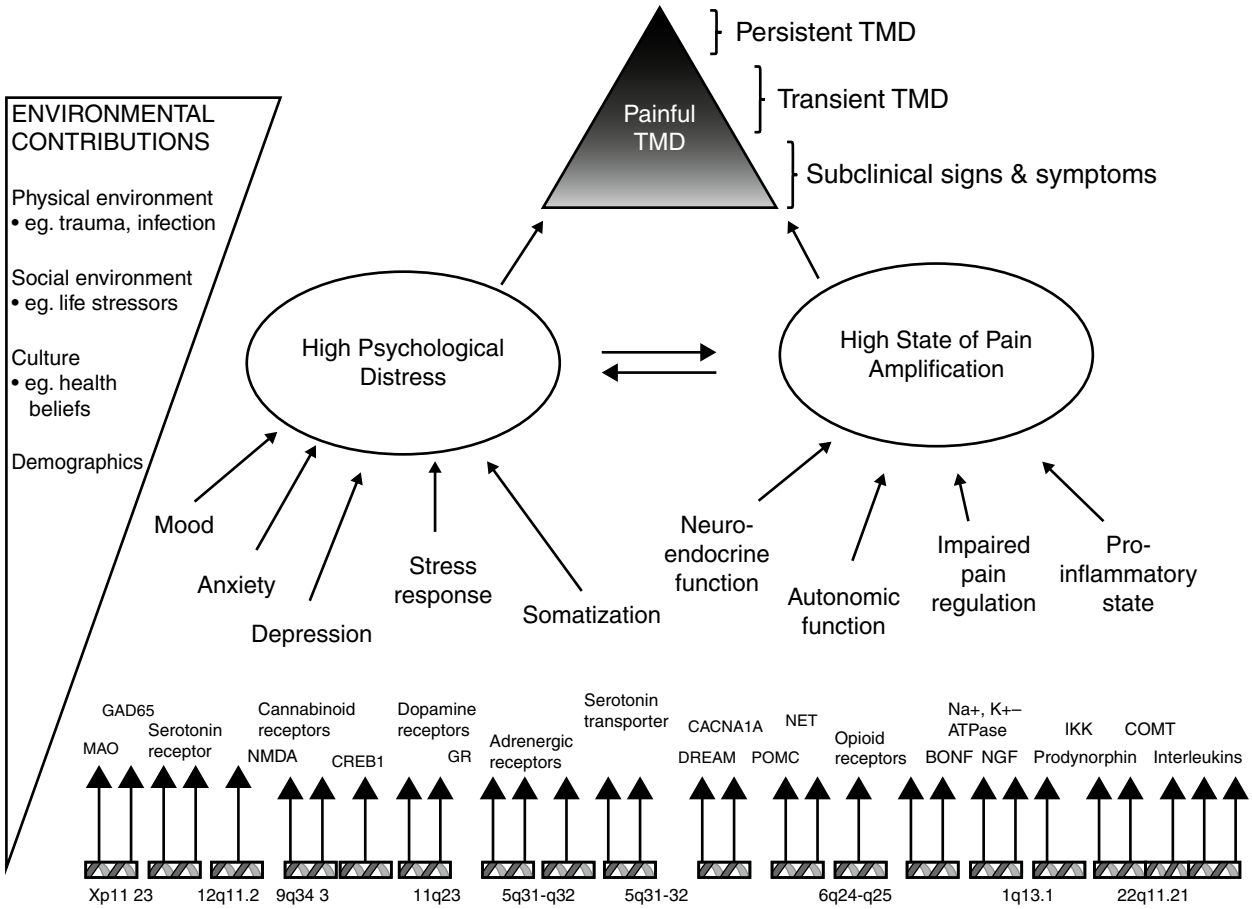
Orofacial Pain Classification

Several classifications have been developed over the years to better categorize the types of OFP. These classifications include the International Classification of Headache Disorders (ICHD-3)[20] and the International Classification of Orofacial Pain (ICOP).[18] Despite the fact these two classifications include TMD, a more specific classification for TMD was developed to assist researchers and clinicians, the first one was developed in 1992, RDC/TMD,[15] and in 2014, DC/TMD.[17] A summary of orofacial pain classifications is shown in Figure 40.2.

Temporomandibular Disorders

TMDs are defined as a subgroup of orofacial pain that involves the TMJ, masticatory muscles, and associated head and neck musculoskeletal structures.[1]

Patients with TMD most frequently present with pain, limited or asymmetric mandibular range of motion, and TMJ sounds.[21,22] The pain or discomfort is often localized to the jaw, TMJ, and muscles of mastication, and cervical muscles are commonly involved. Commonly associated symptoms include ear pain and stuffiness, tinnitus, dizziness, neck pain, and headache. In some cases, the onset is acute, and symptoms are mild and self-limiting. However, about 15% of patients will develop chronic TMD,[23] with persistent pain in association with physical, behavioral, psychological, and psychosocial symptoms similar to those of patients with chronic pain syndromes in other areas of the body (e.g. arthritis, low back pain, chronic headache, fibromyalgia, chronic regional pain syndrome, irritable bowel syndrome),[24–26] all requiring a coordinated interdisciplinary diagnostic and treatment approach.



• **Figure 40.1** This model displays two principal intermediate phenotypes (psychological distress and pain amplification) that contribute to the onset and persistence of temporomandibular disorder (TMD). Each intermediate phenotype represents a constellation of more specific risk factors, all of which are subject to genetic regulation. Interactions between intermediate phenotypes occur in the presence of environmental contributions that further contribute to the onset and persistence of painful TMD. Time is not shown in the model because its effects occur implicitly on a third dimension not readily shown in the diagram. Reproduced with permission from Maixner W, et al. 2011.[29]

Etiology

In 1934, Costen, an otolaryngologist, evaluated 13 patients who presented with pain in or near the ear, tinnitus, dizziness, a sensation of ear fullness, and difficulty swallowing.[27] He observed that these patients had many missing teeth and, as a result, their mandibles were over closed. The patients seemed to improve when their missing teeth were replaced, and the proper vertical dimension of the occlusion was restored. The malocclusion and improper jaw position were perceived to be the cause both of "disturbed function of the TMJ" and the associated facial pain. The emphasis of treatment was on altering the affected patient's occlusion.

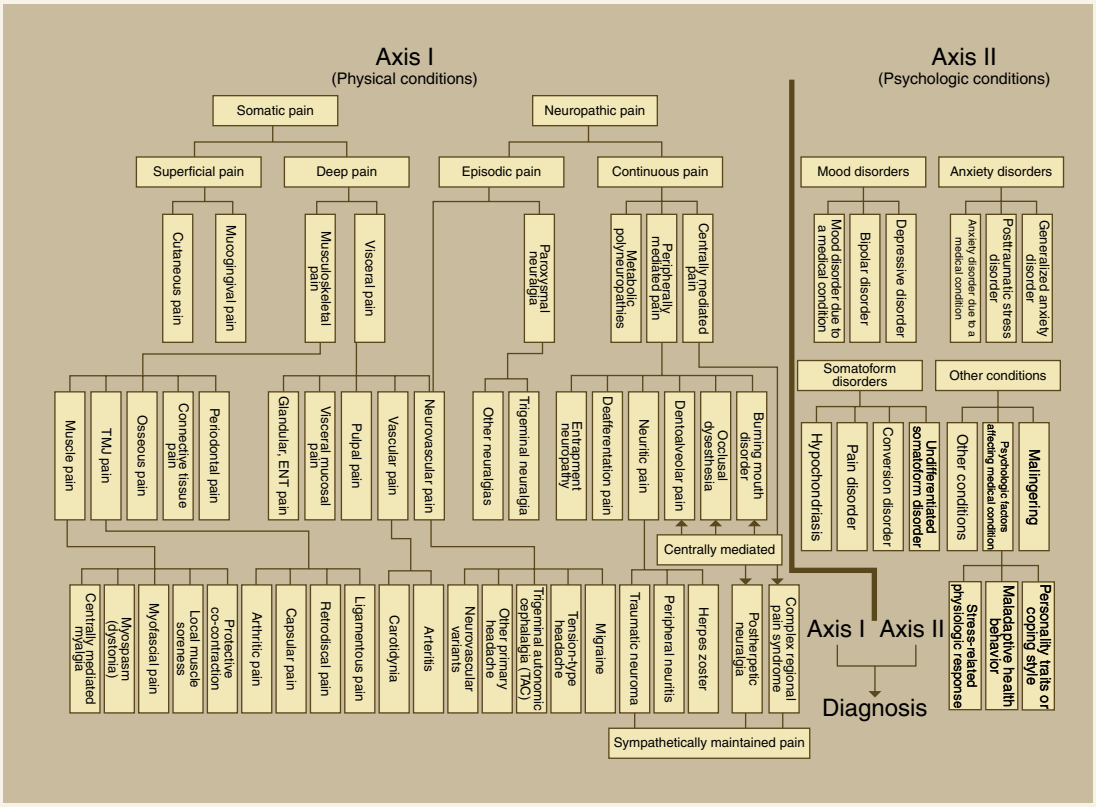
More recently, advances in the understanding of joint biomechanics, neuromuscular physiology, autoimmune, musculoskeletal disorders, and pain mechanisms have resulted in changing concepts of the etiology of TMDs. These disorders are now considered multifactorial in etiology, with biologic, behavioral, environmental, social, emotional, and cognitive factors alone or in combination contributing to the development of signs and symptoms of TMDs (Fig. 40.1).[1,22,28,29]

Various forms of trauma to the TMJ structures (ligaments, articular cartilage, articular disc, bone) can lead to intraarticular biochemical alterations that have been demonstrated to produce oxidative stress and the generation of free-radicals. Subsequent inflammatory changes in synovial fluid with the production of a variety of pro-inflammatory cytokines can then lead to alteration in the functioning of normal tissues and degenerative disease in the TMJ.[30–34]

Genetic marker studies involving catecholamine metabolism and adrenergic receptors suggest that certain gene polymorphisms (e.g. in the catechol-O-methyl transferase gene) might be associated with changes seen in pain responsiveness and pain processing in patients with chronic TMDs.[35–37]

Differences in pain modulation have been reported between women and men with TMDs; women have been observed to demonstrate decreased thresholds to noxious stimuli and more hyperalgesia. In addition, in women with TMDs, some studies suggest that the affective component of pain may be enhanced during the low-estrogen phase of the menstrual cycle.[38–40]

Functional brain imaging studies demonstrating changes in cortical circuitry support the concept that TMDs are very similar to other chronic pain disorders and may be related to abnormal pain processing in the trigeminal system.[41–43] In particular, muscle pain disorders appear to have little, if any, abnormality of the muscles or peripheral tissues and may represent a central sensitization pain producing process. Because of the central sensitization, TMD was classified among other chronic painful disorders as part of the chronic overlapping pain conditions.[44]



• **Figure 40.2** Classification of facial pains. With permission from Dr. Okeson from *Bell's Orofacial Pain.* Quintessence; 2014.

Lastly, numerous bio-behavioral studies support a connection between chronic TMDs and comorbid psychopathology (anxiety and depression disorders, posttraumatic stress disorder, and childhood physical, sexual, and psychological abuse).[45–51] TMDs fall in the 11th major category of the International Headache Society's (ICHD-3) classification.[20] However, most researchers use the RDC/TMD or DC TMD for diagnosis purposes.[15,52]

Temporomandibular Joint Disorders (TMJD)

The TMJ is a ginglymoarthrodial synovial joint capable of rotational and translational movements. A bilateral joint (a single bone—the jaw—with a right and left joint) cannot function separately. What affects one joint also influences the other. It is formed by the articulation of the mandibular condyle with the glenoid fossa/articular eminence of the temporal bone.

The articular surfaces of the condyle and glenoid fossa/articular eminence are covered with fibrocartilage rather than hyaline cartilage, as in other synovial joints except for the clavicle. Fibrocartilage can resist heavy loads and has unique healing and adaptive properties.[53]

An articular disc, made of fibrocartilage, is interposed between the condyle and the glenoid fossa. The disc has a biconcave shape; thicker in its anterior (2 mm) and posterior (3 mm) portions and thinner in the middle. It acts as a "cushion" to absorb stress, distribute loads, and facilitate jaw movements.

The disc divides each TMJ into two articular joint spaces: upper and lower joint space. The rotational movement happens mainly in the inferior joint space, between the condyle and the inferior surface of the disc. The translational movement in the upper joint space, between the upper surface of the disc and the glenoid fossa/articular eminence.[54,55]

The most common TMJ disorders are:[56]

Joint pain (arthralgia, arthritis)
Joint disorders (internal derangement or disc-condyle disorders)
Joint diseases (degenerative joint disease [DJD]: osteoarthrosis and osteoarthritis)

Joint Pain

Joint pain is characterized by localized pain exacerbated by function, parafunction, and provocation.

Arthralgia

According to the DC/TMD,[57] arthralgia is defined as pain of joint origin affected by jaw movement, function, or parafunction, and the replication of the pain occurs during provocation testing of the TMJ.

History has to be positive for both:

1. pain in the jaw, temple, ear, or in front of the ear AND
2. pain modified with jaw movement, function, or parafunction

The clinical examination has to be positive for both:

1. confirmation of pain location in the area of the TMJ(s)
2. report of familiar pain in the TMJ with at least one provocation test:
   - palpation of the lateral pole (0.5 kg pressure) or around the lateral pole (1 kg pressure) OR
   - maximum unassisted or assisted opening, right or left lateral movements, or protrusive movements

Arthritis

Defined as pain of joint origin with clinical characteristics of inflammation or infection: edema, erythema, and/or increased temperature. It may result from trauma. In case of severe unilateral intraarticular swelling or effusion, it could be associated with occlusal changes such as ipsilateral posterior open bite. It is a localized condition, and there should not be a history of systemic inflammatory disease.[58]

History has to be positive for both:

- arthralgia AND
  1. swelling, redness, and/or increased temperature in front of the ear OR
  2. dental occlusal changes (posterior open bite) resulting from intraarticular inflammatory exudate

Clinical examination has to be positive for both:

- arthralgia AND
  - presence of edema, erythema, and/or increased temperature over the joint OR
  - reduction in dental occlusal contacts noted between two consecutive measurements

The patient has to be negative for rheumatologic disease, including those in systemic arthritis, and the pain is not better accounted for by another pain diagnosis.

Joint Disorders

Internal derangement (or disc- condyle complex disorders) is defined as an "abnormal relationship of the articular disc to the mandibular condyle, glenoid fossa and articular eminence, interfering with the smooth movements of the joint."[59] It is a localized mechanical disorder within the joint. The term is often used as a synonym for disc displacement.

The clinical manifestations of internal derangements are clicking joint, intermittent locking, limited mouth opening (closed lock), and open lock.

The DC/TMD includes several forms of internal derangement:

- Disc displacement with reduction
- Disc displacement with reduction with intermittent locking
- Disc displacement without reduction with limited opening
- Disc displacement without reduction without limited opening

Disc Displacement With Reduction

Disc displacements are usually anterior or anteromedial, although posterior and lateral displacements have been described in the literature. This may be partly related to the thinnest discal attachments being on the lateral pole of the condyle and the medial direction of pull by the lateral pterygoid and inward direction of condylar movement during mouth opening. Therefore disc displacement clinically suggests torn or stretched collateral discal ligaments that bind the disc to the condyle.

In disc displacement with reduction, clicking sounds on mouth opening and closing may be present**.** The term reduction is used to describe the misaligned disc temporarily coming back (or slipping back) to its proper interposition between the condyle and articular eminence/fossa during full opening (Fig. 40.3). On closing the mouth, the disc again displaces as the teeth come closer together. This repetitive, ongoing displacement on opening and closing produces a reciprocal noise (clicks) and is hence termed reciprocal clicking (Fig. 40.4). This stage may actually represent a physiologic accommodative stage without the need for therapy other than discussion regarding its anatomic significance.[60]

History has to be positive for at least one of:

1. in the last 30 days, any TMJ noise present with jaw movement or function OR
2. patient report of any noise present during the exam

The clinical exam has to be positive for at least one:

1. clicking, popping, and/or snapping noise during both opening and closing movements, detected with palpation during at least one of three repetitions of jaw opening and closing movements OR
2. clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of opening or closing movements AND
3. clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of right or left lateral or protrusive movements.

Imaging is the reference standard, and when this diagnosis needs to be confirmed with TMJ magnetic resonance imaging (MRI):

1. in the maximum intercuspal position, the posterior band of the disc is located anterior to the 11:30 position, and the intermediate zone of the disc is anterior to the condylar head AND
2. on full opening, the intermediate zone of the disc is located between the condylar head and the articular eminence.

Disc Displacement With Reduction With Intermittent Locking

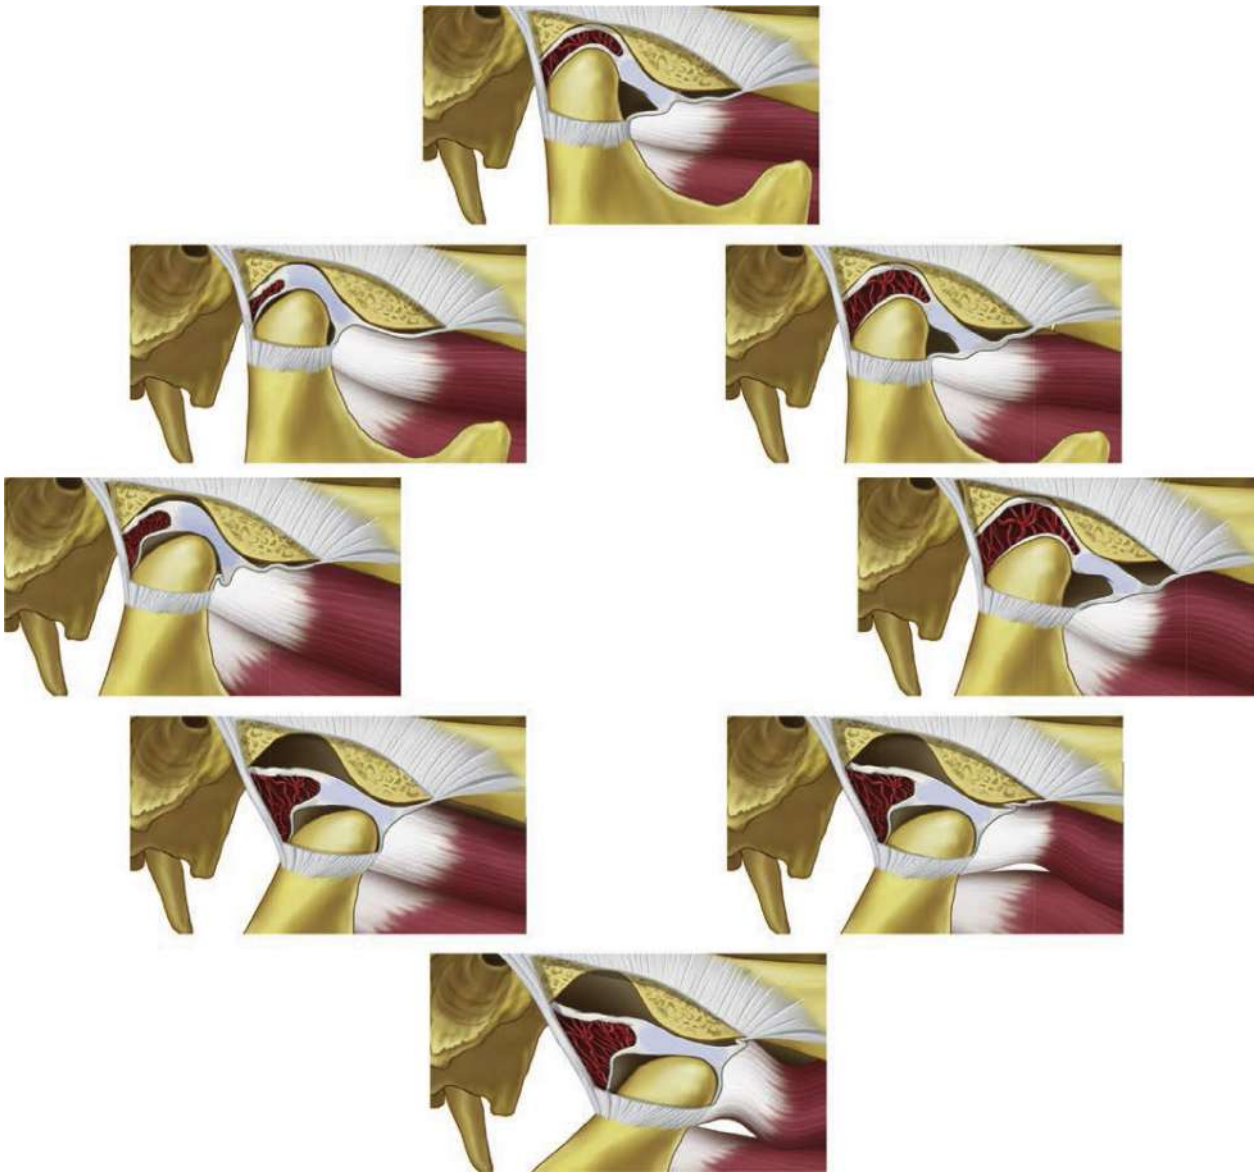
In this intracapsular disorder, the disc does not reduce during mouth opening, causing intermittent, limited mandibular opening. Usually, the patient can unlock the joint.

History has to be positive for:

1. in the last 30 days, any TMJ noise present with jaw movement or function OR
2. patient report of any noise present during the exam AND
3. in the last 30 days, jaw locks with limited mouth opening, even for a moment, and then unlocks.

The clinical exam has to be positive for at least one of:

1. clicking, popping, and/or snapping noise detected during both opening and closing movements, detected with palpation during at least one of three repetitions of jaw opening and closing movements OR



• **Figure 40.3** Disc displacement with reduction. Note that during opening, the condyle passes over the posterior border of the disc onto the intermediate area of the disc, thus reducing the anteriorly displaced disc. This discal movement can lead to momentary mechanical catching or locking. When this is present, the condition is called disc displacement with intermittent locking. With permission from Dr. Okeson.

2. clicking, popping, and/or snapping noise detected with palpation during at least one of three repetitions of right or left lateral or protrusive movements

When this diagnosis needs to be confirmed, the imaging analysis criteria are the same as for disc displacement with a reduction.

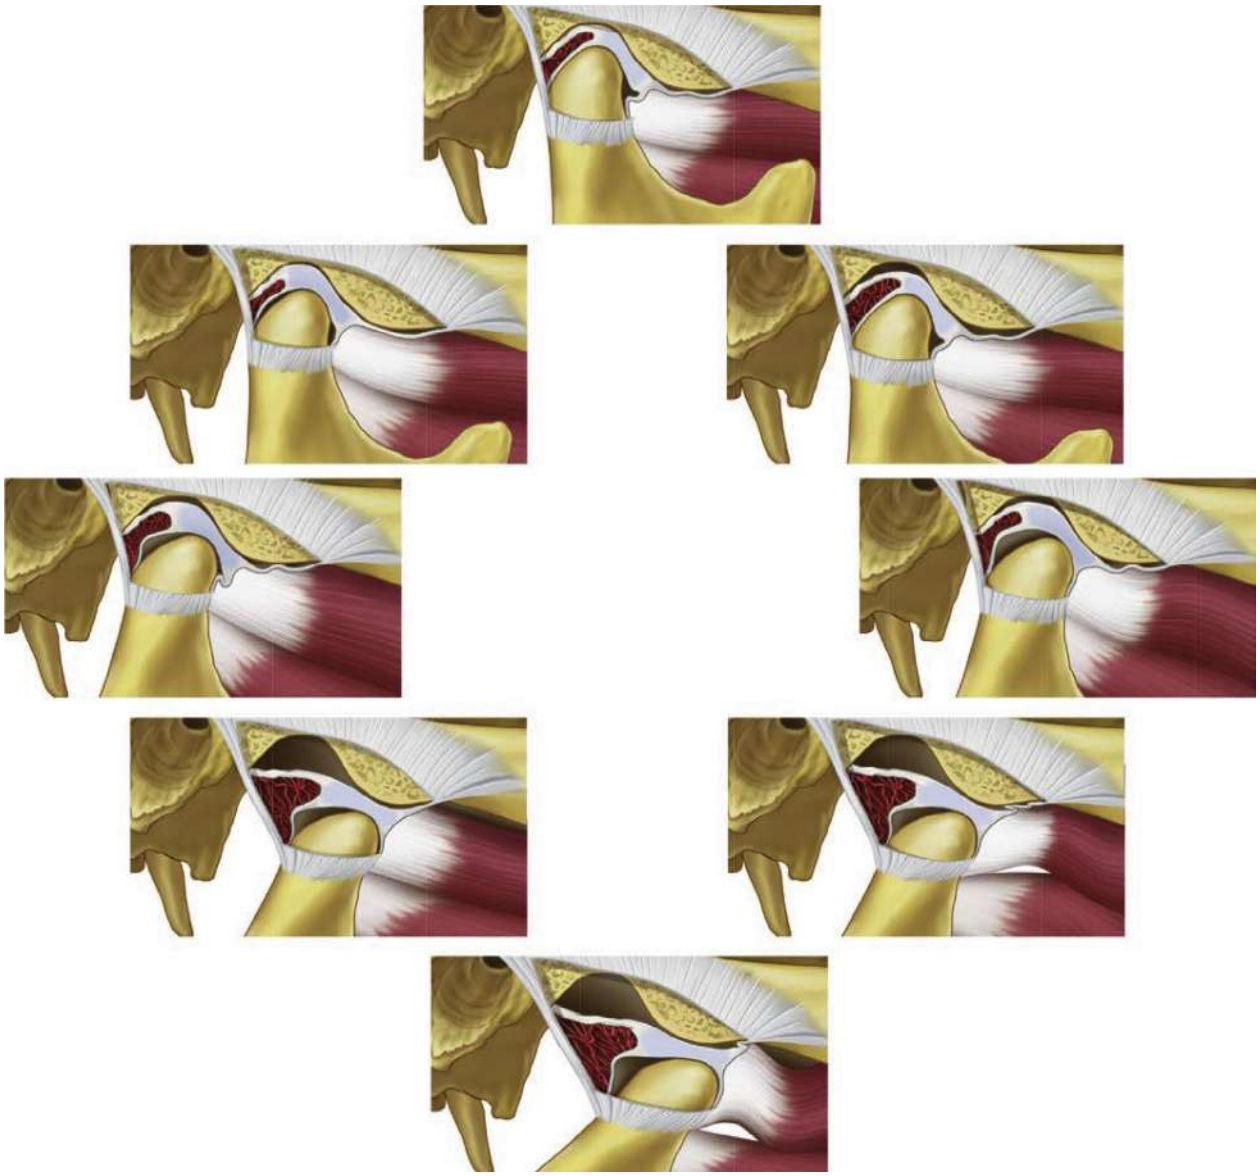
Disc Displacement Without Reduction With Limited Opening

Disc displacement without reduction is sometimes called a "closed lock." This suggests that the disc has been permanently displaced, and the disc's shape has been permanently changed such that it physically prevents the condyle of the mandible from translating to a fully open position (Fig. 40.5). There is a limitation of jaw opening to 22 to 25 mm with pain and a deflection of the mandible to the side of the lock. There is a reduction in the chewing capability because of pain, inflammation at the affected joint, and possible changes in the normal occlusion or "bite." An MRI of the TMJ is the "gold standard" to assess soft tissue details of the articular disc and its displacement, while hard tissue CBCT scans are generally done to assess chronic osteoarthritic or bony changes.[61,62] Considering its positive natural course, treatment should be reserved for painful symptomatic cases, and it should always be conservative (see the section on treatment). The goal of the treatment is the management of pain and improvement in mouth opening.[63,64]

History has to be positive for both:

1. jaw locked so that the mouth would not open all the way AND
2. limitation in jaw opening severe enough to limit jaw opening and interfere with the ability to eat

The clinical exam has to be positive for:



• **Figure 40.4** Disc displacement with a reciprocal clicking. Between positions two and three, a click is felt as the condyle moves across the posterior border of the disc. Normal condyle disc function occurs during the remaining opening and closing movement until the closed joint position is approached. Then a second click is heard as the condyle. With permission from Dr. Okeson.

Maximum assisted opening (passive stretch) movement including vertical incisal overlap <40 mm

When this diagnosis needs to be confirmed, the TMJ MRI criteria are positive for both:

1. in the maximum intercuspal position, the posterior band of the disc is located anterior to the 11.30 position, and the intermediate zone of the disc is anterior to the condylar head AND
2. on full opening, the intermediate zone of the disc is located anterior to the condylar head

Disc Displacement Without Reduction Without Limited Opening

The disc is still permanently displaced in this condition, but the clinical presentation is different: pain is often absent, and there is a restoration of function with normal maximum mouth opening.[65]

History has to be positive for both in the past:

1. jaw locked so that the mouth would not open all the way AND
2. limitation in jaw opening severe enough to limit jaw opening and interfere with the ability to eat

The clinical exam has to be positive for:

Maximum assisted opening (passive stretch) movement including vertical incisal overlap >40 mm

When this diagnosis needs to be confirmed, TMJ MRI criteria are the same as for disc displacement without reduction with limited opening.

Degenerative Joint Disease

In the DC/TMD classification, DJD is defined as a degenerative disorder involving the joint characterized by deterioration of articular tissue with concomitant osseous changes in the condyle and/or articular eminence.[6] DJD can result in dental

• **Figure 40.5** Disc displacement without reduction (closed lock). Note that the condyle never assumes a normal relationship on the disc but instead causes the disc to be maintained in front of the condyle. This condition limits the distance it can translate forward. With permission from Dr. Okeson.

malocclusions, including an anterior open bite, especially when present bilaterally or contralateral posterior open bite when present unilaterally.

DJD can be subclassified in:

- Osteoarthrosis (DJD without arthralgia)
- Osteoarthritis (DJD with arthralgia)

Osteoarthrosis

History has to be positive for at least one of:

- in the last 30 days, any TMJ noise present with jaw movement or function OR
- patient report of any noise present during the exam

The clinical exam has to be positive for:

- crepitus detected with palpation during maximum unassisted opening, maximum assisted opening, lateral or protrusive movements

If imaging is needed to confirm the diagnosis, TMJ CT/CBCT criteria are positive at least for one of:

- subchondral cyst, erosion, generalized sclerosis, osteophyte.

Osteoarthritis

History has to be positive for both:

- in the last 30 days, any TMJ noise present with jaw movement or function OR
- patient report of any noise present during the exam AND
- arthralgia

Clinical examination has to be positive for both:

- crepitus detected with palpation during maximum unassisted opening, maximum assisted opening, right or left lateral movements or protrusive movements AND
- arthralgia

Imaging: same TMJ CT/CBCT criteria as for osteoarthrosis.

Systemic Arthritis

The TMJs can also be affected by systemic inflammatory conditions such as rheumatoid arthritis, juvenile idiopathic arthritis, spondyloarthropathies (ankylosing spondylitis, psoriatic arthritis, infectious arthritis, Reiter's syndrome), and crystal induced disease (gout, chondrocalcinosis). TMJ can also be affected by connective tissue diseases such as scleroderma, Sjögren's syndrome, and lupus erythematosus. Condylar resorption, a consequence of inflammation, can be associated with severe dental malocclusion (anterior open bite).

The diagnosis and management of these conditions should always be done in collaboration with a rheumatologist.[58]

History has to be positive for both:

- rheumatologic diagnosis of a systemic inflammatory joint disease AND
- in the past month, any TMJ pain present OR
- TMJ pain that worsens with episodes/exacerbations of the systemic inflammatory joint disease.

Clinical examination has to be positive for arthritis or crepitus detected with palpation during maximum unassisted opening, maximum assisted opening, right or left lateral movements, or protrusive movements.

TMJ CT/CBCT or MRI is positive for at least one of subchondral cysts, erosions, generalized sclerosis, or osteophytes.

Idiopathic Condylar Resorption (ICR)

ICR is a severe form of joint degeneration that usually affects young female patients (also known as cheerleader syndrome). It is almost always bilateral, resulting in loss of condylar support, causing a severe anterior open bite (Fig. 40.6). The presence of pain or articular sounds is variable. The cause is unknown, but it has been suggested that it may be a severe form of DJD and that estrogen may be implicated.[58]

History has to be positive for progressive dental occlusal changes.

Clinical examination has to be positive for both:

1. anterior open bite AND
2. evidence of progressive dental occlusal change with at least one of:
   a. occlusal facets that cannot be approximated (indicating that teeth were touching before the occlusal changes) OR
   b. change in sequential dental occlusal measurement over time (overjet, overbite, intercuspal contacts)

Imaging has to be positive for one of:

1. CT/CBCT evidence of resorption of part or all of the condyle(s) OR
2. lateral cephalometric change with sequential imaging over time

The patient has to be negative for rheumatologic disease.

Neoplasm

Neoplasm of the joint may be benign (chondroma, osteochondroma) or malignant (primary or metastatic). They may present with the same signs and symptoms of TMD—pain during function, limited mouth opening, crepitus, occlusal changes—which could lead to misdiagnoses. Signs and symptoms suggestive of neoplasia are altered sensation (numbness, tingling, allodynia), motor dysfunction (abnormal or uncontrolled jaw and facial movements, paralysis), and recent visible changes (swelling, facial asymmetry).[66] Diagnostic imaging such as CT/CBCT and/or MRI are essential when a neoplasm is suspected.

Disorders of the Masticatory Muscles

It is believed that the cause of masticatory muscle disorders is overuse and ischemia of the muscles, leading to pain.[67–70] The most common masticatory muscle disorders are myalgia and myofascial pain. However, muscle spasms, masticatory muscle co-contraction, and tendinitis can also be present and be part of the TMD spectrum.

Prevalence of Muscles Disorders

Muscle pain disorders are the most common cause of persistent pain in the head and neck, and they affect about 50% of the population with chronic head and neck pain.[71] They also are a common cause of pain in the general population, with 20% to 50% having the disorder; about 6% have symptoms that are severe enough to warrant patient to seek for treatment.[72,73]

Etiologic Factors

Onset factors of masticatory muscle disorders include direct or indirect trauma (microtrauma and/or macrotrauma) to the masticatory muscles and repetitive strain and stress activities that overload the muscles.[1] Macrotrauma events include a direct blow to the jaw and opening the mouth too wide or for too long a period during activities, such as dental visits, eating, yawning, and sexual activity. In some cases, indirect trauma that is because of a whiplash-type of injury may initiate muscle pain.[74] Local infection and trauma may cause myositis and lead to muscle contracture if not resolved. Occupational and repetitive strain injury may cause myofascial pain and muscle spasm if acute. Sleep disturbance and nocturnal habits can also contribute to masticatory muscle pain.

Oral parafunctional habits, such as teeth clenching, jaw thrusting, gum chewing, and jaw tensing, can add repetitive strain to the masticatory muscles and cause tenderness and pain. Postural strain caused by a forward head posture, increased cervical or lumbar lordosis, some occlusal abnormalities, and poor positioning of the head or tongue have also been implicated in masticatory muscle disorders. Psychosocial stressors, such as relationship conflicts, monetary problems, feeling hurried or overscheduled, or poor pacing skills, can play an indirect role.

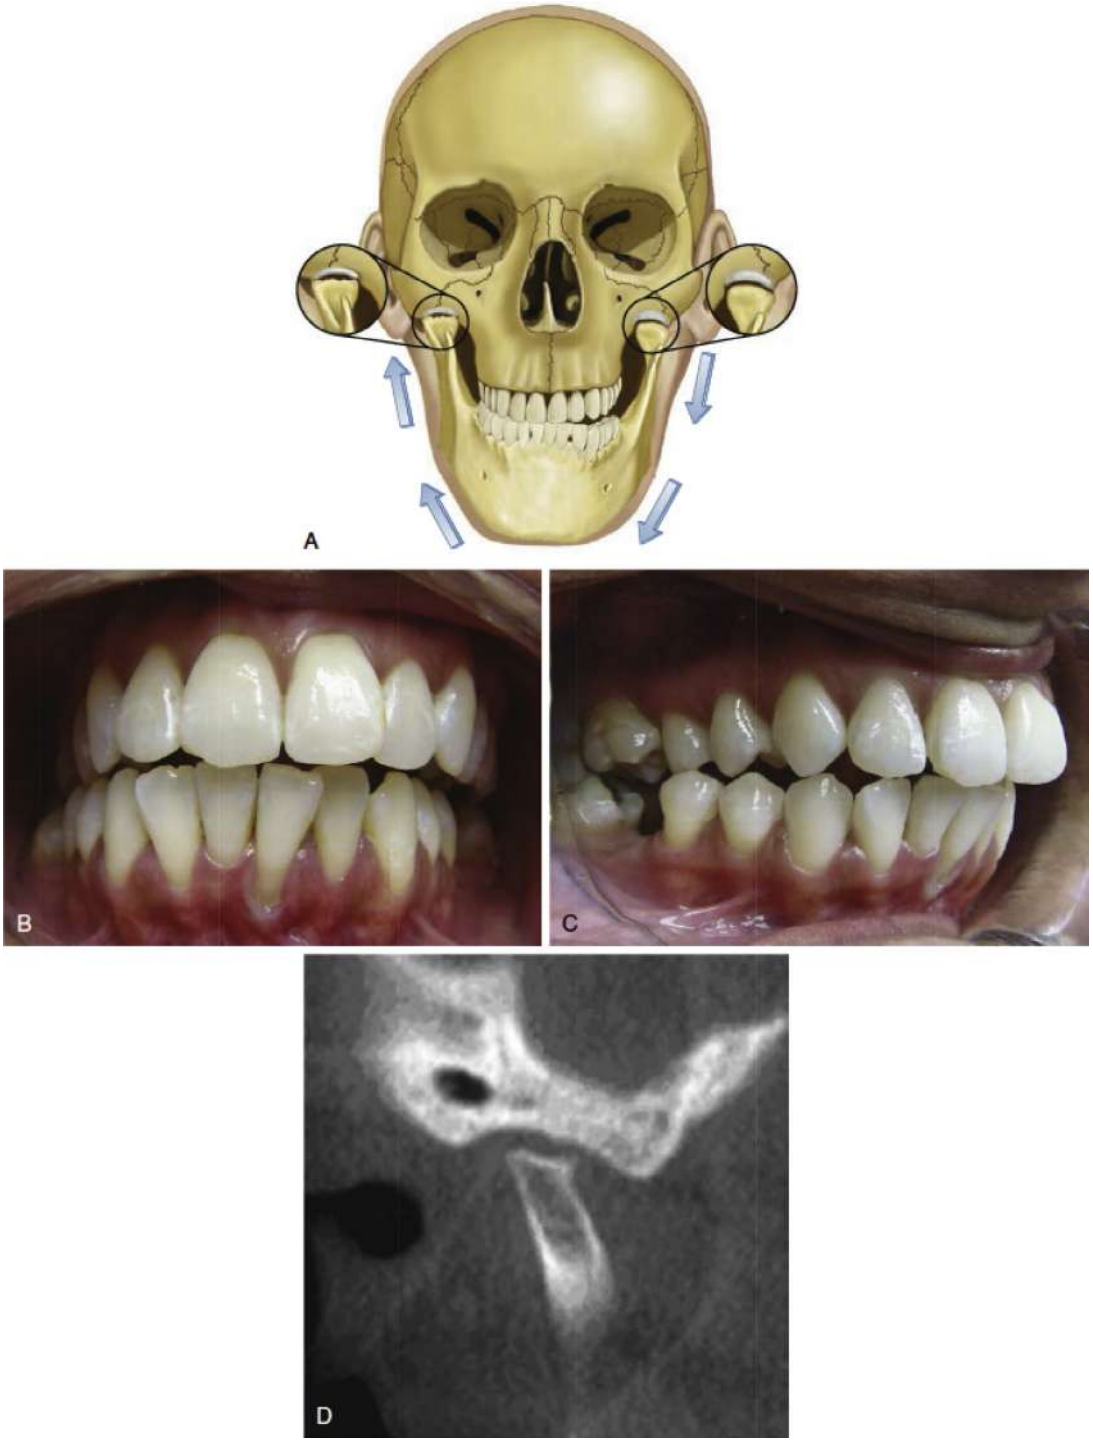
Pathophysiology and Mechanisms

Because there are no specific anatomic changes with muscle pain, no conclusive mechanisms are identified in cases of non-traumatic etiology. Thus several factors may explain the development and persistence of masticatory muscle pain.[1] Including the repetitive strain/stress, neurophysiologic, and central hypothesis.[75]

According to the Diagnostic Criteria for Temporomandibular Disorder (DC/TMD), the most common pain related TMD are myalgia and myofascial pain, and TMJD mentioned above. However, forms of muscle disorders can also be present in orofacial pain, such as muscle spasms and tendinitis.

Myalgia

Myalgia of the masticatory usually occurs with jaw function, parafunction habits (e.g. clenching teeth, chewing gum, biting nails, and others). It can also be elicited by the provocation of the muscles during muscle palpation, which will duplicate the patient's complaint.

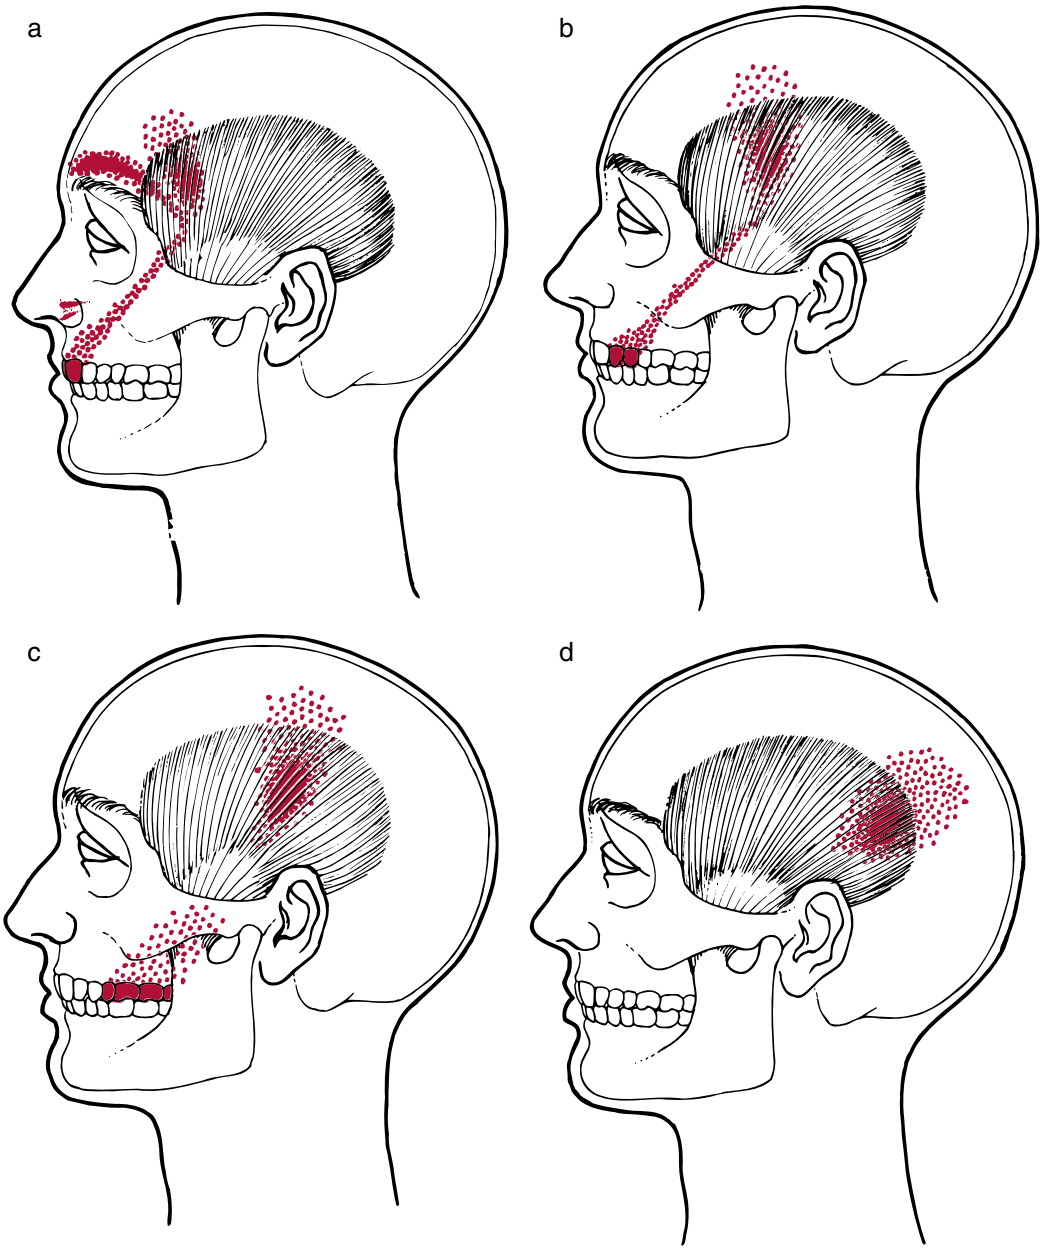


• **Figure 40.6 A,** Sometimes significant osteoarthritic changes occur in only one joint. When this occurs rapidly, the affected condyle collapses, resulting in a shifting of the mandible to that side. This is referred to as idiopathic condylar resorption. **B,** Note that for this patient, there has been a midline shift to the patient's right. This shift is even evident in the relationships of the posterior arches. This idiopathic condylar resorption was isolated to the patient's right condyle. **C,** The loss of condylar support in the right condyle caused a shift to the right, resulting in only the right second molar contacting. **D,** A cone-beam computed tomographic scan of the right condyle. Note the degenerative changes. With permission from Dr. Okeson.

According to the DC/TMD,[17] myalgia is a pain of a muscle origin affected by jaw movement, function, or parafunction and replication of this pain occurs with provocation testing of the masticatory muscles.

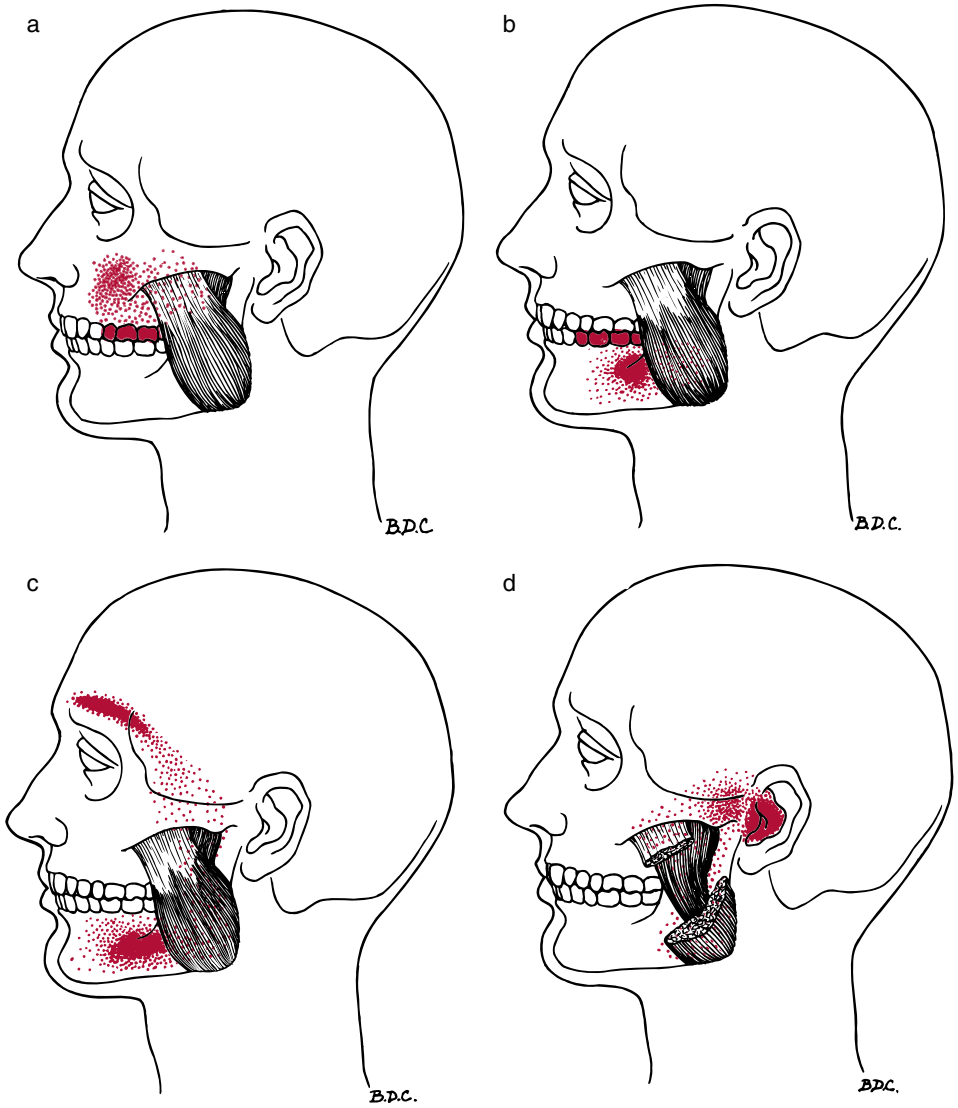
It has to be positive for both:

1. pain in the jaw and temple, in the ear, or in front of the ear, AND
2. pain modified with jaw movement, function, or parafunction

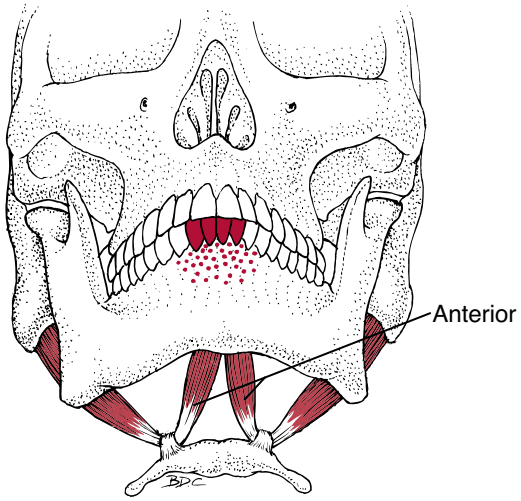


• **Figure 40.7A** Patterns of pain and tenderness referred from trigger points (TrPs) in the left temporalis muscle (essential zone solid red, spillover zone stippled). (a), referred pain from TrPs in the anterior portion of the temporalis muscle; (b and c), represent referred pain arising from TrPs in the middle portion of the temporalis muscle; (d), referred pain from TrPs in the posterior portion of the muscle. (From Donnelly JM: Travell, Simons and Simons' Myofascial Pain and Dysfunction. Third edition. Baltimore, MA: Williams & Wilkins, 2018.)

Continued



• **Figure 40.7B** Referred pain patterns arising from TrPs in the masseter muscle. Solid red shows essential referred pain zones, and the stippled areas are spillover pain zones. (a), Referral patterns from TrPs near the musculotendinous junction of the superficial layer, upper portion. (b), Referral patterns from TrPs in midmuscle of the superficial layer. (c), Referral patterns from TrPs of the lowest portion of the superficial layer, near its attachment. (d), Referral patterns from TrP in the upper posterior part of the deep layer below the temporomandibular joint. (From Donnelly JM: Travell, Simons and Simons' Myofascial Pain and Dysfunction. Third edition. Baltimore, MA: Williams & Wilkins, 2018.)



• **Figure 40.7C** Referred pain patterns of TrPs in the anterior belly of the digastric muscle. (From Donnelly JM: Travell, Simons and Simons' Myofascial Pain and Dysfunction. Third edition. Baltimore, MA: Williams & Wilkins, 2018.)

Positive for both:
1. confirmation of pain location (s) in the temporalis and masseter muscles AND
2. report of familiar pain in the temporalis or masseter muscles(s) with at least one provocation test:
   a. palpation of the temporalis or masseter muscles or
   b. maximum unassisted or assisted opening movements

For local myalgia pain with localization only at the site of palpation when using the myofascial examination protocol.[76]

Positive for both:
1. pain in the jaw, temple, in the ear, or in front of the ear; AND
2. pain modified with jaw movement, function, or parafunction

Positive for:
1. confirmation of pain locations in the temporalis or masseter muscles AND
2. report familiar pain with palpation of the temporalis and masseter muscles AND
3. report pain localized to the site palpation.

Myofascial Pain

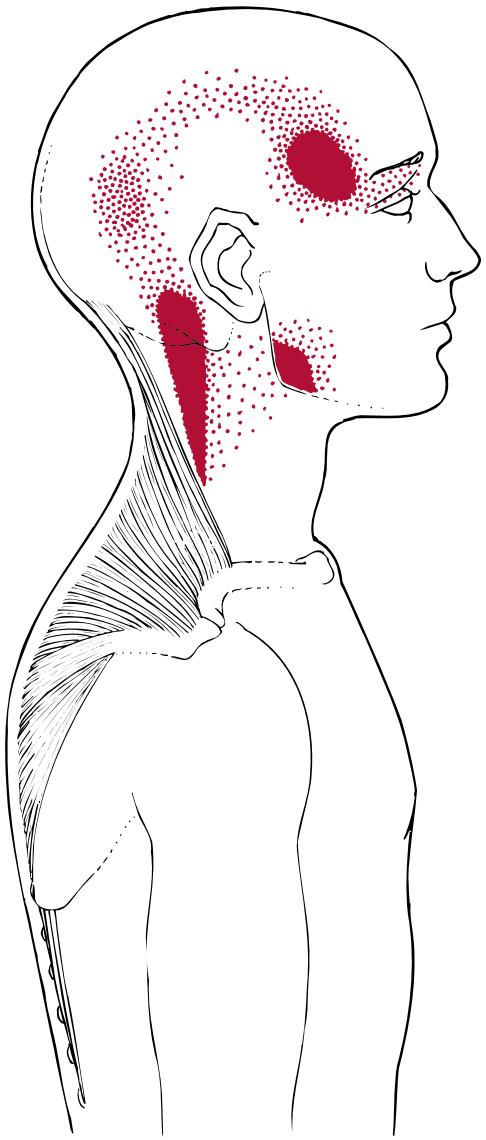
Myofascial pain is a regional muscle pain condition characterized by local areas of firm hypersensitive bands of muscle known as trigger points. Unfortunately, myofascial pain is overlooked and not well understood.[77] Good evidence suggest that myofascial pain originates from the CNS.[69,78] Some other etiologic factors area also known to be clinically present in myofascial pain such as protracted local muscle soreness, constant deep pain, increased emotional stress, sleep disturbance,[79,80] local factors and idiopathic trigger point mechanisms.[77]

Myofascial trigger points are also frequently overlooked and misunderstood sources of the distressingly ubiquitous musculoskeletal aches and pains of humankind. The sensory, motor and autonomic symptoms caused by myofascial trigger points add more challenges for its diagnoses. The specific muscle or muscle group that causes the symptoms should be identified by a trigger point in the muscle associated with a hypersensitive palpable nodule in a taut band. The spot is painful on compression and can give rise to characteristic referred pain, referred tenderness, motor dysfunction, and autonomic phenomena.[81]

Myofascial trigger points can be classified as active or latent. Active trigger points will cause/duplicate the patient's pain when stimulated by compression. A latent trigger point rarely causes pain unless stimulated. When a trigger point is stimulated, the referral pain can have a different degree of severity and quality. It can vary from mild, moderate to severe pain, usually with a deep dull ache quality. Pain can also be exacerbating by jaw function. It is important to recognize that the pain originating from myofascial pain does not follow segmental or neurologic patterns, but it may occur in the same dermatome, myotome, or sclerotome. However, this is not always observed.[82]

All masticatory and cervical muscles can suffer from myofascial pain. The most common muscle groups affected in the orofacial region are the masseter and temporalis muscles. These are the biggest masticatory muscle groups, and also, the cervical muscles are commonly involved, such as the trapezius, splenius capitus, and sternocleidomastoid.

Trigger points in the superficial masseter muscles can refer pain to the eyebrow, maxilla, mandible, mandibular, and maxillary posterior teeth. The deep layer of the masseter muscles can refer pain to the ear (Fig. 40.7). Trigger points in the temporal muscles can refer pain to the posterior maxillary teeth temporal region frontal area above the eyebrow.



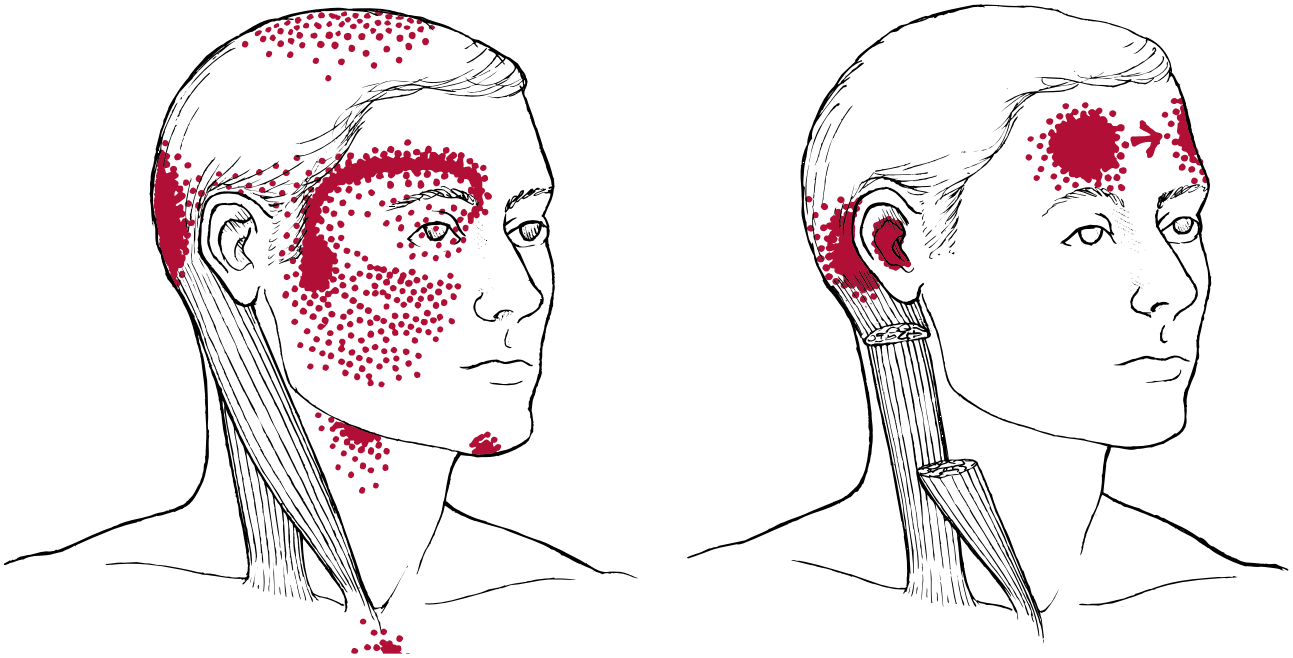
• **Figure 40.8** Referred pain pattern from trigger points located in the most vertical fibers of the upper portion of the trapezius muscle. Solid red shows the essential referred pain zone whereas the stippling maps the spillover zone. (From Donnelly JM: Travell, Simons and Simons' Myofascial Pain and Dysfunction. Third edition. Baltimore, MA: Williams & Wilkins, 2018.)

Cervical muscles trigger points can also refer pain to the head and face and duplicate headaches and facial pain (Figs. 40.8 and 40.9).

According to DC/TMD,[17] myofascial pain is defined as pain of muscle origin as described for myalgia with pain increasing beyond the site of palpation but within the boundary of the muscle when using the myofascial examination protocol.[76]

Positive for both:
1. pain in the jaw, the temple in the ear, or in front of ear AND
2. pain modified with jaw movement, function, or parafunction

Positive for:
1. confirmation of pain locations in the temporalis or masseter muscles AND
2. report familiar pain with palpation of the temporalis and masseter muscles AND
3. report pain spreading beyond the site of palpation but within the boundary of the muscle



• **Figure 40.9** Note how trigger points located in the sternocleidomastoideus refer pain to the temple area typical temporal headache. Note how trigger points located in the trapezius muscle (marked as a star) refer pain to behind the ear, the temple, and the angle of the jaw. (From Donnelly JM: Travell, Simons and Simons' Myofascial Pain and Dysfunction. Third edition. Baltimore, MA: Williams & Wilkins, 2018.)

For myofascial pain with referral, the pain is will refer beyond the boundary of the muscle being palpated when using the myofascial examination protocol. Spreading pain may also be present if positive for both:

1. pain in the jaw, temples ear or in front of ear; AND
2. pain modified with jaw movement, function, or parafunction

And positive for:

1. confirmation of pain locations in the temporalis or masseter muscles AND
2. report familiar pain with palpation of the temporalis and masseter muscles AND
3. report of pain at the site beyond the boundary of the muscles being palpated

Disturbances of motor functions caused by trigger points include spasms of other muscles, weakness, loss of coordination, and decreased work tolerance of the involved muscle. The weakness and loss of work tolerance are often interpreted as an indication for increased exercise. However, if this is attempted without inactivating the responsible trigger points, the exercise is likely to encourage and further ingrain substitution by other muscles with further weakening and deconditioning of the involved muscle.

Management for Temporomandibular Disorders

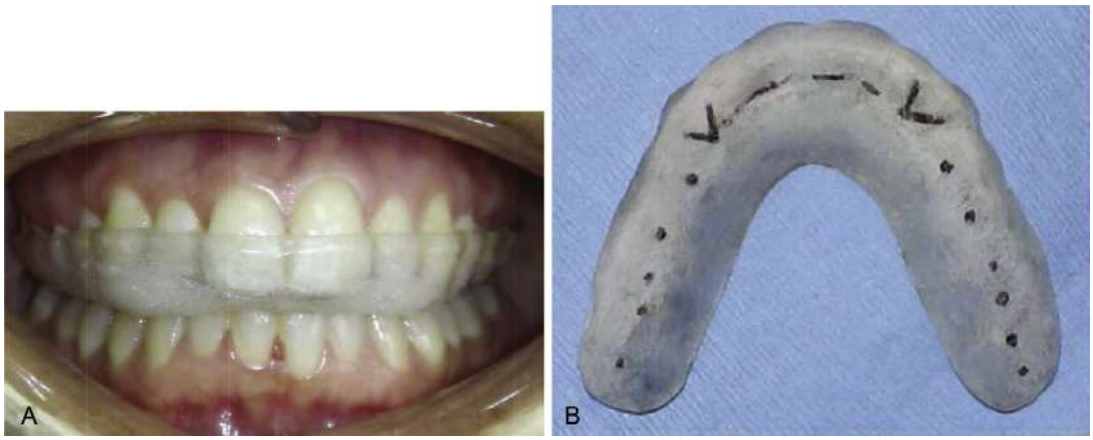
The overall management goals for TMD mimic those of other orthopedic or rheumatologic disorders. Since the etiology of TMD is multifactorial, a multi-disciplinary approach should be used to encompass several treatment modalities that address specific etiologic factors and comorbidities associated with it.

Based on an international consensus, the first line approach for the management of TMD should be evidence-based, reversible, and conservative (non-invasive).[83,84]

Management of TMDs consists of a combination of self-care, cognitive behavior therapy, physical therapy, pharmacotherapy, oral appliance therapy, physical medicine, and alternative medicine such as acupuncture and medical massage therapy, and surgery. Surgery is performed only to treat structural anatomic pathology that is producing pain and dysfunction and after at least six months of a trial of failed conservative treatment. Surgical procedures include arthrocentesis, arthroscopy, open arthrotomy, and combined joint and reconstructive jaw procedures.

Self-care modalities are helpful to allow patients to know their oral habits, posture, and other factors that contribute to the perpetuation of their problems. Once patients know oral parafunction habits, it is easier to control or eliminate them. Application of thermal therapy with ice or heat, 15 to 20 min several times a day, can also be beneficial. Avoiding hard and chewy foods and maintaining a soft food diet can help reduce the stress and pressure into the masticatory muscles and TMJ. Recognizing and eliminating oral habits such as clenching teeth, gum chewing, biting nails, lips, cheeks, and objects such as pens/pencils and others can also reduce stress into the masticatory system.

Oral appliances have been the treatment of choice for many TMD for decades. Several names were designated to it, such as oral orthotics, mouthpieces, occlusal appliances, and others. Several models/designs have been developed over the years with the aim to provide a better maxilla-mandibular relationship, more stable TMJ position, and better and stable occlusion. An extensive review of the literature demonstrated that the effectiveness



• **Figure 40.10** A, Stabilization appliance B, Occlusal contacts have been marked. Note that in the musculoskeletal stable position of the condyles (centric relation), there are even and simultaneous contacts of all posterior teeth (cusp tips contacting flat surfaces). Eccentric guidance is provided by the canines. With permission from Dr. Okeson.

of oral appliances is between 70% and 90%,[85] and that, in general, they help to reduce TMD symptoms.[86–88] Despite this, the evidence for their effectiveness in the management of TMD is poor to moderate.[89–92] However, dentists worldwide still use it to some degree of success. In general, for the management of TMD, a hard-acrylic stabilization appliance with anterior guidance is recommended for both myogenous and articular pain, and in cases of TMJ disc displacement, an anterior repositioning appliance could be used to help reduce the load and promote healing of the retrodiscal tissues (Fig. 40.10).

Physical therapy modalities including manual therapy, dry needling, iontophoresis, ultrasound, TENS, and low level laser therapy can help to improve muscle pain conditions and TMJ pain. The general concept is that physical therapy modalities will help reduce pain and improve the function of the masticatory and cervical muscles and TMJs. The evidence varies according to the study, and some conclusions recommended further and longitudinal investigations.[93–104]

Cognitive behavior therapies aim to reduce patients' maladaptive behaviors and increase adaptive cognitions and behaviors.[105] Several studies[105–108] demonstrated that this management modality is helpful for patients suffering from TMD and also for patients with TMD and other comorbidities.

Pharmacotherapy is a well known treatment modality for TMD. Several classes of medication are known to help with the management of TMD, from acuter to chronic TMD these medications include nonsteroidal anti-inflammatory drugs, muscles relaxants, corticosteroids, anti-depressants, anti-anxiety medications, and anti-convulsants.[109–111]

Oral surgical procedures are also indicated in the management of TMD. Most often, these procedures are not indicated prior to a trial and failure of non-invasive conservative treatment unless a more severe condition such as TMJ tumor, growth disorders, or severe OA of the TMJ where the dental occlusion is affected or misaligned of the jaw occurred and cannot be correct by conservative treatment.[112–115]

Botulinum toxin type A has been used to manage TMD and other facial pain conditions for many years, especially for masticatory muscles disorders, migraines, and bruxism, despite its clinical efficacy. The evidence of botulinum toxin type A in the management of TMD is still lacking.[116–121] Platelet rich plasma and hyaluronic acid have been used for the management of TMD for many years. Recent evidence suggests that these management modalities may be beneficial for TMD and myofascial pai. However, more studies need to be performed to verify their long term efficacy.[122–125]

Neurovascular Pains: Orofacial Manifestations of Primary Headache Disorders

The International Classification of Headache Disorders (ICHD-3) describes headaches as pain located in the head, above the orbitomeatal line and/or nuchal ridge. The first part of the ICHD-3 is dedicated to the classification of the primary headaches, including migraine and trigeminal autonomic cephalalgias (TAC). Facial pain occurring below the orbitomeatal line, anterior to the pinnae, and above the neck is not an integral part of the classification of the primary headaches in the ICHD-3. The classification only acknowledges that otherwise typical patients suffering from migraines without aura could have pain located in their face, "facial migraine."[20]

However, there are several reports in the literature describing patients with orofacial pain that resemble primary headaches. The most compelling evidence is for the migraines without aura (Mw/oA) and the TAC, especially cluster headaches (CH).[126–138] The evidence for orofacial pain resembling other primary headaches, the fourth group of the primary headaches in the ICHD-3, and tension type headaches (TTH) is scarce.[20,139] Recently, a case series presented four patients with paroxysmal facial pain that resemble primary stabbing headaches.[101] Regarding TTH, the overlap between the characteristics of TTH and masticatory myofascial pain may prevent the differentiation between these two entities.[140]

When pain is felt in the orofacial region, dentists are likely the first healthcare provider to see patients seeking resolution.[20] In a survey of Dutch general practitioners, neurologists, and patients that aimed to describe the clinical features that could account for the diagnostic delay of CH, they established that 34% of patients had a consultation with a dentist and 33% saw an ear nose and throat (ENT) specialist before diagnosis, that presence of typical migraine symptoms (nausea, vomiting, and photophobia), and lower age at onset delayed the correct classification.[137] In a sample of 230 patients diagnosed with CH, dentists and ENT surgeons were the healthcare professionals most commonly consulted

before a referral to a neurologist; 45% of patients saw a dentist and 27% an ENT.[141]

Facial pain is commonly associated with intraoral structures like teeth, periodontal and oral mucosa, masticatory muscles, and TMJ. However, primary headaches (neurovascular pain), painful posttraumatic trigeminal neuropathy can mimic a toothache.[142] Dentists are well trained to recognize pain from dental origin. However, unexplained pain in the orofacial region should also raise the possible diagnosis of an atypical presentation of primary headaches or neurovascular orofacial pain.[126,127,134,138,143–145] Failure to recognize orofacial pain resembling primary headaches increases the time of a correct diagnosis, inflicts unnecessary, irreversible treatments, like root canals and extractions, and prolongs patient suffering.[128,140,146–148] Therefore early detection of these disorders is imperative.[141,143]

Until recently, there was no comprehensive, internationally acceptable comprehensive classification for orofacial pain, making it difficult to study the incidence/prevalence, pathophysiology, and treatments of several orofacial pain conditions, including facial pain resembling primary headaches.[19,143] In 2020, the International Classification of Orofacial Pain, first edition (ICOP), was published to fill out this gap. To the interest of this chapter, the ICOP has a dedicated section to primary neurovascular orofacial pains that resemble the presentations of primary headaches in patients with de novo pain in the facial area reminiscent of primary headaches.[18] Table 40.1 summarizes the primary headaches and their orofacial pains counterparts according to the ICHD-3 and ICOP, respectively.

TABLE 40.1 Primary Headaches and OFP Resembling Presentations of Primary Headaches

Primary Headache Pain ICHD-3[1]	Orofacial Pain Counterpart ICOP	Possible Differential Diagnosis[4]
Migraine	Orofacial migraine	NVOP
TTH	Tension type OFP	Myofascial OFP
TACs		
Cluster headache	Orofacial cluster headache	Tolosa-Hunt syndrome Maxillary sinusitis
Paroxysmal hemicrania	Paroxysmal hemifacial pain	
SUNCT/SUNA	SUNFA	
Hemicrania continua	Hemifacial continuous pain with autonomic symptoms	Temporal arteritis Raeder paratrigeminal neuralgia Trigeminal neuralgia Pulpitis
Not applicable	NVOP	Painful posttraumatic trigeminal neuropathy
ICHD-3	International Classification of Headache Disorders, third edition	
ICOP	International Classification of Orofacial Pain, first edition	
TTH	Tension type headache	
NVOP	Neurovascular orofacial pain	
OFP	Orofacial pain	
TMD	Temporomandibular Disorders	
TACs	Trigeminal Autonomic Cephalalgias	
SUNCT	Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing	
SUNA	Short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA)	
SUNFA	Short-lasting unilateral neuralgiform facial pain attacks with cranial autonomic symptoms	

Pathophysiology

Orofacial manifestations of primary headache disorders most likely share the pathophysiology of their headache counterparts. However, the recent ICOP classification will facilitate studies to investigate the pathophysiology of these conditions.[18,144] The pathophysiology of migraine is discussed elsewhere in this book; the pathophysiology of the TACs is briefly presented below.

Cluster headache is the TAC with more information regarding its pathophysiology. The trigeminovascular system, the parasympathetic nerve fibers (trigeminal autonomic reflex), and the hypothalamus are interacting during CH pain attacks.[149] The trigeminal autonomic reflex has its afferent fibers from the ophthalmic division of the trigeminal nerve and efferent pathway from cell bodies in the superior salivatory nucleus, whose outflow through the seventh cranial nerve synapses in the sphenopalatine ganglion and then projects through the greater superficial petrosal nerve.[150] The region of the posterior hypothalamic area seems crucial in the expression of the disorder since it is seen to be activated on imaging studies, and because of CH circadian periodicity, with attacks frequently occurring at night and following a seasonal pattern.[149–152] Extremely important is to rule out pathology of the pituitary gland in the etiology of TAC, since pituitary and peripituitary gland pathology may present as a phenotypic TAC, because of that, it is recommended that a brain MRI scan with pituitary views and pituitary function tests be done as part of workup in all TAC.[150,153,154]

Orofacial Migraine

Orofacial migraine (OM), also referred to as lower-half migraine or facial migraine, is the only primary headache that the ICHD-3 acknowledges could be located in the facial area.[20] The ICOP refers to this migraine as OMs.[18]

According to the ICOP, OM is facial and/or oral pain with characteristics and associated features of migraine without aura according to the ICHD-3.[18,20] OM lasts from 4 to 72 h when it is not treated, or it is unsuccessfully treated, its pain has at least two of the following characteristics: unilateral location, pulsating quality, moderate to severe, aggravation by routine physical activity. In addition, OM has one or both associated features: nausea and/or vomiting, photophobia, and phonophobia.[18] Orofacial migraine can be episodic or chronic. Patients suffering from episodic OM

have at least five attacks. Like migraines, chronic OM has to be present for more than three months, with orofacial pain occurring for 15 or more days per month, and at least eight days have migraine features.[18,20,155]

The ICOP reserves this diagnosis for headache naïve patients with exclusively facial and/or oral pain. Orofacial migraines are rare, and if facial and/or oral pain that meets the criteria for OM is accompanied by headache, the ICHD-3 should be used for its classification.[18]

Epidemiology

Several studies report the presence of migraine with orofacial pain involvement. There are numerous cases reported in the literature. Overall, data show that migraine with head pain and orofacial pain is uncommon and that OM, pain with migraine characteristics only in the facial region, is extremely rare.[126,131–133,135,136,138,146,156–159]

An epidemiologic study of the German Headache Consortium, where 3,351 participants responded to a survey sent to 6,000 people, showed a prevalence of migraine equal to 15.4%, 517 individuals. Almost 30% of the individuals suffering from migraines reported recurrent facial pain. One participant, a 42-year-old male, had migraine pain located only in his lower face. However, he had a previous history of typical migraines. Of the individuals suffering from migraines and facial pain, 80% were women. Patients with migraine and facial pain reported more autonomic symptoms (conjunctival injection, tearing, miosis, ptosis, eyelid edema, nasal congestion, facial flush) than patients with head migraine only, 47% and 7.5%, respectively ($P < 0.001$).[159]

In a tertiary headache and facial pain outpatient clinic, the prevalence of independent facial pain, or facial pain associated with headaches was assessed in 2,912 patients. Patients were divided into three groups: patients that the headache was accompanied by concomitantly face pain (type I), patients that headache pain ceased, followed by facial pain with the same characteristics of the original headache pain (type II), and the last type, patients that have never suffered from headaches attacks and developed de novo orofacial pain (OFP) with similar characteristics of primary headaches (type III).[138] In this group, where 1,935 patients had a migraine or probable migraine, 44 patients (2.3%) had migraine with facial involvement. Looking at these 44 patients, 90% of patients were females. The patient's average age and migraine mean age of onset were 43.2 (SD 14.4) and 30.5 (SD 15.8) years old, respectively. Thirty-eight patients (1.9%) were type I patients, five (0.25%) were type II patients, and only one (0.05%) patient had OM as classified by the ICOP.[18,138] The mandibular branch of the trigeminal nerve was only involved in four patients, and aura symptoms was present in type I patients where the pain was mainly felt in the ophthalmic branch of the trigeminal nerve.[138]

In a prospective audit in a multi-disciplinary facial pain service in England, from 3900 patients assessed, 1176 (30%) had a migraine, including 58 patients with migraine presenting as isolated facial pain (1.4%). The 58 patients included patients that were not naïve to migraine with head pain. However, at the time of assessment, their pain was exclusively in the maxillary (V2) and mandibular (V3) trigeminal nerve branches. Facial pain was mostly present in the V2 branch of the trigeminal nerve, while only 12 (5%) had pain in the V3 branch. Almost 80% of the patients were females. Twenty-three of these patients reported rhinorrhea or nasal blockage, 12 reported lacrimation, eight reported conjunctival injection, two ptoses, eight miosis, and two patients reported facial redness.[158]

Treatment

At this time, there are no published clinical trials investigating a specific drug or intervention for the treatment of OM. However, the literature suggests that OM is responsive to migraine treatments. For example, Gaul et al. reported two cases that responded to migraine specific medications: a case of a 44-year-old healthy female with probable OM that was successfully treated with zolmitriptan 2.5 mg, and another case of a patient with migraine pain located mostly in the maxillary front teeth that responded to combination drug containing ergotamine and diclofenac.[133] A study in a rhinologic setting, 51 patients with migraine pain in the head and face pain did not respond to medical or surgical treatment for rhinosinusitis. However, these patients benefited from antimigrainous medication (sumatriptan, pizotifen, amitriptyline, propranolol, ergotamine, and aspirin), 24 of these patients had pain isolated to the maxillary branch of the trigeminal nerve.[131] In a prospective clinical audit, 58 patients with migraine pain isolated to the maxillary and mandibular branches of the trigeminal nerve, 23 of 30 patients taking triptans successfully and consistently had resolution of facial pain episodes with triptans, and 16 of 40 patients had a reduction in pain episodes after discontinuation of daily intake painkillers. This audit also noted that patients reported that preventive medications were beneficial. The preventive treatments and number of patients using were tricyclic anti-depressants (nine patients), propranolol (four patients), candesartan (nine patients), topiramate (four patients), gabapentin (three patients), pregabalin (one patient), and botulinum toxin type A (four patients). Four patients reported benefit from greater occipital nerve blocks. [158]

Dental treatments like root canals, extractions, dental restoration, TMJ surgery, and other treatments like sinus surgery are ineffective and should be avoided at all costs.[131,158]

More research is needed regarding the treatment of OM and migraines where the main location of the pain in the orofacial structures. For example, we do not know if anti-calcitonin gene-related peptide (CGRP) monoclonal antibodies or small molecules CGRP receptor antagonists are viable treatments for OM.

Tension Type Orofacial Pain

According to the ICOP, tension type orofacial pain (TTOP), episodic or chronic, is pain in the orofacial region, without head pain, with characteristics associated with tension type headache.[18,20] However, the ICOP does not provide a diagnose criteria for TTOP because of insufficient evidence to differentiate among TTOP, TTH, and myofascial orofacial pain.[17,18,20]

Trigeminal Autonomic Orofacial Pain

The ICOP defines trigeminal autonomic orofacial pain as pain attacks with characteristics and associated features of the TAC that occur exclusively in the orofacial region without head pain. Suppose orofacial pain is associated with head pain in this case the TAC should be classified according to the ICHD-3.[18,20] TAC, a group of primary headaches, are severe, unilateral headaches with prominent cranial parasympathetic autonomic features ipsilateral to the pain. TAC are differentiated according to attack duration, frequency, and response to treatment.[20] Like the ICHD-3, the ICOP has four subtypes of trigeminal autonomic orofacial pain: orofacial cluster attacks, paroxysmal hemifacial pain, short-lasting unilateral neuralgiform facial pain attacks with cranial autonomic

symptoms (SUNFA), and hemifacial continuous pain with autonomic symptoms.[18,20]

Orofacial Cluster Attacks

Stereotypical CH attacks are severe, strictly unilateral, located in the orbital, supraorbital, and temporal region, lasting 15 to 80 min and occurring once every other day and eight times a day. Further, the pain is associated with ipsilateral conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and/or eyelid edema. Patients can also present a sense of restlessness and agitation. The circadian periodicity, active and inactive periods, is a primary feature of CH.[150] CH can be episodic or chronic. In episodic CH, attacks occur in periods lasting from seven days to one year, separated by at least three months without pain. In chronic CH, headache attacks occur for one year or longer without remission or with a remission period of less than three months.[20] Orofacial cluster attacks (OCA) have the same characteristics. However, occurring unilaterally in the face and oral region. Several case reports in the literature describe CH in the maxillary and mandibular branches of the trigeminal nerve.[129,132] Some of these reports mentioned pain in the orofacial region only, while a toothache is the chief complaint for others.[91,94,156] Patients often consult with dentists for pain resolution since the pain of CH and OCA is very similar to dental pulpitis, which can lead to diagnosis delay and unnecessary treatment.[127,140,141,144,145]

Paroxysmal Hemifacial Pain

Paroxysmal hemicrania (PH), as described by the ICHD-3, are attacks of severe, strictly unilateral pain in the orbital, supraorbital, temporal regions. The attacks last 2 to 30 minutes and occur several or many times a day. The attacks are usually associated with ipsilateral conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead and facial sweating, miosis, ptosis, and/or eyelid edema. Patients can also present a sense of restlessness and agitation.[20,150] Like CH, PH can be episodic or chronic. In episodic PH, attacks occur in periods lasting from seven days to one year, separated by at least three months without pain. In chronic PH, headache attacks occur for one year or longer without remission or with a remission period of less than three months.[20] Importantly, they have an absolute response to indomethacin.[20] Paroxysmal hemifacial pain (PHP) has the same description as PH, however, with strictly hemifacial pain attacks.[18] The literature also describes cases of PH presenting as a toothache, and like CH, there are reports of unwarranted dental treatment for PH.[128,146,156,160]

Short-Lasting Unilateral Neuralgiform Facial Pain Attacks With Cranial Autonomic Symptoms (SUNFA)

Short-lasting unilateral neuralgiform headache are described as moderate or severe, strictly unilateral, pain attacks occurring in any trigeminal distribution. Pain attacks last 1-600 s, occurring at least once a day, and are usually associated with prominent lacrimation and redness of the ipsilateral eye.[20] Attacks can take three known patterns: short-lived single stabs, groups of stabs separated by short periods of no pain, and longer attacks with many stabs in which the pain does not return to baseline (saw-tooth pain pattern).[20,150] SUNFA has the same description above but without head pain. Both of these entities can be further divided between episodic and chronic. Similar to the CH and PH, chronic diagnosis is given when there is no remission between pain attacks for at least one year, or remission period is less than three months.[18,20,150]

Hemifacial Continuous Pain With Autonomic Symptoms

Hemicrania continua is a persistent, strictly unilateral headache that varies in intensity with associated autonomic signs (conjunctival injection, lacrimation, nasal congestion, rhinorrhea, forehead, and facial sweating, miosis, ptosis, and/or eyelid edema) and/or with restlessness or agitation. The headache is sensitive to indomethacin.[20,150] Migraine symptoms like nausea, photophobia, and phonophobia are more likely to be present during periods of exacerbations.[112] There are reports of pain referral to oral and facial structures, which can complicate the diagnosis.[156,161]

Trigeminal Autonomic Orofacial Pain: Epidemiology

Among the TAC, CH is the most studied condition, and its prevalence is below 0.1%. According to pooled data from studies dated between 1978 and 2009, the one year prevalence is 124 per 100,000 persons (95% confidence interval 101–151), and its lifetime prevalence is 53 per 100,000 persons (95% confidence interval 26–95).[162,163] Cluster headache is more prevalent in males. However, the ratio between males and females has changed over time, 6.2:1 in the 1960s to 2.1:1 in the 1990s. In a meta-analysis of population studies, the overall male to female ratio was 4.3:1.[163] The one year incidence of CH ranges from 2 to 10 per 100,000.[162] In an Italian study, the average age of CH onset was 30.4 years.[164] The suggested mean age of onset between studies varies from 26 to 30 years.[162] Episodic CH is more common than a chronic manifestation of this headache.[150] There are no population studies reporting the incidence and prevalence of OCA. In a study of 608 patients suffering from CH, 330 (54%) had lower syndrome where pain involved at least one infraorbital region. However, it might also extend to the orbital branch of the trigeminal nerve.[129]

PH is a rarer condition than CH. Its prevalence is calculated to be 1% to 3% of CH.[146,165,166] PH onset is between 20 and 40 years, with a mean age of 34 years.[146,166,167] It has the same ratio between males and females, or, it is more prevalent in females with a male to female ratio of 1:2.[129] There are no population studies reporting the incidence and prevalence of PHP.

Similar to the PH, there are no population epidemiologic studies that report the incidence and prevalence of hemicrania continua. However, its prevalence may be higher than expected.[148,166] In a review article, the mean age of onset was 34 years, and the female to male ratio was 1.8:1.[167] However, when summarizing all cases for which gender data are available, a ratio of 2.4:1 can be expected.[166]

The prevalence and incidence of the short-lasting unilateral neuralgiform headache, and its orofacial counterpart, short-lasting unilateral neuralgiform facial pain attacks with cranial autonomic symptoms (SUNFA), are unknown.[165]

Trigeminal Autonomic Orofacial Pain: Treatment

Treatment for CH can be abortive when treatment is targeted to abort cluster attack or prophylactic when medications are used to reduce numbers of attacks.[149,150] There is good evidence that cluster headache attacks are responsive to subcutaneous

sumatriptan within 15 minutes of a single dose, sumatriptan, and zolmitriptan nasal sprays. Cluster attacks also respond to inhalation of 100% oxygen through a high-flow mask at a flow rate of 12–15 L/min.[149,150,168] Lidocaine dripped or sprayed into the ipsilateral nostril is an alternative for patients that triptans are contraindicated or do not respond to oxygen.[111]

Verapamil is considered a first line preventive treatment for long cluster periods or chronic CH. A limited course of corticosteroids can be useful until an optimal dose of other preventives is achieved.[112] High doses of verapamil may be required to be effective, up to 960 mg. Recognizable side effects are gingival hyperplasia, constipation, leg swelling, and cardiac dysrhythmias. Because of the effect of verapamil on heart function, electrocardiogram (ECG) monitoring is necessary. An ECG should be done before and after each increase in dosage and every six months after the dose is established.[111,112] Lithium and topiramate are also used to prevent CH.[111,112] There is evidence that Galcanezumab, a CGRP, humanized monoclonal antibody, reduces the weekly frequency of CH attacks across weeks one to three compared with placebo. However, during weeks four to eight, there was a convergence of results between these treatment groups.[169,170] Electrical stimulation of peripheral structures, like sphenopalatine ganglion, occipital, and vagus nerve, are effective in reducing pain attacks frequency.[111,171–173]

PH, hemicrania continua, and their orofacial counterparts are responsive to indomethacin.[112,167] However, when the treatment with indomethacin is not feasible, cyclooxygenase two selective inhibitors, topiramate, greater occipital nerve block with lidocaine, and methylprednisolone can be effective for some patients.[19,174–176]

Regarding the management of the short-lasting unilateral neuralgiform headache, lamotrigine is the most effective drug; gabapentin, topiramate, and lidocaine IV infusion may also be effective.[150]

Neurovascular Orofacial Pain

The ICOP defines neurovascular orofacial pain (NVOP) as moderate to severe pain in the intraoral region without head pain, although pain referral to adjacent regions is possible. NVOP presents with toothache-like symptoms, or it is pulsating, with at least one mild autonomic and/or migraine symptom. Pain attacks can be relatively short (1–4 h) or long, lasting more than 4 h.[30] Case reports suggest the evidence of dental hypersensitivity to cold without any dental pathology, which can lead to delay in diagnosis and wrong treatment.[134,144,155,177,178] Hypersensitivity to cold, the later mean age of onset, and a higher ratio between females and males (3:1) differentiates this condition from OM.[179] Importantly, as mentioned in the ICOP, NVOP needs a thorough and prospective examination.[18]

Epidemiology

The prevalence of NVOP pain varies from 7% to 52%, depending on the study population.[126,180,181] NVOP was first described in 1997.[126] In this prospective study, 29 (52%) patients, among 55 patients with neurovascular facial pain, could not be classified as suffering from migraine without aura, cluster headache, or PH. The intraoral pain of these 29 patients was severe and episodic, lasting minutes to hours, 42% of patients reported pulsatile pain, and 55% reported at least one autonomic or migraine symptom, nausea being the most common, followed by photophobia and phonophobia. In this group of patients, the mean age of pain onset was 42.6 years old (range 17 to 66 years old), and 70% were female.[126] A different study diagnosed 23 (7%) patients with NVOP among 328 patients from an orofacial pain clinic. In this group, the mean age of onset was higher than in migraineurs, 39.4 (SD ± 13.6) years old, and more common in women.[182] In a cohort of 170 patients suffering from painful posttraumatic trigeminal neuropathy (PTTN) and NVOP, 90 patients had NVOP (52%), and there were no differences regarding mean patient's age, pain onset, and pain intensity.[134] To understand better the incidence and prevalence of NVOP, more sophisticated epidemiologic studies are necessary.

Treatment

Similar to the other orofacial manifestation of primary headaches, NVOP does not answer to dental treatments.[126,142,179,180] NVOP responds to classical preventive and abortive anti-migraine drugs like triptans and propranolol.[126,178,180] However, NVOP response rate to triptans may be lower than in typical migraines. Also, chronic cases with comorbid muscle pain have good results with amitriptyline.[182]

Neuropathic Orofacial Pain

The International Association for the Study of Pain (IASP) defines neuropathic pain as pain caused by a lesion or disease of the somatosensory system.[183] The prevalence of chronic neuropathic pain in the general population is estimated to be 7% to 10%.[184,185] The prevalence of neuropathic pain following surgical interventions in the oral cavity is low, or underdiagnosed, considering the number of procedures done by dentists, or, possibility because of the ubiquitous use of local analgesia.[186]

Neuropathic pain can be classified according to its location, etiology, syndromology (neuralgia or neuropathy), and duration. However, a widely accepted classification for neuropathic pain does not exist.[20,22] Central neuropathic pain is caused by a lesion or disease of the central nervous system (spinal cord and/or brain), for example neurodegenerative or cerebrovascular diseases. Conversely, peripheral neuropathic pain pathology involves small nerve fibers (C fibers, Aβ, and Aδ fibers).[187] Paroxysmal neuralgias are episodic neuropathic pain characterized by sudden bursts of electric-like pain that project heterotopically along nerve distribution. In contrast, continuous neuropathic pains are continuous, unremitting pain with varied intensity.[22]

Pathophysiology of neuralgias and neuropathy pain can be found somewhere else in this book. Below we discuss the most relevant neuropathic pain in the orofacial region according to the ICHD-3.[20]

Cranial Neuralgias

Neuralgias can rise from cervical and craniofacial nerves, for example, the trigeminal nerve, nervus intermedius, glossopharyngeal, vagus, and occipital nerves. There are common characteristics among the neuralgias: paroxysmal, brief, and intense pains described as sharp, lancinating, stabbing, or lightning-like within the distribution of a particular nerve. They are often associated with triggers (e.g. brushing teeth, shaving), and presence of a refractory period.[188] Sodium channel blockers are usually the first line treatment for neuralgias.[188] Cranial neuralgias may or may not have a secondary cause. However, evidence of sensory changes imposes evaluations (neurophysiologic, radiographic, and laboratory evaluation) to identify secondary etiologies.[189] Highlighting

the importance of this is the "numb-chin" sign of trigeminal branch mental neuropathy, which is associated with high mortality because of its frequent association with malignancy.[188,189]

Trigeminal neuralgia (TN) is one of the most studied cranial neuralgia and is discussed in detail below.

Glossopharyngeal neuralgia is less common than TN, and both entities may exist in the same patient.[188] It is described as unilateral brief stabbing pain, abrupt in onset and termination, in the distributions not only of the glossopharyngeal nerve but also of the auricular and pharyngeal branches of the vagus nerve. Pain is experienced in the ear, base of the tongue, tonsillar fossa, and/or beneath the angle of the jaw. It is commonly provoked by swallowing, talking, or coughing and may remit and relapse in the fashion of TN.[20]

Occipital neuralgia is described as unilateral or bilateral paroxysmal, shooting or stabbing pain in the posterior part of the scalp, in the distribution(s) of the greater, lesser, and/or third occipital nerves, sometimes accompanied by diminished sensation or dysesthesia in the affected area, and commonly associated with tenderness over the involved nerve(s).[20] Patients suffering from occipital neuralgia may benefit from nerve blocks with local anesthetic and corticosteroids, neuropathic pain medication, and physical therapy. More invasive treatments, such as pulsed radiofrequency ablation, occipital nerve stimulation, or a trial of botulinum toxin, may be considered if conservative treatment fails.[188]

Trigeminal Neuralgia

TN is characterized by recurrent unilateral brief electric shock-like pains, abrupt in onset and termination, limited to the distribution of one or more divisions of the trigeminal nerve, and triggered by innocuous stimuli. It may develop without apparent cause or result from another diagnosed disorder. Additionally, there could be concomitant continuous pain of moderate intensity within the distribution(s) of the affected nerve division(s). See Box 40.1 for diagnosis criteria.[20] TN is a clinical diagnosis, based on the stereotypical disorder characteristics: short paroxysmal attacks, severe pain intensity, presence of a trigger zone, refractory period. TN is more prevalent during middle and old age, with the peak age between 50 and 69 years old, its incidence increases with age, and women are more affected than men.[190]

• BOX 40.1 Trigeminal Neuralgia ICHD-3 Diagnostic Criteria[1]

A. Recurrent paroxysms of unilateral facial pain in the distribution(s) of one or more divisions of the trigeminal nerve, with no radiation beyond,[1] and fulfilling criteria B and C
B. Pain has all of the following characteristics:
   1. lasting from a fraction of a second to 2 min[2]
   2. severe intensity[3]
   3. electric shock-like, shooting, stabbing, or sharp in quality
C. Precipitated by innocuous stimuli within the affected trigeminal distribution[4]
D. Not better accounted for by another ICHD-3 diagnosis.

Notes:
1. In a few patients, pain may radiate to another division, but it remains within the trigeminal dermatomes.
2. Duration can change over time, with paroxysms becoming more prolonged. A minority of patients will report attacks predominantly lasting for >2 min.
3. Pain may become more severe over time.
4. Some attacks may be or appear to be spontaneous, but there must be a history or finding of pain provoked by innocuous stimuli to meet this criterion. Ideally, the examining clinician should attempt to confirm the history by replicating the triggering phenomenon. However, this may not always be possible because of the patient's refusal, awkward anatomic location of the trigger, and/or other factors.

Trigeminal neuralgia can be classified into three subforms: classical, secondary, and idiopathic trigeminal neuralgias.[20] Classical TN occurs when the development of the TN has no other apparent cause besides the neurovascular compression.[20,191] When an underlying disease is the cause of the TN, the TN is designated as secondary to the disease. Patients with secondary TN may show sensory changes.[20] Some underlying causes of TN are multiple sclerosis, space-occupying legions, and arteriovenous malformation.[192–194] Idiopathic TN does not have abnormal MRI or electrophysiologic tests.[20] Although TN is a clinical diagnosis, brain imaging investigation (computed tomography or MRI) is critical to rule out secondary TN and possible neurovascular compression.[195]

The ignition hypothesis is the most accepted explanation for the pathophysiology of the TN. According to this hypothesis, TN results from specific abnormalities of trigeminal afferent neurons in the trigeminal root or ganglion.[196]

Treatment

TN is best managed using anti-convulsant drugs. The sodium channel blockers carbamazepine (200–1200 mg/day) and oxcarbazepine (600–1800 mg/day) are considered the first line of treatment.[195] Both drugs need blood monitoring for surveillance of low blood cell counts, liver function, and hyponatremia. Furthermore, genetic testing is warranted for carbamazepine because of the risk of developing Stevens-Johnson syndrome and toxic epidermal necrolysis.[197,198] There is limited evidence supporting add-on therapy with lamotrigine and baclofen. The efficacy of other drugs used for the treatment of other neuropathic disorders like gabapentin, pregabalin, serotonin-noradrenaline reuptake inhibitors, or tricyclic anti-depressants is unknown.[195]

Surgical treatment is also used in the management of TN. However, there are significant risks associated with these treatments.[199–201] Microvascular decompression is the most effective surgical treatment for patients with classical TN; shorter duration of pain and arterial compression improve outcomes. However, it is associated with meningitis, CSF leak, transient diplopia, wound infections, temporary hearing loss, ataxia, and more permanent hearing loss and death.[201] Balloon compression, glycerol rhizotomy, radiofrequency thermocoagulation, and gamma knife radiosurgery are procedures with a high rate of initial pain relief. However, pain recurrence is more common, and they are associated with facial numbness and dysesthesia, radiation induced neoplasia and vascular injury, cranial palsies, trigeminal motor weakness, and meningitis, among other side effects.[199,200] These procedures could be an alternative for patients that cannot tolerate microvascular decompression.

Painful Trigeminal Neuropathy

The ICHD-3 defines painful trigeminal neuropathy as facial pain in the distribution(s) of one or more trigeminal nerve branches caused by another disorder and indicative of neural damage. It is distinguished from trigeminal neuralgia because the pain is primarily continuous or near-continuous, and commonly described as burning, squeezing, or likened to pins and needles. However,

brief pain paroxysms can occur. There are clinically detectable sensory deficits within the trigeminal distribution, and mechanical allodynia and cold hyperalgesia are common.[18]

Painful trigeminal neuropathy attributed to herpes zoster (pain is present for less than three months) and trigeminal postherpetic neuralgia (pain persists for more than three months) are conditions associated with herpes zoster virus. In both, facial pain is unilateral in one or more trigeminal nerve branches, with variable sensory changes. The ophthalmic branch of the trigeminal nerve is the most affected by the virus. Postherpetic neuralgia is the most frequent chronic complication after herpes zoster, its frequencies increase with age, and herpes zoster vaccination reduces the incidence of both herpes zoster and postherpetic neuralgia.[202] Treatment of these conditions can be topical (capsaicin, lidocaine patches) or systemic with drugs like anti-depressants, and anti-convulsants.[203]

Painful PTTN is unilateral or bilateral facial or oral pain following and caused by trauma to the trigeminal nerve, with symptoms or clinical signs of trigeminal pain dysfunction. [134] There is a clear history of a traumatic event (mechanical, chemical, thermal, radioactive) and a positive (e.g. allodynia) or negative (e.g. hypoesthesia) sign of trigeminal nerve dysfunction. The pain is located in the distribution of the trigeminal nerve where trauma occurred and has developed within six months of trauma.[20,186]

Painful trigeminal neuropathy attributed to other disorders is pain developed because of other disorders that are not herpes zoster or trauma. It is a unilateral or bilateral pain in the trigeminal nerve distribution with clinical evidence of positive or negative neurologic signs. This condition could be secondary to multiple sclerosis, space occupying legions, or systemic disease.[20]

Idiopathic painful trigeminal neuropathy is unilateral or bilateral pain in one or more trigeminal nerve branches, indicative of neural damage but of unknown etiology.[20]

The general approach to clinical management in painful trigeminal neuropathy is similar to that for other forms of neuropathic pain and is discussed in Chapter 21.

Persistent Idiopathic Facial Pain and Persistent Idiopathic Dentoalveolar Pain (Previously Atypical Facial Pain and Atypical Odontalgia)

Persistent idiopathic facial pain (PIFP) is defined by the ICDH3 and by the ICOP.[18,20] The ICHD-3 describes PIFP as facial and/or oral pain that is daily recurrent, lasting more than 2 h a day for longer than three months.[20] The ICOP defines PIFP as pain occurring in the facial region, and, for persistent pain occurring intraorally, the ICOP uses the term persistent idiopathic dentoalveolar pain (PDAP).[18]

According to the ICHD-3, in addition to PIFP's daily occurrence, pain is poorly localized and does not follow nerve distribution. PIFP has a nagging, dull, or aching quality. Neurologic examination is unremarkable, and pain from odontogenic origin has been excluded.[20]

The ICOP adds on its notes that PIFP and PDAP pain can be deep or superficial, and may radiate from the mouth to the face or from the face to the mouth. More, it acknowledges that somatosensory changes could be present. The ICOP classification further classifies these conditions according to the presence of somatosensory changes when a quantitative sensory test is available.[18]

In the past, the term atypical facial pain was used for PIFP,[20] and atypical odontalgia and phantom tooth pain were terms used for PDAP.[18,186] Historically, atypical facial pain has been used to describe pain in the trigeminal nerve territory that does not resemble the typical presentation of TN.[185] Although the ICHD-3, the IASP, and the ICOP refer to atypical facial pain as a previously used term for PIFP, the International Statistical Classification of Diseases and Related Health Problems (ICD) has maintained the term atypical facial pain.[2,20] The ICD11 describes atypical facial pain as chronic pain of the face that does not meet other diagnostic criteria: https://icd.who.int/browse11/l-m/en.

Constant Unilateral Facial Pain With Additional Attacks

Constant unilateral facial pain with additional attacks is a mild to moderate intensity, dull unilateral pain with distinct moderate to severe pain attacks that last 10–30 min in the same location. Typical autonomic signs and migraine features are absent in CUPFA.[18]

Burning Mouth Syndrome

Burning mouth syndrome (BMS) is an idiopathic chronic pain condition characterized by intraoral burning or dysesthesia sensation, recurring daily for more than 2 h/day over more than three months in the oral mucosa.[20,204] Dry mouth, alteration in salivary function, and taste disturbances are also present in BMS. However, patients with BMS do not have oral mucosa pathology (white lesion, ulcers, erythema, atrophy, stomatitis).[3] Anxiety and depression are associated with BMS.[204,205] Pain is present for most of the day without any interference with sleep. Some patients report that eating or drinking decreases their pain, but most patients avoid hot, spicy, or acidic food/liquids or alcoholic beverages.[204] The anterior two-thirds of the tongue are the most common site for BMS. However, it can be present at the hard and soft palate, buccal mucosa, floor of the mouth, and lips.[204,206] BMS is more prevalent in middle-aged and older women. The overall prevalence ranges from 0.7% to 7%, increasing to 12% to 18% in post-menopausal women.[206]

BMS is a clinical diagnosis of exclusion after investigations to rule out secondary causes of the syndrome are negative. Health history, physical examination, laboratory tests, possible brain and brain stem imaging, salivary flow rate, and psychometric screening should be part of the patients' workup to rule out conditions such as allergic reactions, infection, galvanism, hypothyroidism, diabetes, menopause, vitamin (B complex, iron, zinc) deficiencies, anemia, gastrointestinal abnormalities, medications adverse effects or drug-drug interactions, Sjögren's syndrome, anxiety, depression, and compulsive disorders.[204,205] Box 40.2 has a list of laboratory tests commonly ordered for the diagnosis of BMS.

Treatment

If a specific etiologic factor causes the BMS, management of the syndrome is guided to the etiology. Management of primary, idiopathic BMS is challenging and can encompass cognitive behavior therapy, topical therapies (1 mg tablet of clonazepam for 3 min and then expectorate, 0.15% benzydamine hydrochloride three times per day, topical capsaicin [0.025% cream], or rinsing with Tabasco sauce and water [1:2-4 solution], salivary substitutes, topical antifungals), and a systemic approach (α-Lipoic acid,

• BOX 40.2 Laboratory Tests Commonly Ordered for the Diagnosis of BMS[2]

Complete blood cell count with differential
Fasting blood glucose
Hemoglobin A1C
Serum iron
Ferritin
Total immunoglobulin E
Vitamin B6, B12, and D
Serum antinuclear antibodies
Anti-Sjögren's syndrome-related antigen A and antigen B (SSA/Ro and SSB/La)
Erythrocyte sedimentation rate
Serum antibodies to *Helicobacter pylori* and oral candida
Viral and bacterial swabs

600 mg per day for two months, clonazepam, 0.5 mg per day at bedtime, serotonin/norepinephrine reuptake inhibitors, pregabalin, gabapentin).[204]

Orofacial Pain and Worrisome Differential Diagnosis

Several pain conditions that can mimic toothache are discussed in this chapter, for example, TMD, TN, migraine, neurovascular orofacial pain. However, there are some pain conditions with sinister outcomes that need to be considered when diagnosing OFP.

Giant cell arteritis (GCA) is an inflammatory disease that affects medium and large arteries, and it is most commonly seen in people over 50 years. Its incidence increases with age. GCA has a predilection for external carotid branches, and a prominent temporal artery is often seen in this disease. Blood vessel biopsy is necessary for definitive diagnosis. Erythrocyte sedimentation rate and C-reactive protein tests are done to aid diagnosis. The classical presentation of GCA is new-onset headache, jaw or tongue claudication, pain or weakness in the masticatory muscles, fatigue, anorexia, and weight loss. Corticosteroid treatment is warranted in this condition. If treatment is delayed, there is a real risk of neuro-ophthalmic complications (blindness, stroke). Loss of vision can occur within hours or days. Therefore treatment should not be delayed.[142,145,207–209]

Cardiac pain commonly radiates to the left arm, shoulder, neck, and face. However, infrequently, it can present as dental pain. Heterotopic cardiac pain needs immediate recognition to aid diagnosis. A thorough history of the pain complaint and examination is warranted, specifically addressing if the is pain precipitated by physical effort.[209,210]

OFP may be provoked by the encroachment of brain tumors, like cerebellopontine angle and middle cranial fossa tumors on pain sensitive structures.[211,212] Also, oropharyngeal carcinoma can present with pain in the posterior mandible. OFP can be present prior to the cancer diagnosis.[213,214]

Conclusion

Pain syndromes that involve the face are very common in clinical practice. Many facial pain syndromes are also unique, given the complex anatomy and specialized sensory innervation of the head, face, and neck. These syndromes represent a clinical diagnostic challenge and deserve special attention. The common descriptive terms for facial pain complaints are frequently misleading. Clinicians should be comfortable distinguishing painful conditions that arise from structural pathology, headache syndromes, oral and facial structures, TMJ disorders, myofascial pain disorders, and primary cranial neuralgias.

Key Points

- Pains that involve the face, head, and neck are very common in clinical practice. These painful conditions are often unique and deserving of special attention.
- The common descriptive terms for orofacial pain symptoms are frequently misleading. To avoid confusion, pain clinicians should be familiar with the International Headache Society's Diagnostic Criteria for Head and Neck Disorders, the ICOP, and the diagnostic criteria for TMD. Clinicians should be comfortable distinguishing painful conditions that arise from structural pathology, neurovascular pain, painful musculoskeletal disorders, and orofacial neuropathic conditions.
- Clinicians should be familiar with the clinically relevant head and neck anatomy features and the distinctive neurobiology of pain transmission in this region.
- Chronic/recurrent painful disorders are extremely common in the head and neck, and myofascial pain disorders are among the most common causes of pain and dysfunction in this group. Myofascial pain overlaps several common diagnoses, including TMJ dysfunction, tension headache, and most occipital neuralgia cases. Clinicians should know the diagnostic features, potential etiologies, and exacerbating factors for such disorders. They should also understand how these factors are associated with the various multi-disciplinary options currently recommended for treatment.
- Clinicians should know the unique anatomy and physiology of the TMJ and how jaw position and dental occlusion can contribute to TMD pain symptoms.
- Oral appliances in conjunction with stress management and physical therapy may be a viable treatment option for patients with TMD.
- TN is a unique neurogenic disorder. Patients who meet the clinical TN diagnostic criteria may benefit substantially from anti-convulsant drugs. When pharmacotherapy is exhausted, surgical treatment could be indicated. Patients with other forms of neurogenic facial pain may have a poorer prognosis.

Visceral Pain

KLAUS BIELEFELDT

Introduction

Chronic visceral pain is common. Abdominal pain is among the main reasons for physician visits, with more than 12 million consultations each year in the United States.[1] Patients with visceral pain present unique challenges as the pain is often poorly localized, associated with strong autonomic reactions and changes in visceral function. Pain management, in turn, may further alter visceral function, with opioid effects on the gastrointestinal tract providing a good example. These unintended treatment effects on visceral function can exacerbate pain or lead to additional discomfort, thus showing that rational and effective pain management needs to be based on an understanding of the anatomic and physiologic basis of visceral function *and* pain. Lastly, visceral pain may elicit a stronger emotional response in patients than somatic pain, which may lead to increased pain-related disability and affect the transition to chronicity.[2]

Physiologic Basis of Visceral Sensation and Pain

Anatomy and Physiology of Visceral Afferent Pathway

Most viscera arise from midline structures and thus receive bilateral innervation. As a result, visceral stimuli activate both hemispheres of the brain, with a predominance of the left side in most right-handed individuals.[3,4] In addition, organs in the chest cavity and most viscera within the abdomen receive dual afferent innervation with vagal and spinal nerves conveying sensory input to the central nervous system (Fig. 41.1). While vagal fibers do not reach the pelvic organs, the distal colon, bladder, prostate, and uterus also have a complex sensory innervation with afferents projecting through the thoracolumbar (hypogastric) and lumbosacral (pelvic) nerves to the spinal cord.

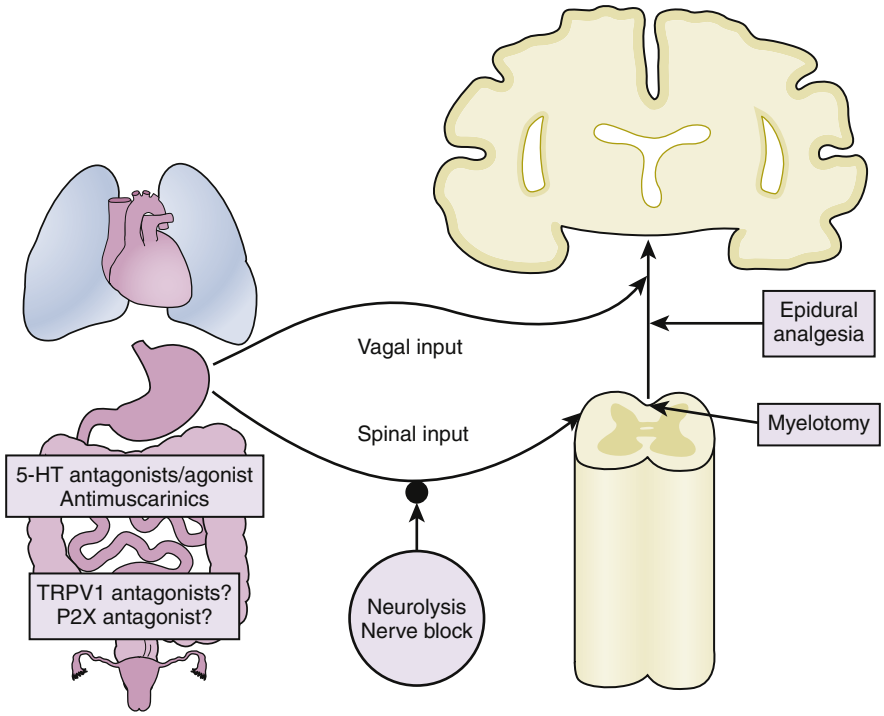
The vagus nerve predominantly comprises afferent fibers (≥80%), which project via the nodose and jugular ganglia to the nucleus of the solitary tract in the brainstem. Spinal afferents pass through the prevertebral (sympathetic) ganglia to the dorsal root ganglia and send their endings to the dorsal horn and central gray of the spinal cord. Information about noxious stimuli is relayed rostrally through the spinothalamic tract. In addition, post-synaptic dorsal horn neurons within the central gray send their central processes through the medial aspect of the dorsal columns, a pathway that has been recognized as uniquely important in visceral pain.[5]

Most physiologic studies characterizing the properties of visceral sensory pathways rely on responses to defined mechanical stimuli. Vagal afferents form a relatively homogeneous group that is activated by low-intensity mechanical stimuli and encodes stimulus intensity over a wide range. The low activation threshold is consistent with the presumed role of these sensory pathways in regulating physiologic processes. In contrast, two classes of mechanosensitive spinal afferents can be distinguished based on their response characteristics: low threshold fibers are similarly activated by low-intensity stimuli and continue to encode stimulus intensity over a wide range, whereas high-threshold fibers are activated by intense, potentially noxious intensities of mechanical stimuli. Thus spinal high-threshold fibers resemble specialized nociceptors that have been described and characterized best in the skin, suggesting that they play a primary role in visceral nociception.[6,7] However, recent studies call such a "specificity" of nociceptive pathways into question as low-and high-threshold fibers project to similar regions in the spinal cord with more intense stimuli recruiting more afferents, a conceptual shift from specificity to intensity coding.[8]

Most studies of visceral afferent pathways rely on mechanical stimulation to identify fibers or neurons projecting to various inner organs. Recent investigations suggest that such a biased search strategy may miss approximately 25% of the primary afferent fibers. While these afferents are referred to as "silent" based on their lack of mechanosensitivity, they likely respond to other stimulus modalities and can be recruited by exposure to inflammatory mediators or chemical signals in the bladder and gut.[9,10] Finally, most visceral sensory neurons are polymodal, meaning they respond to multiple stimulus modalities, including endogenous and exogenous chemicals contained in luminal contents, temperatures (heat or cold), and stretch.

Mucosal Signaling and Visceral Sensation

In the airways, gastrointestinal tract, and urinary bladder, nerve fibers are found close to epithelial cells, which often exhibit specializations with secretory vesicles on the basal surface.[11–13] Structural organization and functional studies suggest that visceral epithelial cells function as an interface between chemical or mechanical stimuli and the nervous system. The best example is serotonin release from enteroendocrine cells in the gastrointestinal tract. The gut is the major source of this signaling molecule and contains 95% of the serotonin in the body. Most of this serotonin is stored in specialized enteroendocrine (enterochromaffin) cells and can be released by chemical or mechanical stimuli, activating intrinsic



• **Figure 41.1** Schematic description of visceral innervation and potential targets for analgesic therapy. As indicated by the arrows, most viscera receive a dual sensory innervation with vagal and spinal afferents. Current symptomatic treatment of peripheral targets relies largely on agents interfering with intestinal contractility. However, the capsaicin receptor (TRPV1) and purinergic P2X receptors constitute promising targets for the treatment of visceral pain. Neurolytic block, myelotomy, and epidural analgesia all target spinal afferent pathways involved in relaying visceral pain.

and extrinsic neurons.[11] Within the urinary tract, epithelial cells release adenosine triphosphate (ATP), which acts on purinergic receptors (P2X receptors) and is involved in normal micturition as well as bladder pain.[14] Bladder epithelial cells also express the capsaicin receptor TRPV1, an ion channel that is activated by acid, temperature, endogenous lipid mediators, and the pungent substance (capsaicin) contained in hot pepper. Animals with a targeted deletion of this channel display altered micturition behavior, again lending to the importance of epithelial cells in visceral sensation.[15] A variety of luminal contents present in the gut can interact with epithelial cells or nerve terminals through the activation of protease-activated-receptors (PAR). For example, PAR-2 receptors are present in the submucosal neurons and extrinsic afferent neurons. Luminal proteases, such as trypsin, protease-released inflammatory cells, or the resident microbiome can cleave the tethered ligand and activate this pathway, thereby contributing to sensitization.[16–18]

Sensitization of Visceral Afferent Pathways

*V*isceral afferents can sensitize in response to inflammation or injury. The release of mediators, such as prostaglandins or bradykinin, rapidly alters the properties of ion channels, leading to an increase in neuronal excitability. In addition, cytokines and growth factors may trigger transcriptional changes, affecting the properties of sensory neurons through alterations in gene expression. As described above, luminal contents may directly affect the functioning of afferent neurons or indirectly influence neuron excitability by activating epithelial or immune cells. Increased peripheral input (*peripheral sensitization*) may secondarily alter sensory processing in the central nervous system (*central sensitization*), with both of these sensitization states contributing to the development and maintenance of visceral pain syndromes. One easily recognized consequence of sensitization of visceral afferent pathways is increased tenderness to palpation over a larger area than what would be expected based on the underlying pathology.[19] Both peripheral and central mechanisms contribute to the increased sensitivity and expanded areas of referred pain, which are common in irritable bowel syndrome (IBS), functional dyspepsia, and patients with painful bladder syndrome (formerly known as interstitial cystitis), or similar disorders.

Central Processing of Visceral Sensation and Pain

Vagal afferents project to the nucleus of the solitary tract and from there via the parabrachial nucleus and ventromedial thalamus to the insular cortex.[20] They form many connections with the hypothalamus, supraoptic nucleus, anterior cingulate cortex, and amygdala, which are essential for autonomic and emotional responses to visceral stimulation.[21,22] Spinal afferents also project to the thalamus. However, they are preferentially found in the posterolateral nucleus, which is connected to cortical areas, including the insula. The lateral components primarily serve discriminative functions associated with pain perception (e.g. location and intensity). At the same time, the medial thalamic nuclei, the main target of vagal input, are more closely linked to emotional and autonomic responses triggered by pain and other visceral inputs. Consistent with the bilateral innervation of organs originating from midline structures, most visceral stimuli activate both cerebral hemispheres, albeit with a preferential activation of one, mostly the left side.[3,23,24] Studies using functional brain imaging have not demonstrated striking differences in the supraspinal processing of visceral and non-visceral pain. However, visceral pain activates the perigenual portion of the anterior cingulate cortex, whereas

non-visceral pain is primarily represented in the mid-cingulate cortex. The physical proximity or even overlap between the processing of visceral pain and emotion in the perigenual portion of the anterior cingulate cortex may well explain the stronger emotional response to painful visceral than non-visceral stimuli.[25–27]

Increased afferent input alters the response properties of second- and higher-order neurons, potentially leading to lasting functional and even structural changes. In addition, factors independent of specific peripheral input, such as anxiety with associated hypervigilance, affect descending modulating mechanisms, which can also facilitate synaptic transmission along afferent pathways and affect the perception and impact of pain. More recently, the potential contribution of glial cells has generated new insights into the role of non-neuronal cells in synaptic plasticity, thereby opening another potential venue for targeted pain management strategies.[28] While experimental approaches typically focus on selecting mechanisms contributing to sensitization, clinicians face the combined impact of synaptic plasticity of afferent pathways driven by different processes, such as inflammation or cancers, compounded by central states or traits, such as anxiety or arousal with anticipation or altered sensory processing and the associated changes in descending modulation. Thus agents affecting a single step or process will have more limited efficacy in clinical practice than in more controlled experimental settings.[29] The mechanisms of central sensitization and potential treatment strategies are not unique to visceral pain and are discussed in more detail in Chapters 8 and 9.

Visceral Pain Stimuli

Visceral events that can produce a conscious sensation or acute pain in humans include traction of the mesentery, distension of hollow organs, strong contractions of muscle layers surrounding such hollow organs, ischemia, and chemical irritants.[19,30] As routine endoscopic interventions have been established, cutting or burning—two clearly noxious stimuli when applied to the skin—are not perceived when applied to the viscera, thus setting visceral apart from non-visceral sensation. Because of its sensitizing influences on sensory pathways, visceral inflammation can trigger pain and/or increase the excitability of visceral afferent pathways (e.g. enhancing low threshold input into a noxious range), which can become chronic (e.g. chronic pancreatitis). Finally, while not studied in as much detail, malignancies can trigger chronic pain because of direct effects of the tumor on afferent nerves (e.g. nerve compression, release of mediators, and growth factors) or because of indirect effects, such as distension of a hollow organ.[31,32]

Clinical Implications

- Current evidence suggests that spinal afferents primarily serve the discriminatory function of nociception, which encodes the location and intensity of visceral pain. Thus treatment strategies, such as regional block or surgical dissection generally target spinal afferent pathways.
- Unilateral nerve blocks are often ineffective, which is least partly because of complex afferent innervation with sensory fibers projecting centrally on both sides in two distinct pathways.
- Visceral pain is a complex experience associated with strong emotional and autonomic reactions, which correlates with the areas activated by visceral pain and emotional processing in the anterior cingulate cortex.
- Impaired function of the viscera, such as decreased transit of material in the gut, may cause or contribute to pain because of the composition of luminal contents, increased distension, or the resulting contractions of visceral muscles. Thus effective pain management needs to consider analgesic therapies and treatment strategies targeting specific visceral functions.

Regional Block and Neural Ablation

Surgical and non-operative approaches have been developed to perform transient nerve blocks or permanently destroy the sensory pathways involved in visceral pain. Given concerns about the irreversible nature of nerve ablation or neurolysis, most studies targeting visceral sensory pathways have involved patients with inoperable cancers and relatively short life expectancies. As these patients typically present in advanced stages of their disease with poor performance status, surgical denervation plays only a minor role in the treatment. Chemical neurolysis, generally using high concentrations of alcohol or phenol, can achieve comparable results without subjecting patients to the risk of an operation. Since the first description by Kappis nearly 100 years ago,[33] several techniques have been developed to optimize the targeted delivery of neurolytic agents and minimize the likelihood of adverse effects. These approaches utilize imaging methods to guide and confirm appropriate needle placement, such as fluoroscopy, ultrasound, or computerized tomography. However, despite this wealth of literature, few systematic studies have addressed the efficacy, outcomes, or adverse effects of these interventions. Problems assessing the effects of visceral pain management with peripheral blocks are further confounded by differences in type, concentration, and amount of the neurolytic agent, primarily alcohol, in both definition and measurement endpoints and in follow up time.

Celiac Plexus and Splanchnic Nerve Block

Spinal afferents innervating organs in the upper abdomen traverse the celiac plexus with two distinct ganglia located caudal to the origin of the celiac artery. The afferents travel centrally behind the crura of the diaphragm in the splanchnic nerves. The traditional dorsal approach uses the 12th rib and spinal process of the first lumbar vertebra as landmarks.[34,35] With the patient in the prone position, a needle is advanced about 7 cm lateral to the midline at a 30–45 degree angle and tilted slightly cranially to reach the lateral wall of the body of the first lumbar vertebra. The needle was then moved anteriorly by approximately 2 cm. If aspiration does not yield blood return, water-soluble contrast (3–5 mL) often mixed with a local anesthetic is injected under fluoroscopic guidance. To better directly target the celiac plexus, the needle can be placed approximately 2 cm more anterior, which requires piercing the diaphragmatic crura and positioning the needle close to the anterolateral aspect of the aorta. Severely ill patients with respiratory compromise, patients with significant ascites, or recent abdominal surgery often poorly tolerate being in the prone position for the time required to complete this procedure. Therefore an anterior approach has been developed with the advancement of the needle from the epigastric area toward the body of the first lumbar vertebra. If the appropriate position is confirmed, a neurolytic agent, generally phenol or alcohol, is given. Current approaches mostly rely on the tissue destructive properties of alcohol, which is used in concentrations between 50%–99% and volumes between 20 and 50 mL per injection. Injections are generally performed bilaterally to destroy the afferent pathways effectively. More recent reports suggest that radiofrequency ablation may provide an alternative and perhaps better approach than chemical neurolysis.[36,37]

However, larger studies are needed to more conclusively show a clinically relevant difference between these approaches.

Various imaging techniques have been used to improve the efficacy of neurolysis and to decrease the potential for adverse effects. The celiac ganglia are too small to allow direct visualization with computed tomography (CT) scanning or transabdominal ultrasound. Using endoscopic ultrasonography, the scanner can be brought into close proximity to the plexus. However, the ganglia do not differ in echogenicity from surrounding structures; thus they do not allow direct imaging and identification of the target structure. Therefore all approaches rely on identifying the celiac artery as the main landmark. CT allows guidance of the needle to the target area and a three-dimensional reconstruction of the area affected by the neurolytic agent, based on the spread of radiopaque contrast.[38] While ultrasound allows real-time guidance without radiation exposure, air in the overlying structures often interferes with sound penetration and imaging, thus limiting its utility for patients undergoing celiac plexus block.[39] Endoscopic ultrasound with the use of an endoscopically advanced needle has been successfully used. Close inspection may identify tumor infiltration as a negative prognostic criterion and thus help in appropriate patient selection.[40] In addition, alcohol injection alters the echogenicity of the affected tissue, thus allowing direct visualization of the spread of the neurolytic agent.[41] Only one trial directly compared endoscopic and conventional percutaneous approaches in celiac plexus block, suggesting the superiority of the endoscopic approach for efficacy outcomes.[42]

Surgical Celiac Plexus or Splanchnic Nerve Ablation

One randomized controlled trial and several small case series have used surgical approaches to ablate the celiac ganglia or splanchnic nerves. Direct visualization during surgical exploration allows targeted injection of neurolytic agents into the celiac plexus if curative resection cannot be performed.[43] Because of advances in preoperative imaging, fewer patients currently undergo exploratory laparotomies, thus limiting the number of patients who might undergo an intraoperative celiac plexus block or ablation. Thoracoscopic resection of splanchnic nerves has been reported with the advent of minimally invasive surgery. As is true for less invasive procedures, approaches have not been standardized with unilateral and bilateral resection with or without vagotomy being performed to achieve pain control in these patients.[44–46]

Efficacy Of Neural Block and Ablation

Despite a wealth of published data, questions about the benefits, the best approach, and potential unintended consequences remain regarding the efficacy of neural blocks and ablation, which are likely because of differences in patient selection, interventional techniques, and outcome measures. A meta-analysis published in 1995 concluded that nearly 90% of patients with various malignancies experienced good pain relief for approximately three months after the procedure.[35] Two small randomized controlled trials demonstrated similar pain control but lower adverse effects because of decreased opioid consumption in patients treated with neurolytic block.[47,48] Subsequent studies point to a slight advantage of ablative treatment over pharmacotherapy. Intraoperative celiac plexus block with 50% alcohol led to stable pain subjective pain severity scores in patients with inoperable pancreatic cancer, while patients receiving saline injection as a control experienced a significant increase in pain scores during follow up. This improvement in pain control was associated with a significantly lower use of opioids.[43] In a posthoc analysis, patients with significant pain had improved survival if they underwent celiac plexus block, compared to controls. However, there was no overall survival benefit when the comparison was made using the original entire study cohort. Three subsequent trials comparing neurolytic celiac plexus block to analgesic therapy confirmed better pain relief after ablative therapy. In two studies, the improvement was transient with progressive recurrence of pain after about one to two months.[49,50] Most patients still required opioids, albeit at lower dosages compared to the control in the two smaller studies.[49,50] A more recent study by Wong et al. did not confirm this decrease in opioid consumption. Consistent with prior studies, their results also demonstrated that appropriate dosing of opioids achieves good pain control and quality of life that did not differ between treatment groups. However, none of these investigations demonstrated a significant effect of neurolytic plexus block on patient survival.[51] This lack of survival difference was called into question by a large study that pointed to a possible detrimental effect of celiac plexus block in pancreatic cancer patients. The retrospective design did not allow a clear answer as to why the intervention was associated with shortened survival. However, baseline characteristics suggest a selection bias with a more advanced illness stage in the group undergoing neurolysis as a potential explanation.[52] As cancer progression may affect the efficacy of ablative procedures by lowering apparent response rates, one small study randomly enrolled patients to perform early and late neurolytic blocks.[53] While both groups reported better pain control than medically treated controls, there were no significant differences between the groups, arguing against disease progression as a relevant confounder. Despite some remaining questions, these data and meta-analyses indicate that pain relief after neurolytic block in pancreatic cancer is at least comparable to conventional analgesic therapy and may be associated with lower opioid consumption and thus fewer treatment-related side effects.[54–56]

Rather than targeting the celiac plexus, one can also block or cut the splanchnic nerve, which has been compared in one trial with celiac plexus block.[57] The reported improved pain control was not consistent across key primary endpoints and was only significant for a secondary outcome measure, which was a decrease in pain intensity from baseline. Thus confirmatory studies are needed to establish whether splanchnic nerve destruction is indeed superior to the neurolysis of the celiac plexus. Similarly, the results of surgical interventions with neurolytic or neuro-ablative therapy of the splanchnic nerve remain inconclusive. While the only randomized controlled trial demonstrated good pain relief and a decrease in opioid consumption,[43] a case series evaluating different palliative operations for pancreatic cancer did not confirm a decrease in opioid use after surgery plus celiac plexus block.[58] Smaller case series reported improved pain control in about 60%–80% of patients after thoracoscopic splanchnicectomy, performed unilaterally or bilaterally with or without a vagotomy.[44–46,59–63] Poor definition of endpoints, limited assessment of analgesic effects, the lack of appropriate control groups, and the fact that comparable results were obtained using a variety of different approaches demonstrate the need for further research with rigorous methodologic design. Splanchnicectomy reduces opioid requirements compared to systemic pharmacotherapy but not compared to celiac plexus block.[46,63] Overall, the current data suggest acceptable pain relief with an at least transient decrease in opioid requirements,[54] but do

not support the superiority of one ablative approach over another. Thus the discussion of available treatment choices for patients and physicians should primarily focus on the risk/benefit ratio of the procedure, the available expertise, and whether a specific institution or provider favors one technique over others because of appropriate training and expertise in specific techniques.

Nerve Block or Ablative Therapy in Benign Disorders

Pain relief after a neurolytic block is often transient, thus decreasing the enthusiasm to use such approaches in patients with non-cancer chronic visceral pain disorders and longer life expectancies. Given this, less information is available regarding the efficacy of nerve blocks in these patient cohorts. Several case series have been published investigating the efficacy of nerve blocks in more than 500 patients with chronic pancreatitis, making this the largest patient group with benign visceral pain disease. The initial response rates to this intervention in this population varied between 30% and 90%, with limited follow up in most cases.[36,42,45,62,64–68] Because of concerns about the use of neurolytic agents, the largest series combined bupivacaine with triamcinolone.[65] While about half of the patients reported an initial benefit, sustained analgesic responses after 24 weeks were seen in only 10% of cases. The commonly practiced addition of corticosteroids has been addressed in a randomized controlled trial, which showed no additional benefit of triamcinolone with response rates of approximately 15% one month after celiac plexus block with bupivacaine plus placebo or the steroid.[69] Moore et al. reported results of stellate ganglion and paravertebral blocks with bupivacaine in 59 patients with refractory angina because of coronary artery disease.[70] About 60% of the patients reported pain relief for more than two weeks. However, the benefit was transient, and most patients required multiple interventions to maintain some benefits. Interestingly, limited experience with differential neuraxial blocks suggests that primarily visceral pain was present only in about one-fifth of patients with chronic pancreatitis, with the majority experiencing "central pain," defined by persistent pain despite surgical anesthesia through epidural administration of lidocaine.[71] Overall, the data highlight the complex etiology of chronic pain syndromes in patients with benign visceral pain disorders and do not support the use of ablative therapies in these patients.

Pelvic Nerve Blocks

Several surgical and non-operative approaches target ganglia or nerve structures projecting to the pelvic structures. The most extensive experience with appropriately designed clinical trials addresses the management of dysmenorrhea and pelvic pain in endometriosis, largely relying on presacral neurectomy or laparoscopic uterosacral nerve ablation (LUNA). Three randomized controlled trials did not show a true benefit when the nerve ablation was added to the surgical treatment of endometriosis.[72–74] Less is known about the impact of presacral neurectomy, which reportedly leads to lasting pain relief in more than 50% of patients described in a large case series.[75,76] Two randomized trials showed inconsistent results with one group reporting complete resolution of pain in 85% vs. 57% of women treated with and without neurectomy, respectively,[77] while an earlier trial concluded that only menstrual pain, but not other forms of the more chronic pelvic pain, improved after surgical nerve ablation.[78] A meta-analysis of published data did not find sufficient evidence supporting the benefit of ablative therapies in dysmenorrhea or chronic pelvic pain.[79]

Various non-operative approaches have been developed to block or ablate afferent pathways that contribute to pelvic pain. As described earlier, the pelvic viscera conveys sensory input through two distinct spinal afferent pathways, which project to the thoracolumbar and lumbosacral segments of the spinal cord. The thoracolumbar afferents give rise to the splanchnic and hypogastric nerves, while the lumbosacral afferents form the pelvic nerve. Several distinct ganglionic structures form and are potential targets for interventions. They include the inferior mesenteric and major pelvic ganglion, as well as the presacral ganglion impar. In addition, the pudendal nerve functions as the primary sensorimotor nerve for the pelvic floor muscles, sphincters, perineum, and genitals. As is true for interventions targeting the celiac plexus, options include interventions guided by cross-sectional imaging, mostly with CT, and fluoroscopic guidance relying on bony structures as landmarks. The indication and performance of the aforementioned nerve blocks depend on the affected nerves, location of the pain, technical expertise, and availability of the equipment. Current data do not show effects on success rates.[80–85]

Adverse Effects of Neurolytic Block

Acute side effects are largely related to the typical complication of invasive procedures or operations and involve injury of neighboring structures, most importantly blood vessels, infections, thromboembolic complications, and pain. Transient pain is the most common side effect of neurolytic agents. While the use of local anesthetic prior to alcohol injection decreases the incidence of this adverse effect, at least 10%–30% of patients experience significant pain within the first hours after the procedure.[39,86–88] The destruction of sympathetic efferent pathways causes vasodilation of splanchnic vessels, resulting in hypotension in up to 20% of patients.[49,86,87] Similarly, the unopposed parasympathetic drive can lead to diarrhea, which has been reported in approximately one-fifth of patients.[47,49,87,88] Pelvic nerve blocks or ablations can trigger constipation or interfere with bladder emptying. These problems can generally be managed medically with appropriate premedication, hydration, post-procedural observation, and appropriate symptomatic therapy.

For procedures targeting the celiac plexus, the posterior approach may traverse the kidney and the pleural space, potentially leading to hematuria or pneumothorax.[34,35,88] The anterior approach requires advancing the needle dorsally and potentially passing through the liver, stomach, or colon. While this is largely inconsequential, clinically relevant perforations can occur and may be difficult to diagnose because of the neurolytic block and often concomitantly administered analgesia.[89] Therefore patients should be well hydrated, receive an intravenous fluid bolus prior to performing the nerve block, and remain under observation for at least 2–4 h after the procedure. The delivery of neurolytic agents near major vessels is another potential source of complications. In all cases, aspiration should ensure that the needle is not inside the vessel before the neurolytic agent is injected. Nonetheless, indirect effects, such as mesenteric venous thrombosis, may rarely occur despite these precautions.[90] Spread of the neurolytic agent within the retroperitoneal space with lumbar nerve injury has been reported.[35] Paraparesis is the most feared and mostly irreversible complication, which is thought to be caused by injury to the nutrient vessels supplying the spinal cord.[34,35] While sufficiently powered studies addressing the likelihood of these adverse effects are not available, current evidence suggests that the incidence does not differ between the different approaches.[41,63,87]

Clinical Implications

- Neurolytic celiac or splanchnic nerve block is a moderately effective method to decrease pain in patients with intra-abdominal malignancies and has been best studied in patients with pancreatic cancer. The benefit is often transient and may decrease the need for opioids but does not clearly affect life expectancy or quality of life compared to conventional pain management.
- Pelvic nerve blocks or ablations can at least transiently relieve chronic pelvic pain but have inconsistent effects when assessed over longer periods of time. Adverse effects are largely minor and transient and can be managed by appropriate medical therapy. Approaches using different imaging techniques or even direct operative treatment do not seem to affect the outcome or incidence of side effects.

Central Treatment Targets for Visceral Pain

Epidural block or pharmacotherapy, spinal cord stimulation, and surgical myelotomy have been used to treat chronic visceral pain syndromes. Two aspects unique to visceral pain syndromes warrant a specific discussion of spinal treatment targets. First, preliminary studies suggest that patients with ischemic heart disease may derive significant benefits from epidural blocks. Second, unlike non-visceral pain, which is primarily relayed to supraspinal sites via the spinothalamic tract, functional and neuroanatomic studies have demonstrated that the dorsal column ascending pathway plays an important role in visceral pain.[91,92] Considering these points and the complex innervation of visceral structures, we cannot extrapolate from studies that focused on spinal approaches to manage non-visceral pain. Unfortunately, only a few studies have systematically evaluated the clinical efficacy of these approaches over long periods, thus limiting their ability to fully assess their therapeutic value.

Epidural Analgesia and Visceral Pain

Spinal drug delivery through epidural catheters allows the delivery of opioids and other agents without a significant risk of systemic adverse effects. Acute or chronic epidural drug delivery alleviates visceral pain in patients with cancer-related pain and some patients with non-cancer pain disorders.[71,93] Interestingly, high thoracic epidural anesthesia significantly improved angina in patients with refractory pain because of coronary artery disease and decreased documented episodes of cardiac ischemia as judged by ST depressions.[94,95] A more recent study provided further insights into the underlying mechanism by demonstrating improved cardiac perfusion during high epidural analgesia, likely because of a concomitant block of sympathetic pathways.[96] While a case series suggested a lasting improvement over periods of more than one year,[97] a small controlled trial randomized patients to saline or bupivacaine and did not see differences in pain control.[98] Epidural analgesia plays a role in perioperative pain control during and after abdominal and pelvic surgeries. It may also help in differentiating peripheral from central pain mechanisms and may thus allow the selection of patients who are more likely to respond to peripheral nerve blocks.[99] Information addressing a more chronic use of epidural pain pumps for chronic abdominal or pelvic pain is limited to isolated case reports, thus not allowing an assessment of efficacy. Independent of questions about benefits, safety issues have not been addressed but will likely be similar to the previously reported complication rate of epidural drug delivery, which is addressed in more detail in a separate chapter.[100–102]

Spinal Cord Stimulation and Visceral Pain

Recently, several case reports have described significant improvements in severe visceral pain with spinal cord stimulation. The largest series compiled data from a total of 70 patients with refractory thoracic, abdominal, or pelvic pain syndromes.[103] Less than 10% did not respond to the temporarily implanted trial electrodes; responders to the trial were then offered a permanent device, which was surgically implanted and led to a maintained improvement with lower opioid requirements in the majority of patients. Two single-center studies focused on patients with chronic pancreatitis and noted a benefit for up to one year in about 80% of the patients.[104,105] However, data were analyzed retrospectively and relied on physicians rather than patient ratings. Finally, complications such as lead migration and device removal have been shown to be as prevalent as 10%–20% and are important caveats that show the need for controlled studies before more broadly introducing this approach into clinical practice. Only one small trial randomly allocated patients with IBS to active treatment or no stimulation in a crossover design. While the lack of an appropriate control intervention leaves questions when testing the effects of an active therapy that can be easily felt, patients experienced less pain during stimulation only.[106] While not targeting the spinal cord, sacral neuromodulation may be effective in chronic pelvic pain. Using an approach that has been approved for the treatment of voiding dysfunction, sacral neuromodulation stimulates the afferent sacral roots through transforaminal implanted electrodes. Meta-analyses included assessments of pain ratings as secondary endpoints and reported improvement.[107,108] However, the degree and duration of this improvement require more detailed data,[109] especially as approximately half of the patients have reinterventions within the first few years, and about 30% will eventually have the device removed.[110,111]

Myelotomy and Visceral Pain

Since its introduction more than 20 years ago, midline myelotomy has been used to treat patients with refractory pain because of visceral malignancies.[112] Open surgical and percutaneous CT-guided approaches have been developed. However, the nature of this intervention as a "rescue" treatment in patients who failed other therapies limits information to small case series and does not allow us to judge its clinical efficacy. Case series are typically limited to patients with advanced malignancies and report improved pain control in about 60% of patients, with symptoms reoccurring in up to half of the patients.[113–116]

Transcutaneous Stimulation

The search for non-invasive treatments and the reported benefit of transcutaneous electrical or magnetic stimulation techniques in non-visceral pain led to the use of these therapies in some visceral pain syndromes. While these techniques are available and, in the case of transcutaneous electrical nerve stimulation (TENS), a part of routine pain management, published data supporting their utility in visceral pain remain limited. TENS improved angina threshold and exercise capacity in patients with coronary artery disease, with an inconsistent effect on pain severity.[117,118] Only one small study of healthy volunteers tested TENS on acute experimental pain

originating in the gut and reported that TENS led to a higher pain threshold during esophageal distension.[119] Similarly, electroacupuncture decreases the sensation of rectal distension in healthy persons.[120] However, it is unclear whether the blunted responses to acute experimental pain in healthy persons indeed translate into a relevant benefit for patients with chronic visceral pain.

Repetitive transcranial magnetic stimulation over the motor cortex showed some initial promise in various disorders characterized by chronic pain.[121] A small blinded crossover trial showed the benefit of active therapy in patients with chronic pelvic pain.[122] While a meta-analysis suggested a possible short-term benefit of this approach to chronic pain independent of locus or presumed mechanism, the authors did not see lasting effects and withheld more conclusive support for this modality because of concerns about bias.[123]

Clinical Implications

While systematic studies have not specifically addressed the efficacy of epidural drug delivery in patients with chronic visceral pain syndromes, currently available data support its use in patients with refractory pain because of ischemic heart disease. Data on spinal cord stimulation or myelotomy remain limited to uncontrolled and often small studies, which suggest a potential, albeit often only partial and transient pain relief, and should be reserved for patients with intractable pain because of terminal disease. Theoretically, non-invasive modalities that rely on transcutaneous electric or magnetic stimulation lack proven efficacy in visceral pain.

Mechanism-Oriented Pharmacotherapy of Visceral Pain

Visceral pain is often associated with abnormalities in organ function, such as constipation, nausea, cardiac failure, or dysuria. These abnormalities may cause or contribute to pain or be caused by pain syndrome or its treatment. Thus the evaluation of patients with visceral pain syndromes should always go hand-in-hand with appropriate functional assessment of the affected organ system(s). Selectively altering these functions may offer options to alleviate discomfort without relying on analgesic agents or interventions that specifically target sensory mechanisms.

Serotonin and Gastrointestinal Pain Management

As described above, the gastrointestinal tract contains 95% of the body's serotonin (5-HT), which is involved in many different functions. Neurons, smooth muscles, and epithelial cells express different serotonin receptors. The ligand-gated 5-HT_3 receptor has been found on vagal and spinal afferents and is involved in visceral sensation, including the perception of nausea.[124,125] Metabotropic 5-HT receptors exert more complex effects on gut function as they act on multiple targets, including muscle and nerve cells, with limited studies suggesting that 5-HT_4 agonists and 5-HT_1 antagonists may decrease visceral sensation in experimental animals and healthy volunteers.[126–128] Currently, selective 5-HT_3 receptor antagonists and 5-HT_4 receptor agonists are available for clinical use. While there is some experience with other serotonin receptor blockers, this experience is limited, mostly demonstrating physiologic changes in healthy controls or short-term effects in patients with mild abdominal discomfort. Anti-depressants alter serotonin signaling, mostly by inhibiting the reuptake mechanism that terminates the effect of the released serotonin and is commonly used in patients with various pain syndromes, including those with visceral pain. Considering their significant impact on central processing, it is impossible to attribute the effects to peripheral changes in serotonin signaling.

Clinical Efficacy of Serotonin Agonists and Antagonists

The 5-HT_3 antagonist alosetron has been successfully used in patients with functional bowel disease, characterized by abdominal pain and diarrhea.[129–132] However, the effect is relatively modest, with a recent meta-analysis showing a small odds ratio (1.8) favoring the active agent over placebo, translating into a number needed to treat of about 7.[133] Other 5-HT_3 receptor antagonists, such as ondansetron, play an important role in the treatment of severe nausea and vomiting but show some efficacy in diarrhea as well with less consistent effect on pain.[124,134–137] The variable impact on pain fits the results of preclinical studies that argue against a direct analgesic effect of these agents.[138] Tegaserod, a 5-HT_4 receptor agonist, significantly accelerates gastrointestinal transit and alleviates symptoms of constipation, including associated discomfort and pain.[139,140] Using global improvement scores, currently available data suggest a relatively low odds ratio (2.0) favoring tegaserod over placebo with a number needed to treat about seven.[141] Tegaserod had been removed from the market in the United States because of safety concerns and recently received approval limited to women under 65 years with chronic constipation. Another 5-HT_4 receptor agonist, prucalopride, improved constipation with an associated increase in quality of life indicators, including abdominal bloating and discomfort. However, the limited information suggests an indirect benefit because of improved constipation rather than a direct analgesic effect.[142,143]

As already mentioned, most anti-depressants affect serotonin signaling, with selective serotonin reuptake inhibitors (SSRIs) being the most commonly used agents. Many studies have addressed the impact of anti-depressants on visceral pain, primarily focusing on gastrointestinal disorders. While individual studies have discrepant results,[144–146] recent meta-analyses suggest improvement of functional gastrointestinal disorders, but not as clearly in pelvic pain.[147–150] Interestingly, there is no clear difference between the less specific tricyclic anti-depressants and agents that selectively interfere with serotoninergic signaling, arguing against a pathway-specific effect. Similarly, it is unclear whether we are truly dealing with changes in pain sensations. For SSRIs, the improvement was primarily because of changes in global assessment scores rather than pain ratings. Considering the potential impact of psychiatric comorbidity as a confounder, one study specifically examined the effect of citalopram in non-depressed patients with IBS and did not demonstrate any benefit.[151] While a case series described cohorts treated with other agents, only one serotonin-norepinephrine reuptake inhibitor, venlafaxine, has been appropriately examined in patients with dyspepsia as a disorder associated with pain and was not superior to placebo.[152] Two small studies examined duloxetine in combination with an α-receptor blocker in chronic prostatitis and pelvic pain, with results suggesting beneficial effects on pain and quality of life.[153,154] Overall, currently available data support the use of anti-depressants, preferentially tricyclics and SSRIs, in functional gastrointestinal disorders associated with pain, especially in patients with coexisting anxiety or depression.

Adverse Effects of Serotonin Agonists and Antagonists

The most common side effect of alosetron and related agents is constipation, which is reported in 20%–40% of patients.[141] Alosetron has been linked to ischemic colitis, a potentially fatal disease, which led to its withdrawal from the market.[133] It is currently only available under a restricted access program with stringent monitoring. Tegaserod use has also been associated with ischemic events, in this context myocardial infarction, and was similarly removed from the market but was recently made available again with a more restricted indication.

Smooth Muscle Relaxants and Visceral Pain

Stretch and tension are stimuli that are adequate to evoke conscious visceral sensation, corresponding to distension of a hollow viscus or contraction of the tunica muscularis.[30] The visceral muscle is morphologically and functionally distinct from striated muscle, thus potentially allowing the use of pharmacologic interventions that may not significantly affect striated muscle. Several strategies have emerged or are currently under investigation. Most rely on the blockade of muscarinic receptors, the main excitatory signaling mechanism between parasympathetic neurons and visceral smooth muscle. Less commonly used strategies employ agonists for α-adrenergic receptors or L-type calcium channel blockers to affect the contractility of the visceral smooth muscle. The latter two approaches have largely been used in healthy volunteers, showed only limited efficacy in small studies involving patients with different painful disorders, and carry a significant risk of adverse effects, primarily symptomatic hypotension.[155–160] Therefore the discussion of spasmolytic agents will focus on muscarinic receptor antagonists, such as hyoscyamine or dicyclomine, with the best evidence emerging from studies performed in patients with functional diseases of the gastrointestinal tract.

Clinical Efficacy of Smooth Muscle Relaxants

Two published meta-analyses concluded that compared to placebo, patients receiving anticholinergic drugs are twice as likely to report an overall benefit, which includes pain relief.[161,162] However, many of the patients experienced relatively mild pain at baseline with only moderate pain relief compared to placebo.[147]

Adverse Effects of Smooth Muscle Relaxants

Approximately 10% of patients experience largely minor adverse effects, mainly because of effects on mucous membranes, the urinary tract and eye, dry mouth, urinary retention, and problems with accommodation. Based on the mechanisms of action, anticholinergic drugs are contraindicated in patients with known glaucoma and should be avoided in patients with micturition problems.

Botulinum Toxin and Visceral Pain

The clinical use of botulinum toxin has expanded significantly beyond the initial target, spastic motor disorders of skeletal muscles.[163] More than 15 years ago, it was shown to affect smooth muscle as well, leading to symptomatic improvement in patients with achalasia.[164] As anecdotal evidence suggested a decrease in pain independent of its effect on muscle activity, botulinum toxin has been increasingly used to treat various pain syndromes, presumably by directly altering peripheral transmitter release from nociceptive afferent nerve terminals.[165] Essentially, all the studies focusing on patients with visceral pain are case series. Patients often present with associated impairment of visceral function, such as dysphagia, gastroparesis, or voiding dysfunction. Considering the likely impact of the agent on muscle activity, it is impossible to differentiate the direct effects on afferent pathways from the results of improved organ function.

Clinical Efficacy of Botulinum Toxin

Few studies have focused on pain and have systematically examined changes in pain intensity after treatment with botulinum toxin type A. In patients with various esophageal motility disorders characterized by pain, injection of botulinum toxin into the distal esophagus significantly reduced the pain score from severe to mild in approximately two-thirds of patients for about five months.[166] In a smaller case series of patients suffering from diffuse esophageal spasm with severe chest pain, endoscopically guided injection of botulinum toxin along the tubular esophagus resulted in nearly complete alleviation of pain for six months.[167] There are limited results about the effects of botulinum toxin in other areas of the gastrointestinal tract, suggesting a potential benefit in disorders associated with pain.[168] In the urinary tract, botulinum toxin has been successfully used to treat voiding disorders. While a case series suggested some effect in painful bladder syndrome, an idiopathic disorder characterized by pelvic pain, urinary urgency, and increased frequency of micturition, results of randomized controlled trials are inconsistent with larger trials that do not confirm superiority over placebo.[169–172] In contrast, smaller single-center studies suggested a potential benefit.[173–175]

Adverse Effects of Botulinum Toxin

Generally, low doses of locally injected botulinum toxin do not cause systemic side effects. Adverse effects are largely limited to transient pain or infectious complications at the injection site, such as urinary tract infections. Injection close to the striated muscle, most notably the sphincteric muscle for the bladder or rectum, may lead to transient incontinence.

κ-Opioids and Visceral Pain

Opioids are potent analgesics for non-visceral and visceral pain. However, μ-opioid receptor agonists commonly cause gastrointestinal side effects, such as nausea, vomiting, and constipation. These unwanted effects may become dose-limiting, especially in patients with gastrointestinal disorders. In addition, the rising incidence of opioid addiction with the associated deaths because of overdoses has led to increasing concerns about the use of these agents in benign disorders. As peripheral visceral afferents express κ-opioid receptors, κ-agonists have been developed to take advantage of their analgesic properties and a lower likelihood of adverse effects.[176] Animal and acute studies in human volunteers demonstrated increased thresholds to painful visceral stimuli, consistent with a potential analgesic effect.[177,178] However, central effects with significant dysphoria limit the use of κ-agonists to peripherally acting agents.

Clinical Efficacy of K-Opioid Agonists

A single small study reported κ-agonist-induced pain relief in patients with chronic pancreatitis who were refractory to μ-opioid agonists. However, patients have only been studied acutely after a single administration of the agonist.[179] Several randomized controlled trials examined the effects of fedotozine, a κ-opioid agonist, in patients with chronic abdominal pain because of functional disorders over two to six weeks, with two of the studies suggesting a small benefit compared to placebo.[180–182] On-demand therapy with asimadoline, a peripherally acting κ-opioid agonist, did not affect pain severity in patients with IBS.[183]

The recently introduced eluxadoline has a complex effect on opioid receptors, functioning as an agonist on μ-and κ-opioid receptors and as an antagonist of δ-opioid receptors. At the recommended dosages, the effects were peripherally restricted. The agent has been approved in the United States for the treatment of diarrhea predominant IBS based on the improvement of a composite endpoint that included improved bowel patterns and pain relief.[184] True visceral analgesic responses independent of the potential indirect effects on intestinal function have not been assessed.

Adverse Effects of K-Opioid Agonists

Randomized controlled trials did not report a significantly higher incidence of adverse effects after administration of peripherally acting κ-opioid agonists than placebo.[141] Eluxadoline may affect the sphincter of Oddi and has been linked to cases of acute pancreatitis with fatal outcomes.[185] As such adverse responses are more common after prior cholecystectomy, the agent should be avoided in patients without a gallbladder.

Agents Targeting the $\alpha_2\delta$ Calcium Channel Subunit

Voltage-sensitive calcium channels play an important role in neuronal excitability and transmitter release. Gabapentin and pregabalin were initially developed as anti-convulsive agents. As changes in neuronal excitability and synaptic plasticity are known to contribute to peripheral and central sensitization, both agents have been used in patients with chronic visceral pain. In healthy volunteers and patients with IBS, these two medications were shown to blunt acute pain triggered by rectal distension.[186,187]

Clinical Efficacy of Agents Targeting The $A_2\Delta$ Subunit

Despite the changes in acute pain sensitivity, pregabalin was not superior to placebo during a two week course of treatment in patients with IBS.[187] A more recent investigation suggested improvement in pain severity but no significant benefit in the global assessment of relief or impact on quality of life.[188] Consistent with the reported impact on pain, another study showed improved pain control and decreased opioid use in patients with chronic pancreatitis treated with pregabalin.[189] A second study combined antioxidants with pregabalin in a cohort of patients with chronic calcific pancreatitis, showing a more significant and lasting pain relief when compared with placebo.[190] Inconclusive results emerged in studies testing these agents for patients with chronic pelvic pain. Pregabalin was not superior to placebo in the treatment of chronic prostatitis.[191] A small trial of gabapentin did not report a clear benefit in pelvic pain,[192] which contrasts with a more recent single-center trial in women that showed improved pain control.[193]

Adverse Effects of Agents Targeting The $A_2\Delta$ Subunit

Overall, gabapentin and pregabalin were well tolerated, without serious adverse events. However, patients may report edema and problems with cognition and balance, often citing feeling as if drunk.

Clinical Implications

Improved understanding of normal visceral function and sensation has led to the development of new therapeutic strategies. In the gastrointestinal tract, muscarinic receptor antagonists, serotonin receptor agonists, and antagonists alter function and may improve the discomfort associated with functional disorders. Anti-depressants are commonly used and may improve the global symptom score, likely because of their effect on often coexisting psychiatric illnesses. A recent study in patients with chronic pancreatitis suggested the efficacy of pregabalin in visceral pain. Several targeted treatments are currently under development using drugs that interact with purinergic receptors and members of the family transient receptor potential channels (TRPV1 or TRPA1).

Luminal Contents and Visceral Pain

Within the last decade, the microbiome has attracted significant interest because of the complex interactions between ingested foods, the microbial flora with its metabolic activities and breakdown products, and the gut may lead to changes in gastrointestinal function, which could contribute to pain. While there may be emerging differences between control populations and persons with IBS, there is significant heterogeneity between studies. More importantly, many patients with gastrointestinal problems alter their dietary habits, which will indirectly affect microbial colonization of the gut, thus leaving us with the question of whether these shifts indeed play a pathogenic role or are driven by the disease and its impact on behaviors, such as food choices.[194] Mechanistic studies suggest a causal role, as the changes in the microbiome are associated with other changes in luminal contents, such as higher protease activity, which can affect gut functions, such as epithelial permeability and sensory function, and thus lead to pain.[195,196] While still inconclusive, these findings prompted studies that alter the microbiome, mostly focusing on patients with IBS. Simple interventions with probiotics that try to modify the microbial colonization of the gastrointestinal tract may provide some relief in diarrhea predominant IBS, with inconclusive data because of variable design and inconsistent results.[197] Conversely, the use of a poorly absorbed antibiotic for two weeks decreased overall symptom severity and lowered discomfort ratings.[198] However, about two-thirds of the responders relapsed within 18 weeks,[199] raising questions about the appropriateness of such a strategy in the context of a typically chronic benign illness and increasing concerns about antimicrobial resistance. A small open-label study targeted a more comprehensive and perhaps lasting change by performing fecal microbiome transfers in a small cohort,

which led to significant benefit.[200] While promising, published data remain sparse and inconclusive, with studies using different endpoints and different methods in often small patient cohorts.[201] Despite the preliminary nature of these results, the interactions between host and microbiome affect the gut function and directly or indirectly influence more distant body areas. As our understanding of these complex interactions evolves, we will likely see more targeted interventions that could affect pain perceptions in areas beyond the gut.

Distension of the hollow viscera is associated with conscious perception and pain and may contribute to discomfort associated with disorders, such as constipation. Experimentally induced constipation indeed triggers pain in healthy volunteers.[202] Conversely, recently introduced secretagogues, such as linaclotide, plecanatide, or lubiprostone, alleviate constipation and decrease pain.[203–205] Specific pathways have been invoked to explain this decrease in pain, and meta-analyses suggest a more indirect effect because of the laxative effects of these agents.[206]

TABLE 41.1 Summary of Interventions Targeting Visceral Pain. Invasive and Non-Invasive Treatments are Listed if Their Use had been Investigated by Randomized Clinical Trials (Rct) and/or Meta-Analysis (Ma)

	EVIDENCE			
Approach/Agent	RCT	MA	Clinical Use	Comment
INTERVENTIONS TARGETING PERIPHERAL PATHWAYS				
Celiac Plexus Block				
-neurolytic	+	+	Pancreatic cancer	Transient effect
-bupivacaine	+/–		Chronic pancreatitis	
Laparoscopic uterosacral nerve ablation	–		Pelvic pain, endometriosis	
Presacral neurectomy	+/–	–	Pelvic pain, endometriosis	
Sacral neuromodulation		+	Pelvic pain	Frequent reoperations
INTERVENTIONS TARGETING THE BRAIN				
Transcranial magnetic stimulation	+	+/–	No specific area	Transient effect, concerns about bias
Psychological treatments	+	+	IBS, functional dyspepsia, functional abdominal pain	
PHARMACOTHERAPY				
Botulinum toxin	+/–		Painful bladder syndrome	Impact on micturition
Serotonin signaling				
-Alosetron	+	+	IBS-D	Approved for women
-Ondansetron	+/–		IBS-D	Off label use
-Tegaserod	+	+	IBS-C	
-Prucalopride	+	+	IBS-C	
Spasmolytics	+	+	IBS	
Secretagogues				
-lubiprostone	+	+	IBS-C	
-linaclotide/plecanatide	+	+	IBS-C	
Probiotics	+/–	–	IBS	Marginal effect in IBS-D
Rifaximin	+	+	IBS-D	High recurrence rate
Eluxadoline	+	+	IBS-D	Pancreatitis risk
Gabapentin/pregabalin	+		Pancreatitis	Marginal pain relief
	+/–	–	Pelvic pain	
Anti-depressants				
-Tricyclic Anti-depressants	+/–	++	IBS, functional dyspepsia, pelvic pain	
-SSRI	+/–			
-SNRI	+/–			

IBS, Irritable bowel syndrome (D-diarrhea predominant; C-constipation predominant); *SSRI*, selective serotonin reuptake inhibitor; *SNRI*, serotonin-norepinephrine reuptake inhibitor.
Evidence Supporting Efficacy is Shown by Symbols and Classified as Beneficial (+) or Ambiguous (+/-)

Psychological Interventions and Visceral Pain

Expert consensus and meta-analyses consistently support the utility of psychological treatment approaches in persons with visceral pain syndromes, which range from cognitive behavioral therapy to mindfulness and hypnotherapy.[207] The main caveats are cost, insurance coverage, and availability, which can be overcome by offering group treatments, lowering the number of direct patient encounters, or relying on remotely directed treatments with virtual or telephone encounters. Such approaches have been tested and seem to be effective.[208–210] Alternatively, limited resources can be focused on groups that are more likely to benefit from these interventions, which could reduce societal costs without reducing the financial burden for individuals using these treatments. While we still have limited insight into potential predictors of treatment success, published data suggest that overall symptom severity, trait anxiety, and anxiety sensitivity at baseline are associated with a higher probability of response to treatment.[211,212]

Conclusion

Visceral pain poses unique diagnostic and therapeutic challenges. Clinicians need to consider the complex interactions between organ function, pain, and pain management when deciding on treatment. Frequently used interventions may be effective in altering organ function rather than directly blunting pain. Beyond an increasing number of medical treatment options, psychological therapies should play a bigger role, especially as novel approaches with remote encounters and shorter treatment courses lower barriers because of availability or cost constraints. Invasive procedures or operative interventions should be reserved for refractory cases. They can at least transiently alleviate pain but do not consistently improve the overall quality of life compared to conventional treatments (Table 41.1).

Key Points

- Visceral afferents have complex innervation with bilateral projections of the spinal and vagal pathways to most organs.
- Visceral input is typically poorly localized and may not accurately differentiate between distinct stimulus modalities and projects to distant dermatomes ("referred pain").
- Visceral pain is associated with strong emotional responses and may thus have a more negative impact than pain triggered in other body areas.
- Treatment of visceral pain with medical and interventional techniques may alter organ function, which can affect the sensation and pain of these structures.
- Epithelial structures and luminal contents can activate visceral sensory pathways and contribute to visceral sensation and pain. Interference with these signaling pathways may alleviate pain.
- Hollow organ distension and contraction can be perceived and can lead to pain. Altering filling status or contractile activity should be considered in the management of pain involving the gastrointestinal tract, bladder, or uterus.
- The human microbiome is emerging as another potential factor that can modify visceral afferent input and perception and may thus be a target for treatment steps.

Pelvic Pain

JAN ALBERTO PAREDES MOGICA, MILANA BOCHKUR DRATVER, ELISE J.B. DE

Introduction

Approximately 10% of people in the United States are living with pelvic pain. Many pain specialists, experts in their fields and adept at managing boundaries of care, decline referrals for pelvic pain. Nevertheless, the pain specialist skilled at differential diagnosis and collaboration is best positioned to impact the outcome in these patients. In this chapter, we outline the differential diagnosis, discuss workup and evaluation, and provide straightforward tools to effectively treat, or at least triage in an impactful manner, the majority of those presenting for treatment of pelvic pain. For completeness, we will also discuss rectal and anal pain.

Most definitions of chronic pelvic pain (CPP) describe a three-to-six-month duration. The American College of Obstetrics and Gynecology (ACOG) states that CPP can be intermittent or constant and persists for at least six months.[1] The European Association of Urology defines CPP as "chronic or persistent pain perceived in structures related to the pelvis of either men or women." They point out that "it is often associated with negative cognitive, behavioural, sexual, and emotional consequences as well as with symptoms suggestive of lower urinary tract, sexual, bowel, pelvic floor or gynaecological dysfunction."[2] A chronic pelvic pain syndrome refers to "the occurrence of CPP when there is no proven infection or other obvious local pathologic condition that may account for the pain." In the United States, 15% of females indicate they have experienced either constant or intermittent pelvic pain during the preceding six months.[3] CPP of three months' duration is present in 8.2% of males. Special circumstances may surround children, transgender individuals, or those with disabilities.[4]

Herein lies the frustration for pain specialists: pelvic pain can derive from urologic, gynecologic, gastrointestinal, musculoskeletal, neurologic, and/or rheumatologic causes and can manifest in the setting of significant psychological and social confounders. The most important strategy is to approach pelvic pain as a multidisciplinary issue. Potential causes should be sought by the appropriate specialists and addressed if found. If no particular cause is identified, the goals are to manage symptoms and provide coping strategies. Given the patient complexity, it is essential to structure the patient evaluation for efficiency and completeness.

To optimize face-to-face provider time, the patient should be given tools to describe symptoms, an inventory on which to keep track of prior evaluations and treatments, and provided with resources to read on their own, such as *Facing Pelvic Pain*, a recent multi-disciplinary publication aimed at the lay public, containing the data inventory the "treatment map."[5] This tool both empowers the patient and reduces work for the team of providers. With the details in hand, the pain specialist can then ask the patient to tell their story, begin formulating the differential diagnosis, and develop a sound treatment plan.

The pain specialist can have a longstanding impact on those with CPP by employing the most basic of tools to start the patient off on the right path:

1. In early, localized cases, the history almost always leads to the differential diagnosis. For example, if pelvic pain began subsequent to gait alteration (e.g. bunion surgery), consider pelvic floor muscle hypertonicity, and treat with physical therapy. Pelvic pain that appeared acutely three months prior with lower urinary tract symptoms and occasional flank pain may simply be a ureteric stone lodged within the section of the ureter traversing the bladder.
2. A physical exam can reveal obvious clues, such as vulvar and perineal varices
3. suggesting pelvic venous congestion or an altered gait and muscle atrophy suggestive of a sacral tumor.
4. In later more complex cases, the comprehensive review of a patient's prior medical records will lead to the most efficient care, but the history is still the essence of a successful outcome. In these complex cases, the pelvic health history form published by the international pelvic pain society or the treatment map from *Facing Pelvic Pain* completed in advance of the visit can save a great deal of time in the clinic.[5,6] An example of complex localized pain might be a patient in her mid-20s with psychological overlay whose bladder and pelvic pain began at 14 years in the setting of a traumatic childhood. Many trials later, fecal symptoms and calf atrophy on exam may lead to the diagnosis of tethered spinal cord.
5. Patients who present with multiple chronic overlapping pain syndromes (COPCs), e.g. pelvic pain, irritable bowel syndrome, migraine, gastroesophageal reflux, tinnitus, and dizziness, may have a systemic issue such as small fiber polyneuropathy, or central sensitization (alterations in the central processing of pain). Certain brain regions or connectivity among brain regions (such as cingulate, insular, and prefrontal cortices) related to pain modulation are shown to be dysfunctional in chronic pain conditions. It may also be that mechanisms driving peripheral sensitization could be present in the CNS or impact the CNS through an impact on the "pain memory." These patients will

benefit from a referral to pain management and/or a neurologist with experience in autonomic dysfunction, or in the case of a rheumatologic symptom array, a rheumatologist.
6. Curate a multi-disciplinary list of urologists, gynecologists, gastrointestinal and colorectal specialists, rheumatologists, neurologists, neurosurgeons, pelvic floor physical therapists, and alternative medicine specialists who will earnestly work with the patient's needs and who will support you in the patient's management.
7. Set expectations from the beginning as to the role of the pain specialist *vis-a-vis* the rest of the team. CPP should only rarely lead to urgent phone calls.
8. Provide backup plans, so the patient does not have as much opportunity to become anxious when pain levels are high. These might range from warm baths and heating pads to rescue medications to asking the primary care doctor to order standing culture orders.
9. The above are all straightforward strategies the pain specialist can use to deeply impact care without knowing a great deal about pelvic pain. Beyond this baseline, the more one knows, the more interesting the population becomes. People with pelvic pain have a high potential for diagnosis, cure, treatment, and management in unique and satisfying ways, especially when prior providers have not served their needs.

Causes of Pelvic Pain and Initial Evaluation

Pelvic pain can originate from virtually any organ system within the human body.[7] This is true in both acute and chronic causes of pelvic pain. Sometimes a single diagnosis can be made, such as constipation, but pelvic pain is often because of a combination of disorders as neighboring organs become sensitized.[8] When psychological and social confounders are present, identifying the cause of pelvic pain can remain a challenge for even the most experienced clinicians, and collaboration with psychology/psychiatry is essential. Some sources cite endometriosis and pelvic venous disorders as the most common causes of CPP, but it is important to note that many patients with CPP remain without a specific diagnosis.[9] One study performed in the United Kingdom reviewed 483 patients with CPP; the most common diagnoses were irritable bowel syndrome (IBS) (19.8%), psychological (9.5%), ovarian cyst (8.4%), endometriosis (7.4%), interstitial cystitis (7.2%), and pelvic inflammatory disease (PID) (6.5%).[10] Only about 50% of the 483 patients received a diagnosis. A study conducted in New Zealand obtained similar results.[11] Findings like these highlight the difficulties in managing pelvic pain and the need for a coordinated, multi-disciplinary approach, especially since it has been shown that delay in treatment can lead to greater pain sensitivity and involvement of other organs.[12]

There are several ways to approach a person presenting with pelvic pain as etiologies can be grouped in different ways: according to location, organ system, sex, or even age. Tables 42.1 and 42.2 show location and organ system involvement, respectively, along with possible etiologies.

It has been reported that 55%–80% of all diagnoses in the primary care setting are made after the history taking and physical examination.[13,14] This fact can provide confidence when approaching the history and initial evaluation of pelvic pain.

History should assess obstetric, gynecologic, gastrointestinal, genitourinary, nervous, and skeletal systems while also noting the quality of pain, radiation, intensity, time of onset, and duration. Relevant surgical interventions include urinary incontinence

TABLE 42.1 Location of Pelvic Pain and its Causes

Location of Pain	Potential Explanations
Vulva	Infection, exposure (irritants), vulvar atrophy (hypoestrogenism), low testosterone, neuropathy, dermatologic conditions (Lichen Sclerosis)
Introitus	Low testosterone, friction (from clothing or sexual activity), irritant (spermicide)
Urethra	Vulvovaginal atrophy, friction, tight external sphincter muscle or stricture, tumor, infection, diverticulum
Pelvic floor muscles	Dysfunctional voiding, muscle overactivity
Bladder	Interstitial cystitis, bladder outlet obstruction
Anorectum	Constipation, fissures, hemorrhoids, levator ani syndrome/proctalgia fugax, hernia
Localized pain	More likely to be organ-based or in a nerve distribution
Widespread pain	Central sensitization, small fiber polyneuropathy, rheumatologic disease, fibromyalgia, association with anxiety, personality disorders, history of sexual abuse

Adapted from *Facing Pelvic Pain*.[5]

TABLE 42.2 Organ System Contributors to Pelvic Pain

Organ System	Potential Explanations
Gynecologic	Endometriosis, endometritis, uterine fibroids, ovarian pathologies, sexually transmitted infection (STI), pelvic inflammatory disease, tumor
Male genital	Prostatitis, epididymitis, testicular pathologies, ejaculatory duct or vas deferens obstruction, STI
Urologic	Interstitial cystitis, stone (distal ureter or bladder), tumor, urinary tract infection or STI, urethral caruncle, stricture
Gastrointestinal	Irritable bowl syndrome, chronic proctalgia, levator ani syndrome, constipation, fissures, hemorrhoids, anal cancer, warts, tumor, diverticulitis, appendicitis, adhesions, inflammatory bowel disease
Musculoskeletal	High tone pelvic floor muscles, back, knee, foot, or hip problem, myopathy, osteitis or osteomyelitis, injury to bones, ligaments, or tendons
Neurologic	Upper and lower motor neuron syndromes, peripheral neuropathies, spinal disc disease, tethered cord, sacral tumor, entrapped peripheral nerve
Psychological-associated conditions	Central sensitization, depression, anxiety, sexual abuse, personality disorders, couple distress, grief over lost function
Vascular	Pelvic venous congestion, vasculitis

Adapted from *Facing Pelvic Pain*.[5]

surgery, prolapse surgery, hysterectomy/oophorectomy, abdominal incisions, bowel or hernia surgery, and spinal surgery. A clear chronology referable to surgery raises suspicion of nerve entrapment. Assessment of previous treatments and whether they have been successful is of vital importance, as this can guide future management.

When conducting the physical exam, a good neurologic exam is essential, including dermatomes associated with the pain and observance of gait. The pelvic exam is easiest to introduce by applying the concept of trauma informed care, for example, "it would be helpful to do an internal exam of the pelvic area, and if you agree we have time to do it today. Is there anything about your comfort with the exam that you would like us to know?" This type of introduction puts the patient in control, as many patients can feel overwhelmed by such an examination.[15]

Laboratory and imaging studies will be ordered based on the diagnostic suspicion. Urinalysis and culture, urine cytology, stool tests, and completion of a voiding diary are easily obtained. With the advent of polymerase chain reaction (PCR) for sexually transmitted infections (STIs), screening can be performed on the urine or a simple vaginal swab without the need for complicated specimen acquisition or how to read a wet prep. Diagnostic studies such as endoscopy, pelvic and abdominal ultrasound or computed tomography (CT) scan, and MRI of the spine, head, abdomen, and pelvis can also help in diagnosis.

Pelvic Pain That Should Not Be Missed: Dangerous Acute Causes and Cancer

The pain management specialist should not often be in the position of evaluating acute pelvic pain or diagnosing cancer; patients typically will have had an evaluation, exam, and imaging by a pelvic floor specialist prior to referral. Given that the pain specialist may have ethical or liability concerns regarding missed diagnoses, acute pain and cancer will be briefly reviewed below.

Acute pelvic pain is defined as the presence of pelvic pain for less than three months' duration but is typically thought of as sudden onset and requiring immediate evaluation.[16,17] The physician will need to rule out etiologies that are potentially life threatening in the setting of the sudden appearance of pain. About 10% of all emergency department (ED) visits correspond to the development of abdominal pain, with some sources citing figures as high as 21%–34%.[17,18] The exact prevalence of pelvic pain in the ED is difficult to estimate, as symptoms are often associated with those of lower abdominal pain.

The initial evaluation of acute pelvic pain should include vital signs, temperature, assessment of symptoms such as fever, chills, discharge, or vomiting, and previous diagnoses (e.g. STIs) and risk factors. A broad differential should be considered, given the number of organ systems contained within the pelvis.[16] Pregnancy status should be assessed if there is any potential via b-hCG (either blood or urine testing) or ultrasound, as it can be used to determine the presence of a gestational sac or free fluid within the abdominal cavity.

The most common causes of acute pelvic pain are gynecologic (e.g. ovarian torsion or cyst, ectopic pregnancy, PID, endometriosis) and gastrointestinal conditions (e.g. appendicitis, diverticulitis, hernia, SBO), followed by urinary tract etiologies (e.g. urinary tract infection [UTI], cystitis, ureterolithiasis).[16,17] The initial approach should rule these out. A low threshold should be maintained for pregnancy tests, urinalysis and culture, serology, imaging, referral to other specialties, and ED evaluation. Table 42.3 summarizes the acute causes of pelvic pain by the organ system.

TABLE 42.3 Acute Causes of Pelvic Pain by Organ System

Organ System	Potential Explanation
Gastrointestinal	Appendicitis, hernia, diverticulitis, small bowel obstruction, adhesions, functional abdominal pain
Gynecologic	Ectopic pregnancy, pelvic inflammatory disease, ovarian torsion, ovarian cyst, ruptured ovarian cyst, endometriosis, malpositioned intrauterine device, toxic shock syndrome, sexually transmitted infection, tubo-ovarian abscess
Male Reproductive System	Testicular torsion, epididymitis, prostatitis
Urologic	Pyelonephritis, ureterolithiasis, urethritis, cystitis
Musculoskeletal	Fractured pelvic bones, enthesitis, seronegative arthritis
Neurologic	Cauda equina syndrome

Cancer is a potential cause of pelvic pain, manifesting with a range of presentations, as it can damage any structure or nerve. Typically, the pain specialist will be collaborating with pelvic specialists who will take responsibility for this part of the differential diagnosis. Somatic pain occurs when cancer extends through the fascial planes and stimulates the nociceptors in supporting structures. Neuropathic pain can occur with direct extension to the pudendal and perineal nerves or lumbosacral plexus. Visceral pain arises when the tumor causes spasms of smooth muscles in hollow organs and distorts the capsule of solid organs. Traction on adjacent organs, ischemia, and inflammation also incur pain. The most common cancers to rule out in this setting are gynecologic cancers (e.g. cervical, uterine, and vaginal cancers) and malignancy within the colon, rectum, prostate, and penis.[19] Blood in the urine, stool, or ejaculate, or vaginal or urethral bleeding should warrant referral for evaluation. In addition, a good rule of thumb is that pelvic pain refractory to the initial evaluation and management warrants imaging and specialty referral.

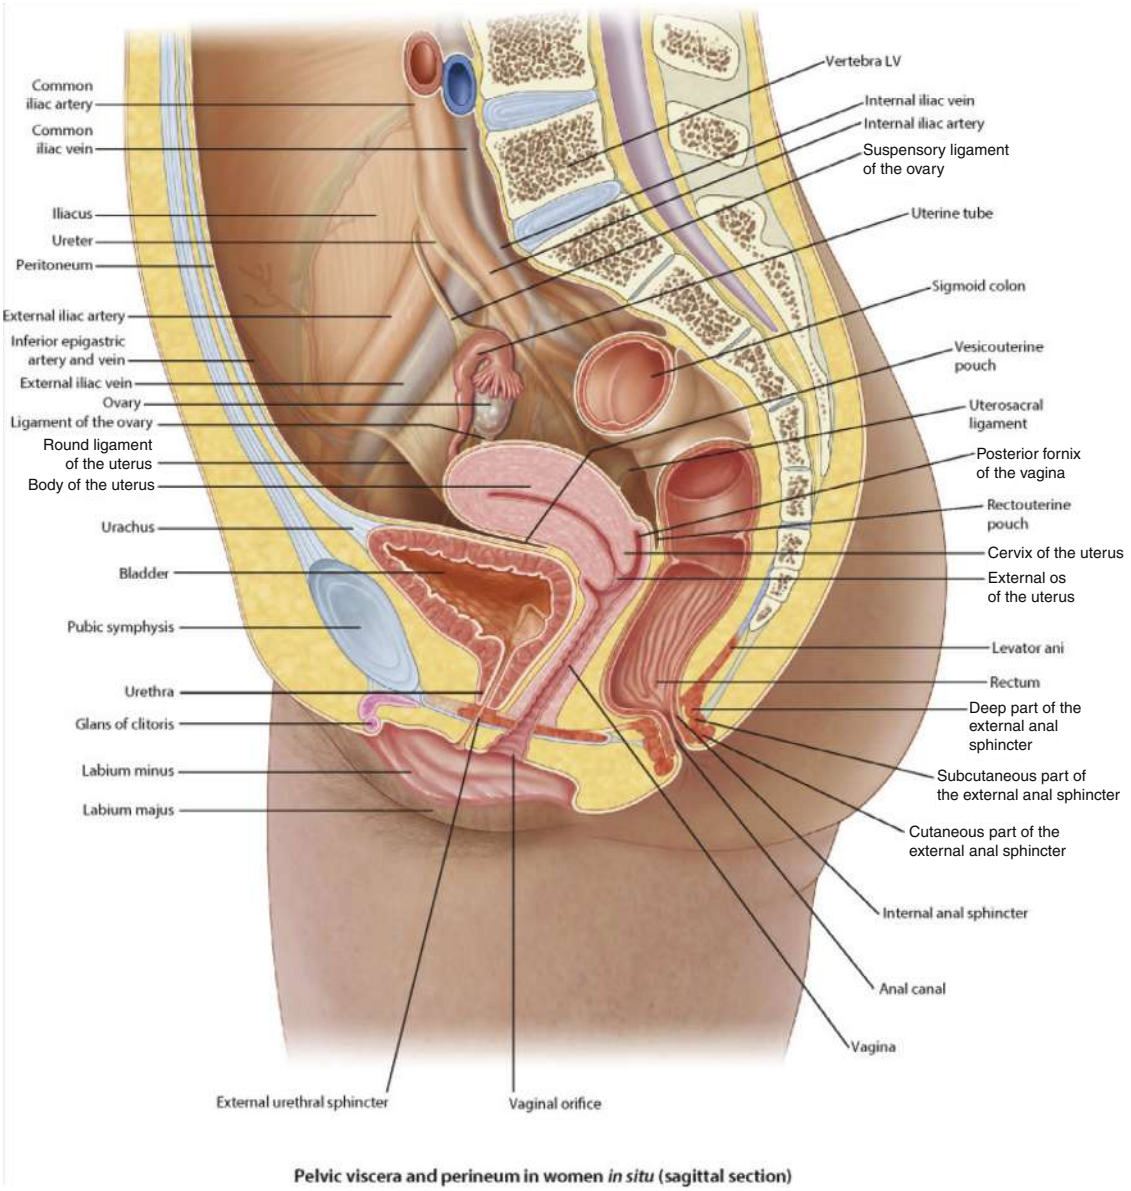
Organ-Based Causes of Pelvic Pain With Treatment

Gynecologic Considerations

This section will discuss acute and chronic gynecologic causes of pelvic pain, referring to pelvic pain stemming from anatomically female internal and external genitalia. Patients born with ambiguous genitalia or who have undergone gender affirmation surgery may benefit from both this and the next section on male anatomy. Fig. 42.1 details the female pelvic anatomy.

Evaluation of female pelvic pain includes a thorough obstetric, gynecologic, surgical, psychiatric, and medical history; and musculoskeletal, abdominal, and pelvic exam. Imaging may include ultrasound and MRI, and laboratory tests may include hormones, vaginal evaluation for infectious organisms, and tumor and inflammatory markers.[20]

Common gynecologic causes of acute pelvic pain include ectopic pregnancy, ovarian cyst rupture, Mittelschmerz (a milder form of ovarian cyst rupture, which is a natural part of ovulation), ovarian or fallopian tube torsion, PID, tubo-ovarian abscess, fibroid degeneration or torsion, and endometriosis. When evaluating acute causes of gynecologic pelvic pain, conditions such as UTI,



• **Figure 42.1** Female pelvic anatomy. From: Drake RL, Vogl A, Mitchell WA. Pelvic viscera and perineum in a female *in situ* (sagittal section). In: *Gray's Atlas of Anatomy*. 3rd ed. Philadelphia, PA: Elsevier; 2021:213–292.

kidney stones, appendicitis, diverticulitis, bowel obstruction, volvulus, intussusception, or bowel ischemia must be considered.

In acute gynecologic pelvic pain, the priority should be on determining if emergent care is needed or if the condition can be managed in an outpatient setting. Emergent treatment, including potential surgery, is necessary for conditions related to intra-abdominal hemorrhage, organ infection, or acute ischemia (e.g. torsion). Pain refractory to over-the-counter medications, fever, nausea, and vomiting, inability to ambulate, fainting, or orthostasis should prompt emergent care referral. The two most concerning acute gynecologic conditions are ectopic pregnancy and adnexal torsion. Appendicitis and diverticulitis need to be considered as well. If a patient has a positive pregnancy test coupled with pelvic pain, with or without vaginal bleeding, pelvic ultrasound should be performed, and obstetric referral for ectopic pregnancy should be prioritized as soon as possible. If diagnosed, surgery is indicated in the setting of a ruptured fallopian tube; methotrexate administration may be an option to preserve an intact fallopian tube if the patient is stable. Neither treatment will salvage the pregnancy. In the case of ruptured ovarian cyst, it is often sufficient for physicians to monitor for signs of infection and bleeding and to trend complete blood counts while managing pain. Surgery is required if the hemoglobin drops significantly or if the ovary or fallopian tube is twisted/torsed and therefore ischemic. Expedient diagnosis (typically via duplex doppler ultrasound) is necessary to salvage the organ. Less emergently, torsed uterine fibroids may require surgery. Endometriosis is more of a chronic pain diagnosis that can exhibit acute manifestations. Evaluation of acute pain should include an abdominal and pelvic exam, pregnancy test, complete blood count with differential, cervical cultures/PCR for sexually transmitted infection, a pelvic ultrasound, and focused assessment sonography for trauma exam as indicated (e.g. to evaluate for the

presence of free fluid within the abdominal cavity). Acute pain management should first be attempted with prescription strength ibuprofen, ketorolac, or other nonsteroid medications before proceeding to narcotics.

CPP is common in females, as mentioned above, affecting 15%. Endometriosis affects about 6%–10% of all females. In endometriosis, tissue similar to the lining of the uterus is found at ectopic locations. This ectopic tissue reacts to cyclic hormones in the same way that the endometrium lining the uterus does, leading to chronic inflammation and scarring. Clinical symptoms suspicious for endometriosis include excessively painful menstruation, painful sexual intercourse, or painful bowel movements. The cyclic pain is the hallmark symptom because of irritating prostaglandin release and bleeding. A physical exam can reveal deposits of endometrial tissue in the vagina or palpable endometrial nodules posterior to the uterus, but often exams and imaging are unrevealing. MRI or pelvic ultrasound may show blood-filled ovarian cysts. Definitive diagnosis may require laparoscopy for direct visualization of organs and biopsy. Treatment of endometriosis includes medical management and surgery. Medications include nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen for pain, but hormonal therapy to counteract endometrial growth resulting from estrogen is the mainstay of treatment. Examples include oral contraceptive pills, progesterone-only birth control (including the progesterone-releasing intrauterine device [IUD], contraceptive implants, medroxyprogesterone acetate injections, and norethindrone), and agents impacting gonadotropin-releasing hormone (leuprolide acetate, goserelin, and elagolix). Surgery is utilized to remove or destroy the ectopic tissue through the removal of ovarian cysts and excision or cauterization of ectopic foci, while hormonal medication is often used postoperatively to prevent recurrence.[21–25]

Adenomyosis is an endometriosis variant, occurring when endometrial tissue invades into the myometrium. Adenomyosis causes hypertrophy, hyperplasia, and fibrosis in the uterine wall. Adenomyosis *can* cause severe menstrual pain and heavy menses. Adenomyosis causes severe menstrual pain and is less common in nulliparous females. Pain is usually localized to the suprapubic midline and is worse during menstruation but may be present throughout the month. Hysterectomy is the definitive cure, but hormonal medications, particularly progesterone-releasing IUDs, which deliver hormone directly to the area of interest, are first line therapy. The desire for future fertility is a fundamental consideration in management.

Ovarian cysts can manifest as painless, chronically painful, or symptomatic during exercise, sex, or menstruation. Pain that aligns with ovulation (also known as mittelschmerz) occurs because of natural functional cysts that rupture when the egg is released. The pain often alternates sides monthly. Mittelschmerz is relieved by medications that stop ovulation, such as oral contraceptives, progesterone implants, or medroxyprogesterone acetate injections. A complete evaluation by a gynecologist is necessary to rule out cancerous cysts, but benign cysts are much more common. Benign ovarian tumors may lead to chronic one-sided pain that does not become acutely painful unless ovarian torsion or rupture is involved. The most common type of benign cyst is a dermoid or mature teratoma, including hair, fatty fluid, cartilage, or teeth; other benign cysts include serous or mucinous adenomas. Evaluation of cysts begins with ultrasound, and if they are symptomatic and causing pain that affects the patient's life to an unmanageable degree, laparoscopic ovarian cystectomy can be performed. If the cyst is small and painless without concerning imaging features, it can be monitored with ultrasound.

Over 50% of females have uterine fibroids by the time they are in their 40s. They are usually painless unless they are located at the lining of the uterus and cause heavy menstruation, or they become large enough to outgrow their blood supply and begin to degenerate. Treatment of submucosal fibroids involves removal via hysteroscopy, while intramural or subserosal fibroids can be removed through an abdominal approach.

PID stems from infections of the uterus, fallopian tubes, and ovaries. PID often originates from bacteria that enter the uterus through the vagina, such as those from STIs, but can also arise from vaginal or gastrointestinal tract bacteria. The time course from onset may vary, but PID can lead to chronic pain that may stem from low grade infection or residual scar tissue. Standard evaluation of females with CPP includes sexually transmitted disease testing.

Pelvic organ prolapse is sometimes a cause of female pelvic pain. Prolapse is caused by vaginal wall relaxation/herniation and laxity of the fascial supports, leading to protrusion of bladder, bowel, or the uterus toward the vaginal opening. Pain is typically present in the upright position and worsens as the day goes on. Patients often, but not always, appreciate a vaginal bulge. Diagnosis is based on pelvic exam, and treatment includes observation, pelvic floor physical therapy, pessary, or surgery. Pelvic floor myofascial dysfunction and pelvic venous disorders discussed below can mimic a feeling of pelvic organ prolapse.

Vaginal pain may be caused by vaginal atrophy, myofascial pain, inflammation/infection, or pain disorders such as endometriosis or painful bladder syndrome. More rarely, a vaginal septum, a Gartner's duct cyst (remnant of the mesonephric duct), a chronically inflamed appendix, or scarring from prior surgery can cause pain. Complete evaluation involves a speculum exam, vaginal swabs or cultures if indicated, and an internal digital exam of the levators, bladder, and rectum through the vaginal wall. Treatment options include topical creams or suppositories, pelvic floor physical therapy, transvaginal trigger point injections, or treatment of the aforementioned underlying conditions. If pain with sexual activity is involved, a professional sexual health therapist may be beneficial.

Causes of vulvar pain may involve vaginal atrophy, chronic infections, inflammatory skin conditions, scarring from childbirth, or neurologic cause (such as vulvodynia or neuropathy). Diagnostic workup includes an external vulvar Q-tip exam (targeting the Skene's glands at 11 and 1 o'clock and the vestibular glands at 5 and 7 o'clock) and internal vaginal exam, often cultures, and potentially a biopsy. Treatment can include topical ointments, oral medications, and physical therapy. Vulvovaginal atrophy can cause burning or UTI, which can be treated with topical estrogen cream. Surgery is only rarely indicated in vulvar pain. One successful intervention is the simple avoidance of irritants such as filamentous paper products, perfumes, spermicides, and harsh cleansers.

Gynecologic cancer is a rare cause of pelvic pain. Ovarian cancer may involve abdominal bloating, distention, or a vague diffuse pelvic pain. Other symptoms include increased urinary frequency, constipation, or anorexia. Diagnostic evaluation for malignancy includes pap smears, internal and external pelvic exam, pelvic ultrasound, and biopsy of suspicious tissue. Imaging is indicated in refractory pelvic pain.

Pain related to sexual activity may need to be specifically raised by the interviewer. It may occur during or after penetrative sex, arousal, or orgasm and can be very disruptive to a relationship. Pain with sexual activity can affect individuals at any age, of all sexual orientations and sex. Diagnosis and evaluation of pelvic pain stemming from sexual activity requires an external and

internal pelvic exam to include the pelvic floor muscles and may necessitate additional testing such as complete blood count (CBC) (e.g. to evaluate for the presence of occult bleeding), chemistry testing, thyroid function test, urinalysis with reflex to urine culture, luteinizing hormone, follicle-stimulating hormone, estradiol (E2) or imaging (likely ultrasound). The most common gynecologic causes of sexual pain are genitourinary syndrome of menopause, infection, endometriosis, and benign gynecologic tumors, but high tone myofascial dysfunction is the most common cause of pain with penetration. Treatments, such as lifestyle modifications, physiotherapy, pharmacotherapies, psychosocial treatments (including a certified sex therapist), or surgery, should be utilized appropriately depending on the underlying causes identified.[26]

An important but rare entity to be aware of is persistent genital arousal disorder. Females complain of unwanted clitoral sensation ranging from engorgement to arousal to pain. Etiology can be local (a foreign body under the prepuce), neurologic (small fiber polyneuropathy or radiculopathy, Tarlov cysts), medication-related, or vascular (arteriovenous formation).

Treatment for CPP is best achieved using a multimodal approach involving non-pharmacologic treatments and medications. The goal should be to tailor treatment as much as possible to the underlying causes. More than 50% of females with CPP will have no clear inciting cause identified, so more global approaches can be just as important. Non-pharmacologic therapies include pelvic floor physical therapy, psychotherapy, acupuncture, and neuromodulation. Pharmacologic interventions include non-opioid analgesics, hormonal modulation, membrane stabilizers, antidepressants, and in rare cases, opioids.[27]

Male Urologic Problems (Including Sexual Pain)

This section will discuss pelvic pain related to male anatomy, including the prostate, epididymis, seminal vesicles, testis, and penis. Myofascial dysfunction of the pelvic floor, discussed below, commonly affects males as well. Fig. 42.2 details de male pelvic anatomy.

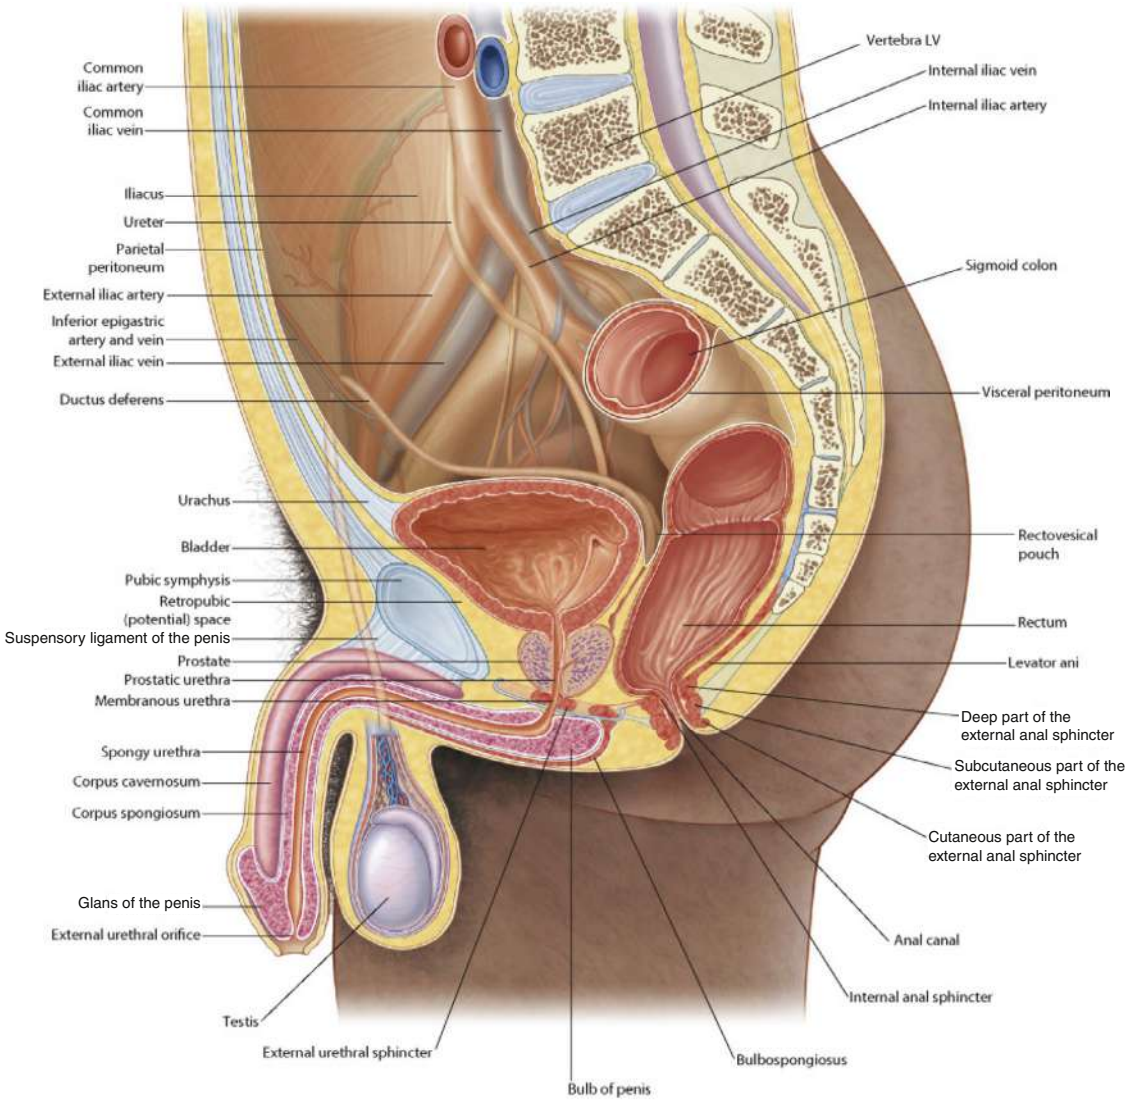
Several conditions related to the prostate may result in pelvic pain, including benign prostatic hyperplasia, acute prostatitis, and prostate pain syndrome (PPS).[28] As males age, the prostate can increase in size. The tone of the smooth muscle within the prostate and bladder neck is important and, if high, can cause a weak urinary stream, urinary urgency or frequency, or incomplete bladder emptying. Bladder outlet obstruction may lead to pain as the bladder strains and becomes relatively ischemic during urination or if residual volume is increased. Treatment will include α-blocker medications, which relax the smooth muscle of the bladder neck, and prostate, and potentially pelvic floor muscle physical therapy. *Acute prostatitis* is caused by bacterial infection of the urinary tract and prostate; this leads to pain in the pelvis, lower abdomen, testicles, penis, and urethra or during actions such as urination or ejaculation. Symptoms can include fever, nausea, and vomiting and require emergent medical attention. Diagnosis is by urinalysis and culture, physical exam showing a tender boggy prostate (however, as the exam can lead to sepsis, it is avoided where possible), and imaging (ultrasound, CT scan, or MRI). PPS, previously called chronic prostatitis, has symptoms similar to acute prostatitis, but there is often no evidence of infection. Treatment in this case would not include antibiotics but rather pelvic floor physical therapy and muscle relaxant or anti-inflammatory medications. Evaluation of prostatic causes of pelvic pain includes urine culture, digital rectal exam to include the pelvic floor muscles, measurement of post-void residual urine assessment, potentially cystoscopy or urodynamic testing, and imaging studies such as ultrasound, CT, or MRI. Surgery may be beneficial, especially if an obstruction is present or if prostate stones are identified and thought to be harboring bacteria (30%–70% success).

Management of chronic pain in the epididymis, seminal vesicles, testes, and penis can include physical therapy, anti-inflammatories, neuromodulators, acupuncture, and nerve blocks. These paragraphs will address more specific causes and treatments, best managed with a urologist subspecialized in infertility and men's sexual health. Pain in the epididymitis may be acute or chronic. Acute epididymal pain is likely because of infection and necessitates urgent medical evaluation. In younger males, it is more typically because of STIs such as *C. trachomatis*; in older males, epididymis is more likely to be from gastrointestinal bacteria such as lactose positive colibacillus. Viral epididymitis is also possible, more so in children. Symptoms include pain and swelling of the epididymis and scrotum, urethral pain and burning during urination, pain above the pubic bone, and occasionally fever, chills, and flank discomfort. Diagnosis is based on urine PCR for STI, urine culture for UTI, and scrotal ultrasound. Treatment includes scrotal elevation, pain control, and antibiotics. Pain often takes up to six weeks to dissipate after treatment initiation (an important counseling point); it is imperative to treat such conditions immediately as complications include abscess formation, secondary infertility, and (rarely) testes infarction. Chronic epididymal and vas deferens pain may be associated with cysts, but often the workup is non-specific. Management varies depending on clinical exam and symptoms (for example, identification of an associated varicocele).

The seminal vesicles and ejaculatory ducts are rarely causes of pain, with congenital anomalies being the most likely cause (e.g. ejaculatory duct cyst). Rarer causes of chronic infections such as tuberculosis or schistosomiasis may occur. The primary symptoms are usually pain with ejaculation or low ejaculate volume, and evaluation entails a physical exam, urine culture, and transrectal ultrasound or pelvic MRI. Treatment is based on the underlying anatomic finding, such as an ejaculatory duct stone.

Testicular pain can also be separated into acute and chronic causes. Acute testicular pain is a medical emergency as it can be because of testicular torsion. Other essential diagnoses include testis fracture, a palpable mass that may point to malignancy or orchitis. Chronic causes of testicular pain should be evaluated by physical exam (intermittent torsion secondary to bell clapper deformity) and scrotal ultrasound with attention to blood flow, mass, or abscess. Chronic pain may be treated empirically with a trial of antibiotics or anti-inflammatory medication if the cause is unclear. Potential causes include nerve hypersensitivity, especially in the setting of systemic neuropathy or a prior surgical procedure. Suppose conservative treatment, including pelvic physical therapy and gabapentinoids, fails. In that case, one can try an anesthetic nerve block, targeted denervation of the spermatic cord, targeted peri-spermatic cord cryoablation, an off-label botulinum toxin injection, and potentially a more generalized nerve block.

Pain in the penis can stem from infectious or non-infectious origins. Symptoms of infection include urethral discharge, ulcerations, blood in the urine, or referred pain from the urethra. An acute penile fracture is often accompanied by a sudden "popping" and is diagnosed via ultrasound or MRI; it requires urgent surgery. More chronic pain during intercourse may be connected to Peyronie's disease, prostatitis, or inflammation of the seminal vesicles.



Pelvic viscera and perineum in men *in situ* (sagittal section)

• **Figure 42.2** Male pelvic anatomy. From: Drake RL, Vogl A, Mitchell WA. Pelvic viscera and perineum in a male *in situ*. In: *Gray's Atlas of Anatomy.* Philadelphia, PA: Elsevier; 2021:213–292.

Peyronie's disease is diagnosed by a history of an angled erection and via physical exam revealing an induration of the penile shaft (tunica albuginea). This may be visible as a plaque on penile ultrasound. Peyronie's disease does not always require treatment, but injecting collagenase clostridium histolyticum into the scar tissue may relieve pain. Surgery is used to correct severe curvature to restore sexual activity but is not a targeted treatment for pain.

It should be remembered that systemic neuropathy, rheumatologic, vascular, and myofascial disorders can contribute to the above sources of seemingly sex- or organ-based pain.

Urogenital Etiology of Pain

This section will discuss pelvic pain related to the bladder, urethra, and ureter. Urethral pain is usually related to voiding and can be accompanied by dull pressure that radiates to the groin, sacrum, or perineum. Urethritis is typically caused by a UTI. Diagnosis is based on a voided urine test with a culture of over 100,000 colonies of one bacteria strain and over ten white blood cells from the urine sediment or on a catheterized specimen with over 10,000 colonies of bacteria. Urethritis that is not from a UTI is commonly caused by STIs. Physical exam may show STI-specific findings, including rashes, but typically evaluation is by screening with a vaginal swab in females and urine or urethral discharge analysis in males, sent for broad PCR amplification and analysis. The most common STIs are chlamydia and gonococcus; rarer organisms include urea plasma and mycoplasma genitalium. Treatment for both urinary tract infections and STIs is provided with appropriate antibiotics and, if necessary, behavior change. A rarer cause of urethral pain is a urethral diverticulum. Urethral diverticula are benign epithelium-lined outpouchings of the urethra, which are much more common in females than males.[29] Many people

are asymptomatic, but signs and symptoms may include CPP, post-void dribbling, urinary obstruction, stress urinary incontinence, intermittent passage of pus or blood in the urine, recurrent UTI, painful vaginal mass, and pain during vaginal penetration. The most sensitive diagnostic tool is MRI, but suspicious physical exam findings include a palpable mass. Mechanical pressure on the urethra can cause milky urethral fluid to elicit via the meatus. Cystoscopy may show an ostium (opening) in the urethral lumen. A Skene's duct cyst can cause urethral pain in females but does not connect to the urethra and is found at the distal urethra. Other urethral causes of pain specific to females are urethral caruncle and urethral mucosal prolapse, occurring almost exclusively in the setting of vaginal atrophy. Urethral caruncle is a benign growth of the posterior urethra, and urethral mucosal prolapse is a loosening and slippage of the mucosal lining of the urethra. Most commonly, there are no symptoms, but some females have blood in the urine, vaginal bleeding, or severe pain with a large edematous inflammation of the lesion. In asymptomatic cases, treatment is not needed. Estrogen cream is the first line treatment if symptoms occur and there is no contraindication (e.g. breast cancer). If the caruncle or mucosal prolapse does not respond to treatment, is large, changes in size or appearance, or has an unusual appearance, further evaluation with cystoscopy or biopsy may be warranted to rule out malignancy. Urethral pain in males and females can also occur because of nerve sensitivity, such as small fiber polyneuropathy or nerve entrapment (pudendal and/or genitofemoral nerve). Chemical irritants, food sensitivities, or vaginal atrophy can affect the nerves of the urethra.

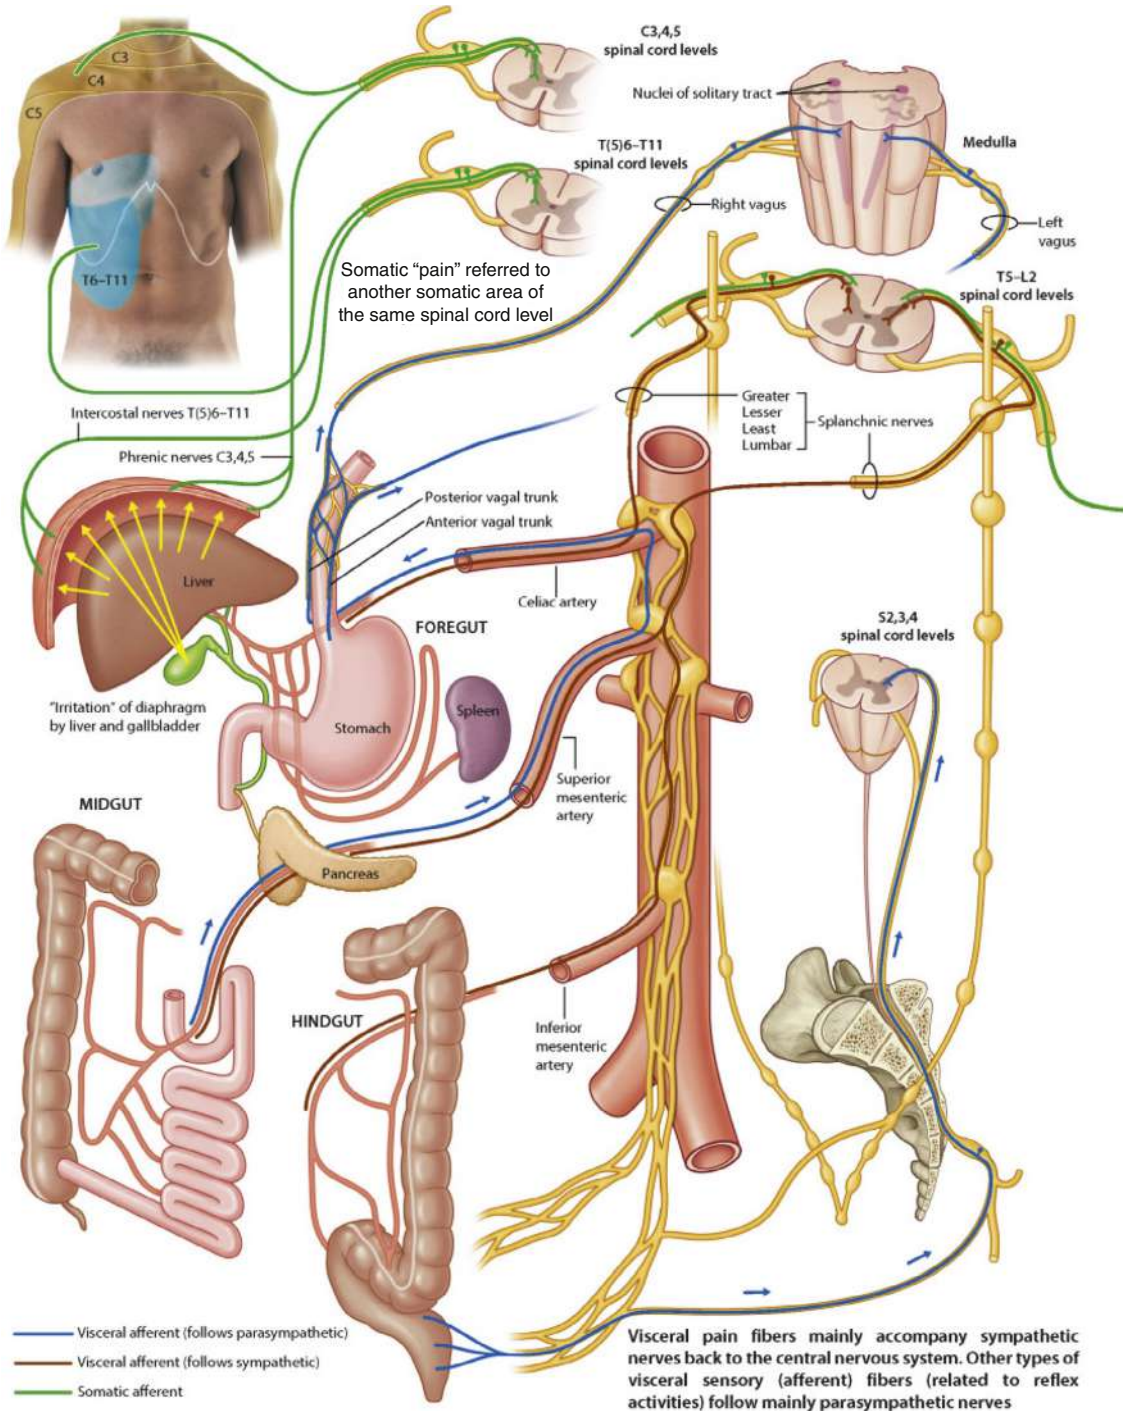
There are several bladder related conditions that can lead to pelvic pain. Interstitial cystitis or bladder pain syndrome is a diagnosis of exclusion and is defined as "(…) an unpleasant sensation (pain, pressure, discomfort) perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than six weeks' duration, in the absence of infection or other identifiable causes."[30] Pain is often exacerbated by specific food or beverages and improves with voiding. It may radiate to the urethra, vulva, vagina, rectum, lower back, or abdomen. Evaluation includes a thorough history, physical exam, voiding diary, urine testing, and potentially cystoscopy. Treatment begins with habit modification, then physical therapy and medications, hydrodistension, off-label botulinum toxin injection, off-label sacral neuromodulation. Treatment can progress to medications such as immune-based cyclosporine A and (rarely) extirpative surgery. Another potential bladder source of pelvic pain is overactive bladder (OAB), a syndrome characterized by urinary urgency with daytime frequency, nocturia, and urgency urinary incontinence. Diagnosis is via physical exam, history, questionnaires, urine analysis, and post-void residual bladder scan. Treatment begins with dietary irritant modification, pelvic physical therapy, and bladder training. It then progresses to anticholinergic and β3 agonist medications. Treatment may include on-label sacral neuromodulation or botulinum toxin injection to the detrusor muscle. Bladder outlet obstruction is characterized as either functional or anatomic. Anatomic obstruction in females is typically because of anterior vaginal wall prolapse (cystocele), urethral diverticulum, or complications from a previous intervention such as a sling. In males, obstruction can occur because of an enlarged or tightened prostate or in both sexes from a urethral stricture. All these causes are treated surgically. Functional obstruction accounts for most bladder outlet obstruction in females and is diagnosed via video urodynamic studies.[31] It is typically caused by increased tone or failure of relaxation of the bladder neck. High tone in the external urethral sphincter can be seen in the setting of pelvic floor muscle dysfunction. Neurologically mediated obstruction is often the first sign of multiple sclerosis and is caused by dyssynergia of either the internal (bladder neck) or external urethral sphincter. Treatment of female bladder outlet obstruction begins with pelvic floor physical therapy, α-blockers, intermittent self-catheterization, and off-label injection of botulinum toxin. If neurologic disease is suspected, a referral is made concurrent with intervention, and physical therapy may be less likely to succeed. Underactive bladder can cause pelvic pain because of high post-void urine residual volumes. It is characterized by prolonged urination time, possible feeling of incomplete emptying, urinary hesitancy, weak stream, and straining when urinating. It is diagnosed via post-void residual measurement and urodynamic testing and may require cystoscopy to exclude other etiologies. Treatments include behavior modification, pelvic floor physiotherapy, α-blocker medication, and intermittent or indwelling catheterization. Further treatment steps may include indwelling suprapubic catheter or diversion of urine; in idiopathic (non-neurogenic) retention, sacral neuromodulation may be successful.

CPP arising from the ureters is rare but can most certainly occur in the setting of a missed distal ureteral stone. Clues would include sudden onset of pain and urinary symptoms with occasional flank pain. Obstruction of the ureter can occur because of endometriosis or surgical scarring, or because of a congenital abnormality (ureterocele). Diagnosis would be via ultrasound, MRI, or CT scan, and treatment includes NSAIDs, α-blocker medications, and surgical management of any anatomic lesions. Hyperalgesia can persist in the ureters after stone passage.[32]

Malignancy of the urinary tract should be investigated if gross hematuria is present; this should neither be confused with dietary or synthetic changes to urine color (e.g. beets) nor ignored because of the use of anticoagulation. Microscopic hematuria is defined as ≥3 red blood cells per high power field in the absence of infection. Hematuria obligates renal mass protocol kidney imaging and cystoscopy with a urologist.[33]

Gastrointestinal Problems, Anal, and Defecatory Pain

Several gastrointestinal disorders may contribute to pelvic pain because of the complex visceral innervation of the abdomen (Fig. 42.3). Anorectal causes of pelvic pain can include prolapsed hemorrhoids, anal fissures, abscess, prolapsed rectum, proctalgia fugax, and anal cancer. Gastrointestinal sources may include IBS, inflammatory bowel disease such as ulcerative colitis or Crohn's disease, severe constipation, stricture, obstruction, diverticular disease, or colon cancer. A thorough history of the pain is necessary and should include explicit questions regarding rectal bleeding or black stool, fever, nausea, vomiting, weight loss, swollen joints, skin rashes, severe fatigue, and eye pain. Surgical, medical, gynecologic, and obstetric history may be relevant as well. Signs that point to a gastrointestinal cause of pelvic pain include pain associated with bowel movement, eating, specific foods, and changes in bowel habits. A physical exam should involve visual anal inspection, a digital rectal exam, and potentially an exam with an anoscope. Depending on the initial exam, further investigation may include colonoscopy, MRI, x-ray, defecography, endoanal ultrasound, CT scan, anorectal manometry, or sitzmark study. Below we discuss some specific intestinal and anorectal disorders that cause pelvic pain.



• **Figure 42.3** Visceral innervation of the abdomen. From: Drake RL, Vogl A, Mitchell WA. Gray's Atlas of Anatomy. 3rd ed. Philadelphia, PA: Elsevier; 2021:133–212.

IBS is a functional disorder related to changes in bowel habits that can lead to both chronic abdominal and pelvic pain. Symptoms vary, and diagnosis is often by exclusion. IBS can be associated with traumatic early life experiences, depression, anxiety, and other hypersensitivity disorders such as migraine headaches, chronic fatigue, and fibromyalgia. Various foods can trigger this benign condition, and treatment should begin with diet restriction to exclude dairy, gluten, and fermentable carbohydrates. Treatment may include medications such as gabapentin and low dose anti-depressants, depending on individual patient symptoms. Some patients may be hesitant to discuss symptoms, having been told that it is "all in their head"; thus providers need to explain that there is a biologic cause for IBS symptoms.

Inflammatory bowel disease is commonly split into ulcerative colitis and Crohn's disease. Ulcerative colitis affects the innermost lining of the large intestine, resulting in continuous inflammation that typically begins distally at the rectum and progresses proximally; symptoms include severe (bloody) diarrhea, crampy abdominal pain, fever, weight loss, and fatigue. Evaluation includes colonoscopy to confirm the diagnosis.[34] Crohn's disease

causes "skip-lesions" and can affect any segment of the gastrointestinal tract from the mouth to the anus discontinuously, often with rectal sparing, and involves the entire thickness of the bowel wall. Complications include stricture, abscess, and fistula. Evaluation involves a colonoscopy, CT scan, and blood tests such as fecal calprotectin. Treatment for mild ulcerative colitis may be sufficient with mesalamine, and treatment for severe ulcerative colitis and Crohn's disease can include prednisone and other immune modulators such as azathioprine, remicade, humira, ustekinymba, and vedolizumab.

Refractory constipation can be caused by slow colon transit or pelvic floor dysfunction and other disorders such as colon stricture, rectal inflammation, neurologic disorders, or colon cancer. Evaluation includes a thorough history, colonoscopy, anorectal manometry, sitzmark test, functional testing, or imaging as indicated. Patients may not know they are constipated. Treatment is based on the cause and may include pelvic floor physical therapy, dietary changes, or laxatives.

Previous abdominal surgery can lead to adhesions, which can cause changes in bowel movements or irritation of the peritoneum and is diagnosed via laparoscopy.

Hernias occur when abdominal organs or tissues protrude from a weakening in the peritoneum, with femoral or inguinal hernias most commonly associated with pelvic pain. Inguinal hernias are more common in males and femoral hernias are more common in females. Reducible or painless hernias do not always require intervention, but urgent surgery is necessary if hernias become incarcerated or strangulated. Symptoms of hernia requiring emergent surgery include sudden onset pain, a red or purple bulge, loss of bowel movements, fever, and vomiting.

Hemorrhoids (internal and external) derive from enlarged blood vessels within and surrounding the anal canal. It has been estimated that 75% of individuals will experience hemorrhoids in their lifetime, and the predominant symptom is painless rectal bleeding.[35] Other signs may include anal pain, itching, or discomfort during touching of the anal area. External hemorrhoids typically are asymptomatic unless they become thrombosed, and internal hemorrhoid pain is related to prolapse, strangulation, or thrombosis. Evaluation of hemorrhoids will include a rectal exam, an anoscope exam, and a colonoscopy if other sources of bleeding need to be excluded. Management should prioritize preventing constipation, optimizing positioning during bowel movements, sitz baths, topical preparations, and suppositories that contain hydrocortisone. For hemorrhoids that are not alleviated with conservative therapy, procedures such as banding, cauterization, and sclerotherapy are choices. Surgical options include ligation with or without mucopexy or hemorrhoidectomy.

Irritant dermatitis can occur subacutely from exposure to feces and manifests as skin erosion, erythema, and scaly damage without well-defined borders. Related conditions include overlying fungal (yeast) infection. Older adults are at higher risk of developing irritant dermatitis. Management involves cleaning the skin daily to maintain acidity and keeping the area dry; a skin barrier product containing zinc oxide, petrolatum, or dimethicone should be utilized in cream, lotion, ointment, or liquid form and reapplied after cleaning with every bowel movement. If a fungal or yeast infection is also present, medications such as clotrimazole and miconazole should also be applied. Bulk-forming fiber and products that reduce stool frequency may be useful; avoiding greasy and spicy foods may help stools maintain solidity.

Anal fissures are a tearing of the inner lining of the anal canal either from high anal sphincter tone or from repetitive anal trauma (e.g. chronic constipation). Symptoms include severe pain with bowel movements, minor bleeding, discharge, itching, and burning. Diagnosis can usually be made via history, but gentle physical exam with Q tips may be necessary. Treatment is primarily focused on preventing constipation, while topical agents such as nifedipine or diltiazem (calcium channel blockers) and glyceryl nitrate (GTN) or botulinum toxin injection may also be helpful. If the fissure does not heal with conservative therapy, a fissurectomy or lateral internal sphincterotomy may be required.

Pruritis ani is chronic anal itching leading to perianal skin irritation, pain, and bleeding that can be caused by fecal soiling, contact dermatitis, psoriasis, infection, or certain foods. Diagnosis may require a skin biopsy to exclude Paget disease or malignancy. Addressing the underlying cause is ideal, but barrier creams, maintaining perianal hygiene, and keeping the area dry may help.

Rectal prolapse occurs when there is full-thickness protrusion of the rectum through the anus and is more common in those with weak pelvic floor muscles and rectal fascial attachments or an elongated sigmoid colon. It is more common among females, and risk increases with age. Symptoms include rectal bleeding, mucous discharge, and pelvic discomfort. Usually, the tissue can be mechanically pushed back in; if not, this becomes an urgent issue that requires prompt medical evaluation, as strangulation of the tissue can occur. Evaluation typically necessitates colonoscopy, potentially defecography, and anorectal manometry, and surgery is the ultimate treatment.

Levator ani syndrome involves recurrent dull pelvic or rectal pain lasting for 30 min or more and is often related to levator ani spasm. Treatment can include digital rectal massage, physical therapy, sitz baths, heat or ice, albuterol inhaler, muscle relaxants, botulinum toxin injection, gabapentin, and pain blocks. Proctalgia fugax is a related disorder, with pain lasting up to 30 min and is often more minor, with most patients experiencing fewer than five episodes per year. This pain is thought to be caused by abnormal smooth muscle contraction of the anal sphincter complex. Treatment primarily involves supportive care and topical agents such as diltiazem and glycerol nitrate or inhaled salbutamol.

Musculoskeletal Etiology of Pelvic Pain

Musculoskeletal factors are often overlooked when undertaking a CPP evaluation.[36] However, they have been estimated to have a prevalence ranging from 8%–22% in the United States.[37,38] Taking these numbers into account, it is important to keep musculoskeletal cause high in the differential when evaluating CPP. The patient history should consider previous lower extremity fractures, foot (bunion), ankle, or knee pain, scoliosis, change in ergonomics, or chronic sitting or lifting (e.g. carrying a work bag or young child on one side). Disorders that affect the pelvic girdle or pelvic floor muscles are involved in the development of vaginismus, vulvodynia, proctalgia fugax, and dyspareunia and can even cause entrapment of the nerves (i.e. pudendal neuralgia).[5,39] Pain in the lower back, hips, abdominal muscles, bladder, or bowel may refer pain to the pelvic region. Other common causes of referred pain include damage to the ilioinguinal or hypogastric nerves of the abdominal wall by prior surgery. Alleviating pain from the primary region will typically improve pelvic pain.

Pelvic floor muscles (PFMs) support the pelvic organs, pelvis, and spine, assist with posture, and allow for normal bladder and bowel function in all sexes. Pathologic strain in the PFMs arises from trauma, repetitive use or underuse, or inherent muscle disease, while the pain itself arises from the resulting muscle spasm,

overactivity, or increased muscle tension.[5,40] Hypertonicity of the PFMs is a common cause or contributor to pelvic pain in males and females. It is present on physical exam in up to 87% of females with CPP and 13% of females on screening physical exam.[41,42] Reaction to pain or the stress of musculoskeletal imbalances is a cause of myofascial pelvic pain. This may be associated with symptoms in other pelvic structures such as the bladder, gastrointestinal tract, hip, and back. Myofascial pain is often coupled with pelvic pressure and pain with intercourse, urination, or bowel movements. Diagnosis is based on physical exam, most notable for tight muscle bands, discomfort with palpation, or distinct trigger points similar to those seen in fibromyalgia on exam of the levator, obturator, coccygeus, and piriformis muscles (Fig. 42.4). Diagnostic imaging is not indicated, but the shortening of the muscles has been demonstrated on MRI. Treatment includes pelvic floor physical therapy, relaxation techniques, and medications such as muscle relaxants or off-label trigger point injections with botulinum toxin, steroids, or local anesthetics. Fig. 42.5A–B illustrates the PFMs.

Pathologies that affect the pelvic girdle can also be involved in the development of CPP. For the pelvis to adequately transfer load, it must be well coordinated with all the neuromuscular and articular systems that surround it.[43] Abnormalities within the bones themselves, joints, tendons, or ligaments can make the load distribution inadequate/ imbalanced and precipitate pelvic pain. Fractures of the pelvic bones can occur secondary to osteoporosis or high energy collisions. Damage to the symphyseal ligaments can also occur, either because of trauma or childbirth, resulting in, for example, pubic symphysis diastasis. These patients can experience pain in the anterior pelvis when walking postpartum, and diagnosis is by radiographic separation of >10–13 mm (FPP).

Perhaps unsurprisingly, alterations within structures neighboring the pelvis can also contribute to the development of pain. Dysfunction in the spine or the lower limbs (e.g. scoliosis, flat foot, hamstring tendon rupture) can also impact the transfer of load and have been looked at as potential causes of CPP.[44] The abdominal wall frequently has an impact on pelvic pain, either via radiating/referred pain or by affecting the pelvic girdle mechanics.[45] The hip joints, a common place for arthritis to develop, can also cause CPP via referred pain.[5]

The diagnostic approach should be focused on the history and physical examination (see subsection on H&P) as no single gold standard test exists for the diagnosis of musculoskeletal CPP. Along with the usual questions, history should include any previous history of trauma or symptoms such as pain with defecation, urination, or intercourse. Previous surgical interventions or childbirth instrumentation should also be noted.

For the physical exam, it is important to assess the range of motion, posture, gait, lower limb strength and length, reflexes, and sensory examination. Assessment of internal and external pelvic musculoskeletal structures (e.g. ability to contract or relax, muscle tone, and tenderness) is also of great importance when assessing musculoskeletal causes of CPP. The pelvic floor muscle

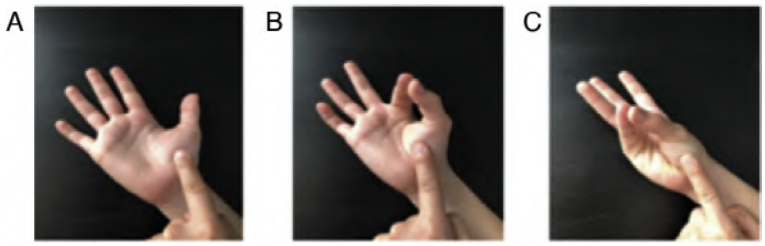
overactivity (firmness) manual examination is a pragmatic four-point scale of hypertonicity based on comparison of the PFMs to the thenar eminence. Fig. 42.6 illustrates how to quickly assess the tonicity of PFMs.

An asymmetric Trendelenburg gait can be seen with hip dysfunction and myopathies impacting the gluteus medius. Heel or toe walking should raise suspicion of neuropathic weakness. Pain with pubic diastasis will be elicited by bilateral pressure on the trochanters and hip flexion with the legs in extension. Osteitis pubis, which is found typically in young female athletes, leads to painful isometric adductor contraction. The Patrick (FABER: flexion, abduction, external rotation) test can diagnose sacroiliac joint



• **Figure 42.6** The pelvic floor muscle overactivity (firmness) manual examination is a pragmatic four-point scale of hypertonicity based on a comparison of the pelvic floor muscles to the thenar eminence. Normal **(A)**, moderate **(B)**, and severe **(C)** high tone. Hypotonicity would feel softer than the relaxed thenar muscle.

and iliopsoas pain. A positive FABER test suggests sacroiliac joint dysfunction or iliopsoas pain (see Chapter 30).

Some diagnostics that have been of aid in diagnosis in the musculoskeletal cause of pelvic pain include pelvic radiographs, ultrasonography measured sacroiliac joint laxity, and bone mineral density, but in general, unless unstable bony or neurologic lesions are suspected, physical evaluation with a physical therapist certified in pelvic health will be the first (and often only) step.[36]

As with other causes of CPP, multimodal therapy might be needed to achieve the best outcome. Physical therapy techniques are the most important. Musculoskeletal pain can also be treated with a combination of medications and minimally invasive interventions.[46] Tricyclic anti-depressants (TCA's) have proven useful in the management of chronic pain and specifically myofascial pain. NSAIDs (i.e. ibuprofen, naproxen) have had success in musculoskeletal pain, as long as comorbidities allow empiric use (e.g. renal disease, peptic ulcer disease). Opioid use is reserved for severe or refractory cases by consensus among providers as they are limited by efficacy, side effects, and potential for tolerance/dependence.[7,46]

Muscle relaxants can be used. However, a systematic review has shown that muscle relaxants increase adverse effects by 50% (relative risk of 1.50, 95% confidence interval, 1.14–1.98), including sedation, headaches, blurred vision, and dependence.[47,48]

Physical therapy is considered the cornerstone of treatment for musculoskeletal components of CPP because, as discussed above, muscle imbalances, bad posture, or alterations that affect load distribution in the pelvis are important sources of pain.[49] Close follow up should be scheduled with orthopedics in the case of pelvic fractures as it can take up to a year to completely heal, and the risk for sequelae is high.[5]

Therapeutic injections (e.g. 1%–2% lidocaine) directed at trigger points or with botulinum toxin can be attempted if the previous interventions fail in improving pain.[46,50] Targets include the obturator internus, piriformis, pubic symphysis, coccyx, the sacroiliac, or hip joint. In patients with concomitant neurogenic pain, lumbar or epidural injections can help in reducing the muscle spasm, in turn reducing the musculoskeletal source of pain. Therapeutic injections should be used along with other treatment modalities such as physical therapy.

Focal Neurologic Conditions Causing Pelvic Pain

Neurologic causes of pelvic pain can arise anywhere in the nervous system. Conditions that affect the CNS or the peripheral nervous system, and systemic neuropathies, can manifest as CPP. This section will emphasize the focal neurologic etiologies of pelvic pain while exploring the more systemic causes of neurologic CPP later.

The pelvis is innervated by an array of nerve systems. The lumbar, hypogastric, and sacral plexuses are the main nerve groups innervating the pelvis.[51] They contain somatic and autonomic fibers (both parasympathetic and sympathetic). The somatic component is found within the lumbosacral, femoral, sciatic, obturator, and pudendal (arising from the nerve roots S2–S4), while the parasympathetic and sympathetic components arise from T12–L2 and S2–S4, respectively.[52] Fig. 42.7 illustrates the parasympathetic and sympathetic innervation of the abdomen, pelvis, and bladder.

The parasympathetic fibers (mostly the pelvic splanchnic nerves, aka the pelvic nerve or nervi erigentes) regulate the contraction of the bladder and rectum and relaxation of the sphincters. The preganglionic neurons are located in the sacral parasympathetic nucleus. Axon fibers from these neurons travel through the ventral nerve roots to the peripheral ganglia. Postganglionic neuron cell bodies are located in the detrusor wall and pelvic plexus (inferior hypogastric plexus). Therefore cauda equina or pelvic plexus injury is decentralized but not necessarily denervated. Sexual functions such as erection are also regulated by the parasympathetic splanchnic nerves. Sympathetic fibers (mainly from the superior hypogastric plexus) are involved in ejaculation, inhibition of the detrusor muscle, and the involuntary closure of the bladder neck.[53] Signaling is noradrenergic. The peripheral nerves involve the sympathetic chain ganglia, the inferior mesenteric ganglia, the hypogastric nerves, then the pelvic plexus (inferior hypogastric plexus) (Fig. 42.8). Voluntary sphincter control is somatic from the pudendal nerves, whose motor neurons are in Onuf's nucleus. Pelvic somatic fibers can be motor, sensory, or mixed; the main somatic nerves to consider are the obturator, pudendal, gluteal, genitofemoral, lateral femoral cutaneous, ilioinguinal, and femoral nerves. The interactions of these nerves are complex. For example, in urination, storage reflexes are maintained by parasympathetic low level firing and afferent firing from the pontine micturition center stimulating the spinal guarding reflex via sympathetic outflow, simultaneously inhibiting the detrusor and stimulating contraction of the bladder outlet, and pudendal outflow to the external urethral sphincter. Voiding reflexes are as follows: vesical afferent activity intensifies, activating the pontine micturition center. This inhibits the spinal guarding reflexes, stimulates high level parasympathetic outflow, and ascending afferents maintain the voiding reflex until the bladder is empty.

Lesions can result from direct damage (e.g. childbirth, surgery) or compression of the nerves from adjacent structures.[54]

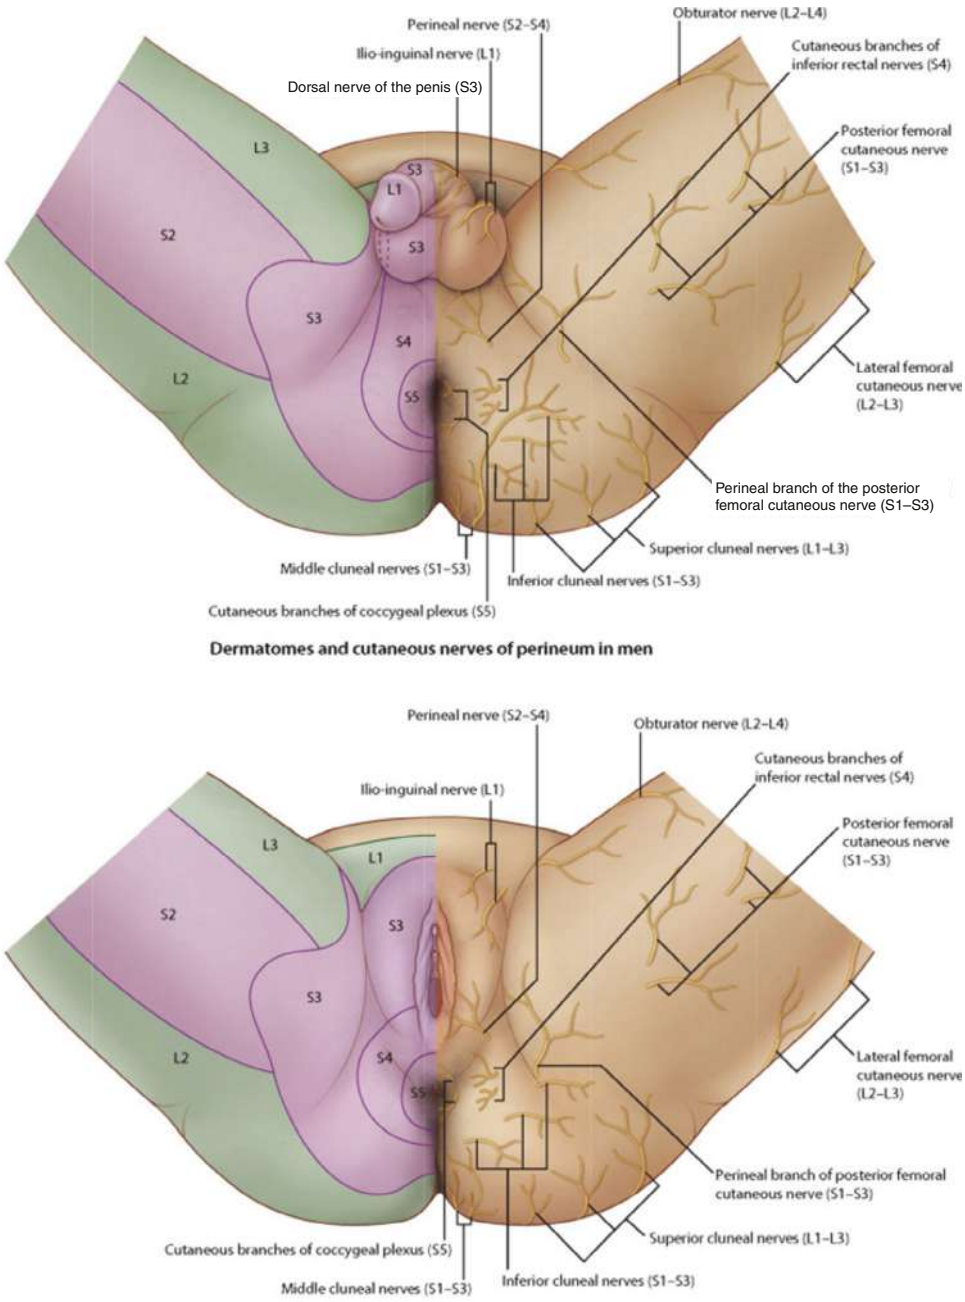
Neuropathies such as Small Fiber Neuropathies and infection (e.g. by herpes viruses) can also incur damage to the pelvic nerves.[5]

The sensory innervation of the pelvic structures is diffuse and demonstrates crosstalk, making it challenging to pinpoint a source of pain. Pain characteristics can help by suggesting whether it is visceral or somatic pain. Visceral pain arising from injury to visceral nerves is often described as dull, poorly localized, and is associated with autonomic symptoms (such as nausea).[51,55,56] Somatic pain results from nociceptive signals associated with tissue damage, while neuropathic pain is associated with neural damage at the level of the nerve, plexus, nerve root, or central nervous system. Neuropathic pain is associated with symptoms such as paresthesia, hyperalgesia, allodynia, or abnormal thermal sensations. Muscle weakness in the myotome of the affected nerve may also be seen. Fig. 42.9 illustrates the nerve distribution in the pelvis.

The most common causes of neuropathic pelvic pain because of peripheral nerve injury are discussed in Table 42.4. Pudendal neuralgia is the most commonly considered nerve entrapment in



• **Figure 42.9** Distribution of select nerves of the pelvis that may contribute to chronic pain. Perineal dermatomes showing the dermal distribution territories of the iliohypogastric, ilioinguinal, genitofemoral, femoral, pudendal, inferior cluneal, obturator, posterior femorocutaneous, lateral femorocutaneous, and the coccygeal plexus, which may present frequent anatomic variations and interconnections. the differential of pelvic pain. Direct compression of the pudendal nerve can occur at several levels, and non-mechanical causes of pudendal neuralgia such as viral infections or diabetes can also occur.[57] Location of a discrete lesion occurs at the sacrospinous/sacrotuberous ligaments in 42% of cases, Alcock's canal (medial to the obturator internus, within the fascia) in 26% of cases, and is at multiple levels in 17% of cases.[58,59] It can occur at the level of the piriformis, although the frequency is not reported. The more distal the lesion along the pudendal nerve, the less likely the anal region will be involved. Pudendal neuralgia presents with pain and dysfunction in the S2, S3, and S4 nerve distributions (including the rectum, genitalia, and urinary tract), sexual and sphincter dysfunction, and pain typically worse with sitting.[60] Nantes Criteria is used as a diagnostic tool for pudendal nerve pain.[61] Treatment is with neuromodulators, physical therapy, trigger point injection, botulinum toxin injection, neuromodulation, and in select cases, surgical release. Surgical release can be effective for decompression of discrete lesions. If pain has

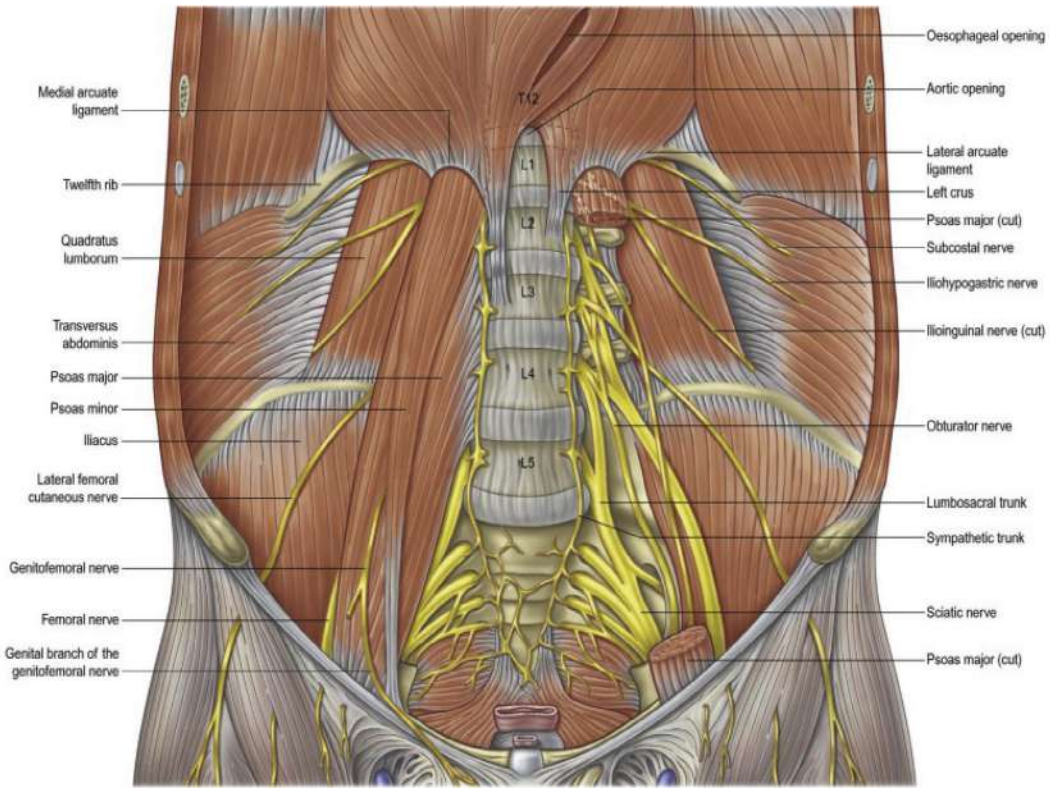
TABLE 42.4 Peripheral Nerve Injury Associated With Pelvic Pain and Dysfunction

Nerve Involved	Presentation
Ilioinguinal nerve (T12, L1)	Groin pain with radiation to the vagina, labia majora, root of the penis or upper scrotum, mons pubis, lateral waist.
Iliohypogastric nerve (T12, L1)	Lateral gluteal and suprapubic pain.
Obturator nerve (L2, 3, 4)	Pubic pain radiating to the inner thigh and knee. Weakness of adduction (adductors) and lateral rotation of the hip (gracilis muscle). Injury can occur during pelvic lymphadenectomy, deep endometriosis, dissection of the paravesical fossa, retzius space, or iliolumbar fossa.
Anterior abdominal cutaneous nerves	Abdominal pain usually lateral to the rectus sheath.
Lateral femoral cutaneous nerve (L2, L3)	Pain and numbness of the lateral thigh. Injury can occur secondary to obesity, tight pants or belts, or with impingement secondary to prolonged hip flexion.
S1 nerve root	Pain and numbness on the external aspect of the posterior thigh, calf, and leg and the exterior aspect of the foot. S1 nerve root entrapments can cause gait disturbances and loss of ankle stability.
S2 nerve root	Pain and numbness on the internal half of the posterior thigh, calf, and leg, internal surface of the foot, vulva, and clitoris (female), penis, and scrotum (male). Usually associated with urinary urgency and frequency. Genital arousal disorders, erectile dysfunction, and/or lack of vaginal lubrication may be present.
S3/4 nerve root *(usually entrapped together because of proximity)*	Pain and numbness on the buttock, anus, perineum, vulva, and clitoris (female), penis, and scrotum (male). Usually associated urinary and bowel urgency and frequency, pain on passing urine or stool. Often associated with vaginal and/or rectal foreign body sensation.
Sciatic nerve (L4, L5, S1, S2, S3)	Buttock, posterior thigh, calf, lateral leg, and foot pain. Impact on muscles of the posterior anterior and lateral compartments of the lower leg, foot drop. Lies 2 cm from the sacrospinous ligament and can be injured during sacrospinous ligament vault fixation. Hip replacement, and even improperly performed buttock injections.
Genitofemoral nerve (L1, L2)	Genital branch: Pain in the inguinal fold, mons pubis, base of the penis, labia majora, anterior vulva, clitoris, and urethra femoral branch: superomedial thigh. Injury can occur during, e.g. pelvic lymphadenectomy or psoas hitch.
Pudendal nerve (S2, 3, 4)	Pain and dysfunction in the S2, S3, and S4 nerve distributions (which includes the rectum, genitalia, and urinary tract, urethra), Urgency or pain associated with urination or bowel movement, sexual and sphincter dysfunction (erectile dysfunction, lack of lubrication), and pain that is typically worse with sitting. It can be an injured surgical leg. During sacrospinous ligament vault fixation, because of infection (e.g. herpes) or entrapped by a hypertonic muscle.
Posterior femoral cutaneous nerve and inferior cluneal nerves	Inferior gluteal (buttocks) pain.
Autonomic nerves Sympathetic: superior hypogastric plexus, hypogastric nerves, inferior hypogastric plexus Parasympathetic: pelvic splanchnic nerves, inferior hypogastric plexus, visceral nerve branches	Injury to the sympathetic nerves can lead to urinary incontinence and urgency. The hypogastric nerves can be encountered during sacral dissection. Injury to the parasympathetics can lead to atonic bladder, reduced bladder and rectal sensation, decreased vaginal blood flow, and lubrication. Abdominoperineal resection or application of mesh for prolapse can injure the inferior hypogastric plexus and rectal plexus visceral nerve branches, respectively.

Adapted from *Facing Pelvic Pain.*[5]

been present for fewer than six years, 66% of patients improve. If >6 years, 40% improve.[59] Another pathologic condition, sacral radiculopathy, can present with similar symptoms and is often confused with pudendal neuralgia.[62] Symptoms exclusive to sacral radiculopathy include the addition of back pain, gluteal pain, and sciatica. The most common causes include surgical damage, compression by varicose veins, endometriosis, sacral tumors, tethered cord, and Tarlov cysts.[63] Pudendal neuralgia is but one of many peripheral nerve lesions that cause pelvic pain. Please refer to Table 42.4 for diagnostic guidance. Figs. 42.10–42.12 illustrate the pelvic nerve, cutaneous nerves, and dermatomes.

Lesions within the spinal cord can result in injury to the nerve fibers, which can present as pelvic pain (Table 42.5). CPP in patients with spinal cord pathologies can be especially prevalent. One study in the United States reviewed 1,295 patients with spinal cord injury and approximately 25% of the cohort presented with chronic pain throughout the pelvic girdle.[62] Tumors, Tarlov cysts, disk herniations, and tethered spinal cord are causes of neurologic pelvic pain originating in the spinal cord (Fig. 42.13). Symptoms such as cauda



• **Figure 42.10** The lumbosacral plexus. These peripheral nerves (nerves that connect the spinal cord and brain to the limbs and organs) innervate many structures in the pelvis, although some of them originate outside of the pelvis. Reproduced from Standring S. *Gray's Atlas of Anatomy. The Anatomical Basis of Clinical Practice*. 41st ed. Elsevier; USA, 2016:1083–1097.e2. Figure 62.14.

equina syndrome can present acutely, including bowel or bladder dysfunction, saddle anesthesia, bilateral sciatica, and leg weakness. This is most commonly caused by a tumor or midline disc and is considered a medical emergency. Other causes of cauda equina syndrome include abscess, arachnoiditis, tethered cord, chronic inflammatory demyelinating polyneuropathy, herpes simplex and zoster, Lyme disease, and tuberculosis.[5] Pathology within the brain itself can also lead to pelvic pain, especially through central sensitization of pain. This concept is discussed further in the chapter.

The diagnostic approach to the neurogenic cause of pelvic pain is via full genital and neurologic exam. History should focus on risk factors such as pelvic or abdominal surgeries, thrombosis, obstetric history, and pathologies of the CNS. It is important to note the characteristics of pain, timing, quality, intensity, and the presence of radiated or referred pain. The physical exam should assess for muscle strength, muscle tone, and range of motion. Sensation is assessed in all the dermatomes of the lumbosacral region. Proprioception, vibration, and reflex testing should also be performed. Focality or multifocality, upper versus lower motor neuron findings should be recorded.

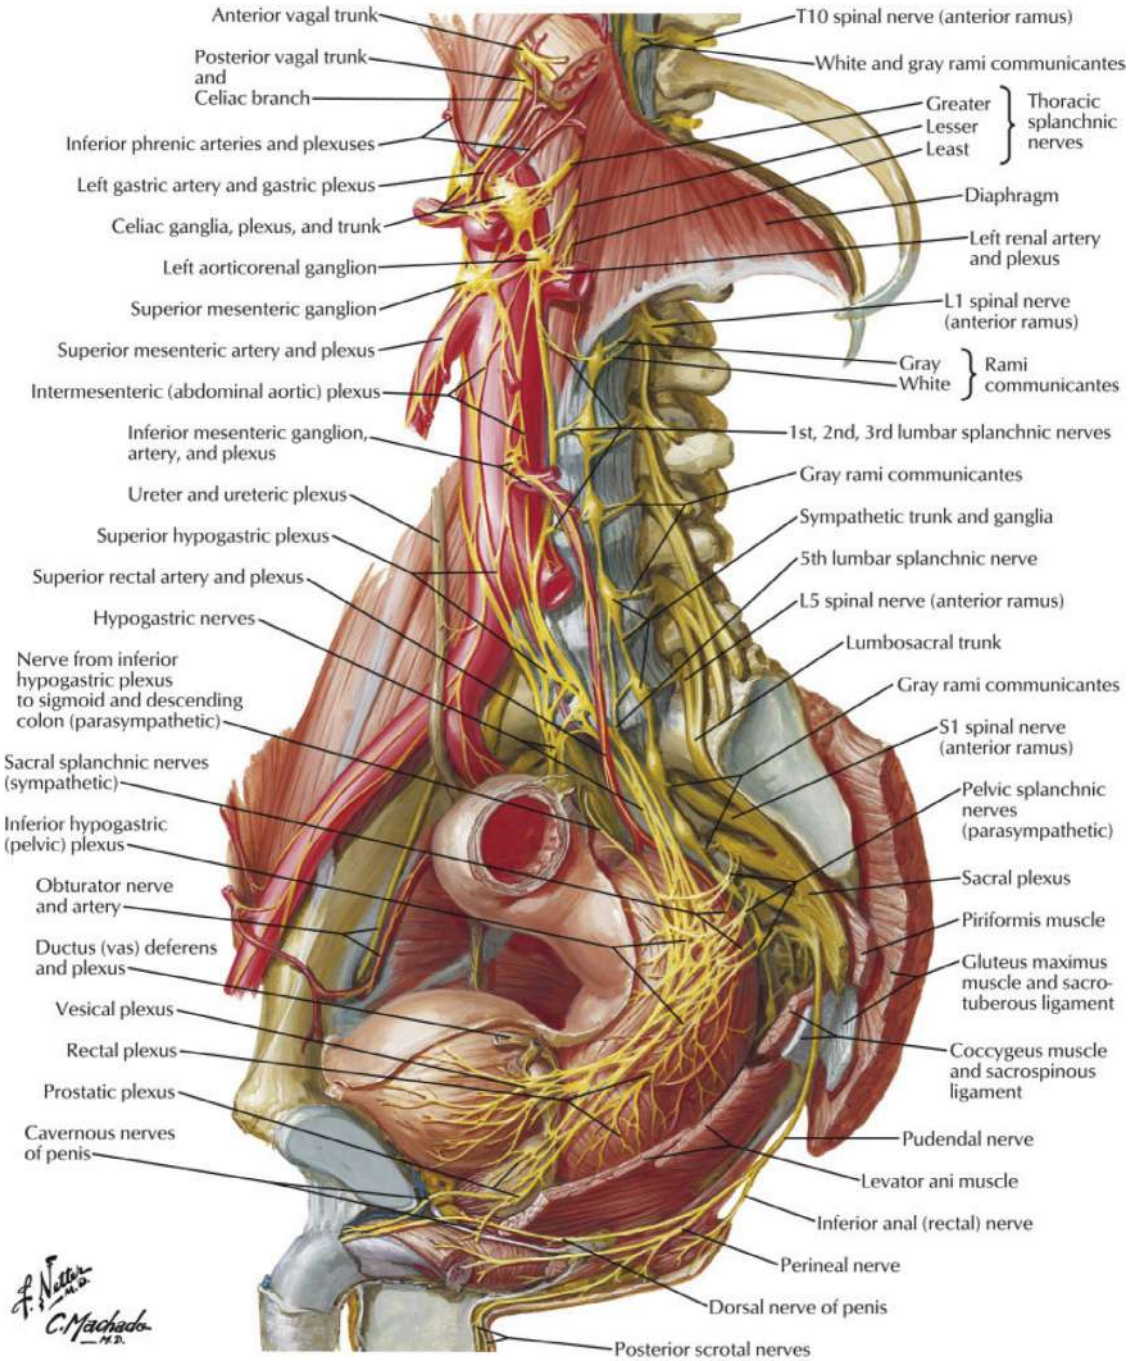
Some pathologies, e.g. pudendal, abdominal wall, or sacral neuropathies, can be diagnosed effectively with a selective nerve block.[51] Additional tests such as ultrasound or urodynamic testing (bladder function), defecography (bowel function), and electromyography (EMG) can help in determining the cause. It is important to note that standard physical exams and EMG assess only the large nerve fibers. Small fiber neuropathy, discussed further below, requires quantitative sensory (mechanical and thermal) testing for diagnosis.

There are several treatment options in the management of neurogenic pelvic pain, ranging from conservative physical therapy to invasive procedures. Physical therapy alone remains controversial in the management of radicular pain, particularly in the acute setting, as some studies have noted no difference in outcome between physical therapy and rest.[64,65]

Medical treatment includes NSAIDs, acetaminophen, or serotonergic compounds. It is of note that their lack of selectivity for neurologic processes might limit their efficacy in the most severe cases. Opioids can be effective in the management of these patients; however, special attention should be made to avoid the development of tolerance and opioid-induced hyperalgesia, and most recommend their use primarily in the acute setting.[66,67] The development of side effects and dependence also limit opioid use. Pregabalin has been proven effective in the management of pelvic pain of neurologic cause as it reduces neuronal hyperexcitability in the spinal cord and suppresses hypersensitivity in visceral pathways.[68]

It has been argued that if etiologic treatment is possible, it should take priority over solely medical symptomatic treatment.[51] Targeted therapies such as therapeutic injections, either directed at a single nerve (e.g. local anesthetics, glucocorticoids, botulinum toxin) or as epidural injections (e.g. steroid injections), have proven very effective.[66,69] Other therapies such as neurolysis, nerve decompression surgery, or neurosurgical or spinal procedures are also effective in management for specific indications.

Neuromodulation has had considerable success in the treatment of refractory pelvic pain, with improvement seen in 50% up to around 90% of patients presenting with CPP, depending on



• **Figure 42.11** Nerves of the pelvic viscera (male). Reproduced from Netter FH. Plate 392. *Atlas of Human Anatomy*. 2018: pp. 36.

the modality of neurostimulation performed.[70] Examples include spinal cord stimulation, nerve root stimulation, and pudendal nerve stimulation. Motor cortex stimulation is also an approach that can be attempted in cases refractory to other neurostimulation modalities.[71]

Vascular Causes of Pelvic Pain

Vascular causes of pelvic pain can stem from either venous or arterial disorders. Most of the arterial supply of the pelvis arises from the internal iliac artery and its numerous branches. The pudendal artery supplies the perineum, the buttock region is supplied by the gluteal arteries, and the pelvic organs are supplied by the vesical, rectal, and uterine arteries (in the case of females).[72] The veins that arise from the pelvis mostly drain into the internal iliac vein. The major exceptions are the gonadal arteries and veins, which arise from the abdominal aorta and drain into the inferior vena cava (IVC).[73] It should be noted that the left gonadal vein drains into the left renal vein prior to the IVC. Figures 42.14 and 42.15 illustrate the vascular structures present in the pelvis.

Although arterial etiologies are a rare cause of pelvic pain, these disorders should be ruled out if the context suggests their presence,

TABLE 42.5 Central Nervous System Causes of Pelvic Pain

Spine Diagnosis	Symptoms	Physical Exam Finding
Herniated disc: disc protrusion causes spinal cord or nerve root compression.	Back pain, shooting pain or numbness that follows a specific dermatomal pattern (e.g. a T10 through L1 disc herniation may radiate into the skin of the groin or abdomen), or sciatic symptoms in the leg; persistent genital arousal disorder has also been attributed to the spine.	Abnormal gait, pain with provocative maneuvers (e.g. pain with low back flexion, positive straight leg test that radiates pain with spine range of motion), possible increased or decreased reflexes.
Tarlov cysts: fluid-filled nerve root cysts found most often at the sacral level of the spine; small cysts may be a normal variant and are present in 5%–10% of people.	Symptoms vary but may present with pain over the buttocks and sacrum or with bowel, bladder, or sexual dysfunction.	Pain with sitting, standing, or walking; may have increased sensitivity or loss of sensitivity to touch over the sacrum and buttock; may present with lower extremity weakness.
Spina bifida occulta.	Typically *asymptomatic* but may cause lower extremity symptoms, including weakness, and urinary, sexual, or bowel symptoms, pelvic pain, and impaired sensation of the genitals, bladder, or bowels. Sometimes symptoms begin during growth spurts because of an associated *tethered spinal cord.*	May present with lower extremity weakness; the skin over the spine may present with an abnormal tuft of hair, dimple, or birthmark.

Continued

TABLE 42.5 Central Nervous System Causes of Pelvic Pain—cont'd

Spine Diagnosis	Symptoms	Physical Exam Finding
Tethered spinal cord: caused by tissue attachments that limit the movement of the spinal cord within the spinal column; these attachments cause an abnormal stretching of the spinal cord, and therefore upper and lower motor neuron findings can be present; associated with spina bifida.	Back pain or shooting pain in the legs, weakness or numbness in the legs, lower extremity spasms, bowel or bladder dysfunction (over or underactive).	Lower extremity weakness, abnormally low or high reflexes, diminished lower extremity sensation. Gluteus or calf atrophy.
Cauda equina syndrome: caused by central spine nerve compression, such as stenosis in the lumbar region from a large herniated disc or tumor.	Symptoms may include severe lower extremity weakness and/or pain, decreased sensation in the legs and/or the lower pelvic region *("saddle anesthesia"),* new-onset difficulty urinating or sudden urinary incontinence, and stool incontinence. If the above symptoms are acute, they require emergency evaluation.	Lower extremity weakness, reduced or absent reflexes in the legs, gluteus, or atrophy if chronic.
Sacral tumor: benign or malignant growths around the sacral nerve roots.	May present with symptoms similar to Tarlov cysts and herniated discs, such as back pain, lower extremity pain, lower extremity weakness, numbness or tingling, rectal dysfunction, urinary retention or incontinence, erectile dysfunction.	May present with tenderness over the sacrum or lower extremity weakness. A mass may be felt in the sacral area. Gluteal and calf atrophy may be present.

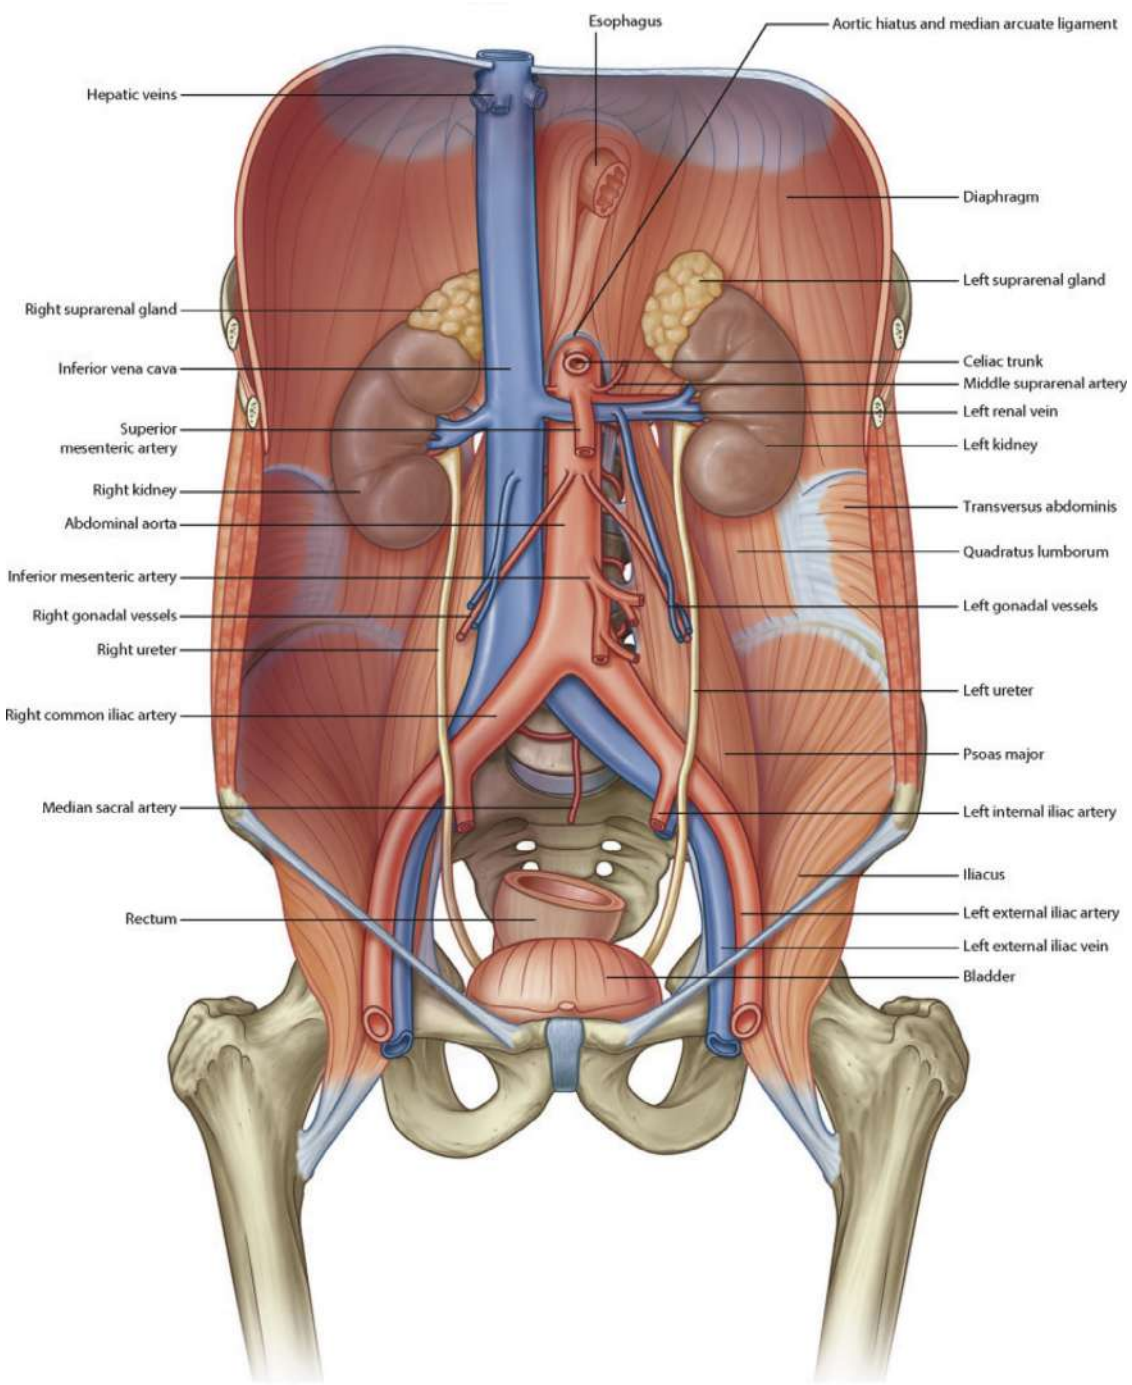
namely because vasculitis and ischemic disease can have serious implications.

Vasculitis is a rarely identified cause of pelvic pain and can be difficult to diagnose because of the non-specific signs and symptoms it presents, as it can affect any blood vessel in the body. In these disorders, the vessel wall is infiltrated by white blood cells with resultant inflammatory reaction. Vasculitis can arise either as a primary disorder or secondary to another process and can occur because of a systemic disease or as single organ vasculitis. Both can cause CPP.[74] Single organ vasculitis (SOV) can be either the first presentation of systemic vasculitis or a local inflammatory reaction to injury (e.g. tumors or pelvic surgery), with the latter being most common.[75,76] The progression of true SOV to systemic vasculitis is uncommon (less than 1%) and often requires just symptomatic management beyond the treatment of the underlying diagnosis.[77] Often, the precise cause of vasculitis remains unknown, but etiologies include autoimmune or rheumatic disorders, reaction to a medication, or infection. There is still an ongoing effort to develop a universal classification for vasculitis, but it is usually classified according to the size of the vessels involved (i.e. small, medium, and large sized vessels). Among the systemic vasculitides, giant cell arteritis (GCA; previously, temporal arteritis) is most prevalent in patients with pelvic pain. The classic symptoms of GCA include headaches, vision loss, jaw claudication, scalp tenderness, muscle stiffness, and pain.[78] The high level of association between GCA and polymyalgia rheumatica (PMR) plays a role in the presentation of pelvic pain. Around 50% of patients with PMR have been documented to have concomitant GCA by biopsy. Pelvic girdle pain occurs bilaterally in these circumstances and is present in about 50%–70% of patients afflicted by PMR.[79,80] It is important to have a high level of suspicion when diagnosing pelvic pain because of GCA, secondary to its potential to cause blindness. Other examples of systemic vasculitides which can cause pelvic pain include the following:

Large Sized Vessels

- Takayasu's arteritis, a large-vessel vasculitis that affects the aorta, with major branches to the extremities, and sometimes internal organs, usually occurring in females under 50 years
- Giant/temporal cell arteritis, already discussed above

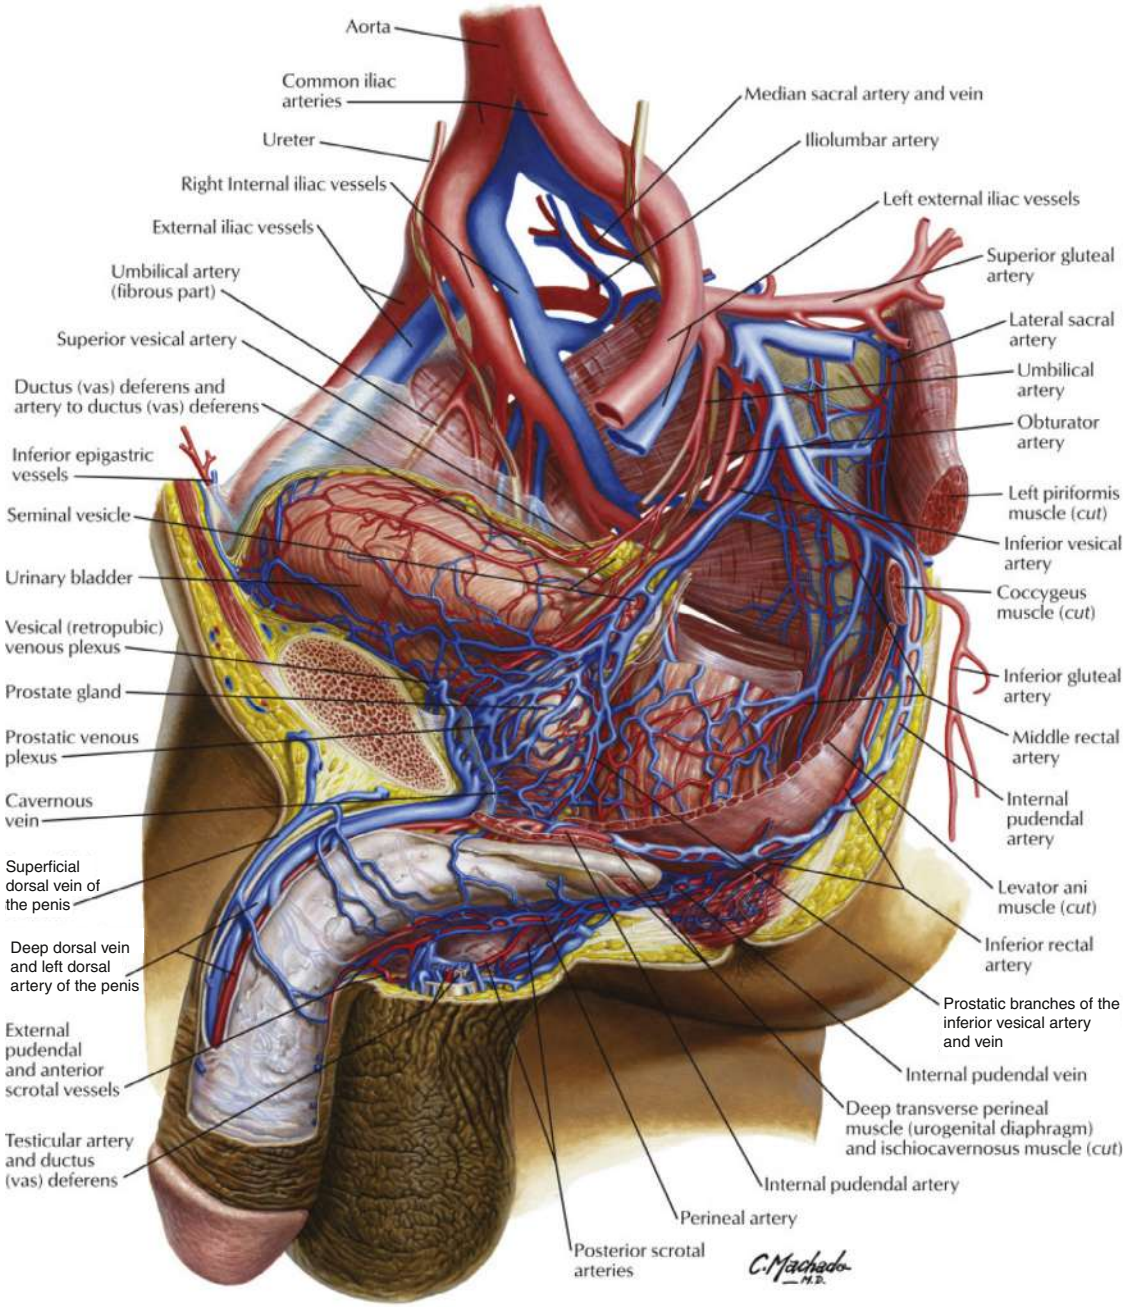


• **Figure 42.14** Vessels of the posterior wall. From: Drake RL, Vogl A, Mitchell WA. Gray's Atlas of Anatomy, 2021, pp. 133–212.

Small- and Medium-sized Vessels

- Granulomatosis with polyangiitis (GPA), formerly known as Wegener's, which is a systemic disease that involves the lungs, kidneys, upper respiratory tract, and other organs associated with the autoantibody ANCA.
- Eosinophilic granulomatosis with polyangiitis (EGPA), formerly known as Churg Strauss, which is associated with asthma, nasal polyps, sinusitis, elevated eosinophil counts, and vasculitis and tends to involve the lungs, peripheral nerves, skin, kidneys, and heart.
- Microscopic polyangiitis: A systemic vasculitis affecting small and medium-sized blood vessels also associated with ANCA.
- Polyarteritis nodosa: The prototype of systemic vasculitis involving many different organ systems such as the intestines and kidneys.

The less common causes of vascular CPP, such as vasculitis, should be suspected in patients with systemic symptoms and evidence of organ dysfunction, while ischemic disease should be ruled out in patients with risk factors for peripheral artery disease.[81]



• **Figure 42.15** Plate 385 arteries and veins of the pelvis: male. From: Netter FH. Plate 385. *Atlas of Human Anatomy*. 2018: 367–44D1.e11.

Laboratory studies such as C-reactive protein or erythrocyte sedimentation rate are of particular aid in diagnosing vasculitis. Doppler ultrasound has been found to have a sensitivity ranging from 70%–92% and a specificity of around 96% for the diagnosis of GCA.[82,83] For the diagnosis of congestive pelvic venous disorders, venography (either by CT or MRI) is considered the gold standard, often demonstrating pelvic varicosities. Venous duplex/Doppler ultrasound is also used.

Treatment of vasculitides usually includes the administration of corticosteroids (dosing of 40–60 mg per day) with a more aggressive approach in the setting of visual symptoms such as in GCA (intravenous [IV] methylprednisolone, 1 g daily for the first three to five days).[84] However, because of adverse effects of long-term corticosteroid dosing (up to 85%), steroid-sparing agents such as tocilizumab or abatacept are under research and have shown promise in early trials.[83]

While rare in the context of CPP, ischemic disease can present as pain within the pelvic girdle. The abdominal aorta and the bifurcation of the common iliac arteries is a common place for atherosclerotic plaques to form, affecting pelvic blood flow.[85] Chronic pelvic ischemia affects mainly the perfusion of the lower urinary tract. Ischemia in this region can precipitate the development of an overactive bladder, bladder pain syndrome, and associated sexual dysfunction can be present.[86,87] Little has been written about the treatment of ischemic disease as a source of CPP, possibly because other manifestations of the disease are

taking clinical precedence. Treatment should revolve around lifestyle changes such as smoking cessation. The addition of cardiovascular mortality-lowering medication, such as clopidogrel and aspirin, could be considered. Cilostazol is an effective medication for symptom control in intermittent claudication as it helps with vasodilation, but little information is available concerning chronic pelvic ischemia. Medications such as silodosin, tadalafil, mirabegron, and melatonin have been found to produce protective urodynamic parameters for bladder function in these patients, but further studies are needed.

Pelvic venous disorders: Pelvic venous disorders have been cited as one of the most common causes of CPP, with figures as high as 31% of all CPP cases in females.[7,88] They are more common in multiparous, premenopausal females. The complicated interplay of the pelvic venous vasculature and vague symptomatology has made it difficult to approach these disorders; it has been proposed to look at them as three interconnected systems: the renal and gonadal veins, the iliac veins, and lower extremity veins. Pain originating from venous disorders is most likely because of venous hypertension arising within these systems. The constellation of different signs and symptoms depend on what venous reservoir the venous pressure is being transmitted to (renal hilar, pelvic, or leg). The clinical manifestations include pelvic pain, pelvic varicosities, leg varices, and symptoms related to renal venous hypertension (e.g. hematuria, left flank pain).

This increase in pressure usually is from primary or secondary insufficiency of the left gonadal vein, left renal vein (LRV), or the common iliac veins (CIV). Primary insufficiency of the pelvic veins can be congenital or acquired. In contrast, secondary insufficiency arises from pathologies such as nutcracker syndrome (compression of the LRV by the superior mesenteric artery) or May-Turner syndrome (usually compression of the left CIV by the left internal iliac artery).[88]

The diagnosis of a vascular cause of pelvic pain relies on a combination of the patient's history, physical examination, and ultimately imaging studies. Questions should be directed at identifying the timing of pain onset and its characteristics. Pain arising from pelvic venous disorders is typically described as dull, throbbing, and achy. It arises or becomes worse when standing for long periods and is usually relieved when in a supine position. There can be a cyclic component. Low back pain, dyspareunia, and bladder and bowel symptoms may be present. The pain is often worse during menstruation, prolonged standing, or intercourse and is described as aching, throbbing pressure, or cramping. This condition is more common in females who have given birth, and the left side is more often affected because the left gonadal vein inserts into the LRV (or in the case of May-Turner, the configuration of the left common iliac vein with respect to the artery). The physical exam in females should assess for ovarian point tenderness or cervical motion tenderness: ovarian point tenderness on examination with a history of postcoital ache has been reported as 94% sensitive and 77% specific for pelvic congestion syndrome (PCS).[89] The presence of varicosities in the lower extremities, the vulvoperineal region in the case of females, or varicoceles in the case of males should be documented. Moreover, 33% of those with PCS have vulvar varicosities (hemorrhoids or varicosities of perineum, vulva, buttocks), and 90% have lower extremity (LE) varicosities. However, of note, only 5% of those with LE varicosities have PCS. Imaging may show pelvic varicosities on ultrasound. MR Venography is considered diagnostic and will show dilation, most commonly of the left gonadal vein.[90,91]

Endovascular or surgical approaches are the best options for the management of pain stemming from pelvic venous congestion. Medication treatment with medroxyprogesterone or goserelin has been tried in females on the basis that pelvic venous vasculature is highly respondent to estrogens, but no sustained relief has been achieved, and the adverse effects are significant.[92] Surgical management, including ovarian vein resection or hysterectomy, is practiced, but is invasive, carries a risk of hemorrhage given the dilated vasculature, and is associated with high relapse rates (up to 33% in hysterectomy). For venous valvular incompetence/reflux, endovascular procedures include simple coil embolization, glue embolization, or sclerotherapy to manage reflux in the primary ovarian and internal iliac veins. Endovascular stenting has also been found to be beneficial in compressive syndromes such as May-Turner and Nutcracker Syndromes.[7] In May-Turner Syndrome, angioplasty followed by stenting may be considered as the first treatment option before embolization of dilated pelvic veins or formal surgical approaches. Following iliac venous stenting, pain relief and resolution of dyspareunia resolved in 80% one year after the procedure.[93] In nutcracker syndrome, there is more robust data regarding formal surgical repair (LRV transposition) with the resolution of symptoms in 87% of patients at a mean follow up of 37 months.[94,95] Endovascular stenting shows promise. However, data is lacking thus far, and stent migration, embolization to the right heart, and thrombosis have been described.

Systemic Causes of Pelvic Pain

It can prove useful to evaluate systemic diseases, as sometimes CPP can manifest a larger process occurring within the body. A fundamental concept guiding evaluation is to determine whether pain is localized to the pelvic or whether the patient presents with multiple coexisting pain syndromes. Some of the established systemic causes of CPP are briefly discussed.

Neurologic

As discussed, CPP can have a neurologic component involving direct or indirect injury to the central and peripheral nervous systems. However, some systemic neurologic diseases can present with widespread pain; the numbers range between 20% and 40% in patients afflicted by a primary neuronal disorder.[96]

Alterations within the structure and chemistry of the brain result in an aberrant communication among sensory, modulatory, cognitive, and emotional systems. These changes can precipitate pain in patients even when peripheral stimuli are no longer present. Complex regional pain syndrome is an example, as a small injury in a peripheral nerve induces changes at the thalamic and subthalamic level and can even include changes in the parietal lobe and basal ganglia.

Other CNS disorders such as Parkinson's disease, Alzheimer's disease, stroke, multiple sclerosis (MS), and amyotrophic lateral sclerosis (ALS) can present with widespread pain, in some cases with high rates of prevalence. In MS, for example, widespread pain is reported in as many as 86% of patients.[97] In Parkinson's disease, pain is present in approximately 40% of patients, in some noted as the major complaint, even ranking above motor symptoms.[98] Prevalence is also considerably high in Alzheimer's disease (57%), stroke (particularly if the thalamus is affected) (8%–14%), and ALS (15%).[99–101] Management can be attempted with pharmacologic treatment (e.g. anti-epilepsy drugs, anti-depressants, and membrane stabilizers), brain stimulation techniques, or even targeted delivery of medication to the CNS using CT or MR imaging.

Peripheral neuropathy is essential to consider when evaluating patients with pelvic pain, particularly when CPP is refractory to intervention or occurring in concert with other pain syndromes. Peripheral neuropathy is experienced by approximately 40 million people in the United States. Many peripheral neuropathies are mixed neuropathies with both large fiber and small fiber involvement (Table 42.6). Increasingly recognized is the demonstration of specific involvement of small myelinated or unmyelinated fibers, e.g. small fiber neuropathies.[102]

In our population of complex pelvic pain patients (refractory or multisystem pain), 64% (25 of 39) had a skin biopsy positive for small fiber polyneuropathy. Comorbid conditions included gastroesophageal reflux disease in 46%, migraine in 38%, IBS in 33%, lower back pain in 33%, fibromyalgia in 38%, endometriosis in 15%, interstitial cystitis in 18%, vulvodynia in 5%, and other chronic pain syndromes in 36%.[103] Of note, in separately published studies, approximately 50% of patients who have been diagnosed with fibromyalgia in several published studies have demonstrated findings consistent with small fiber polyneuropathy (SFPN) on diagnostic biopsies.[104,105] Muscle cramps can be a symptom of SFPN. Small fiber neuropathies (SFN) occur when injury to the peripheral nerves predominantly or entirely affects the small myelinated (Aδ) or unmyelinated C fibers. The fibers affected include both small somatic pain fibers and autonomic fibers. Thermal perception and nociception, enteric function, cardiovascular, genitourinary, perspiratory, lacrimal, and salivary gland function are subserved by small fibers.[106]

Most SFNs occur in a length dependent fashion, first stocking distribution changes and later glove distribution. Less common but no longer rare, non-length dependent SFN can result in symptoms involving the face, trunk, proximal limbs, or other more localized areas such as the pelvis. The pathogenesis of injury to small fibers is not well understood and can progress to involve the myelinated and therefore better protected large fibers. Epidemiologic data from the Netherlands suggest a minimum incidence of SFPN of 12/100,000 people.[107] Children can also experience SFN. Disorders associated with SFPN include diabetes, sarcoidosis, thyroid dysfunction, vitamin B12 deficiency, Guillain-Barre syndrome, chronic inflammatory demyelinating polyneuropathy, systemic lupus erythematosus, amyloidosis, Ehlers Danlos Syndrome, hereditary sensory and autonomic neuropathies, alcohol use, Lyme disease, metronidazole, statins, and celiac disease/gluten intolerance.

TABLE 42.6 Large and Small Fiber Polyneuropathies

	Large Fiber Neuropathy	Small Fiber Neuropathy
Symptoms	Numbness, pins and needles, tingling, poor balance	Pain: burning, electric shocks, stabbing pain, numbness
Exam findings	Reflexes, proprioception Vibration, +/– motor	Thermal, pinprick sensation, allodynia
Functional changes	Pressure, balance, fall risk	Nociception; protective sensation
Diagnostic test	EMG/NCV, sural nerve biopsy	QST, nerve biopsy, Intraepidermal nerve fiber density (skin biopsy)

Symptoms vary widely in severity. Often affected individuals describe a gradual onset of vague distal sensory disturbances, for example, feeling like there is sand in the person's shoe, a sock feeling as if it has pebbles in it, pins and needle sensations, cold painful sensations or tingling, burning pain in the extremities, allodynia, and hyperesthesia. Socks or bedsheets on the feet may be painful. Symptoms are often worse at night. Autonomic and enteric dysfunction may be present, including dry eyes, dry mouth, lightheadedness with changes in posture, syncope, abnormalities of sweating, erectile dysfunction, gastrointestinal symptoms such as nausea and emesis, constipation, diarrhea, and changes in urinary frequency, including nocturia. Diagnosis is by history, quantitative sensory testing (QST), skin biopsy, and autonomic testing. The neurologic examination (which assesses large fibers) may be normal. However, possible findings include decreased pinprick, diminished thermal sensation, hyperalgesia, or dry skin. Autonomic (tilt-table) testing may show abnormal heart rate responses to deep breathing, heart rate and blood pressure responses during Valsalva maneuvers, heart rate and blood pressure response to a 70-degree tilt, and sudomotor responses (sweat production). The standard biopsy is a 3 mm skin punch biopsy that can be taken from anywhere over the body. Because of the need to compare to normal values, the LE 10 cm proximal to the lateral malleolus is most commonly assessed (of relevance, length dependent SFN is more common than non-length dependent). The results are expressed as the number of intraepidermal fibers per mm. The sensitivity (78%–92%) and specificity (65%–90%) are fairly high for this technique.[106] Once diagnosed, workup depends on the suspected cause: metabolic, nutritional, infectious, autoimmune, allergic, paraneoplastic, neurotoxins, or hereditary. Lumbar puncture may be indicated if inflammatory, autoimmune, or paraneoplastic etiologies are suspected. If an underlying cause of SFN can be determined, optimal treatment of the causative condition may lessen the symptoms of SFN. Few studies and no guidelines have examined the pharmacologic treatment of the pain associated with SFN. In one such study, both gabapentin and tramadol were found to be effective for SFN. Tricyclics, IV lidocaine, serotonin-norepinephrine reuptake inhibitors, selective serotonin reuptake inhibitors, and intravenous immunoglobulin have all been used.

Rheumatologic

The most common cause of CPP because of a rheumatologic process is PMR, but it is important to note that rheumatologic disease is not as common a cause of CPP as other conditions. Nevertheless, if a rheumatologic condition affects the joints in the pelvic girdle (e.g. inflammatory arthritis), it can manifest as pelvic pain. Out of these, the sacroiliac joint is one of the most commonly affected. The most prevalent disorders associated with inflammatory arthritis are rheumatoid arthritis, ankylosing spondylitis, and gouty arthritis.[108] Systemic lupus erythematosus, myopathy, and osteomalacia are other examples. Rheumatoid arthritis (RA) can cause pelvic pain if it directly affects joints in the pelvis or the bones that make up the pelvic girdle. Some cases of mutilating type of RA have been involved in the development of insufficiency fractures of the pelvic ring, manifesting as progressively worsening pelvic pain.[109,110] RA has also been found to have an association with bladder pain syndrome/interstitial cystitis.[111] Ankylosing spondylitis (AS) is characterized by inflammatory back pain (typically associated with improvement with exercise, insidious onset, nocturnal symptoms, no improvement with rest, and morning stiffness >30 min). Pelvic joint lesions have been reported to be present in about 25%–35% of all patients with AS,

with the severity of hip involvement being correlating to the overall functional status.[112] Gout, on the other hand, is an extremely rare cause of pelvic pain, as fewer than ten cases of gout affecting the pubic symphysis have been reported.[113,114] Treatment of pelvic pain in rheumatologic diseases is directed at treating the underlying condition. NSAIDs, disease modifying anti-rheumatic drugs (DMARDs, e.g. methotrexate), and TNF-inhibitors are the mainstay of treatment in these diseases. Other medications such as colchicine or glucocorticoids in gout can also be considered. Last, there is a significant overlap of CPP and fibromyalgia to the extent that pelvic pain is part of the diagnostic criteria. The levator muscles may benefit from pelvic floor physical therapy and, because of potentiators of muscle tension and trigger points, training with a wand to self-treat at home.

Special Considerations

Children and Adolescents

Special considerations should be taken when evaluating pelvic pain in children and adolescents. As with adults, pelvic pain may stem from gastrointestinal, genitourinary, reproductive, orthopedic, neurologic, congenital, traumatic, or infectious sources, emphasizing the need to take a thorough history to include bowel function, athletic injury, fall, and menstruation. Sensitive questions must be addressed, including inquiry regarding inappropriate touching and other non-consensual physical exposures. This may require the clinician to ask parents and guardians to recuse themselves for part of the patient interview. A female escort must be present for this part of the interview and the physical exam. Examination of the genitals and perianal tissue may be indicated in addition to the neurologic exam, depending on the patient's comfort level and the thoroughness of prior exams within other specialties. A urinalysis should be performed routinely, with cultures, labs, and imaging as indicated. Adolescent males typically only experience pelvic pain after puberty. It is most commonly because of urologic or injuries to the coccyx, genitals (e.g. straddle, zipper, or sexually transmitted disease), or hips. The most common causes of pelvic pain in adolescent females are painful menstruation and constipation, with symptoms often including bloating, nausea, and heartburn. A physician should evaluate significant menstrual pain, and when a young female misses a period three months in a row, periods occur fewer than three weeks apart, or there is frequent bleeding between periods at any point from the initiation of menstruation.[115] A transabdominal pelvic ultrasound may be required, but internal vaginal exams are not typically necessary in children and adolescents. Occasionally a cotton swab may need to be placed into the vagina to test for obstruction or infection. About 70% of adolescent females with pelvic pain are diagnosed with endometriosis.[116] Recommended treatment for endometriosis in adolescents is conservative surgical therapy for diagnosis and treatment, along with continuous suppressive hormonal therapy (i.e. an oral contraceptive) to prevent endometrial proliferation.[117] Because endometriosis implants in adolescents can be difficult to identify as they typically appear clear or red, it is important to refer patients to gynecologists familiar with adolescent endometriosis.

Both male and female adolescents may have myofascial pain from a primary injury or secondary to a known pelvic disorder. Muscles may spasm and become tender to touch, and pelvic floor dysfunction can cause pain with urination or bowel movement. Unlike adults, myofascial pelvic pain in adolescents is not usually associated with local nerve irritation or nerve entrapment, and though a diagnostic nerve block can help differentiate pain from the abdominal wall, spine, and pelvic muscles from other sources, about 95% of adolescent myofascial pelvic pain improves with physical therapy.[118] In adults, pelvic floor physical therapy often involves the vaginal wall, but in adolescents, great benefit can still be derived from indirect stimulation from the external abdominal, hip, thigh, and lower back muscles. Treating chronic pain in adolescents is often easier than in adults because of neuroplasticity. It is often best to address pelvic pain in children and adolescents as a multi-disciplinary team, including pediatricians, adolescent gynecologists, urologists, gastrointestinal medicine doctors, pediatric pain physicians, physical and occupational therapists, and child and adolescent psychologists.

Pelvic Pain in Those With Disability

Patients with intellectual disability (ID) might pose a challenge when managing chronic pain because of communication difficulties, unconstructive behavior, and preexisting conditions complicating diagnosis. Note should be taken of patients' individual circumstances, as every patient with a disability may have different resources, coping skills, and mechanisms.[119] Prevalence of chronic pain has been estimated to be close to 15% in patients suffering from ID. With the understanding that persons with a disability might not be able to communicate distress as effectively, this figure could potentially be higher.[120] Self-reporting is considered the gold standard for assessing pain and should be considered whenever possible. Patients with ID have found some success when it comes to self-reporting and often need the aid of scales such as the visual analog scale. Behavioral observation methods with the aid of observational pain assessment tools have proven beneficial when the patient cannot self-report pain. Tools such as the non-communicating children's pain checklist or the faces, legs, activity, cry, and consolability scale consider several non-verbal cues that provide valuable information about whether pain is present. Management of these patients must include cognitive behavior therapy (CBT) or relaxation therapy in conjunction with medical treatment and teaching family members to identify when a patient is in pain. Coping strategies should be tailored and taught to the needs of each patient, all while giving preference to active coping methods (e.g. functioning despite pain) rather than passive ones (e.g. avoiding the development of pain).[5,121]

Pelvic pain in those with a physical and neurologic disability may best be served by a team including pain management, physical medicine and rehabilitation, neurology, physical therapy, and occupational therapy expertise. Sensory deficits can lead to prolongation of noxious stimulus, for example, prolonged sitting on the coccyx in a wheelchair. In ambulatory individuals, the provider should be cognizant of gait deviations, pain, and weaknesses that can lead to biomechanical compensation. Therapeutic exercise and adaptive equipment applied appropriately can reduce these strains.

Psychological Considerations

People experiencing CPP should be assessed for psychological comorbidities and offered support. It is very important to emphasize that treating the impact of the pain on one's life, psychological amplifiers of pain, and treating the whole person, is important to a good outcome, but that the pain is not thought to be because of a psychological disorder. Most female patients presenting to the clinic experience moderate to severe anxiety, and around 25% have reported moderate to severe depression.[122] These comorbidities,

along with the catastrophizing of pain, can complicate treatment if severe.[5] Relationships and sexual function might also be affected by pelvic pain. Anticipatory anxiety or pain during intercourse can reduce sexual satisfaction and interest. This can lead to concerns about becoming less attractive to existing and new partners.[123] Also of concern is the possibility of past trauma such as sexual abuse or other nonconsensual sexual activities. It has been documented that adolescent girls with a history of sexual abuse are almost twice as likely to report CPP development.[124] A history of trauma is not uncommon in male patients. In all genders, including transgender individuals, a trauma informed approach making room for, but not requesting disclosure of past events while placing the locus of control in the patient's hands usually leads to an easy clinical interaction for all parties involved. CBT and mindfulness-based therapy have both shown success in the treatment of CPP.

Chronification of Pain (Central and Peripheral Sensitization of Pain)

We have discussed some of the central and peripheral neurologic causes of CPP, but it is important to understand that many patients with chronic pain have undergone changes in their neurophysiology. Chronification of pain refers to the transformation of acute pain into chronic pain. It involves the sensitization of peripheral and central nervous systems.[124] The transmission of pain from a nociceptor to the cerebral cortex involves signal transduction, action potential generation, and its transmission to the thalamus and posteriorly to the parietal cortex.[125] Changes within this pathway induce sensitization to pain stimuli (hyperalgesia).

Nociceptors are chemoreceptors that react to inflammatory molecules (bradykinin, prostaglandins, and substance P). Repeated stimulation in the peripheral nervous system results in the upregulation of nociceptors and an increase in neuronal excitability (e.g. by upregulating sodium channels). Second and third order neurons transmit the pain signals to the thalamus and the cerebral cortex, respectively. Central sensitization occurs when these neurons lower the threshold for their action potentials and end up reacting to subthreshold stimuli. The aforementioned sensitization occurs because of an upregulation of N-methyl-D-aspartate receptors, glutamate, and substance P interaction with membrane G-coupled-receptors, and a decrease in γ-aminobutyric acid inhibitory signals.[124]

There are different etiologies of acute-to-chronic pain syndromes. The most common being chronic post-surgical pain (CPSP) and opioid-induced hyperalgesia, with individual patient factors playing a role in the potential for pain chronification. Preexisting conditions or genetic polymorphisms (e.g. mutations in the *COMT* gene) can render an individual more susceptible to developing chronic pain. Obesity, female sex, and young age are also risk factors.[126]

Patients at risk can be preemptively treated with perioperative ketamine, gabapentinoids, NSAIDs, and regional anesthesia. These interventions lower the risk of CPSP.

For the treatment of chronic pain associated with central sensitization, brain-based treatments are centered on re-interpreting messages from the nerves. Interventions can be based on altering memories or fear of pain.[127] TENS units, meditation, relaxation, mindfulness, mind-body medicine, CBT, and exercise can all be beneficial. The provider should focus on reducing any contributing physical pain promotors present (for example, a patient whose pain is complicated by chronic sitting, bladder irritant, and vulvar atrophy).

Employing a multi-disciplinary approach can change how the patient responds to the stimuli, often helping cope with the chronic condition.[128]

Summary

CPP improves or resolves in the majority of patients with a careful, informed, multifaceted approach. The care of these individuals can be very satisfying, and the more knowledge one has, the more effective one will be. Usually, CPP responds to the more straightforward interventions, and the differential diagnosis can be expanded based on the content above where needed.

Key Points

- Pelvic pain can arise from virtually any organ system in the body.
- The approach to acute pelvic pain should rule out life threatening conditions.
- Management of CPP requires a multi-disciplinary team.
- Some serious conditions, such as cancer, might manifest as progressive or refractory CPP.
- Special considerations should be taken when dealing with pediatric patients and patients with disabilities.
- History taking and physical examination should be performed with care because of the nature of the condition.

Acknowledgments

We thank the authors of *Facing Pelvic Pain* for expanding our knowledge in the treatment of pelvic pain enough to write this chapter and to Kenneth Barron, MD, for his suggestions on the gynecologic pain section.

Pediatric Chronic Pain Management

ANGELICA A. VARGAS, RAVI SHAH, BONNIE S. ESSNER, SANTHANAM SURESH

Chronic pain is a significant yet underreported problem in the pediatric population, with a prevalence of up to 25%–45%.[1] It has psychological, emotional, and social implications for both the child and the family.[2] Common pain related functional issues include sleep problems, inability to pursue hobbies, eating difficulties, school absence, and inability to interact with friends.[1] The potential for such consequences to negatively impact a child's quality of life has fostered the development of a multi-disciplinary approach to treat pediatric pain.[3,4] A variety of behavioral, pharmacologic, and physical therapies are employed in pediatric chronic pain treatment regimens. Interventional procedures may be introduced after patients fail other treatment approaches.[5] In this chapter, we discuss common chronic pain syndromes in children, along with their assessment, diagnosis, and management (Box 43.1).

Assessment of Chronic Pain in Children

Assessment of children with chronic pain requires a biopsychosocial framework. Multidimensional models focus on various biologic, developmental, behavioral, affective, sociocultural, and situational factors that contribute to pain severity and the course to recovery.[6,7] Each domain may become a target of assessment and intervention. Several developmentally sensitive validated instruments are now available to measure various aspects of children's pain (Table 43.1).

Two standardized interviews for school-age and adolescent children and their parents provided comprehensive yet practical evaluations of the child's chronic pain: the Children's Comprehensive Pain Questionnaire (CCPQ)[8] and the Varni-Thompson Pediatric Pain Questionnaire. These interviews separately assess both the child's and parents' experiences of pain problems with open-ended questions, checklists, and quantitative pain rating scales. Some studies suggest potential limitations of these self-report measures because of cultural or cognitive differences among children.[9] Additionally, the Pain Behavior Observation Method is a 10 minute observational pain behavior measure that can be used in children with chronic pain who may have difficulty with self-report measures because of age or cognitive limitations.[10] Studies have supported the use of electronic versus paper pain diaries in children with chronic pain; electronic diary use was shown to be feasible and resulted in greater compliance and accuracy in diary recording than did traditional paper diaries in children with recurrent pain.[11]

The well documented comorbidity between pediatric chronic pain and psychiatric disorders,[12] particularly internalizing disorders such as depression and anxiety,[13] obligates the clinician to screen for these disorders. The Children's Depression Inventory (CDI)[14] is a widely used self-report questionnaire for assessing depression in children aged seven to 17 years. It is important to assess anxiety symptoms because pain related disability is associated with anxiety sensitivity, a stable predisposition to fear of anxiety related sensations,[15] and pain related avoidance behavior in children as well as adults with chronic pain.[16] The Children's Anxiety Sensitivity Index (CASI)[15] is the only instrument developed to assess this characteristic in children.

Several well validated self-report questionnaires assessed anxiety in children (see Table 43.1). Two instruments, the Self-Report for Child Anxiety Related Disorders (SCARED)[17] and the Spence Children's Anxiety Scale (SCAS),[18] include subscales that distinguish among specific anxiety disorders listed in the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition (DSM-IV). The Multidimensional Anxiety Scale for Children (MASC)[19] and the Revised Children's Manifest Anxiety Scale (RCMAS)[20] include subscales that focus on other dimensions of anxiety. These subscales include physical symptoms, social and separation anxiety, and harm avoidance (the MASC) and physiologic symptoms, worry and oversensitivity, and concentration factors (the RCMAS), as well as social desirability items to detect inconsistency or randomness in reporting. The SCAS and SCARED provide both child and parent forms of the instrument, which allows examination of the convergence, or lack thereof, of the child's and parents' assessment of the child's anxiety symptoms.

Factors that are closely linked with a child's ability to function with chronic pain, such as perceived stress[21] and coping,[22] can assist in planning behavioral interventions. The pain coping questionnaire (PCQ),[23] pain response inventory (PRI),[24] and pain catastrophizing scale for children (PCS-C)[25] assess pain specific coping strategies. The identification and modification of maladaptive coping responses constitute the core elements of cognitive behavioral approaches for treating pediatric chronic pain.

The ability to function in tasks of daily living is a critically important outcome measure to assess when treating children and adolescents with chronic pain. Frequently, pain cannot be completely relieved, and the child must learn to accept, cope, and adapt to the pain to enable participation in normal developmental activities and tasks, such as going to school, participating in extracurricular activities, and developing and sustaining social relationships. Several measures have been developed to assess a child's functional abilities and quality of life. For example, the Pediatric Migraine Disability Scale (PedMIDAS) measures headache-related disability in children with chronic pain.[26] This six-question tool assesses school, recreational, and social areas of participation and disability, domains relevant to all children with

• Box 43.1 Chronic Pain in Children: Common Diagnoses

- Neuropathic pain
  - Complex regional pain syndrome type 1
  - Peripheral nerve injuries
  - Postamputation pain
  - Deafferentation pain
- Headache
- Chest pain
- Chronic illness
  - Sickle cell crisis
  - Cystic fibrosis
  - Collagen vascular disease (e.g. juvenile rheumatoid arthritis, systemic lupus erythematosus)
- Recurrent abdominal pain
- Juvenile primary fibromyalgia
- Pelvic pain
- Back pain
- Cancer-related pain

chronic pain. The Child Activity Limitations Interview (CALI)[27] assesses the impact of recurrent pain on children's daily activities as a way to identify appropriate targets for treatment. Additionally, the Functional Disability Inventory (FDI),[28] developed to assess illness-related disability in children and adolescents, is a useful tool for evaluating the functional status of pediatric patients with chronic pain, a particularly important concern in children with pain disorders associated with psychological factors and pain associated disability syndrome.[29] Pain related disability increases with age, and sex differences emerge in adolescence, with more girls than boys reporting pain related functional disability.[30]

Quality of life can also be assessed in children and adolescents with chronic pain and as an index of treatment progress. One study found that the quality of life of children with recurrent headaches is similar to that of children with rheumatoid arthritis or cancer.[31] The Child Health Questionnaire, including both children (CHQ-CF87) and parent reports (CHQ-50),[32] and the PedsQL[33] are measures that may be used to assess the general quality of life in children with chronic pain and have the advantage that the scores obtained on these instruments can be compared with standardized samples of scores obtained by children with other medical illnesses.

Other instruments that may further elucidate the psychological factors contributing to a child's behavioral adaptation to chronic pain include the Children's Somatization Inventory (CSI),[34] which measures a child's propensity to somatization, and the Harter Scales of Perceived Competence,[35] which assesses a child's judgment about his or her capabilities in important domains such as school performance, peer relationships, and athletic abilities. The child's own judgment of his or her competencies in these domains is useful in understanding other factors that may contribute to

TABLE 43.1 Methods for Assessment of Chronic Pain in Children and Adolescents

Pain Measure	Disability or Quality of Life	Stress and Coping	Anxiety	Depression	Other Behavioral Measures
Varni-Thompson Pediatric Pain Questionnaire (PPQ) Ages: 5–18	Functional Disability Inventory (FDI) Ages: 8–17 (plus parent form)	Children's Hassles Scale (CHS) Ages: 8–17	Multidimensional Anxiety Scale for Children (MASC) Ages: 8–19	Children's Depression Inventory (CDI) Ages: 7–17	Children's Somatization Inventory (CSI) Ages: 8–18 (plus parent form)
Children's Comprehensive Pain Questionnaire (CCPQ) Ages: 5–19	Child Health Questionnaire (CHQ) Ages: 5+ (plus parent form)	Pain Coping Questionnaire (PCQ) Ages: 8–18	Self-Report for Childhood Anxiety Related Disorders (SCARED) Ages: 9–18 (plus parent form)	Beck Depression Inventory-II Ages: 13+	Harter Scales of Perceived Competence for Children Ages: 4–12
Pain diary (written, electronic) Ages: 8+	Pediatric Quality of Life Inventory Generic Core Scales (PedsQL 4.0) Ages: 5–18 (plus parent report ages 2–18)	Pain Response Inventory (PRI) Ages: 8–19	Spence Children's Anxiety Scale (SCAS) Ages: 8–12 (plus parent form)		
Pain Behavior Observation Method Ages: 6–17	Pediatric Migraine Disability Assessment Scale (PedMIDAS) Ages: 6–18	Pain Catastrophizing Scale (PCS) Ages: 8-16	Revised Children's Manifest Anxiety Scale (RCMAS) Ages: 6–19

			Childhood Anxiety Sensitivity Index (CASI) Ages: 7–12		

the child's functioning.[36] For example, children with chronic pain who rate themselves as low on social and academic competency may have multiple reasons to avoid returning to school.

A thorough assessment of a child's baseline status and progress is essential to guide interventions for chronic pain and evaluate the response to treatment. The core elements of assessment include a comprehensive evaluation of the child's pain problem and screening for psychiatric comorbidity and functional status (Box 43.2). More intensive screening of the child's perceived stress and competencies and the parents' and family's functioning adds valuable information to treatment planning, especially in a child with long-standing pain problems who has not responded to previous treatment efforts.

Psychological Pain Management Methods

A rehabilitative approach that emphasizes improving the child's and family's ability to cope with a chronic condition characterizes the course of most chronic pain treatment programs for children. The focus shifts from the narrow goal of pain reduction, which might be used in the treatment of acute pain, and broadens to decrease pain related emotional and behavioral disability, thereby increasing the child's functional status.[29,37] Research on the use of psychological therapies has focused mostly on clinical trials in children with headache.[38,39] In a meta-analysis conducted to evaluate the efficacy of behavioral interventions for pediatric chronic pain, Eccleston et al.[40] concluded "There is strong evidence that psychological treatment, primarily relaxation and cognitive behavioral therapy, are highly effective in reducing the severity and frequency of chronic pain in children and adolescents." Additionally, findings by Logan et al. suggest that interdisciplinary pediatric pain rehabilitation may facilitate increased willingness to self-manage pain, which is associated with improvements in function and psychological wellbeing.[39] Finally, promising psychological treatments have also been used for children with disease-related chronic pain, including sickle cell disease,[41] recurrent abdominal pain,[42] complex regional pain syndrome (CRPS) type 1,[43] musculoskeletal pain,[44] and juvenile primary fibromyalgia syndrome,[45] and further support the probable efficacy of psychological approaches to pediatric pain management.

These evidence-based psychological treatment programs are primarily rooted in cognitive behavior therapy (CBT) principles. Traditional CBT and more recent and emerging CBT variations, such as acceptance and commitment therapy, include a diverse array of standard intervention components that treat chronic pain by modifying children's cognitive, affective, and sensory experiences of pain, their behavior in response to pain, and environmental and social factors that influence the pain experience. Education about chronic pain and problem solving for improving the child's functional status is central to the child and family, assuming an active role in managing chronic pain. Cognitive techniques are targeted at modifying the child's thoughts about the pain, in particular, to increase a sense of predictability and control over the pain, to alter memories about painful experiences,[46] and to reduce negative cognitions about pain, notably catastrophizing.[47] Decreasing somatic preoccupation, pain related rumination,[37] and passive coping and learning to accept that the pain may persist are also key interventional goals in the psychological management of pain.[48] Please see Table 43.2 for sample components of CBT in the treatment of pediatric chronic pain.

7. Family environment and stress
8. Coping skills
9. History of psychiatric illness
10. Medical problems

Techniques to alter the sensory aspects of chronic pain include relaxation training, biofeedback, imagery, and hypnosis. Interventions aimed at modifying situational factors that exacerbate chronic pain and disability include contingency or behavioral management methods, modification of activity and rest cycles to achieve a steady pace of activity, and a gradual, structured plan for exposing patients and families to situations previously avoided because of pain.[37,48] Few analyses have been conducted to determine which components of psychological therapies may be essential in the management of pediatric chronic pain, but it is likely that for most chronic pain conditions, a combination of modalities will provide the best opportunity to affect the desired change. Changes in the emphasis of various behavioral components may present an opportunity to individualize treatment for a specific child by taking into account developmental, psychological, parental, and family factors, which may provide a way to tailor specific treatment to a child.

There is growing acknowledgment of parents' crucial role in the successful rehabilitation of children with chronic pain, and thus they are increasingly becoming included as active partners in their child's treatment.[49] Parental interactions with their child related to pain and the family characteristics of children with chronic pain that may be associated with the development of maladaptive coping with pain are areas of active research.[50,51] Particular types of parental behaviors have been shown to influence a child's ability to cope with pain. Walker et al.[51] found that girls with functional abdominal pain are more vulnerable than boys to the symptom-reinforcing effects of parental attention. Interestingly, although the children with pain rated parental distraction as a helpful strategy, their parents rated distraction as having greater potential for a negative impact on their child than attention. Such findings help guide behavioral interventions for children with chronic pain and their families because parents' beliefs in the most effective pain management strategies need to be targeted in any intervention designed to increase the functional abilities of children with chronic pain.

Several methods for the delivery of psychological interventions for recurrent or chronic pain in children have been shown to be effective, including those that involve intensive inpatient or outpatient treatment; those that are self-administered,[52] school-based,[53] Internet-based,[54,55] CD ROM-based[56]; and those that involve minimal clinic contact with home-based practice.[55] The variety of methods for the delivery of these interventions offers opportunities to reach a broad population of children with chronic pain, thus increasing the potential to reach many more children than can be treated in specialized pediatric pain treatment centers. Optimally, the child's school and other caretakers are included in the treatment team to ensure a consistent and comprehensive approach to the child's pain and disability.

The complex nature of chronic pain in children creates many challenges with regard to its assessment and treatment, but this

TABLE 43.2 Sample Components of Cognitive Behavioral Therapy for Pediatric Chronic Pain Treatment

Treatment Domain	Intervention Aims	Intervention Examples
Psychoeducation	• Enhance health literacy • Create positive treatment expectations and optimism for change	• Engaging didactic instruction on basic neuroscience of pain • Analogies describing how chronic pain operates as a faulty alarm and psychological treatments re-set pain signaling in the brain and body
Relaxation Practices	• Activate parasympathetic nervous system • Reduce emotional distress • Enhance self-efficacy	• Diaphragmatic breathing • Progressive muscle relaxation • Guided imagery
Cognitive Skills	• Increase awareness of cognitive patterns • Adopt adaptive thinking patterns • Neutralize affective response to thoughts	• Thought record and detective thinking for self-monitoring of thought-emotion-pain-action patterns • Didactic instruction on cognitive distortions and thinking traps • Cognitive reframing and positive reappraisal practices • Cognitive defusion practices
Behavior Change Skills	• Promote adaptive physical activity • Increase daily developmentally adaptive daily activities • Enhance healthy behaviors	• Graduated exposure to experiences and environments associated with pain exacerbation and distress • Structured physical activity pacing and behavioral activation strategies • Graduated improvements to diet and eating behaviors • Graduated implementation of behavioral sleep medicine principles to decrease nighttime cognitive arousal
Family-focused Skills	• Enhance general family functioning • Promote adaptive parent responses to pain • Improve family communication patterns	• Operant strategies for rewarding adaptive behavior changes • Promote parent and family modeling of adaptive coping with pain and distress • Communication strategies • Structured problem solving skills training

complexity can be exploited to provide the most efficacious methods for pain control and functional rehabilitation. Multidimensional assessment provides the foundation for optimal pain management and functional rehabilitation of chronic pain in children. Psychological interventions include a diverse array of techniques that treat chronic pain by modifying children's cognitive, affective, and sensory experiences of pain, their behavior in response to pain, and environmental and interactional factors that influence the pain experience. Medical treatment of a child's chronic pain may result in poorer outcomes without addressing the psychobehavioral factors that may contribute to pain and pain related disability. Research informed by multidimensional models of pediatric chronic pain can guide investigators in efforts to identify effective pain treatments, as well as the children for whom they work best.

Integrative Medicine Techniques

It has been reported that nearly 75% of pediatric patients, particularly those with chronic health disorders, have used some form of complementary and alternative medicine.[57] A few of the tenets of integrative medicine (IM) include an emphasis on preventative health and lifestyle as well as a consideration of all dimensions of health, including body, mind, and spirit. These concepts make this field a promising adjunct for the treatment of pediatric chronic pain. Data regarding the implementation of IM in pediatric pain practice are limited to headache management and irritable bowel syndrome/functional abdominal pain syndrome. Despite this, a recent study found that it was common for pediatric pain clinics to provide IM, including acupuncture, mind-body therapies, massage, aromatherapy, nutrition counseling, and/or art/music therapy.[58] We frequently recommend these therapies to our patients, as well as other techniques such as vitamin supplements/herbal remedies, chiropractic manipulation, and biofeedback.

Chronic Pain Syndromes

We will briefly discuss the diagnosis and management of some common chronic pain syndromes diagnosed in pediatric patients referred to chronic pain clinics. The introduction of multidisciplinary pediatric pain clinics has allowed children to be seen in a single office visit by several consultants who can provide services for the child and develop a comprehensive pain management plan. An example of this model includes an anesthesiologist specializing in pain management, a pediatric pain psychologist, a physical therapist, a complementary medicine practitioner (including massage therapy and acupuncture therapy), and a specialist in biofeedback. This comprehensive approach reduces the need for multiple visits and exposes patients to a multimodal therapeutic approach.

Common pain syndromes in children include CRPS type I, headache, abdominal pain, juvenile primary fibromyalgia, chest wall pain, back pain, pelvic pain, and cancer-related pain. We address each of these conditions with a specific emphasis on accepted current therapy.

Complex Regional Pain Syndrome

CRPS type I or reflex sympathetic dystrophy (RSD), as originally named, is a complex syndrome consisting of neuropathic pain symptoms including allodynia and hyperalgesia, sudomotor dysfunction, and motor/trophic changes. In the pediatric population, it occurs more commonly in the lower extremity,[59] with a female preponderance.[60] Significant trauma is found with less frequency than in the adult population.[60] Though there is a case report

involving a two and half-year-old girl,[61] it is generally seen in children older than nine years and more frequently in adolescents 11–13 years of age.[62] Compared to adults, children are thought to better respond to non-invasive and treatment strategies and have a more favorable prognosis with treatment.[43] However, early recognition and management are the major factors in improving outcomes and preventing resistant CRPS.[63] Data regarding the epidemiology of CRPS type I is limited, though case reports exist describing pain in the sciatic distribution patients as young as three years old.[64,65]

Evaluation of Complex Regional Pain Syndrome I

History

A detailed history of the nature of the injury, the type and duration of the pain, relieving and aggravating factors, and dependence on medications is mandatory before evaluation.

Physical Evaluation

Thorough and systematic neurologic examination should be performed. Complete evaluation of the motor, sensory, cerebellar, cranial nerve, reflex, cognitive, and emotional functioning should be conducted. A concerted effort must be made to rule out a rare but possible malignancy or central degenerative disorder that may include laboratory evaluation, imaging such as X-rays, magnetic resonance imaging (MRI), or computed tomography (CT), or electromyography of the affected limb.

The strength of the extremities should be evaluated on several occasions. It is important to compare it with the strength in the contralateral extremity because CRPS I can occur in both extremities at the same time. Allodynia, pain to a stimulus that is not typically painful, is a common finding. Hyperalgesia, an increased painful response, is also common, particularly to cold sensation.[66] Similarly, in adults, distribution is not generally restricted to particular dermatomes and commonly occurs along a glove-and-stocking distribution. Although nerve conduction studies may provide insight into a specific nerve injury, sensory abnormalities appear in different combinations in patients despite similar clinical presentations pointing to a central origin of pathogenesis.[67] Quantitative sensory testing (QST) with thermal and vibration sensations and thermal pain detection thresholds in the affected limbs can be compared with data from normal healthy children. Although this involves cumbersome equipment, bedside QST may play a greater role in the diagnosis of CRPS I in children and adolescents.[68] Bone scans may be helpful in the diagnosis of CRPS. However, there is limited data on their diagnostic accuracy in children. A decrease in isotope uptake was observed with suspected CRPS I.

Diagnosis

The diagnosis of CRPS I in children was based on symptoms and signs (Table 43.3). The characteristics of pain and sensory, motor, and sudomotor changes may vary among patients. The 1994 International Association for the Study of Pain (IASP) criteria for CRPS I and the 2003 Budapest criteria can be applied to children and adolescents (see Box 43.3a and 43.3b). However, it should be noted that although the Budapest criteria have been found to have nearly 100% sensitivity and 70%–80% specificity in the adult population, these criteria have not been validated in the pediatric population.

Treatment of CRPS I. Treatment of CRPS should be immediate and directed toward restoration of extremity function and rehabilitation.[69] Management of CRPS (Box 43.4) can be frustrating for the caregiver and the patient as no single therapy can uniformly provide relief to these patients. The treatment plan should be multidisciplinary in nature. Although medications can be prescribed and procedure-based treatments may be performed in children, rehabilitative treatments show the best evidence for positive outcomes. Logan et al. studied the effects of an intensive, multi-disciplinary model of daily cognitive behavioral and physical occupation therapies with medical and nursing services for pediatric CRPS over a three week timespan[39] and found that patients experienced significantly decreased pain perception, improved functional ability and limb function, and improved emotional functioning.

One of the primary goals is to return the child to a functional state and school, as a definitive resolution of the pain is not always possible. Most management techniques have been extrapolated from work done in adult patients.[70] It is imperative to build trust with the patient and the parents. Family dynamics are important because the added burden of familial disharmony or parental abuse can worsen the symptoms. There seems to be a greater propensity for enmeshment in these families.

Psychological and Behavioral Therapy

Psychologic therapies are a pillar in the treatment of pediatric CRPS and may require the expertise of a pain psychologist. Although no one therapy has been proven to be the "gold standard," CBT is generally the accepted treatment strategy. Other

TABLE 43.3 Symptoms and Changes in Stages of Chronic Regional Pain Syndrome Type 1

Characteristic	Acute	Dystrophic	Atrophic
Pain	Hyperpathic, burning	Chronic	
Blood flow	Increased	Decreased	No change
Temperature	Increased	Decreased	No change
Hair and nail growth	Increased	Decreased	Chronic change
Sweating	Decreased	Increased	No change
Edema	None	Brawny edema	Wasted muscles, atrophic skin
Color	Red	Cyanotic	Atrophic

• Box 43.3a International Association for the Study of Pain Diagnostic Criteria for Complex Regional Pain Syndrome

1. Presence of an initiating noxious event or cause of immobilization
2. Continuous pain, allodynia, or hyperalgesia in which the pain is disproportionate to any known inciting event
3. Evidence at some time of edema, changes in blood flow, or abnormal sudomotor activity in the region of pain
4. Diagnosis excluded by the existence of other conditions that would otherwise account for the degree of pain and dysfunction

Adapted from Bruehl S, Harden RN, Galer BS, et al. External validation of the IASP diagnostic criteria for complex regional pain syndrome and proposed research diagnostic criteria International Association for the Study of Pain. *Pain*. 1999;81:147–154.

• Box 43.3b Budapest Criteria

Budapest Criteria for Complex Regional Pain Syndrome

1. Continuing pain, which is disproportionate to any inciting event
2. Must report at least one symptom in *three of four* of the following categories

Sensory	Reports of hyperesthesia and/or allodynia
Vasomotor	Reports of temperature asymmetry and/or skin color changes and/or skin color asymmetry
Sudomotor/edema	Reports of edema and/or sweating changes and/or sweating asymmetry
Motor/trophic	Reports of decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)

3. Must display at least *one sign at time* of evaluation in *two or more* of the following categories

Sensory	Evidence of hyperalgesia (to pinprick) and/or allodynia (to light touch and/or deep somatic pressure and/or joint movement)
Vasomotor	Vasomotor: evidence of temperature asymmetry (>0.6°C) and/or skin color changes and/or asymmetry
Sudomotor/edema	Sudomotor/edema: evidence of edema and/or sweating changes and/or sweating asymmetry
Motor/trophic	Evidence of a decreased range of motion and/or motor dysfunction (weakness, tremor, dystonia) and/or trophic changes (hair, nail, skin)

4. There is no other diagnosis that better explains the signs and symptoms

techniques, including biofeedback, visual guided imagery, and structured counseling, have been shown to assist in the development of adequate coping skills.[71] Participation in a day program for acute psychological intervention has been valuable for some of our patients, specifically those with significant psychiatric co-illness. More detailed explanations of the various psychological interventions have been provided in a previous section.

Physical Therapy

Physical therapy is geared toward the adequate functional ability of the child. Transcutaneous electrical nerve stimulation (TENS) is widely used, and its efficacy has been studied in adults and children. The therapeutic benefits of TENS in children with RSD have been reported by Kesler et al.,[72] who used TENS regularly in their practice, along with physical therapy, which consists of both active and passive physical modalities. The physical therapy program is geared toward individual patients, with the primary goal of maximum participation. It may be necessary to have input from a specialized pediatric physical therapist or occupational therapist for adequate management. Commonly used treatment options for CRPS include desensitization, graduated weight bearing, exercise therapy, graded motor imagery, warm and cold baths, massage therapy, and water emersion therapy.

Medical Therapy

Most medical treatment strategies for children have been extrapolated from adult data. These include pharmacotherapy, regional anesthetics, sympathetic blockade, and neuromodulation. Over counter medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs), are typically trialed by patients and families for initial pain treatment. However, there are mixed data regarding their efficacy.[62] Anti-neuropathic pain medications can be trialed sequentially, although toxicities and side effects should be monitored closely in pediatric patients (see Box 43.4).

Tricyclic Anti-depressants. Adults are frequently prescribed tricyclic anti-depressants (TCAs) for the management of NP.[73] Despite the lack of adequately controlled studies in pediatric patients, TCAs are widely prescribed for several forms of NP.[74] Because amitriptyline may cause sedation, it is our practice to use nortriptyline, which appears to have less sedative and fewer anticholinergic side effects. A thorough examination of the cardiovascular system is necessary before instituting TCA treatment because of associated tachydysrhythmia and other conduction abnormalities of the heart, particularly prolonged QT syndrome.[75,76]

Anti-convulsants. Anti-convulsant medications have been used for several years to manage NP.[77] Although carbamazepine and oxcarbazepine have been used extensively to treat NP, the introduction of gabapentin and pregabalin has revolutionized the world of pain medicine.[78–80] Despite the lack of controlled trials in children to demonstrate the efficacy of either drug, both of these voltage-gated calcium channel blockers have been used in our clinic with promising results. More controlled trials are needed to better determine the dosing and efficacy of this class of drugs in children with CRPS 1.[80] An important side effect that we have noted in our clinic setting is the potential for increased somnolence and the potential for weight gain. Similar to other anti-convulsant medications, there are concerns regarding mood changes and increased agitation and aggression in adolescents taking gabapentinoids. As such, the Food and Drug Administration

• Box 43.4 Management of Neuropathic Pain

1. Nonpharmacologic Treatment
   - Hypnosis, biofeedback, visual guided imagery
   - TENS, physical therapy, occupational therapy
   - Individual and family therapy (day program if required)
2. Pharmacologic Therapy
   - Acetaminophen, NSAIDs
   - Tricyclic anti-depressants (e.g. amitriptyline, nortriptyline, doxepin); start at low doses, 0.1 mg/kg, and advance slowly
   - Anti-convulsants (gabapentin, pregabalin, carbamazepine, phenytoin, and clonazepam), systemic local anesthetics (mexiletine, lidocaine)
   - Serotonin and norepinephrine reuptake inhibitors
   - Opioids (morphine, methadone administered orally, intravenously, or via a regional technique [epidural or intrathecal], especially in cancer patients)
3. Regional Blockades for Chronic Pain
   - Epidural, subarachnoid and sympathetic plexus, peripheral catheter blockade
   - Sympathetic blockade for CRPS 1
   - Continuous catheter techniques may be used for five to seven days
   - Epidural and subarachnoid block for cancer patients: left in place for longer periods by subcutaneous tunneling
   - Neurolytic blockade for cancer

CRPS, Complex regional pain syndrome; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *TENS*, transcutaneous electrical nerve stimulation.

(FDA) has issued a warning for increased suicidiality[81] with these medications, and families should be counseled prior to initiating therapy.

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors. Despite the lack of proven efficacy of the use of selective serotonin reuptake inhibitors in the management of pain in children and adolescents, they are occasionally used to treat psychological comorbidities, including depression associated with pain.[82] More recently, serotonin-norepinephrine reuptake inhibitors have been successfully used to treat NP, especially in patients with psychological comorbidity.[83]

Systemic Vasodilators. Several patients with RSD have benefited from the use of vasodilators such as prazosin, nifedipine, and phenoxybenzamine. However, the overwhelming adverse effects of orthostatic hypotension often offset the efficacy of this therapy.

Regional Anesthesia and Sympathetic Blocks. A common treatment for these syndromes is to interrupt the apparent pathologic reflexes by performing sympathetic blocks (Box 43.5). Regional anesthesia, although used often in adults for the diagnosis and management of CRPS, is generally introduced in children after pharmacologic, physical therapy, and cognitive behavior management have been exhausted.[5] Recently, Zerkinow et al. synthesized a review of invasive procedures for children between 8 and 15 years of age with complex regional pain syndromes. They found 36 studies with a total of 173 patients who underwent a procedure, and the procedures varied depending on the decade they were performed. Because of the poor quality of the studies and lack of control, the effectiveness of invasive therapies in pediatric CRPS remains uncertain, and further randomized controlled studies are required.[84] In this section, we discuss the different regional techniques that can be useful in children for the management of CRPS.

Central neuraxial blockade is used in children with severe pain to facilitate the introduction of physical therapy. An indwelling epidural catheter is placed in the lumbar or cervical area and infused with a low-concentration local anesthetic solution, which allows better cooperation from the patient and the parents to introduce a physical therapy regimen. In addition, intrathecal analgesia has been reported to be an effective method for treating refractory CRPS 1 in children.[85,86]

Bier block has been used for mild to moderate cases of CRPS 1 as a primary modality for providing analgesia and sympathetic blockade. Although a myriad of substances have been used to provide a Bier block, a local anesthetic in combination with either an α_2-agonist or an NSAID appears to produce better results. In our case series of children who received intravenous regional anesthesia with lidocaine and ketorolac, we demonstrated a marked improvement in symptoms and the ability to perform physical therapy.[70]

• Box 43.5 Regional Anesthesia for Complex Regional Pain Syndrome Type 1

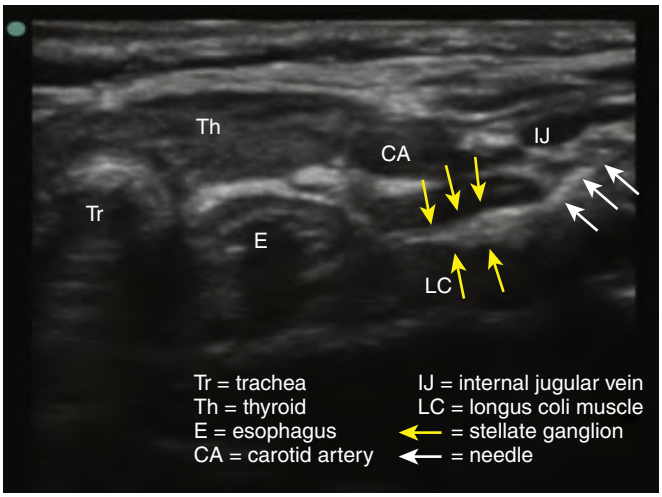
- Intravenous regional anesthesia-guanethidine, bretylium, lidocaine-ketorolac
- Epidural analgesia (continuous)
- Intrathecal analgesia
- Sympathetic chain blocks
  - Stellate ganglion blocks
  - Lumbar sympathetic blocks
- Brachial plexus catheters
- Sciatic nerve catheters

Peripheral nerve blocks are used to facilitate physical therapy while providing a sympathectomy and have become more plausible, especially with the use of ultrasound guidance.[87] Serial peripheral nerve blocks may be performed, which provides pain relief that may outlast the duration of conduction blockade. This may be because of reduced central sensitization, as well as interruption of the circuit established between the nociceptor, central nervous system, and motor unit.[88]

Continuous peripheral nerve blocks (CPNBs) have been reported to be effective in controlling pain and facilitating physical therapy in children with CRPS.[89] Despite such reports, limited data exist regarding the feasibility, safety, and efficacy of CPNBs in children.[90] After perineural catheter placement, a dilute solution of local anesthetic is infused with the view of providing analgesia while allowing physical activity. The catheter is left in place for four to five days; this can be done on an inpatient basis, or the patient may be sent home with a portable infusion device. We prefer sciatic nerve catheter placement for the lower extremities (see Fig. 43.1) and interscalene or infraclavicular brachial plexus catheters for the upper extremities. Concurrent physical therapy is indicated to improve the range of motion and function. We instituted physical therapy at the time of provision of a nerve block to enhance the patient's experience with therapy.

Sympathetic blockade was used in children after exhausting the aforementioned techniques. A stellate ganglion block may be performed under ultrasound guidance for upper extremity CRPS (see Fig. 43.2), and a lumbar sympathetic block is performed

• Figure 43.1 Sciatic nerve catheter for the management of complex regional pain syndrome type 1.



• **Figure 43.2** Image of ultrasound guided stellate ganglion blockade.

under fluoroscopic guidance for lower extremity CRPS.[91] A crossover trial of fluoroscopically guided lumbar sympathetic blocks demonstrated a decrease in allodynia and pain intensity compared with intravenous injection of lidocaine in adolescents with CRPS.[92]

Neuromodulation via spinal cord stimulation, though commonly performed in adults for refractory cases of CRPS, is very rarely used in the pediatric setting.[93] Spinal cord stimulation has been reported to achieve favorable outcomes in adolescents with therapy-resistant CRPS.[94] The use of peripheral nerve stimulators is gaining ground in the pediatric setting and may benefit children with refractory CRPS with a nerve distribution.

Headaches

Headaches are common in children and adolescents. Few physicians discussed headaches in children until 1873, when William Henry Day, a British pediatrician, devoted a chapter to the subject of headaches in his book *Essays on Diseases in* Children.[95] Modern medical literature and the study of pediatric headaches have grown significantly. In 1962, Bille published a landmark study of 9000 children, showing reported migraine headaches in 3.9% of children younger than 12 years and a 6.8% incidence of nonmigrainous headaches daily.[96] Since then, the reported incidence has grown. In a meta-analysis of 27,000 children between 1977 and 1991, it was reported that up to 51% of children experienced a significant headache by the age of 7 years, which gradually increased to nearly 82% by age 15 years.[97]

Most headaches in children are linked to either organic or nonorganic causes and may be deemed acute or chronic based on the duration of the headaches. Chronic daily headache is classified as a headache that occurs at least 15 times monthly for three months and can last for more than 4 hours daily.[98]

Evaluation of Headache

A thorough history and physical examination helped determine the nature of the headache. Specific questions about neurologic symptoms, such as ataxia, lethargy, seizures, and visual impairment, should be asked. Other medical conditions, such as hypertension, sinusitis, and emotional disturbances, must be evaluated. Physical examination, including a thorough neurologic examination and blood pressure measurement, is mandatory for children with headaches. Neuroimaging may be required, and lumbar puncture may be advised in some cases. Benign intracranial hypertension or idiopathic intracranial hypertension is a constellation of symptoms and signs, including headaches, diplopia, tinnitus, and eye pain. These conditions usually have normal imaging results.[99] Although a diagnostic lumbar puncture may be needed in some settings, patients with chronic daily headaches may be prone to post-lumbar puncture headaches.[99]

Pathophysiology of Headache

Headache is modulated by extracranial and intracranial structures (Box 43.6).

Classification of Headache

Classification of headaches is based on the presumed location of the abnormality, its origin, its pathophysiology, or the symptom complex that the patient has (Box 43.7).

• Box 43.6 Pathophysiology of Headache

1. Pain-Sensitive Headache
   - Extracranial
     - Skin
     - Subcutaneous tissue
     - Muscles
     - Mucous membranes
     - Teeth
     - Larger vessels
   - Intracranial
     - Vascular sinuses
     - Larger veins
     - Dura surrounding the veins
     - Dural arteries
     - Arteries at the base of the brain
2. Pain-Insensitive Headache
   - Brain
   - Cranium
   - Most of the dura
   - Ependyma
   - Choroid plexus

• Box 43.7 Classification of Headaches: Differential Diagnosis

Acute headache
- Systemic illness
- Subarachnoid hemorrhage
- Trauma
- Toxins such as lead or carbon monoxide
- Electrolyte imbalances
- Hypertension

Acute recurrent headache
- Migraine
- Tension headache

Chronic progressive headaches
- Organic brain disease
- Ventriculoperitoneal shunt malfunction

Chronic nonprogressive headache
- Functional in quality

Mixed headache

Evaluation of Headache

Comorbid symptoms are associated with headaches. Sleep deprivation is the most common comorbidity. Delayed sleep is a frequent disorder observed in children with headaches. Many also have symptoms of dizziness, which may be associated with postural hypotension and tachycardia (postural orthostatic tachycardia syndrome). Orthostatic hypotension should be treated by increasing fluid intake, and in some cases, a β-blocker may be needed. A history of a new-onset severe headache, pain that awakens a child from sleep, headaches associated with straining, changes in chronic headache patterns, or the presence of a headache accompanied by nausea or vomiting suggests a more pathologic origin of the headache and must be carefully evaluated (Box 43.8).

It is imperative to evaluate any relevant neuroimaging studies before the patient's appointment in the pain clinic. After establishing that the headaches are not secondary to any intracranial pathology, the following information is obtained:

1. Neurologic status, including a complete neurologic examination.
2. Physical/functional status of the patient.
3. Does the headache prevent the child from performing normal activities (e.g. interacting with others and participating in sports)?
4. Is there a history of school absenteeism?
5. What is the child's interaction with the parents and siblings at home?
6. Are there any factors that relieve the headache?
7. Has the child been taking medications for pain? Has there been any improvement in the clinical characteristics of the pain?
8. Are postural changes associated with headaches? Is there a diurnal variation in headaches?
9. Family history is crucial in these children; a family history of migraine is suggestive of childhood migraine.

After careful evaluation and classification of the type of headache, treatment is initiated in a stepwise fashion. An example of an algorithm for the management of headaches is presented in Fig. 43.3.

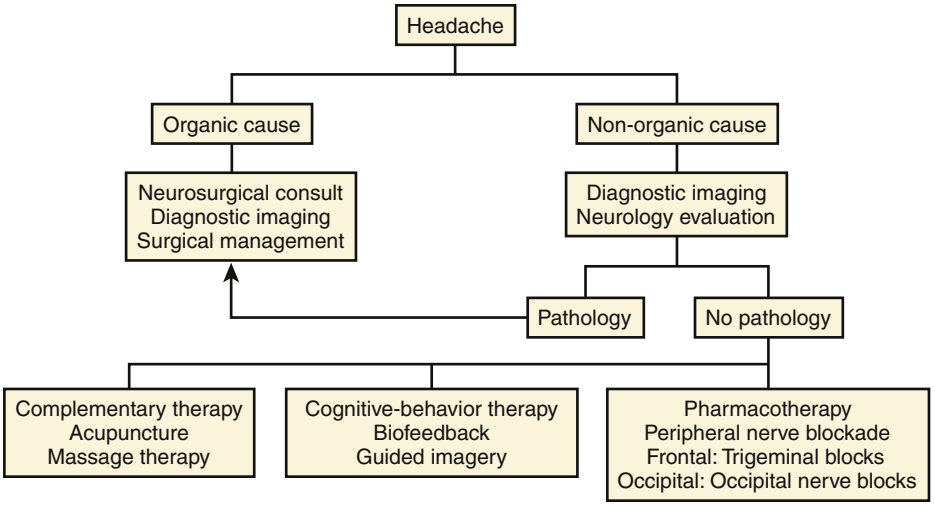
Patients with migraine headaches are frequently managed by neurologists and are referred to the pain clinic only in refractory cases. We have intervened in providing peripheral nerve blocks for headaches. A trigeminal nerve block for frontal headaches and occipital nerve blocks for persistent occipital pain have been shown to be effective in children.[100]

• Box 43.8 Evaluation for Headache

1. General Physical Examination
   - Blood pressure, postural hypotension
   - Careful skin examination for café-au-lait spots, adenoma sebaceum, hypopigmented lesions, petechiae
2. Neurologic Examination
   - Cranial circumference measurement
   - Bruit on auscultation of the cranium
   - Tenderness in the sinuses or presence of occult trauma indicating a battered child
   - Funduscopic examination- optic atrophy, papilledema
   - Cranial nerve examination for the presence of damage
   - Mental status
   - Alteration in language skills
   - Alteration in gait
   - Cranial nerve examination
3. Laboratory Tests
   - Electroencephalography-very non-specific
   - Computed tomography scan, especially with contrast enhancement, may be useful in determining vascular abnormalities.
   - Magnetic resonance imaging- best for delineating abnormalities in the sella turcica, posterior fossa, and temporal lobes
   - Lumbar puncture helpful in determining acute infectious causes
   - Psychological tests to determine whether the headache has a psychological basis
   - Tilt test- if postural hypotension is present (postural orthostatic tachycardia syndrome)
   - Angiography (venous or arterial) if intracranial pathology is suspected.

A tension-type headache is perhaps the most common type of headache that we observed in our pain clinic. These patients frequently complain of debilitating frontotemporal or frontoparietal headaches. Headaches result from contraction of the temporalis muscle and tension on the scalp muscle.[101] Management of tension-type headaches includes the use of relaxation techniques, as well as biofeedback. These patients frequently benefit from the routine use of nonsteroidal agents.[102]

Migraine headaches can be treated with abortive medications such as triptans or with common analgesics, including acetaminophen, aspirin, ibuprofen, naproxen, or opioids such as hydrocodone or tramadol. Medication overuse headache can occur with the



• Figure 43.3 Algorithm for the management of headaches. If the patient experiences nausea, vomiting, or other signs of increased intracranial pressure, neurosurgical consultation should be obtained.

frequent use of these medications and can occur if medication use is more than 10 days per month or more than 15 days per month for a period greater than three months.[103] In these cases, preventative medications should be considered, such as propranolol, amitriptyline, topiramate, or similar medications. OnabotulinumtoxinA and erenumab-aooe are injectable medications that have been approved for the prevention of migraines. However, studies regarding its efficacy in pediatric patients are lacking.[104]

Children occasionally have persistent neuropathic headaches. This commonly occurs in patients who have undergone ventriculoperitoneal shunt revision or surgical decompression for Chiari malformation. After CBT, we attempted to use serial peripheral nerve blocks in these patients. This includes trigeminal nerve blocks for the frontal and occipital nerve blocks for occipital headaches. An ultrasound guided approach to the occipital nerve allows easy access to the C2 nerve root, thereby providing a more robust blockade than can be achieved with a peripheral subcutaneous injection.[105] Local anesthetic is injected with or without a small dose of steroid to provide analgesia.

Juvenile Primary Fibromyalgia Syndrome

Juvenile primary fibromyalgia syndrome (JPFS) is an idiopathic pain syndrome that affects up to 6% of children and adolescents.[106,107] It is a condition characterized by chronic widespread musculoskeletal pain, sleep disturbance, fatigue, and multiple discrete tender points to palpation. Clinical diagnosis is based on history, physical examination, the absence of other pathologic conditions that would explain fatigue and pain, and normal laboratory workup. Other associated symptoms include chronic anxiety, chronic headaches, soft tissue swelling, and pain modulated by physical activity, weather, and emotional stress.[108] There is significant morbidity associated with JPFS, including poor school attendance, difficult physical functioning, poor social acceptance, and comorbid mood disorders.[107] Adolescent patients with JPFS have a high likelihood of continuing symptoms into adulthood.[28] It most frequently affects adolescents between 10 and 15 years of age and has a propensity to affect females more than males.[106]

Diagnosis of Juvenile Primary Fibromyalgia Syndrome

Previously, the diagnosis of JPFS was made using the Yunus and Masi 1985 criteria, including three months of associated fatigue, sleepy difficulty, anxiety, and painful tender points on examination.[107] However, it lacked validation and critical analysis. In 2010, Wolfe et al. proposed criteria for adult fibromyalgia that included the Widespread Pain Index (WPI) and Symptom Severity (SS) Scale for key symptoms of fibromyalgia Table 43.4. This has been found to be an effective screening and diagnostic tool in the adolescent female population with JPFS and is the diagnostic tool utilized in our clinic.

Treatment of Juvenile Primary Fibromyalgia Syndrome

A multi-disciplinary model is the most accepted treatment strategy for JPFS. This includes biobehavioral, pharmacologic, and exercise-based modalities. Psychological therapies, most prominently CBT, have significant evidence demonstrating efficacy in the treatment of JPFS. There is a paucity of data regarding the pharmacologic treatment of JPFS. Various medication classes have been trialed in treating JPFS. However, efficacy data remain limited.[106] As such, pharmacologic treatment strategies are extrapolated from validated adult studies. Tricyclic anti-depressants (TCA), most notably amitriptyline, have been found to be effective in several parameters in adult fibromyalgia syndrome. Selective serotonin reuptake inhibitors and serotonin-norepinephrine reuptake inhibitors have also been tested in JPFS, given the high prevalence of comorbid depression and anxiety. However, the "black box warning" for suicidal ideation in adolescents with a history of major depressive disorder should be considered and monitored with close parental and psychiatric follow up.[109] Opioid antagonists, such as low dose naltrexone, have been actively researched in recent years for the treatment of adult fibromyalgia syndrome. It is hypothesized that low doses of naltrexone, 1–5 mg daily, inhibit glial inflammatory response by Toll-like receptor 4 modulation and systemically upregulate endogenous opioid providing analgesia. In adults, it has been shown to decrease pain and anxiety and improve sleeping habits from baseline after a three month treatment period.[110] Typical doses range from 1–5 mg daily. Despite a lack of studies on its use in pediatric patients, it has a relatively low side effect profile and relative tolerability by patients, making it an ideal adjunct in the treatment of JPFS. Other medications that have been trialed without variable support include gabapentinoids, muscle relaxers, and nonsteroidal anti-inflammatory drugs.

Abdominal Pain

Abdominal pain is a frequently encountered problem in infants, children, and adolescents. When evaluating abdominal pain, it is imperative that all organic causes are eliminated. Abdominal pain may be classified as visceral, parietal, or functional.[111] Functional abdominal pain (FAP) is defined as pain unrelated to an identifiable organic gastrointestinal disorder.[112] Once a diagnosis of FAP is established, CBT along with family centered therapy has proven effective.[113] Several authors have described an affective component of FAP.[114] Furthermore, Walker et al. suggested that children with FAP are at increased risk for the development of chronic pain in adulthood.[115] This may be because of mechanisms linked to heightened central sensitization. Amitriptyline has been described as an effective treatment for FAP in children, although a randomized prospective trial demonstrated no significant difference between control and amitriptyline.[116]

Diagnosis of anterior cutaneous nerve entrapment syndrome (ACNES) is often missed because of the focus on the visceral system as well as misdiagnosis of FAP.[111] However, Siawash et al. found that ACNES was present in 13% of pediatric patients with abdominal pain.[117] Pain can often be superficially localized and described as a stabbing or burning sensation. Given that it is primarily a condition of the abdominal wall, the pain can be aggravated by daily activities such as running or cycling. Commonly, patients show a positive Carnett sign, which involves increased tenderness in painful locations with muscle tension.[117]

Serial nerve blocks in children with abdominal pain, particularly those in whom NP develops after abdominal surgery. The use of serially performed ultrasound guided rectus sheath blocks or transversus abdominis plane blocks has decreased abdominal pain in our cohort as well as in patients with ACNES.[118] By blocking the thoracolumbar nerve roots, analgesia is provided to the anterior abdominal wall (see Fig. 43.4).

Ilioinguinal neuralgia following hernia repair is an underreported cause of abdominal pain in older children and adolescents[119] and is probably secondary to major dissection during surgery. TENS may be helpful, and peripheral nerve blocks can be used to manage pain. Serial ultrasound guided ilioinguinal nerve blocks have been demonstrated to be effective.[120] A perineural catheter may be left in place in severe cases. Implantable peripheral nerve stimulation for inguinal post-surgical neuralgias

TABLE 43.4 Widespread Pain Index (WPI) and Symptom Severity (SS) in the Diagnosis of Fibromyalgia

Widespread Pain Index

A. Have you had pain in the following location in the last week?

Shoulder, right	Shoulder, left	Upper arm, right	Upper arm, left
Lower arm, right	Lower arm, left	Hip (buttock), right	Hip, left buttock
Upper leg, right	Upper, left	Lower leg, right	Lower leg, left
Jaw, right	Jaw, left	Chest	Abdomen
Upper back	Lower back	Neck	

Symptom Severity (SS)

B. How much of a problem have the following been for you during the past week?

	No problem	Slight mild problem, generally mild or intermittent	Moderate, considerable problem, often present	Severe, pervasive, continuous, life disturbing problem
Fatigue	0	1	2	3
Waking still feeling tired	0	1	2	3
Concentration or memory problems	0	1	2	3

C. Have you had problems with any of the following during the past three months?

Muscle pain	Headache	Sun sensitivity	Chest Pain
Muscle weakness	Dizziness	Blurred vision	Hair loss
Numbness/tingling	Shortness of breath	Loss/changes in taste	Fever

Fibromyalgia if WPI greater than or equal to 7 and SS greater than or equal to 5 or WPI 3–6 and SS greater than or equal to 9.

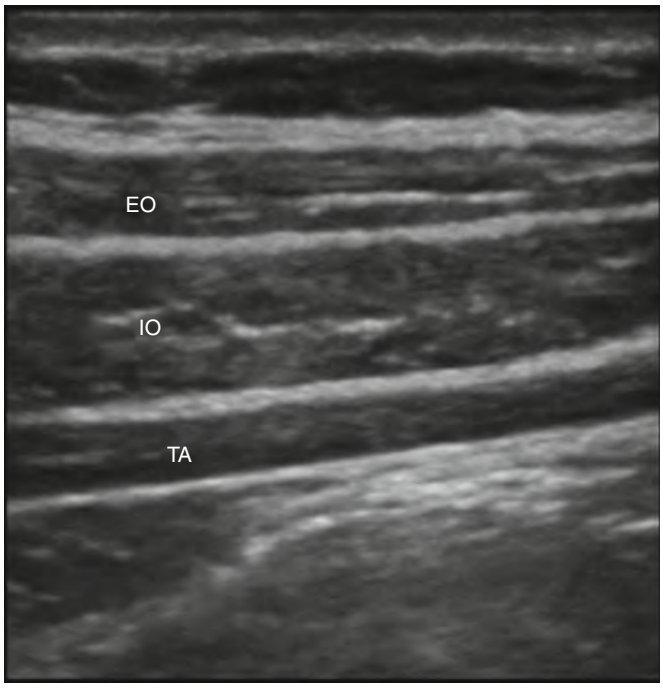
has promising results in the adult population. However, data are limited in pediatrics.[121]

Chest Pain

Chest pain is a common symptom in older children and adolescents. A study conducted in Belgium reported a greater preponderance in men.[122] Most children encountered in the emergency department complained of chest tightness with pain located lateral to the sternum.[123] In a study of 96 patients with a mean age of 13 years, 37% had idiopathic chest pain. A major life event, such as a family divorce or death of a relative, was a significant factor predisposing to chest pain in more than 30% of these children.[124]

Causes of Chest Pain

The most common causes of chest pain include chest wall pain (64.5%), cardiac (5%), respiratory (13%), gastrointestinal (3%), psychological (9%), and traumatic causes (5%). After cardiac causes are ruled out with an electrocardiogram and a careful physical examination, other causes of chest pain should be considered.[124] Each has similar initial symptoms, although the diagnostic workup may be different, depending on the physical findings (Table 43.5).



• **Figure 43.4** Sonographic anatomy of the transversus abdominis (*TA*) plane. *EO*, External oblique muscle; *IO*, internal oblique muscle.

TABLE 43.5 Causes of Chest Pain

Cause	Manifestations
Chest wall pain	Musculoskeletal chest wall pain, costochondritis, Tietze's syndrome
Respiratory disease	Pneumonia, pleuritis, asthma, upper respiratory infection
Psychogenic	Anxiety, depression, hyperventilation
Traumatic	Soft tissue injury, pneumothorax
Cardiac	Carditis, arrhythmia, mitral valve prolapse, ischemia
Digestive	Esophagitis, gastritis
Miscellaneous	Sickle cell disease, cystic fibrosis related

Chest Wall Pain

This is often seen in teenagers and manifests as acute pain along the costal margin. The most common chest wall pain is secondary to costochondritis.[124] The diagnosis is made by eliciting pain along the costochondral margin with deep pressure. Other chest wall pain syndromes include Tietze's syndrome and slipping rib cage syndrome,[125] which usually consists of the use of NSAIDs. We have seen several patients with slipping rib cage syndrome who have not experienced relief despite surgical resection of the slipping rib. We used CBT as well as alternative therapies, including acupuncture and massage therapy, for these children. In addition, we successfully placed intercostal nerve blocks under ultrasound guidance and achieved good relief in children with severe recurring chest wall pain. Serial blocks are performed with adequate resources available for biofeedback and massage therapy to alleviate any pain associated anxiety.

Pulmonary Causes

The most common respiratory emergencies manifesting as acute chest wall pain occur in children with acute asthma attacks, who may have primarily chest pain without concurrent respiratory symptomatology. Other common causes include bronchial pneumonia and respiratory illnesses, including severe lower respiratory tract illnesses. Management includes treating respiratory illness with antibiotics, anticholinergics, and inhaled bronchodilators.

Cardiac Causes

Cardiac causes of chest pain are probably the most compelling reasons for a thorough diagnostic workup. The most common cardiac causes of chest pain include mitral valve prolapse and dysrhythmias. Workup may include echocardiography, electrocardiography, and, in some cases, Holter monitoring for diagnosis. It is important to address pain in an expeditious manner with a close evaluation.

Abdominal Causes

Gastroesophageal reflux is the most common abdominal cause of continued chest pain in children. In addition, the presence of eosinophilic esophagitis should be ruled out by upper endoscopy because it can usually be treated.

Psychogenic Causes

Usually, there is a family history of intercurrent cardiac illness, including a recent myocardial infarction in an older family member or possibly the death of a family member from cardiac causes that can lead to chest wall pain. In most cases, adequate family therapy should be offered.[126] With the increasing availability of diagnostic methodologies, the diagnosis is far more accurate in these children than it was several decades ago.

Back Pain

Back pain is a common problem in adults and is now becoming a significant health issue in children.[127,128] With high impact sports that involve a greater degree of stress on the back muscles, such as gymnastics, children seem to have a higher degree of back injury.[129] Common back problems include spondylolysis,[130] spondylolisthesis, disk degeneration, disk herniation,[131,132] tumors of the spinal cord, and other diseases, including sickle cell disease. Given that up to 57% of back pain in children is because of a non-organic cause,[133] management in children is usually conservative, with an emphasis on exercises for the back. A study of 177 pediatric patients in the emergency setting found that 77% of the visits were non-pathologic in nature. Imaging was performed in 38% of patients, and positive findings were only noted in 17% of radiographs.[134] Advanced imaging, such as CT or MRI, is warranted in refractory back pain, nighttime pain, association with systemic symptoms, or if sensory or motor radicular symptoms exist. If conservative treatment fails, epidural steroid injections may be considered with appropriate imaging studies. Alternative medicine, including massage therapy and acupuncture, is used for the management of children and adolescents with back pain. These therapies may be especially effective when pain has a myofascial component.

Pelvic Pain

Pelvic pain is often reported in female adolescents.[135] A thorough history has to be obtained, including a history of sexual activity. Children with a history of sexual abuse have a greater

preponderance of chronic pelvic pain.[136] Although not common, a subpopulation of these adolescent girls has a history of endometriosis. This could lead to severe pelvic pain and may need to be treated more aggressively than occasional pelvic pain. Alteration of the ovulatory cycles with birth control pills, as well as the use of strong NSAIDs, should be implemented in these patients. We have had success with the use of active massage therapy and physical therapy as adjuncts for the management of these patients.

Cancer-Related Pain

Cancer remains the second leading cause of death in children. Cancer is diagnosed in more than 12,000 children annually, and 2200 children die each year of this disease.[137] Pain is a common symptom during different phases of cancer treatment. The incidence of cancer-related pain in children at the time of diagnosis is estimated to be 75%, with ongoing pain affecting 50%.[138,139] However, the incidence of pain in the terminal phase of the disease is likely to be higher than 89%.[139] Cancer pain in children is because of several reasons: (1) cancer-related pain (e.g. solid tumor or bony metastatic tumors), (2) pain caused by treatment (e.g. mucositis or surgical pain), and (3) NP secondary to tumor invasion or surgery. Pain caused by treatment and procedural pain are cited as the most frequent types of pain experienced by children with cancer.[140]

Management of pediatric cancer-related pain must be individualized, and caregivers must be empathetic to family needs and concerns. Although more than most pain complaints can be managed by the implementation of the World Health Organization cancer pain ladder paradigm, a significant number of children may require additional therapies or techniques for pain management because of escalating or intractable pain. Only allopathic techniques are discussed in this section. The pediatric doses for most medications are off-label recommendations, and dosing is based on the current pediatric clinical literature.

Oral Medications

Most pain management is achieved with oral maintenance dosing. Around-the-clock scheduling is supplemented with the as-needed analgesic doses for breakthrough pain. Oral techniques include sublingual and transmucosal applications for breakthrough and procedural pain.

Sublingual application of morphine is as effective as intravenous morphine for pediatric postoperative pain.[141] Because sublingual administration avoids hepatic first-pass dosing, it is comparable to intravenous administration. Sublingual morphine may be a suitable alternative to intravenous morphine for pain control in children with cancer-related pain if enteral tolerance or intravenous access is limited. Sublingual buprenorphine, 5–7 μg/kg per dose, has demonstrated similar analgesic efficacy as intravenous morphine, 150 μg/kg.[142] Oxycodone concentrate prepared at 20 mg/mL is appropriate for sublingual application, but small changes in volume can cause large changes in dose. When using this concentrated formulation, an increment of 0.1 mL (from 0.2–0.3 mL) constitutes a 50% increase in dose; an additional 0.1 mL increase (from 0.2–0.4 mL) represents a 100% increase or doubling of the dose administered. Thus prescribing dosing increments that are less than 5 mg may result in variations in the actual amount of oxycodone concentrate delivered. Oxycodone concentrate is not recommended for use in small children.

Intravenous preparations administered via the transmucosal route have been attempted with some success. Oral administration of the intravenous formulation of fentanyl can achieve a pharmacokinetic distribution similar to that of oral transmucosal fentanyl citrate (OTFC) lozenges, but there is much interpatient variability. OTFC lozenges have been used to treat breakthrough and procedural pain in children. Oral mucositis pain treated with 200 μg OTFC lozenges is tolerated but ineffective in adult cancer patients.[143] The effective oral dosage range for postoperative pain management is 10–15 μg/kg for buccal application.[144] Schechter et al.[145] found 15–20 μg/kg of OTFC to be effective for pediatric procedural pain, but one-third of the children experienced vomiting. Transmucosal oxycodone (200 μg/kg) provides relief similar to 10 μg/kg of OTFC for procedure-related pain.[143]

Tablets designed for buccal delivery aim to enhance bioavailability and drug uptake and speed the onset of pain relief. Hepatic first-pass effects are avoided.[146] Studies on fentanyl effervescent buccal tablets have revealed pain relief onset times of 10–15 minutes. The efficacy of the system is dependent on pH because higher plasma levels are achieved at a lower pH. Another benefit of the technique is its discrete nature since the tablets are held between the cheek and gum without telltale evidence of drug intake. The buccal tablet is designed for faster onset than with oral or transmucosal delivery, and thus it is particularly useful in the management of breakthrough pain and may be helpful in cases of anticipated incident pain or potentially noxious activity. This formulation may be an alternative route of administration for those with an inability to swallow medications because of dysphagia or a history of pill aversion.

Integumentary Applications

Transdermal Delivery Systems

Transdermal delivery systems of analgesics and adjuvants can be effective for treating chronic pain. The ideal characteristics of a transdermal delivery system include low molecular weight, lipophilicity, high potency, and reliable patch adhesion.[147] The solubility of the drug in the adhesive, its diffusion coefficient, and its permeability coefficient also play major roles in the time to steady-state release into the skin.[148] The release rates of the agent are dependent on the drug concentration and type of matrix used. A steady-state skin flux is required to yield consistent rates of drug release with zero-order kinetics. Several transdermal systems are available for opioids, α_2-agonists, and anesthetics.

Fentanyl. Transdermal fentanyl was approved for use in children in 2002.[149] A prospective study has cited improvement in pain and quality of life in children 2–16 years of age who had established opioid requirements for cancer and chronic noncancer pain.[150] In pediatric oncology studies, 75%–90% have reported that transdermal fentanyl therapy is "good" or "very good" for the relief of cancer-related pain. These findings suggest that transdermal fentanyl is effective and acceptable for children and their families.[151]

Buprenorphine. Transdermal buprenorphine has been used for the treatment of nociceptive pain and NP. Buprenorphine is a long-acting, partial μ-opioid agonist with antagonistic action at κ-opioid and δ-opioid receptors.[152] Reversal of respiratory depression and sedation from this mixed agonist-antagonist is difficult to achieve with naloxone.[153] Patients with previous opioid use have experienced up to a 30% dose reduction in analgesic requirements. Pediatric tolerance is associated with marked ventilatory reduction with buprenorphine in comparison to morphine and warrants close observation for the initial 24 hours of use.[153]

Clonidine. The transdermal application of clonidine has been the most studied mode of delivery of α_2-agonists. Transdermal

clonidine is well studied in adults, but it is difficult to use for the management of acute or chronic pain. Although neuraxial clonidine has a role in cancer and chronic pain management, it has limited evidence of analgesic efficacy or opioid sparing.[154] However, transdermal application does appear to increase the release of enkephalin-like substances and may therefore be an agent enhancer in balanced analgesia techniques.[155]

Lidocaine Patch

The 5% lidocaine patch is a topical peripheral analgesic that has been approved by the United States FDA for the treatment of postherpetic neuralgia.[156] It has been used for nociceptive pain and NP in non-cancer patients. This technique may be useful for treating malignancy-induced peripheral nerve diseases. Unlike other transdermal delivery systems, which work by systemic uptake, the lidocaine contained in the patch penetrates the skin to act locally on damaged or dysfunctional nerves and soft tissue under the skin. Each 10 × 14 cm 5% lidocaine patch contains 700 mg of lidocaine in an aqueous base. It should be applied to intact skin only because of the risk of systemic uptake. The patch is applied directly or beside the area of pain. Patches can be cut before the release liner is removed to fit the target area. The recommended use is a 12-hour-on, 12-hour-off dosing schedule. It should be used with caution in patients taking oral local anesthetic antiarrhythmic drugs, such as mexiletine, to prevent additive effects. Patients sensitive to amide local anesthetics, such as bupivacaine or ropivacaine, should not use the lidocaine patch. The 5% lidocaine patch has not been studied extensively in children. However, a recent study showed excellent tolerance in patients with vaso-occlusive crisis.[157]

Topical Local Anesthetic

Eutectic Mixture of Local Anesthetics. A four percent tetracaine gel and a eutectic mixture of local anesthetics (EMLA), lidocaine and prilocaine, as a cream or patch have proved effective in relieving pain in children undergoing cancer-related procedures.[158] Studies in children 3–21 years of age have shown these commercial preparations to be beneficial in reducing the pain associated with lumbar puncture, venipuncture, and central port access. These preparations should not be used in premature infants because of the risk of local anesthetic toxicity. The plasma concentrations of lidocaine and prilocaine were well below the toxic level for each agent. Moderate plasma lidocaine levels (4.5–7.5 μg/mL) may cause restlessness, dizziness, blurred vision, or tremors. At high levels (>7.5 μg/mL), lidocaine can produce generalized tonic-clonic seizures.[159] Buccal application of EMLA has not led to local anesthetic toxicity. A study of 12 subjects showed peak concentrations at 40 minutes for lidocaine and prilocaine, and the maximum concentration measured in any subject was 418 ng/mL for lidocaine and 223 ng/mL for prilocaine, each below toxic plasma levels.[160] Methemoglobinemia from prilocaine has been reported with the application of EMLA onto newly regenerated postburn or abraded skin.[161] An occlusive dressing was also used in both cases. Methemoglobin levels below 3% are nontoxic, but skin cyanosis may occur. Levels above 3% can be associated with agitation, and levels higher than 50% result in coma, seizures, arrhythmias, and acidosis.[162] Adverse effects of EMLA include transient skin blanching, erythema, urticaria, allergic contact dermatitis, irritant contact dermatitis, hyperpigmentation, and purpura.

Liposome-Encapsulated Lidocaine. Another option for topical pain control before venipuncture is 4% liposomal lidocaine (L-M-X4), an over-the-counter topical local anesthetic that poses no risk for methemoglobinemia because it does not contain prilocaine. Both 4% tetracaine gel and 4% liposomal lidocaine are effective within 30 minutes of application.

Compounding Topicals

Creams and gels applied topically to the skin target the primary site of pain and discomfort. Pluronic lecithin organogel is a poloxamer used for topical delivery with a bioavailability of 10%–60%.[163] The advantage of using topical medications is that a high concentration of the drug is deposited exactly where it is needed, and purportedly little drug is taken up systemically. This would reduce or eliminate the usual side effects of these medications when administered orally. With a prescription, compounding pharmacies can locally prepare selected agents into topical preparations that are not currently available in the open market. However, variations in concentration, sterility, and lack of FDA regulatory control require caution when used with these agents. Commonly compounded agents for topical application include NSAIDs (e.g. aspirin and ketoprofen), membrane stabilizers (e.g. amitriptyline, clonidine, gabapentin, lidocaine), muscle relaxants (e.g. cyclobenzaprine, baclofen), and antibiotics (e.g. amoxicillin and clavulanate). The topical application of clonidine has been shown to be beneficial in children with cancer. The successful use of topical clonidine ointment in a child with herpetic neuralgia after bone marrow transplantation relieved the associated pain, pruritus, and insomnia.[164]

Parenteral Medications

Subcutaneous Infusions

Subcutaneous infusions are considered equivalent to intravenous infusions once a steady plasma state is achieved. Up to 5 mL/h can be absorbed by subcutaneous infusion, thus making this route of delivery feasible for pediatric cancer pain management.[165] This technique should be considered when oral management is not practical, but long-term opioid requirements have been substantiated. The success of this technique depends on patient selection, ongoing home health care support, and the choice of analgesic drug. Highly concentrated solutions were well tolerated and resulted in lower infusion rates. Opioid concentrations of up to 30 mg/mL have been used in adults and tolerated for up to seven days, with rotation of the site of delivery every 72 hours.[166] Patient-controlled analgesia (PCA) can be delivered by subcutaneous infusion if intravenous access is not possible. Access via small-caliber needles, such as a 27-gauge butterfly needle, or access with a 22-gauge tunneled intravenous catheter can be maintained in situ for infusion. Combined subcutaneous and intravenous infusion techniques may be indicated when venous access is limited, but titration of individual agents is needed.

Intravenous Infusions

Outpatient use of intravenous opioids and adjuvants is indicated for gastroenteric intolerance, escalating pain inadequately controlled with adjusted oral medications or intolerable side effects from oral agents. Intravenous access via peripheral catheters or central ports and catheters is often used in situ for chemotherapy or nutrition. Because of limited access, the coadministration of analgesics with parenteral nutrition should be considered to limit the interruption of access and control the risk of infection. Trissel and coworkers[167] studied the compatibility of parenteral nutrition solutions with selected drugs during simulated Y-site administration. They reported that parenteral nutrition solutions are compatible with many agents, including opioids, for 4 hours

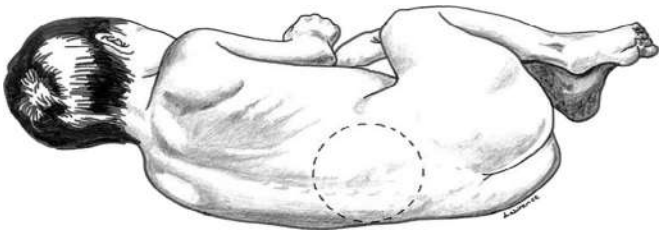
at 23°C, and morphine, fentanyl, hydromorphone, and oxymorphone are compatible via a filter with total parenteral nutrition. Despite visual compatibility testing, admixtures of analgesics in nutritive solutions are not advised. Delivery of the analgesic drug at the Y-site in the central catheter system was the best.

Neuraxial Delivery System

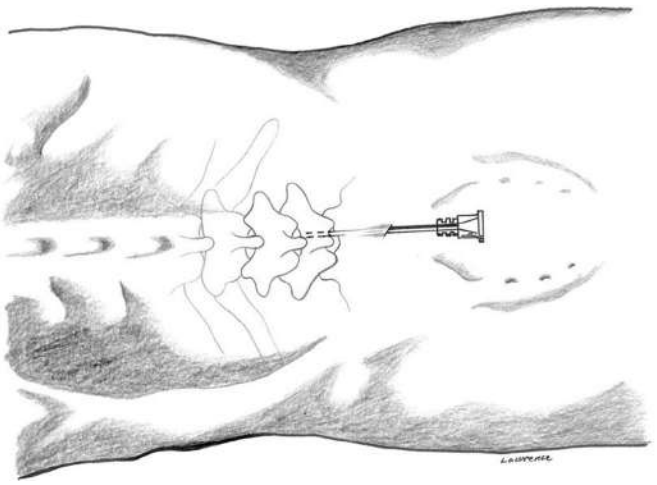
Children with solid tumor disease compounded by extension of the neoplasm to peripheral nerves or nerve roots at the neuraxis are more likely to require larger opioid doses than children with nonsolid tumors (e.g. leukemia).[168] It has been proposed that hyperalgesia and NP are associated with reduced opioid antinociception and contribute to the massive dose requirements. Systemic morphine doses as high as 518 mg/kg/h have been cited in the pediatric literature.[169] The use of neuraxial (epidural and intrathecal) analgesia is indicated for the management of cancer pain when other routes are impractical or yield intolerable side effects. Retrospective reviews of adult and pediatric populations suggest that neuraxial (epidural or intrathecal) infections are rare. A review by Strafford et al.[170] revealed no serious complications in 1620 general pediatric subjects who underwent short-term epidural catheterization. Bacterial colonization of caudal and lumbar epidural catheters in children has been studied prospectively. Kost-Byerly et al. associates[171] found a 35% colonization rate of epidural catheters and an 11% occurrence of local inflammatory changes when catheters remained in situ for up to five days (mean duration, three days).

Long-standing epidural analgesia is effective and safe for the spectrum of cancer-related pain, as well as for terminally ill patients, but proper management of infection risk and strict catheter care are imperative. Tunneling of epidural catheters is performed to decrease the likelihood of infection, improve catheter stability, and aid patient mobility during prolonged administration of neuraxial analgesia. A percutaneously inserted tunneled catheter connected to an externalized pump is a feasible technique for prolonged care (Figs 43.5 to 43.8). Use of a 0.2 μm filter, regular changing of the pump tubing, and weekly or biweekly dressing site care performed with sterile technique may decrease the risk of infection. In a retrospective pediatric study of 25 children, the externalized catheters remained in place for up to 240 days without the occurrence of an epidural abscess or meningitis.[172] The duration of tunneled catheter use by region was 22 days for thoracic (three catheters), 240 days for lumbar (12 catheters), and 42 days for caudal (10 catheters).

The risks and benefits of tunneled epidural analgesia in patients with cancer and coexisting NPs should be closely weighed. It is recommended that totally implanted systems be considered for patients with NP.[173] The signs and symptoms of epidural infection include fever, escalating back pain, back or neck ache, MRI evidence of inflammation, elevated sedimentation rate, C-reactive protein level, and white blood cell count. Superficial infection may include local tenderness, erythema, subcutaneous phlegmon,



• **Figure 43.5** Positioning for epidural placement in a child.

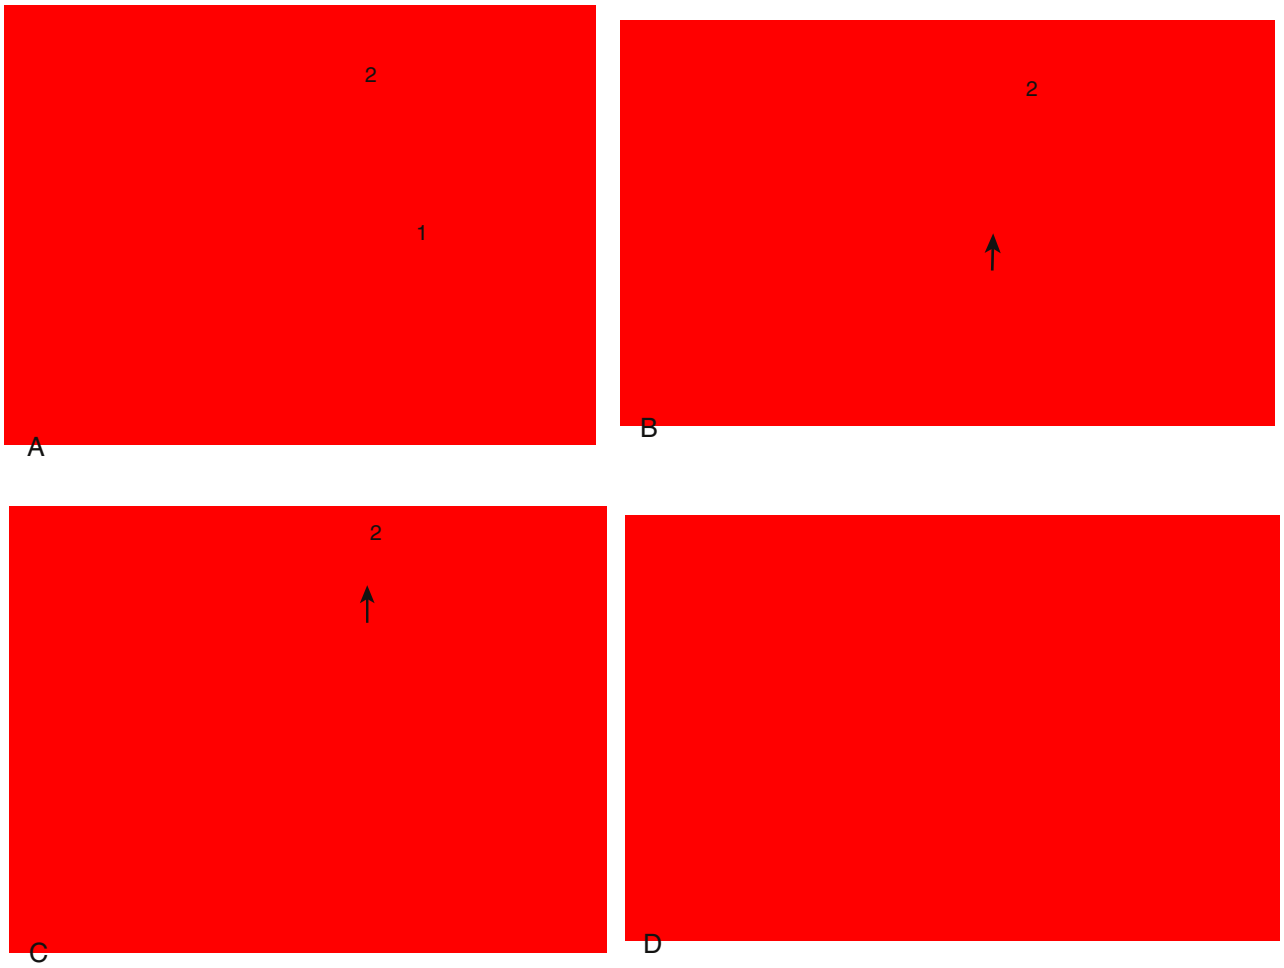


• **Figure 43.6** Percutaneous placement of an epidural.

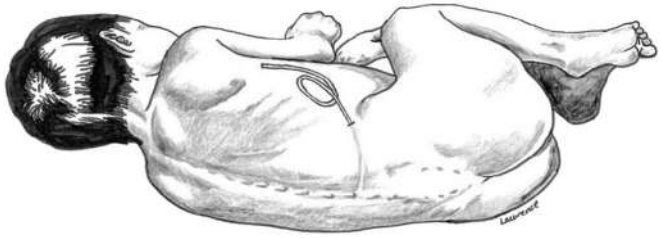
and exudates at the exit site. The presence of an epidural abscess is confirmed by aspiration of exudates, an epidurogram with dye loculation at the catheter tip or retrograde flow, positive culture of the catheter tip, or positive culture of epidural lavage material. Removal of the epidural catheter is indicated in those with temperatures of 39°C or higher, and if any of the aforementioned signs and symptoms are present. Superficial infections are treated with a 7–14 day course of antibiotics. Epidural abscess management includes six weeks or more of intravenous antibiotics with or without neurosurgical drainage of the epidural abscess.[174]

Analgesia via the neuraxial route is associated with less sedation and fewer adverse effects because significantly smaller doses of opioids are used. Spinal opioids provide selective pain blockade without sympathetic nervous system blockade.[175] The more hydrophilic or hydrophobic opioids have limited uptake in epidural fat and its vasculature and yield greater rostral spread in cerebrospinal fluid (CSF) than hydrophobic lipophilic opioids such as fentanyl. Intrathecal opioids bypass the bloodstream and have a direct CSF spread. The onset of action of intrathecal morphine is 15–45 minutes. Delayed respiratory depression is a concern for spinal opioids. Gregory and coworkers[176] noted that peak morphine levels in the medulla coincided with peak ventilatory depression 6 hours after lumbar intrathecal injection. Nichols et al.[177] injected 0.020 mg/kg of morphine into the intrathecal space at the L4-5 interspace; this showed the greatest depressed ventilatory response to carbon dioxide at 6 hours that persisted for up to 18 hours, and infants 4–12 months of age responded in a similar fashion to children 2–15 years old. Other side effects do not appear to be dose dependent and include nausea, vomiting, pruritus, and urinary retention. However, side effects are worse with intrathecal administration than with epidural opioids.

The most commonly used adjuvants to improve pain and decrease opioid requirements include local anesthetics and α_2-agonists. The literature has consistently documented appreciable pain control when clonidine is administered by the intravenous and neuraxial routes as an adjuvant to opioids or local anesthetics.[178] The benefits of clonidine as an adjuvant include the following: (1) reduction in the amount of opioid required for analgesia and thus a probable decrease in side effects because of opioids; (2) titrated sedation and anxiolysis without additive respiratory depression when administered in combination with opioids; and (3) vasodilation and improved circulation of the cerebral, coronary, and visceral vascular beds.[178]



• **Figure 43.7** **A,** The epidural catheter is threaded, and the second needle is tunneled to exit the initial (first needle) entry site. This is performed before the removal of the first needle to avoid shearing of the catheter. **B,** The second needle acts as a trocar. This step can be repeated for a longer tunneled section that can be brought to the anterior. **C,** The first needle is removed, and the catheter is threaded in a retrograde fashion into the tip of the second needle and exits the hub. **D,** The second needle is then withdrawn.



• **Figure 43.8** The externalized catheter can be connected to a balloon-type pump or patient-controlled analgesia apparatus.

Continuous intravenous infusion of clonidine has been cited as a safe adjuvant for pain control in adult and pediatric populations, but the question of long-term impact on neurobehavioral function has been raised. The amount of opioid required by patients experiencing procedural pain was reduced by 30%. Hemodynamic stability was maintained within normal limits because patients experienced less than a 10% change in mean blood pressure. Clonidine has the further advantage of producing sedation associated with only small reductions in minute ventilation and has no effect on hypercapnic or hypoxic respiratory drive.[179]

Pain in Terminal Illness

There has recently been a surge in treatment modalities for pain, and treatment of children is now part of a cure-oriented and technology-based healthcare system. Recently, with the involvement of facilities such as hospices, the care of terminally ill children has been based on the same philosophy as that for adults.[180] Pain can be a significant problem in children who require terminal care. When some children with a life-threatening illness have a significant setback, there may be no firm criteria to stop treatment and direct palliative care.

Alternative novel methods for providing analgesia have been used by our pain service for children who do not have intravenous access. Nebulized opioids[181] or transdermal delivery systems have been used to offset pain in children with intractable pain. Adverse effects associated with the long-term use of opioids include tolerance and withdrawal. Careful rotation of opioids, along with the judicious use of other adjuvants such as *N*-methyl-D-aspartate receptor antagonists, should be considered in the care of children and adolescents.

Several approaches to pain management can be taken depending on the state of the patient, involvement of the disease process, and the general state of the caregivers. PCA has been widely used in our institution for homebound patients with terminal cancers. Smaller, more user-friendly pumps have been devised for easy programming

and less frequent changes. In patients without venous access, we recommend the use of subcutaneous PCA. Other drugs are useful for terminally ill children. NSAIDs and steroids are particularly helpful in the management of bone pain because of metastasis. Carbamazepine, gabapentin, pregabalin, and TCAs are useful in the management of NP. Hypnosis, biofeedback, and distraction techniques can be used effectively in children who are not heavily sedated.

A child's view of death is very different from that of an adult. There is a consistent progression of the conceptual aspects of death as children grow older. Finally, a school-age child understands the permanence of death. Home care may be useful for families to cope with grief and sorrow. It also allows other siblings to spend some time with the loved one. A home care coordinator should be available to manage adverse conditions. Knowing the family helps the coordinator understand the goals of the family. One basic tenet of hospice care is to enable the patient to lead a full life, of the best quality, for whatever time remains. Cooperation between the family and caregiver should allow the child to die with as much dignity as possible. It is the responsibility of the home coordinator to provide caregivers with sufficient information about the management of pain.

Targeted and titrated delivery of antinociception is becoming a reality, as more receptor-specific agents have been devised. More pediatric studies are needed to substantiate the use of the agents and techniques discussed for the management of cancer-related pain in children and adolescents. Regardless of how creative advancements in pain management may become, patient safety must be put first. Novel applications of older agents have broadened the armamentarium of pediatric anesthesiologists and pain management specialists.

Conclusion

Chronic pain in children is underrecognized. Early diagnosis and intervention help ensure adequate recovery. A dedicated CBT program is a helpful adjunct to medical management and physical therapy. Complementary therapy, including massage, acupuncture, and biofeedback, can be used to reduce pain and decrease the need for additional pain medication. Interventional techniques, including serial nerve blocks, can be helpful in refractory cases. A dedicated pain treatment center facilitates adequate and early management of pain in children to ensure rapid recovery to normal function. Future research in the paradigms for managing chronic pain in children needs to be conducted to shape treatment strategies and develop novel approaches to care for this challenging group of patients.

Key Points

- Assessment of pain in children involves a multi-disciplinary approach specifically tailored to the biomedical, psychological, and social elements of each patient and family.
- Psychological interventions can treat pain effectively by modifying the child's cognitive, affective, and sensory experiences of pain, behavior in response to pain, and environmental and interactional factors that influence the pain experience.
- Pediatric CRPS management includes physical therapy, pharmacologic therapy, regional and sympathetic blockade, neuromodulation, and psychological interventions.
- Headaches in children should be evaluated carefully to determine their cause before initiating treatment.
- Headache management includes pharmacologic therapy, CBT, peripheral nerve blocks, and complementary therapy.
- FAP is best treated with CBT, anti-depressants, and serial rectus sheath or transversus abdominis plane blocks.
- Noncardiac chest wall pain may be treated with nonsteroidal anti-inflammatory drugs, CBT, and complementary techniques, including acupuncture and massage therapy. Nerve blocks may be used in refractory cases.
- Common causes of pediatric back pain include spondylolysis, spondylolisthesis, disk degeneration, disk herniation, tumors of the spinal cord, and other diseases, including sickle cell disease.
- Management of pediatric cancer-related pain is individualized and based on family needs and concerns.
- Pain can pose a significant problem in children who require terminal care. Approaches to pain management are based on the state of the patient, involvement of the disease process, and the general state of the caregivers.

Geriatric Pain Management

KEELA A. HERR, STAJA Q. BOOKER, LYNN NAKAD, DAVID J. DERRICO

Introduction

The global population is aging rapidly, with demographic shifts resulting in the proportion of adults ages over 65 years and above significantly increasing globally from 6.1% to 8.8%.[1] The rising prevalence of chronic conditions, of which persistent pain is a common and distressing symptom,[2] is strongly associated with advancing age. Multimorbidity, the presence of three or more interacting chronic conditions, is a major contributor to persistent pain.[3] Persistent pain, which exists beyond the expected healing time, often has no identifiable physical cause, and bothersome pain afflicts 52.9% or 18.7 million older adults.[4] In nursing home residents, Lapane and colleagues found that 27.9% reported mild pain, 46.6% moderate pain, and 25.6% reported severe pain.[5] Besides increasing age, risk factors associated with the development of persistent pain include sex, as women are more likely to report greater persistent pain than men,[6] low income,[7] mental health conditions such as depression and anxiety, and obesity.[8] Prevalent causes of persistent pain in older adults are osteoarthritis, cancer, injuries/falls, chronic low back pain, and diabetes (i.e. diabetic neuropathy).[9]

Conditions such as frailty[10] and the residual effects of emerging health threats like that of communicable diseases such as Ebola and coronavirus-2 (SARS-CoV-2; known as COVID-19) may increase the risk and burden of chronic pain, especially in older adults who make up 80% to 95% of all COVID-19 fatalities in the United States and Europe, respectively.[11] In fact, some speculate that COVID-19 will indeed increase chronic pain overall in the general population citing infections, inflammation, and psychological triggers as underlying drivers.[12] This will likely result in new challenges in effectively managing multiple types of pain in older adults and perhaps necessitate multidisciplinary rehabilitation[13] and implementation of COVID-19 pain guidelines.[14]

Unrelieved persistent pain in later life has many debilitating consequences, including psychological distress, social isolation, impaired sleep quality, physical disability, increased fall risk, and loss of independence.[3,15] Optimizing pain management is important, but obstacles to the identification, assessment, and management of pain underscore the importance of providing close attention to older patients.[16] Consideration of an older adult's health, functional capacities, and cognition are essential in relation to the patient's ability to reliably report pain, and when formulating a pain management plan where they can engage in their care. This chapter provides the reader with an overview of the most current perspectives on the assessment and management of persistent pain in older adults and describes challenges healthcare providers may encounter when delivering pain care to older persons.

Barriers to Successful Pain Management in the Older Patient

Physiologic and Sensory Impairments

Anatomic and physiologic changes normally observed as part of the aging process are progressive, and concomitant injury or disease can rapidly worsen the health status of the older individual. Changes in pain transmission, tolerance, and threshold can decrease the speed of processing nociceptive stimuli and thus reduce older adults' ability to sense and respond to early pain stimuli.[17] Therefore older adults may have a greater susceptibility to burns and other injuries such as lacerations because they are not as likely to sense the initial pain and do not respond (e.g. removing hand) as quickly as younger adults. These alterations may reflect aging-associated reductions in peripheral intraepidermal nerve fiber density and small fiber neuropathy and contribute to sensory losses and pain. Additionally, sensory impairments are common among older adults and can negatively impact the management of pain.[18] Visual impairments such as cataracts, macular degeneration, and diabetic retinopathy that can make it difficult to read prescription labels or participate in recommended exercise programs.[18] Use of good lighting in patient exam rooms, asking older patients to wear eyeglasses, and providing reading materials in large font can help mitigate the negative impact of poor vision on pain care. Hearing impairments are also common.[19] Handheld amplifiers, speaking slowly while facing the older patient directly to allow for lip reading, and providing written instructions can help to decrease the negative impact of hearing loss when managing pain among older adults with hearing deficits.

Cognitive Impairment

Cognitive deficits are common in later life but remain under recognized and under treated.[20] Although a recent study suggests pain treatment in those with moderate-severe dementia has improved, 45% of residents experienced moderate to severe pain[21] and still less likely to receive pain treatment than cognitively intact

residents.[22–24] Numerous barriers exist to provide appropriate analgesia to this group, both at the patient and provider levels. Communication is a major challenge to both assessing and managing pain in this patient population, and cognitively impaired older patients tend to under report pain.[25] Manifestation of pain in cognitively impaired older patients can also vary, from behavioral disturbances, such as lethargy and physical aggression, to more expected reactions such as groaning and grimacing.[26] Cognitive impairment creates additional challenges to assessing pain in older adults. As the severity of cognitive impairment increases, a patient's ability to self-report pain diminishes, particularly if experiencing multiple cognitive issues such as delirium, agitation, and dementia.[23,27]

Caregiving

As the prevalence of pain increases among older adults, so does the demand for caregivers, especially informal caregivers. Informal caregivers and unpaid caregivers, such as family members, relatives, friends, and partners, who take care of loved ones are playing a greater role in their managing the older adult's condition and symptoms.[28] One of the most challenging tasks for caregivers is the management of pain, and caregivers encounter a variety of barriers related to the management of their loved one's pain, including lack of education, ineffective communication with providers, and their own wellbeing. Attention to these needs is essential as the caregiver could be a great asset or adjunct to pain management across the life span.[29] Adequate pain management skills training and education of caregivers can improve patient outcomes.[30]

Beliefs and Attitudes About Aging and Pain

Certain beliefs that older adults and providers have about pain and pain treatments may negatively influence their expectations, behaviors, and decisions regarding treatment recommendations and engagement and/or adherence. As noted, many older individuals consider pain as a natural part of getting older, and rather than seek care,[31] often consider it as something to bear.[32] Beliefs such as these can lead to stoicism or acceptance of the status quo.[32] Although relatively little research has examined whether these beliefs are associated with specific health behaviors, beliefs can negatively affect an older patient's willingness to seek treatment or adhere with a recommended treatment plan.[31] Prior research has also shown that some older adults endorse beliefs and fears (e.g. addiction and dependence) about pain medications that decrease their willingness to engage in or adhere with pharmacologic interventions.[33–34] These concerns may also be voiced by older patients' caregivers, often a spouse or an adult child. Thus some healthcare providers may be more reluctant to prescribe opioid medications for older patients with non-cancer pain because of a fear of causing patient harm.[35] Older adults with pain who endorse this belief report minimizing medication use except when the pain is "very bad."[34] Others show that severe pain is associated with opioid and psychotropic medication use in older adults.[36] Providers should be diligent in ascertaining these beliefs during regular clinical encounters and provide research-based education to counter ageist misconceptions. Within a pain management context, this would mean asking patients open questions about their views on the origins and cause of pain, the meaning and impact of pain, their views about treatment and treatment goals, and educational needs.

Cultural Differences

Pain assessment and management must be individualized and consider an older person's culture and language. Pain specialists may provide pain care to patients of different racial groups, cultures, religions, and recent migrants. Pain beliefs and behaviors are further influences by factors such as acculturation, time since migration, and sex. Understanding and appreciating cultural diversity in older patients' pain beliefs and behaviors can help in the provision of appropriate and acceptable pain care.[37] However, this can be challenging when little evidence is available to support bias-free best practices in diverse groups.

Older adults who are members of minority groups (race, religion, gender) face particular barriers to adequate pain management. Some evidence suggests that older adults of some ethnic minority groups (1) are more reluctant to report pain, (2) have a higher prevalence of more severe, persistent pain, functional limitations, and health consequences, (3) may be less likely to seek help for their pain, and (4) are less likely to receive consistent and adequate medical treatment.[38–39] Reasons for the established disparities in pain management are complex but include socioeconomic disadvantage, discriminatory healthcare systems, and healthcare policies, and misguided pain beliefs and behaviors. We acknowledge that "minority" is not synonymous with socioeconomic disadvantage but is an important consideration for many older adults. Socioeconomic disadvantage and broader discriminatory systems cannot easily be changed by providers but can be improved by providers taking the time to understand each patient's circumstance and perspective. A simple cultural framework that applicable in clinical settings is the "ASKED MYSELF" mnemonic, which has been adapted for Black Americans with pain but can be easily used in multiple racial/ethnic groups.[40] Each letter of the mnemonic guides providers through knowledge- and attitude-based questions about their ability to care for Black Americans with pain; for example, A = Awareness: Am I **aware** that Black Americans experience immense pain disparities related to diagnosis, treatment, and outcomes?[(p. 66)], K = Knowledge: Am I **knowledgeable** about pain-related beliefs, practices, and cultural values, such as the use of spirituality?[(p. 67)]

Language barriers may require additional help in communicating or the services of interpreters ("translators") within health care. This also includes having validated pain assessment scales translated into multiple languages. Recent and older migrants may find health care challenging if they are not fluent in the country's dominant language and may rely on family or friends as means of accessing health care and communication with providers. An informal interpreter may influence a consultation, not only because of the accuracy of language translation but also because of cultural beliefs and social roles in the healthcare interaction, which may be influenced by age, sex, and social position.[41] Not only must providers be aware of language barriers but also the different ways in which cultural groups verbally and non-verbally communicate pain and its impact.

Access to Healthcare Services and Technology

The proportion of older adults in the population is increasing more rapidly in rural areas where access to health services is limited and expensive. This has motivated efforts to identify new and efficient healthcare delivery models, especially for chronic condition management, such as pain management.[42] There is a potential for technology to overcome these barriers by decreasing or

eliminating the need for patients or providers to travel to deliver or attend to health services and pain management.[43] In addition, technology can help facilitate and promote self-management of pain, which is routinely encouraged for chronic pain.[43–44] Technology, such as digital devices (e.g. smartphones, tablets, computers, voice-assistants, or other internet-enabled devices) and software (e.g. email, video-chat applications, online healthcare portals, social networking/media) can be used to improve patient care through more effective monitoring of treatment outcomes, enhanced patient-provider communication, and by providing new ways to deliver treatment.[9,43] These technologies are referred to as eHealth (electronic health) or mHealth (mobile health). eHealth is a broad concept that often encompasses telehealth and telecare technologies but can also include online education and patient-health professional consultations. Telecare involves monitoring aspects of patient's activity (e.g. fall alarms, motion sensors, wearable activity trackers), while telehealth technologies require active involvement from the patient to take readings (e.g. blood pressure and online pain diary) that are regularly submitted to providers for review.[42] Other technologies, such as virtual reality, can supplement as adjuvant non-pharmacologic treatment options in older adults.[45] Implementation of eHealth or other technologies to support pain management should be gradual and begin with supplementation of existing care and should be mindful of a patient's circumstances, capability, current use of everyday technology, and preferences. The acceptance of technology among older adults may relate to existing personal and social contact levels and may be greater where technologic help is not perceived as replacing in person care.[44]

Assessing Pain in the Older Adult

Although accurate assessment of pain is the critical first step in the pain management process, this step can challenge even seasoned clinicians. Older adults typically present with multiple symptoms and medical conditions, leaving healthcare providers little time to address pain in the context of a busy office visit. We described the implications of these barriers in the prior sections of this chapter. Recognizing these challenges and taking steps to address them is an important first step in the assessment and management of pain in older adults.

The key to developing an effective treatment plan is a comprehensive evaluation for the underlying cause of pain, pain characteristics, and impact on physical and psychosocial function and quality of life. Pain and common associated factors (e.g. anxiety, depression, beliefs, insomnia, biomechanical issues) can cause impairment or dysfunction, and each should be considered. Identifying underlying diseases known to be painful (Table 44.1) and current and prior prescription and over-the-counter analgesic history (regarding effectiveness and adverse effects) provides

TABLE 44.1 Types of Pain and Management Approaches

Type of Pain & Description	Pain Characteristics & Related Presentation	Example Pain Conditions
Nociceptive - Responds best to non-opioid (e.g. acetaminophen, NSAIDs) and opioid medications along with non-pharmacologic therapies (e.g. heat, acupuncture, massage, exercise, aquatic therapy, TENS).		
Somatic: tissue injury of bones, soft tissue, joints, muscles	Well-localized, constant; aching, stabbing, gnawing, throbbing	Arthritis, low back pain, tendonitis, acute postoperative, fracture, bone metastases
Visceral: tissue injury of visceral organs including heart, lungs, testes, and biliary system	Diffuse, poorly localized, referred to other sites, intermittent, paroxysmal; dull, colicky, squeezing, deep, cramping; often accompanied by nausea, vomiting, diaphoresis	Renal colic, constipation, urinary tract infection
Neuropathic - Often treated with adjuvant medications, e.g. anti-convulsants, (tricyclic anti-depressants, selective serotonin, and norepinephrine reuptake inhibitors) and opioids if needed; non-pharmacologic therapy that act on nervous system mechanisms is important (e.g. neurostimulation, CBT).		
Peripheral nervous system: injury to the nervous system—nerves	Prolonged, usually constant, but can have paroxysms; sharp, burning, pricking, tingling, pins-and-needles, shooting electric-shock-like; associated with other sensory disturbances, such as paresthesia and dysesthesias; allodynia, hyperalgesia, impaired motor function, atrophy, or abnormal deep tendon reflexes	Cervical or lumbar radiculopathy, postherpetic neuralgia, trigeminal neuralgia, diabetic neuropathy, phantom limb pain, herniated intervertebral disc, drug toxicities
Central nervous system: injury to the nervous system at the brain or spinal cord level	Same as above. Pain may be experienced above, below, or at the level of the spinal cord	Central post-stroke syndrome; spinal cord injury-related neuropathic pain; multiple sclerosis
Mixed or Nociplastic - Treatment may consist of non-pharmacologic therapy (e.g. exercise, CBT), non-opioids, opioids, and adjuvant medications to manage multiple characteristics of pain		
Central, undetermined, or mixed: pain from altered nociception despite no clear evidence of actual or threatened tissue damage; neurologic dysfunction and/or nociceptive issues and uncertain causes	No identifiable pathologic processes or symptoms out of proportion to identifiable organic pathology; widespread musculoskeletal pain, stiffness, and weakness; fatigue, sleep disturbance; taut bands of muscles and trigger points; sensitivity to sensory stimuli	Myofascial pain syndrome, somatoform pain disorders, fibromyalgia; post-stroke pain; temporomandibular joint dysfunction, tension headache

CBT, Cognitive behavior therapy; *NSAIDs*, nonsteroidal anti-inflammatory; *TENS*, transcutaneous electrical nerve stimulation.

important information to guide treatment planning. Assessment of basic and instrumental activities of daily living helps determine the impact of the pain on function. A complete physical examination of the pain source and the musculoskeletal, peripheral vascular, and neurologic systems is important to identify treatment targets. The physical examination should also target potential pain contributors (e.g. leg length discrepancy, myofascial pain, sacroiliac joint syndrome) that can be addressed. Although laboratory and diagnostic tests can be used to establish an etiologic diagnosis, radiographic evidence of degenerative joint disease is often not associated with pain severity, and imaging studies may not be justified.[46] This aligns with the International Association for the Study of Pain's updated definition of pain, "An unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."[47]

Older patients should be asked routinely about pain (and because many older adults will not endorse experiencing "pain," they should also be queried about the presence of ache, hurting, discomfort, or burning sensations) at each visit. Description of pain is essential to determine the type of pain for treatment planning. Gathering information on physical and psychosocial function is important to fully understand pain and its impact and guide treatment planning.[15] Table 44.2 and the following section outline age-appropriate approaches and assessment tools for use with both cognitively intact and cognitively impaired older adults.

Assessment Tools

A wide range of assessment tools is available for use with older adults, many of which are well validated. Unidimensional pain scales (e.g. those that assess pain intensity only) are feasible for use in the context of a busy clinical encounter. Examples include the verbal pain descriptor (none, mild, moderate, or severe) and numeric rating (0–5 or 0–10) scales, the Pain Thermometer, and Faces Pain Scale, all of which have been validated for use in older populations to include individuals with mild to moderate cognitive impairment.[48] Using instruments that capture the multidimensional experience of pain to include its impact on function is strongly recommended.[49] Brief measures that assess pain and its impact on function that can be readily incorporated into geriatric pain practice include the Brief Pain Inventory-Short Form (BPI-SF), the Pain, Enjoyment, and General Activity (PEG) Scale, or the Functional Pain Scale (FPS).[50]

Assessing Pain in Older Patients With Cognitive Impairment

Cognitive impairment occurring in dementia can alter the pain experience and contribute to difficulty interpreting pain signals increasing vulnerability to pain.[51] Pain assessment in older patients with cognitive impairment requires an adapted approach to recognize potential pain problems that include a search for diagnoses or conditions known to be painful, observe pain-related behaviors and changes in interactions, activity patterns or routines, or mental status, obtain proxy input from family or caregivers, and ultimately, if necessary, use an analgesic trial to validate pain presence.[16,52] These steps are amplified in Table 44.2.

Behaviors that suggest underlying pain include facial expressions (grimacing, frowning), vocalizations (noisy breathing), changes in activity patterns (eating, sleeping), changes in mental status (confusion, irritability), body movements (guarding, bracing), and interpersonal interactions (aggressive, disruptive, social withdrawal).[51] Numerous observational tools are available and can help providers assess pain among older patients who cannot communicate verbally. The most recent systematic review of behavioral pain scales identified the strongest supported tools as the Pain Assessment IN Advanced Dementia (PAINAD), Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC), and DOLOPLUS-2.[51] Two new tools that attempt to delineate the behaviors that are best to identify pain in those with dementia may guide practice recommendations in the future.[53–54] Observation of behaviors should occur during movement and not just at rest.[16] The information collected using pain assessment or behavior scales will help in developing a comprehensive management plan.

Management of Pain in Older Adults

Various biologic, social, and psychological factors contribute to pain, and whether acute or chronic, require a strategic multimodal pain management plan that integrates best evidence with patient preferences. Treatment should be viewed broadly, not focused only on reducing pain intensity but also in addressing contributing factors and preventing long-term effects of pain. Developing a pain management plan involves evaluation of the patient goals for outcomes and treatment options with risk/benefit analysis to ensure safety and quality. A multimodal management plan is a personalized approach that includes multiple non-pharmacological strategies, medications, techniques, and pain management devices to gain the best control of pain (Fig. 44.1). This treatment plan might always include analgesics but should start with non-pharmacologic interventions, as many are accessible, inexpensive, easy to use, and result in fewer side effects.[55] Recent guidelines from the American College of Rheumatology recommend managing osteoarthritis pain using a comprehensive approach.[56]

Non-Pharmacologic Management and Self-Management

With rising concerns of opioid misuse and the greater likelihood of older adults to experience adverse effects from polypharmacy and medication interactions, consider non-pharmacologic pain management as early options when managing pain in the older patient. A range of physical and psychological modalities are available for persistent pain and include physical techniques such as repositioning, use of heat and cold, massage, transcutaneous electrical stimulation and therapeutic touch, and psychological therapies, such as distraction, relaxation, and guided imagery.[57–58] Research evaluating their use in the cognitively impaired population is limited; however, based on their efficacy in cognitively intact older adults, their general use can be inferred in this population. Individualize the appropriate complementary therapy as the level of cognitive impairment may limit the use of certain interventions, particularly behavioral modifications.

Physical activity and exercise can help reduce pain-related disability and increase physical function and quality of life for older adults with persistent pain. With regular moderate exercise (at least 150 minutes per week for all United States adults), older adults can increase physical function, slow the progression of physical deterioration, and improve range of motion. However, fear of pain and pain itself is often cited as a barrier to initiating and maintaining physical activity and exercise, and this can result in

TABLE 44.2 Steps for Focused Pain Assessments in Older Adults

Cognitively Intact and/or Able to Self-Report	Cognitively Impaired and Unable to Self-Report
Step 0: Determine willingness, ability, and reliability to provide self-report pain by observing coherence of verbal communication, assessing conceptual understanding on how to use a pain scale by asking where mild pain and severe pain are represented on a zero to ten pain scale, and/or administering a cognitive screen, such as the Mini-COG or mini-mental status exam (MMSE). Older adults who score 18 or above on MMSE can usually reliably self-report pain.	**Step 0: Determine willingness, ability, and reliability to provide self-report pain, and also note if there is a diagnosis of cognitive impairment or dementia**. Some older adults with mild-moderate dementia remain able to self-report; in these situations, refer to the left column. If unable to self-report, continue with steps one to five in this column.
Step 1: Be attentive or identify potential sources and causes of pain by reviewing the health history, physical examination, diagnostic tests, laboratory values, and medication history. There may be multiple sources/locations and types of pain resulting from multiple morbidities. See Table 44.2.	**Step 1: Search for possible etiologies of pain** such as a history of pain conditions, pathological (e.g., chronic diseases, infections), procedural (e.g., postoperative pain, blood pressure cuff pain, wound care), accidental (e.g., skin tears), trauma (e.g., falls, concussions, elder abuse), and emotional causes (e.g., depression, anxiety, PTSD).
Step 2: Determine presence/absence and intensity of pain by asking older adult if s/he is experiencing pain "right now" or "at this moment." Alternative descriptors, such as ache, sore, hurt, and discomfort, should be used if "pain" is denied. **Measure self-reported pain intensity using a valid, reliable, and preferred pain scale** such as the Faces Pain Rating Scalerevised (FPS-r), Revised Iowa Pain Thermometer (IPT-R), Verbal Descriptor Scale, or Numeric Rating Scale.[48,73] The verbal descriptor scale with or without a thermometer is preferred by most older adults, although best practice is to ask the older adult the tool they prefer to use. Also, ask about location and radiation, duration, frequency or pattern, and precipitating and ameliorating factors to help determine the cause.	**Step 2: Attempt self-report to determine the presence and intensity of pain.** A patient with limited verbal and cognitive skills may provide a simple yes/no, other vocalizations, or gestures to communicate pain. *See adjacent text.*
Step 3: Assess the impact of pain on function to determine pain tolerability and interference with life activities. Different patients will find different pain intensities more tolerable, and this information is essential to establish pain treatment goals. Use established measures such as the BPI-SF, the FPS, or the PEG.[50]	**Step 3: Observe for potential pain behaviors using an appropriate pain behavior observation tool.** Observation of facial expressions, verbalizations/vocalizations, body movements, changes in interpersonal interactions, changes in activity patterns or routines, and mental status changes may help confirm pain. When there is a change in older adults' behavior, consider pain as an etiology. Select a recommended pain behavior observation tools, such as the Pain Assessment in Advanced Dementia Scale (PAINAD) or the Pain Assessment Checklist for Seniors with Limited Ability to Communicate (PACSLAC-II) to consistently evaluate pain-related behaviors;[16] other pain behavior tools may be appropriate and clinically usable for different populations, settings of care, and languages.
Step 4: When appropriate, engage the patient care team and family or unpaid caregivers in the assessment. The patient care team can include the patient, selected family and significant others, caregivers, and healthcare providers who may be able to provide additional recognition of the presence of pain and its impact on function when the older adult is reluctant to report pain.	**Step 4: Engage the patient care team and family to obtain proxy reporting** (e.g., nurse, certified nursing assistant) about older adult's usual behavior, communication style, functional patterns, and mood. Proxies need recent knowledge of pain problems, activity level, and normative behavior to recognize subtle changes that may otherwise go unnoticed.[99]
Step 5: Develop and implement a comprehensive plan for management guided by realistic goals for comfort, function, and mood. A comprehensive plan is driven by patients' goals and preferences for care and integrates both pharmacological and non-pharmacological interventions. Continue to re-assess regularly based on pain severity and type using the same self-report pain intensity scale.	**Step 5: Initiate analgesic trial** if (a) pain is the suspected cause of behaviors as demonstrated by a pain behavior observation tool, (b) behaviors do not respond to non-drug interventions, or (c) etiology known to be painful and other causes ruled out. The type of pain suspected (e.g., nociceptive or neuropathic), comorbidities, and contraindications determine the stepped approach taken. The trial length can range from one to seven days. Improved behavior after administration of an analgesic is support for assuming pain is present; then develop a multimodal treatment plan guided by attainable goals for continued comfort, function, mood, and behavioral improvement. Continue to re-assess behaviors using the same pain behavior observation tool. If unresponsive to analgesic trial, explore other potential causes and/or consult a pain management specialist.

the avoidance of movement and consequentially reduced physical function and greater pain.[59] Prescribed exercise should be individualized, supervised for those with either severe pain or significant physical disability, and include flexibility, strength, and endurance exercises.[55] Alternative movement-based therapies, such as tai chi and yoga are safe and low impact strategies to engage older adults in physical activity.[55]

Poor coping skills and negative beliefs about pain and its management make managing persistent pain difficult regardless of patient age. Psychological therapies, such as cognitive behavior therapy (CBT), acceptance and commitment therapy, and mindfulness promote positive pain coping, beliefs, and behaviors. Consideration of the treatment goals of older patients is important for these therapies, such as increased social interaction and functional independence for activities of daily living. CBT aims to promote and reinforce self-management and positive health behaviors and pain beliefs.[55] CBT is recommended for older adults with persistent pain disorders and can be provided as a structured, professional-led program, which can be delivered on an individual or group basis, in person or online.[9] However, the limited number of providers skilled in delivering psychological therapies may restrict their availability.[9]

Self-management strategies, both physical and psychological, are important aspects of chronic pain management.[9,55–56] Pain self-management is a patient-centered process involving the acquisition, practice, and execution of skills needed to respond to and manage pain and its associated symptoms. Successful and optimized pain management requires that older patients be confident and manage the everyday symptoms and consequences of pain. Identifying older patients who are already effective self-managers and those who would benefit from additional support remains a difficult area. Factors such as pain beliefs, attitudes, and motivation, also influence self-management participation.[31,60] For older patients who require additional support, various materials and interventions are available, including professional or lay-led group courses (delivered in person or online), educational resources (i.e. manuals, pamphlets, websites, videos), and self-help groups. Decisions about how best to support older patients' self-management will largely be determined by what is available and accessible to the patient locally. However, to the extent possible, older patients should be encouraged to choose between available formats, selecting individual strategies that best meet their needs.

Clinicians must discuss non-pharmacologic and self-management strategies with older patients. These strategies can improve quality of life and reduce pain and the associated impact of pain upon daily life by adopting positive pain behaviors and coping responses. Although many strategies can appear harmless, unknown risks may exist. For example, some dietary supplements or herbal remedies may pose a risk to the older patient when taken with particular pharmacologic agents.[61] It is therefore imperative that clinicians ascertain the full extent of their older patients' pain and pain management behaviors, and consider cultural, lifestyle, and socioeconomic factors that may influence these experiences.

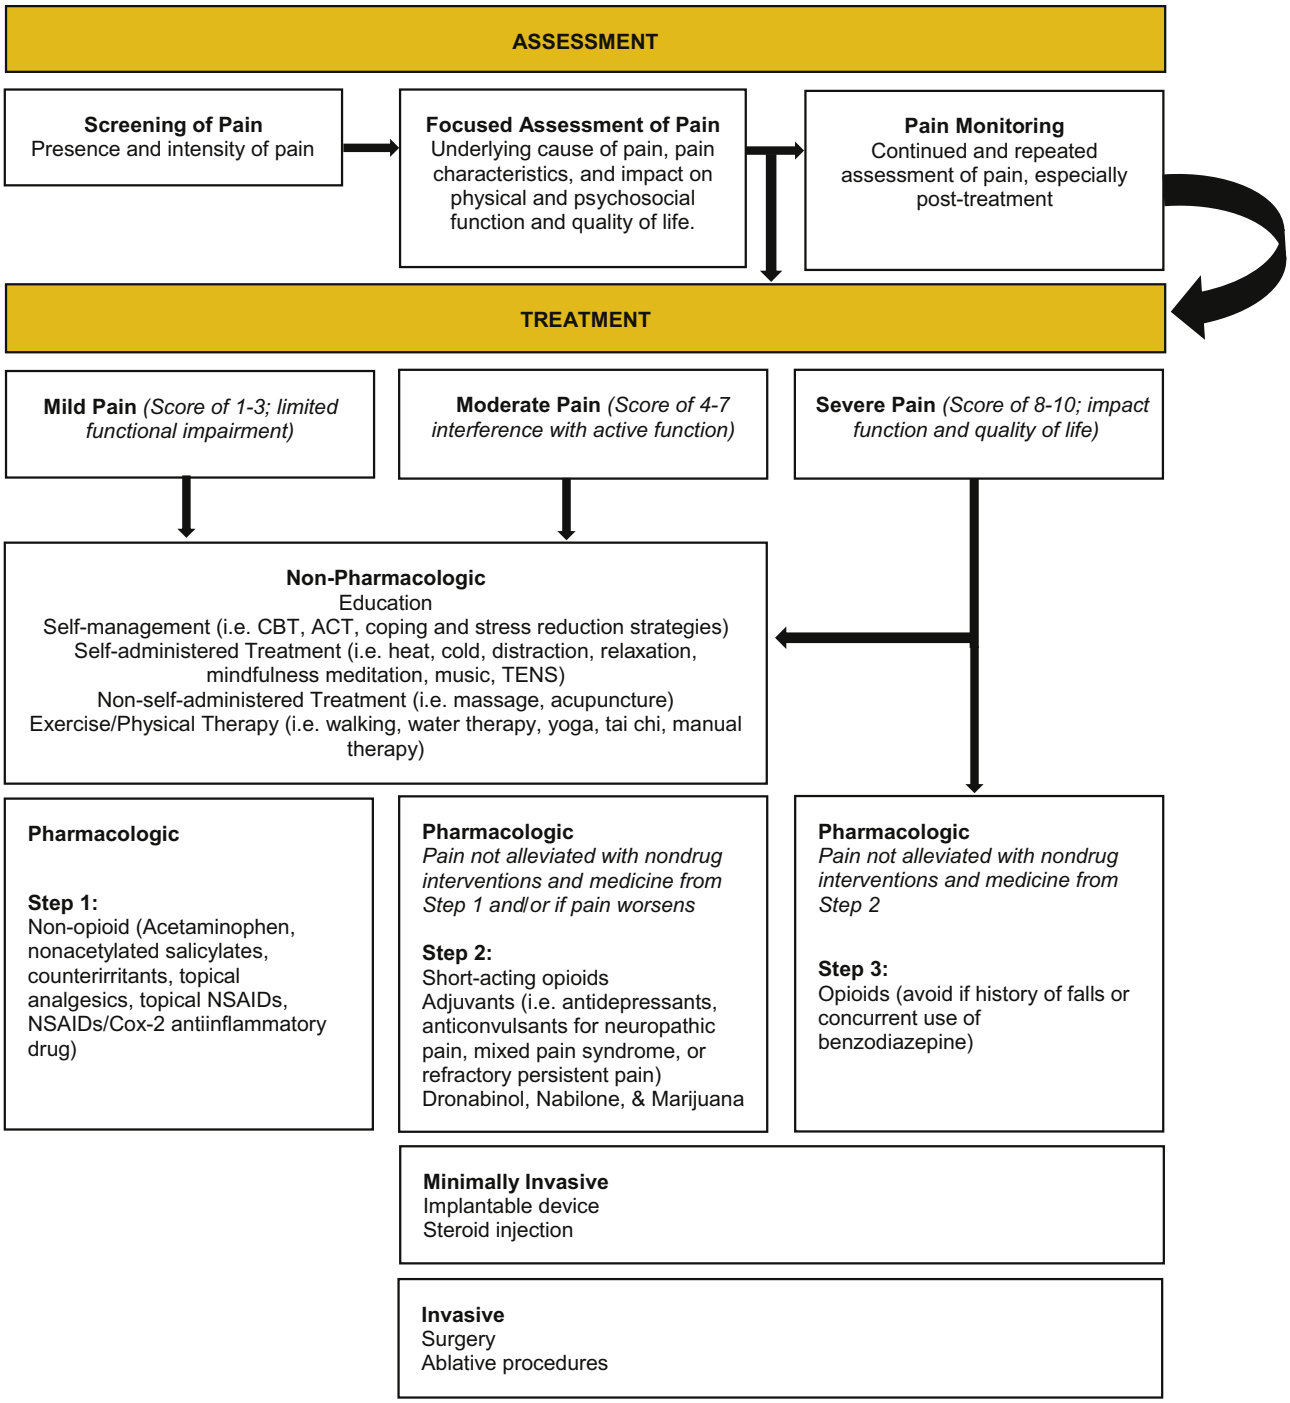
Pharmacologic Management

General principles for pharmacologic management of pain in older patients include a collaborative assessment of pain, administration of around-the-clock analgesics, frequent reassessment of the verbal, behavioral, and functional responses to treatment, and timely titration of analgesics.[62] The United States Centers for Disease Control and Prevention opioid guidelines recommend non-pharmacologic and non-opioid therapy first,[63] but implementation challenges have been raised, and analgesic medications continue to constitute the primary treatment for older adults with persistent pain.[64–65] Older persons with chronic non-cancer pain regard analgesics as an important method for managing pain, particularly when other interventions are difficult to access.[64,66] In a study of older home care adults with chronic pain in Germany, 81.4% used pain medication regularly.[67] Nonetheless, a multimodal pain management plan should be inclusive of pharmacologic medications and non-pharmacologic therapies.

Determination of the best pharmacologic approach hinges on evaluating individual characteristics and risk/benefit analyses for the options available. Age-related changes in both pharmacokinetics (alteration of absorption, distribution, metabolism, and excretion of drugs) and pharmacodynamics (drug-related adverse side effects) necessitate a modified approach to pain management in the older patient.[62,68] Renal impairment is quite common, leading to increased half-lives of medications that are excreted by the kidneys. In addition, hepatic function can decline, reducing arterial hepatic blood flow and increasing elimination time for hepatically metabolized drugs. Reductions in dose strength and frequency of analgesic dosing are necessary to decrease toxicity risk. Older age is also associated with a change in the volume of distribution. Total body fat increases while total body water decreases, translating into higher peak plasma concentrations for water-soluble drugs and prolonged half-lives for lipid soluble drugs. Lower albumin levels in frail older adults impact drugs that bind primarily to proteins.

Pharmacologic management of persistent pain in older adults is often only partially effective and limited by side effects, including urinary retention, constipation, sedation, cognitive impairment, and increased risk of falls.[69] Barriers to effective pharmacologic management of pain among older adults are diverse and include age-related physiologic changes that often dictate altering dose and frequency of analgesic administration. For many classes of pain-relieving medications, older patients may demonstrate increased analgesic sensitivity.[70] However, it is important to remember that older adults are a highly heterogeneous group, so dosing guidelines must carefully weigh a patient's pain, its' impact on their functional status, and the patient's comorbidities and other factors (e.g. polypharmacy, sociodemographic, health literacy issues). Older adults with a persistent pain disorder frequently have multiple chronic conditions (MCCs) such as diabetes, hypertension, and osteoporosis, which must be considered when formulating a treatment plan. MCCs often result in many older adults experiencing polypharmacy (defined as the use of multiple medications with five or more being a typical threshold criterion) that frequently complicates the pharmacologic management of pain.[3] Various patient sociodemographic factors can also operate as barriers. Although adequate social support enhances medication adherence,[71] many older adults live alone with limited social support.[7] In addition, many older adults cannot afford the costs of certain pain medications. Furthermore, some older adults may lack the necessary skills to read and process basic healthcare information, including understanding pill bottle instructions, information present in patient hand-outs, and clinicians' instructions about medication side effects.[72] Low health literacy can lead to problems with medication adherence, such as taking too much or too little pain medication.

Among older adults with persistent pain, commonly prescribed analgesic agents include non-opioids, opioids, and adjuvant therapies (Fig. 44.1). Issues related to the safety and efficacy of these three analgesic classes are briefly summarized.



• **Figure 44.1** Assessment and treatment approaches for pain management in older adults. (Copyright 2020 K. Herr. Used with permission K. Herr, University of Iowa, College of Nursing.)

Non-Opioids

Guidelines recommend acetaminophen as the first line agent for mild to moderate chronic pain in older adults. It is the most commonly prescribed analgesic for the treatment of mild to moderate persistent pain because of its low cost, overall safety profile, and modest efficacy.[73] Acetaminophen is an ingredient in more than 600 over-the-counter (OTC) and prescription drugs; therefore unintentional overdose can easily occur and lead to acute liver failure.[74] Unintentional overdose remains the leading cause of acetaminophen-induced hepatotoxicity as a result of treating pain.[75]

Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used for chronic pain in older adults when acetaminophen fails to control the pain effectively. NSAIDs are particularly helpful in treating an inflammatory type of pain where acetaminophen has limited efficacy.[76] NSAIDs continue to be one of the most commonly prescribed and consumed analgesic agents, particularly as OTC products. Although oral NSAIDs are widely considered more effective pain relievers than acetaminophen, NSAID use has

significant limitations in the form of renal, gastrointestinal, and cardiovascular toxicity, particularly among older patients. Compared with younger patients, older patients are at increased risk of experiencing gastrointestinal (GI) complications in the form of peptic ulcer disease and GI bleeding.[77] Use of either cyclooxygenase-2 (COX-2) selective inhibitor NSAIDs (e.g. celecoxib) or non-selective NSAIDs is associated with increased risk for myocardial infarction, stroke, and mortality.[78–79] Given the risks associated with oral NSAID use, increasing attention has focused on the development and testing of topical NSAIDs. Topical NSAIDs have been approved for use by the United States Food and Drug Administration, and numerous topical agents are available OTC as well.[80] A systematic review and network meta-analysis examined the relative efficacy found that topical NSAIDs were effective and safe for osteoarthritis. Diclofenac patches were the most effective topical NSAID for pain relief, while no serious gastrointestinal or renal adverse events were observed. A retrospective cohort study of patients with rheumatoid arthritis who were newly starting therapy with non-selective topical NSAIDs or oral NSAIDs found the topical NSAID group had a 36% lower risk for cardiovascular events than the oral NSAID group (hazard ratio, 0.64; 95% confidence interval 0.43–0.95).[79]

Opioids

Although well-accepted as a means of treating both acute and cancer pain, opioid analgesics remain controversial in the treatment of persistent non-cancer pain.[73] Nonetheless, opioids are considered the most powerful pain-relieving drugs available for older adults with moderate to severe persistent pain.[81] Use of opioids by older adults has increased, particularly in long term care settings where challenging pain problems exist; however, there remains limited evidence of long term effects of opioid use for chronic pain.[82] Opioids for chronic pain management in older adults may be justifiable when less potent medications have failed or are contraindicated.[83] Many older adults and healthcare providers are reluctant to use opioids because of fears of addiction and side effects, such as nausea, pruritus, constipation, drowsiness, cognitive effects, and respiratory depression.[83] Clinical monitoring and supervision are needed to manage potential side effects associated with opioids, including dry mouth, constipation, sedation, nausea, delirium, urinary retention, respiratory depression, and cognitive impairment. Other less common side effects are hypogonadism, immunosuppression, and hyperalgesia.[46] Despite these side effects, evidence from trials shows that opioid therapy for older adults can be safe and effective with appropriate cautions, including the lower starting doses, slower titration, longer dosing interval, and more frequent monitoring.[84] Still, a risk/benefit/cost analysis, along with adequate education, should be completed prior to initiating long-term opioid therapy.

Benefits may occur when clear treatment goals for opioid use are established, and patients are educated about the risks and benefits of opioid drugs.[85] According to the American Geriatrics Society's Beers Criteria 2019 Update for Potentially Inappropriate Medication Use in Older Adults, opioids should be avoided except for pain management in the setting of severe acute pain (e.g. recent fractures or joint replacement) because they may cause ataxia, impaired psychomotor function, syncope, and falls.[86] If opioids must be used, reduce simultaneous use of other central nervous system–active medications that increase risk of falls and fractures and implement strategies to reduce fall risk.[86] Further, kidney function must be closely monitored, and persons with existing kidney disease may have contraindications to morphine. Medications with codeine should be avoided. A recent systematic review demonstrated that both improvements and impairments to cognition occurred in studies with higher mean opioid doses.[87] A brief screening tool to assess cognition changes might be useful.

Opioid misuse. Opioid misuse refers to opioid use in any way not directed by a prescriber, including use without a prescription of one's own or use in greater amounts than prescribed.[88] The prevalence of opioid misuse is increasing among adults ≥65 years old, a population rapidly growing in number that requires special consideration, monitoring, and management when on opioid treatment.[89] Results from multivariable analyses among older adults visiting emergency departments suggest that the odds of opioid misuse among adults aged 65–74 years old are 6.75 times ($p < 0.001$) larger than otherwise similar adults aged 85 years and older, and the odds of opioid misuse among adults aged 75–84 years old are 2.16 times ($p < 0.001$) larger than their otherwise similar adults aged 85 years and older.[90] However, while the use of opioids under clinician supervision provides many older adults with necessary pain relief, some older adults may use opioids without a prescription, without pain, or without medical indication.[88]

Although clinicians should remain vigilant about the possibility of misuse/abuse of opioid agents among all patients irrespective of age, it is important to note that advancing age is associated with a significantly decreased risk of opioid misuse/abuse.[91] Consequently, opioid misuse may go unrecognized in older adults because of provider perceptions about older adults' behavior and the absence of efforts to screen for such misuse in this population. Older studies suggested that the underuse of opioids in older populations constitutes a bigger problem.[92] However, recent trends reveal that emergency department visits by older adults with opioid use disorder rose by 220% from 2006–2014 in the United States.[90] In Canada, the hospital admission rates from opioid overdose are higher for older adults (≥65) than younger adults.[93] Given these increases, it is important that clinicians screen for potential risk for misuse/abuse and use a valid tool such as the Opioid Risk Tool.

Adjuvant Agents

Adjuvant agents are medications administered in conjunction with analgesics to relieve pain, including anti-depressants and anti-convulsants, which are typically prescribed to treat neuropathic pain.[94] However, two Cochrane reviews did not find sufficient evidence to support the use of tricyclic anti-depressants (TCAs), such as nortriptyline and desipramine, for the treatment of chronic neuropathic pain conditions.[95,96] Although the use of low doses can mitigate side effect occurrence, many older adults experience treatment limiting anticholinergic side effects in the form of dry mouth, urinary retention, and constipation as well as an increased fall risk. Therefore the use of these medications must be considered in the context of what has been tried and the effect of pain on function; the small effects of TCAs may still be worthwhile for some older adults with severe pain. Duloxetine is a selective serotonin and norepinephrine reuptake inhibitor (SNRI) that has been shown to be effective in lowering pain levels among patients.[94] Patients co-prescribed an opioid were less likely to report a pain response to venlafaxine, suggesting that clinicians may wish to consider either non-opioid or alternative anti-depressant approaches to pain management in these complex patients.[97] Nausea is a commonly reported side effect with both SNRIs.

Anti-convulsant drugs such as carbamazepine are considered front line therapy for neuralgia management.[76] A particular area of concern in older adults is the risk of hyponatremia with carbamazepine because studies show that older patients with hyponatremia are more likely to have injuries from falls than those without hyponatremia. [98,99] Therefore routinely monitor sodium levels carefully with carbamazepine administration, initiated with low dosages, and slowly increased. Anti-convulsant drugs pregabalin and gabapentin have also been useful in treating neuropathic pain.[94] Side effects such as sedation, confusion, and peripheral edema can limit the use of pregabalin. Gabapentin in older patients has been associated with increased rates of falls; consequently, it is important to screen all older patients for fall risk when prescribing anti-convulsants.[98] The 2019 Beers Criteria indicates that anti-convulsants and anti-depressants, including SNRIs, may cause ataxia, impaired psychomotor function, syncope, and falls. Therefore the safety and need for these medications must be evaluated carefully and compared to their other medications to minimize increased central nervous system adverse effects.

Practice Recommendations

Here, we provide recommendations for the assessment and management of pain in older adults.

Assessment

- Identify pain-causing etiologies and perform a thorough physical exam, including any appropriate laboratory tests.
- Ask about the presence of pain, then measure its intensity and impact on function and quality of life using valid and culturally appropriate pain and function scales.
- For cognitively impaired individuals, determine ability to reliably self-report, and if impairments limit communication of pain, use a valid pain behavior tool to observe for changes as condition changes.
- Assess pain at regular intervals to establish changes in pain character (frequency, duration, triggers, and intensity) and location.

Management

- Incorporate non-pharmacologic agents to enhance relief and sense of pain control. Promote and support self-management.
- Engage older adults and any caregivers in shared treatment decision making.
- Assess and manage changing physical and cognitive abilities that can influence treatment trajectories.
- Target analgesic selection based on pain etiology and mechanism after careful individual evaluation for risks and benefits.
- If treatment goals are unmet and the patient is tolerating the therapy, consider advancing the dose before prescribing another therapy, in addition to introducing a new non-pharmacologic therapy.

Conclusion

Older adults deserve quality pain care derived from robust research, provider expertise, and patient values. Although numerous challenges and barriers exist that make assessment and treatment complex, online resources are available to guide providers, patients, and caregivers (e.g. geriatricpain.org). The goals are to detect pain early and treat it safely and effectively so that older adults can thrive and survive.

Key Points

- Evidence-based approaches to assessment and management can help older adults thrive and have a good quality of life.
- A wide range of validated tools are available to assess pain in older adults, including individuals with cognitive impairment.
- A multimodal, comprehensive approach to pain management is imperative.
- Providers need to be aware of and work to address barriers that often occur in assessing and managing pain in this age group, to physical and cognitive impairments as well as social and cultural issues.
- The full range of available pharmacologic, non-pharmacologic pain management and coping approaches should be considered.
- Providers are strongly encouraged to support older patients' efforts to become active participants in their own care.

Managing Pain During Pregnancy and Lactation

GEETA NAGPAL, FEYCE M. PERALTA, JAMES P. RATHMELL

Use of Medications During Pregnancy

Medical management of the pregnant patient should begin with attempts to minimize the use of all medications and use nonpharmacologic therapies whenever possible. When opting for drug therapy, the clinician must consider any potential for harm to the mother or the fetus and the course of the physiologic state of pregnancy itself. The degree of protein binding and lipid solubility of the medication, speed of maternal metabolism, and molecular weight all affect the placental transfer of medications from mother to fetus. Except for large polar molecules (such as heparin and insulin) and ionized molecules (glycopyrrolate), almost all medications will reach the fetus to some degree.

Approximately 3% of newborns will have a significant congenital malformation.[1] Only 25% of fetal malformations have a known genetic cause, and only 2%–3% have a clear environmental link, such as maternal medication exposure during organogenesis.[2] One of the major limitations in evaluating any medication's potential for causing harm to a developing human fetus is the degree of species specificity for congenital disabilities. A classic example of this specificity is the drug thalidomide; nonprimate studies have revealed no teratogenic effects, but severe limb deformities occurred in human offspring when thalidomide was prescribed during pregnancy.[3]

The most critical period for minimizing maternal drug exposure is during early development, from conception through the tenth menstrual week of pregnancy (the tenth week following the last menstrual cycle). Drug exposure prior to organogenesis (prior to the fourth menstrual week) usually causes an all-or-none effect; that is, the embryo either does not survive or develops without abnormalities.[4] Drug effects later in pregnancy typically lead to single- or multiple-organ involvement, developmental syndromes, or intrauterine growth retardation.[2] Certain medications may not influence fetal organ development directly but have the potential to influence the physiology of pregnancy adversely. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) may delay the onset of labor, decrease amniotic fluid volume, or place a newborn at risk for pulmonary hypertension or renal injury.

The United States Food and Drug Administration (FDA) had developed a well known five-category labeling system for all approved drugs in the United States with pregnancy letter categories (A, B, C, D, and X). Based on available scientific and clinical evidence, this labeling system rated the potential risk for teratogenic or embryotoxic effects. In 2014 this labeling system was removed as it was determined to be confusing and did not accurately or consistently communicate differences in degrees of fetal risk. Effective 2015, a gradual process was started to remove pregnancy letter categories by June 2020. Because the risk-benefit decisions regarding the use of a drug during pregnancy are more complex than the category designations suggest, reliance on these may result in inadequately informed clinical decision making. To replace the lettering system, narrative summaries of the risk of a drug during pregnancy and discussions of the data supporting those summaries are given to provide more meaningful information to healthcare providers. Because few medications have undergone large-scale testing during human pregnancy, most medications have summaries indicating incomplete knowledge and potential for benefit and harm with drug therapy. More specifically, our present knowledge about the adverse effects of uncontrolled pain and the risks of administering medications during pregnancy remain incomplete. The physician will be left to weigh the risks against the benefits of instituting pharmacologic therapy for each individual.

Use of Medications in the Breastfeeding Mother

Many mothers are inappropriately advised to discontinue breastfeeding or avoid taking essential medications because of fears of adverse effects on their infants. This over cautious approach may be unnecessary in many cases as only a small proportion of medications are contraindicated in breastfeeding mothers or are associated with adverse effects in the infants. The same physicochemical properties that facilitate transplacental drug transfer affect drug accumulation in breast milk. High lipid solubility, low molecular weight, minimal protein binding, and the un-ionized state all facilitate the excretion of medications into breast milk. The neonatal dose of most medications obtained through breastfeeding is 1%–2% of the maternal dose.[5] Even with minimal exposure via breast milk, neonatal drug allergy and slower infant drug metabolism must be considered.[6] Only small amounts of colostrum are excreted during the first few postpartum days. Thus early breastfeeding poses little risk to the infant whose mother received medications during delivery.[7]

Most breast milk is synthesized and excreted during and immediately following breastfeeding. Taking medications after

breastfeeding or when the infant has the longest interval between feedings and avoidance of long-acting medications will minimize drug transfer via breast milk.[8] However, effective treatment of chronic pain often necessitates the use of long-acting medications, particularly long-acting opioids. To weigh the risks and benefits of breastfeeding, multiple factors should be considered: (1) the need for the drug by the mother, (2) the potential effect on milk production, (3) the amount of drug excreted in the milk, (4) the extent of absorption by the infant, (5) potential adverse effect on the infant, (6) the age of the breastfeeding child.

As with the categorical ranking of medications for use during pregnancy, the American Academy of Pediatrics (AAP) retired their grading system for the use of a drug and compatibility with breastfeeding (categories one to three). Per the FDA changes in 2015, labels now must have three headings for breastfeeding risks: risk summary, clinical considerations, and data. In a clinical report published in 2013, the AAP provides guidance to physicians regarding drug exposure and reaffirms the recommendation that most medications are safe during lactation.[9]

It is difficult for any publication to keep up with the rapidly changing information from published studies and drug approvals. Providers prescribing to the lactating mother should be familiar with a current and comprehensive database called LactMed (Drugs and Lactation Database), which can be found through the National Institute of Health.

Medications Commonly Used in Pain Management

Nonsteroidal Anti-inflammatory Drugs (NSAIDs) and Acetaminophen

NSAIDs have both analgesic and anti-inflammatory properties and are commonly used for musculoskeletal pain.[10] Although the exact mechanism of action is uncertain, NSAIDs decrease pain by acting as non-selective inhibitors of cyclooxygenase (COX) and then inhibiting prostaglandin synthesis.[10] During pregnancy, prostaglandins modulate many key processes, including stimulation of uterine activity, maintaining patency of the fetal ductus arteriosus (essential for adequate *in utero* blood flow), and promoting fetal urine production (which contributes to the level of amniotic fluid in the second and third trimesters). As expected, alteration of prostaglandin metabolism then has varied effects on the pregnancy, depending on the timing and duration of use. For example, short-term use of indomethacin in the second trimester is effective for the treatment of pain caused by degenerating fibroids; use for long periods (more than 48 hours) in the third trimester has been associated with narrowing of the ductus arteriosus[11,12] and oligohydramnios.[13] To complicate this picture further, aspirin, the prototypical NSAID, is used in a therapeutic manner in low doses (80–160 mg/day) to decrease the incidence of pregnancy complications in certain high-risk groups but is associated with premature narrowing of the ductus arteriosus at higher doses.[14] Therefore NSAID use in pregnancy must be carefully planned to achieve the proposed benefit and avoid fetal risk. In general, if NSAID use is indicated, the duration should be short (less than 48 hours) without monitoring fetal ductus flow and amniotic fluid volume. All NSAID use for pain should be discontinued by 34 weeks of gestation to prevent pulmonary hypertension in the newborn.[15]

NSAIDs are among the most commonly used drugs during the first trimester of pregnancy.[16,17] Over the counter use of this medication is very common in this population. With their use so common, many women may not realize that there is potential for deleterious effects on them or their developing fetuses. Furthermore, as the age of first-time mothers increases, more women are likely to take NSAIDs for conditions such as joint and musculoskeletal pain. The effects of NSAID exposure on the fetus in the third trimester are well documented, associated with premature narrowing of the ductus arteriosus leading to pulmonary hypertension in the newborn. However, there is controversy as to the risk associated with maternal exposure and other congenital anomalies.[18]

There is no role for routine use of NSAIDs for pain in pregnancy other than that related to rheumatologic disease or uterine fibroids. In the largest published series of NSAID use during pregnancy to date, Ostensen and Ostensen[19] have detailed a series of 88 women with rheumatic disease, comparing the outcome in 45 who received NSAID therapy during pregnancy with 43 who were not treated during pregnancy. The most common agents used were naproxen (23/45) and ibuprofen (8/45). NSAIDs were most frequently used during the first and second trimesters because many patients stopped therapy once pregnancy was recognized. Many of the rheumatic conditions remitted later in pregnancy. They found no significant differences in pregnancy outcome (duration of pregnancy and labor, vaginal delivery rate, maternal bleeding requiring transfusion, or incidence of congenital anomalies) or the health status of offspring at long-term follow up (ranging from six months to 14 years). The authors concluded that NSAID therapy limited to periods of active rheumatic disease until weeks 34–36 did not adversely affect the neonate.[19] However, it is noted that women with rheumatic disease have poor pregnancy outcomes in general; thus these outcome data should not be applied to the general obstetric population.

More recently, Ofori and collegues[18] published a case-control study regarding the risk of congenital anomalies in pregnant users of NSAIDs. Using a population-based pregnancy registry from 1997–2003 in Quebec, they identified 93 births with congenital anomalies in 1056 women (8.8%) who filled prescriptions for NSAIDs in the first trimester of pregnancy, compared to 2478 in 35,331 (7%) women who did not. They concluded that there might be a greater risk of having children with congenital anomalies, particularly those related to cardiac septal closure.

Despite the physiologic effects of NSAIDs, the results of the Collaborative Perinatal Project have suggested that first trimester exposure to aspirin does not pose an appreciable teratogenic risk,[20] nor does ibuprofen or naproxen, the most commonly used NSAIDs. Patients who conceive while taking NSAIDs can be reassured that this will not impair pregnancy outcomes. However, NSAIDs can interfere with implantation and placental circulation. In a population-based cohort study, the risk of miscarriage was 1.8 (95% confidence interval [CI] 1.0, 3.2) with any NSAID use and was increased to 8.1 (95% CI 2.8, 23.4) if used for more than one week around the time of conception.[21]

Aspirin has well known platelet-inhibiting properties and, theoretically, may increase the risk of peripartum hemorrhage. Neonatal platelet function is inhibited for up to five days after delivery in aspirin-treated mothers.[22] Although low dose aspirin therapy (60–80 mg/day) has not been associated with maternal or neonatal complications, higher doses appear to increase the risk of intracranial hemorrhage in neonates born prior to 35 weeks of gestation.[13] Low dose aspirin has been used to improve pregnancy outcomes for women with both preeclampsia and anti-phospholipid antibodies.[23] However, as with other NSAIDs, aspirin crosses the

placenta. Although it has not been implicated in causing congenital abnormalities, it has been associated with an increased risk of vascular disruptions, particularly gastroschisis.[23,24] Data from two retrospective meta-analyses suggest that there may be a two- to three-fold increase risk of gastroschisis with aspirin exposure.[24,25] However, there are reassuring data from over 30,000 women in randomized, control trials of low dose aspirin verses placebo that have not shown any significant risk of intraventricular hemorrhage, other neonatal bleeding, or poor pregnancy outcomes.[23]

Ketorolac is an NSAID available for oral and parenteral administration. According to the manufacturer's prescribing information,[26] ketorolac did not cause congenital disabilities in the offspring of pregnant rabbits. However, ketorolac administration during labor did lead to dystocia in rodents. Ketorolac shares the platelet-inhibiting properties of other NSAIDs.[27] Although ketorolac has not undergone evaluation for its effects on the fetal ductus arteriosus or renal vasculature, it is likely to have effects similar to those of other NSAIDs. Until more information is available, it may be prudent to choose more extensively studied NSAIDs for use during pregnancy.

Based on our clinical experience and a review of the available literature, we have formulated recommendations for the use of NSAIDs during pregnancy (Box 45.1). NSAIDs use in pregnancy must be carefully planned to achieve benefit and avoid fetal risk. In general, if NSAID use is indicated, the duration should be short (48 hours) in the absence of monitoring fetal ductus flow and amniotic fluid volume. Chronic use of NSAIDs should be avoided in pregnancy, especially in the third trimester. Before the 24th week of pregnancy, the use of NSAIDs should be used with caution. It is preferable to use both low dose and short half-life NSAIDs.

Because of the anti-platelet properties of NSAIDs, many anesthesiologists are concerned about the risk of epidural hematoma formation as a result of epidural catheter placement. To date, there are no outcome studies on which to base practice recommendations. There is no evidence that low dose aspirin therapy or the use of other NSAIDs increases the risk of epidural hematoma formation following spinal or epidural placement.[28] As part of our routine history and physical examination of the parturient, we screen for any evidence of bleeding diathesis or easy bruising and, in their absence, proceed with epidural placement without further laboratory testing. This practice is consistent with the practice guidelines published by the American Society of Regional Anesthesia.[29]

Salicylic acid is excreted into breast milk in breastfeeding women, with higher doses of aspirin resulting in disproportionately higher milk concentrations. If continuous, high dose therapy is considered, an alternate drug would be preferred. With the use of daily, low dose aspirin (75 to 325 mg), no aspirin is excreted into breastmilk, and salicylate levels are low. Caution should still be exercised if more than occasional or short term aspirin use is contemplated during lactation because neonates have very slow elimination of salicylates.[30] High-dose aspirin can lead to rashes, platelet abnormalities, and bleeding in nursing infants. As for the use of NSAIDs for pain management in breastfeeding women, ibuprofen is the preferred agent because of its short half-life and safety profile for use in infants. The doses used for infants are much lower than what is excreted in breast milk. While naproxen is considered compatible with breastfeeding, other agents may be preferred because of the longer half-life. Diclofenac and indomethacin are also considered acceptable, but other agents may be preferred because of minimal data available.[31]

Little information is available on the safety of maternal ketorolac use during lactation. One study has found that ketorolac concentrations ranged from 1%–4% of maternal serum levels in breastmilk.[32] The analysis of the breast milk in 10 women given ketorolac 10 mg PO Q6 hours for four days resulted in clinically insignificant levels that the nursing infant would be exposed to.[32] Considering the bioavailability of ketorolac after oral administration, this would likely result in neonatal blood levels between 0.16% and 0.40% of the maternal dose. Ketorolac is commonly given after Cesarean section. However, the colostrum has very little excreted. The manufacturer indicates a contraindication with breastfeeding; therefore another agent should be considered 24–72 hours after birth when more breast milk is produced.

Acetaminophen is a frequently used painkiller and antipyretic drug among pregnant women. It provides similar analgesia without the anti-inflammatory effects seen with NSAIDs. Acetaminophen has no known teratogenic properties, does not inhibit prostaglandin synthesis or platelet function, and is hepatotoxic only in extreme overdosage.[13,33] As with most drugs, there are no controlled studies in pregnant women in the first trimester. In animal studies, acetaminophen has not demonstrated fetal risk. Data obtained from 88,142 patients in the Danish National Birth Cohort (1996–2003) who had information on acetaminophen use during the first trimester of pregnancy indicated that ingestion of acetaminophen during pregnancy is not related to an overall increased prevalence of congenital abnormality or an increased prevalence of the most frequent abnormalities.[34] If persistent pain demands the use of a mild analgesic during pregnancy, acetaminophen appears to be a safe and effective first-choice agent. Acetaminophen does enter breast milk, although maximal neonatal ingestion would be less than 2% of a maternal dose.[35] Acetaminophen is considered compatible with breastfeeding.[9]

• Box 45.1 Recommendations for the Use of NSAIDs During Pregnancy

- Consider non-pharmacologic management or acetaminophen use first.
- Consider the use of a mild opioid or opioid-acetaminophen combination analgesic.
- Continue aspirin or other NSAID if the symptoms cannot be controlled non-pharmacologically or with acetaminophen alone.
- Institute close fetal monitoring during the second trimester. If high doses of NSAIDs are required, periodic fetal ultrasound, including fetal echocardiography, should be used to monitor amniotic fluid volume and patency of the ductus arteriosus.
- Discontinue NSAID use after weeks 34–36 to reduce the risks of peripartum bleeding, neonatal hemorrhage, and persistent fetal circulation.

NSAID, Nonsteroidal anti-inflammatory drug.

Opioid Analgesics

Many women of childbearing age are prescribed opioids for intermittent or continual pain management. Much of our present knowledge about the effects of chronic opioid exposure during pregnancy is derived from the study of opioid-abusing patients.[36-38] Chronic opioid use in pregnancy is associated with low birth weight and decreased head circumference. However, the contribution of comorbidities, including polysubstance abuse and smoking, is not clear. Enrollment and compliance with methadone therapy for opioid dependence improves birth weight and prolongs gestation, supporting the role of therapy during gestation.[38]

Until recently, there was no evidence to suggest a relationship between exposure to any of the opioid agonists or

agonist-antagonists during pregnancy and large categories of major or minor malformations. The Collaborative Perinatal Project monitored 50,282 mother-child pairs and included exposures to codeine, propoxyphene, hydrocodone, meperidine, methadone, morphine, or oxycodone.[20] Only codeine was found to have an association with malformation (respiratory), but other studies have not confirmed this. No evidence was found for either agent to suggest a relationship to large categories of major or minor malformations. In the spring of 2011, a study by Broussard and colleagues used data gathered from the National Birth Defects Prevention Study (1997–2005), which consisted of an ongoing multi-site, population-based, case-control study of over 30 types of major structural congenital disabilities.[39] They reported that opioid treatment between one month prior to pregnancy and through the first trimester was associated with a greater risk of conoventricular septal defects, atrioventricular septal defects, hypoplastic left heart syndrome, spina bifida, and gastroschisis. Codeine and hydrocodone represented 69% of all reported exposures. However, these results should be interpreted with caution, as some sample sizes were borderline, and further investigation is necessary. It is important to understand that the increased relative risk of a rare congenital disability with exposure to medications usually only translates into a modest absolute increase in risk above baseline. Healthcare providers must weigh the risks and benefits when prescribing to pregnant women or those of childbearing age.

It is important to note that there is an increased risk warning for neonatal opioid dependence when mothers are treated with opioid medications for prolonged periods during pregnancy. Abrupt cessation of opioids in the opioid dependent patient late in pregnancy can precipitate fetal withdrawal *in utero*, characterized by fetal tachycardia and fetal death.[40] Therefore pregnant women who are opioid dependent, regardless of whether the use is prescription or illicit, should not undergo acute withdrawal late in pregnancy without careful fetal monitoring. The general recommendation is to offer continuation of narcotic medication (for prescription use) or opioid substitution therapy such as methadone or buprenorphine for women using illicit drugs, with entry into treatment programs.[41-43] Additional benefits of treatment programs include improved prenatal care, higher birth weight, and reduced infectious risk to the neonate.

Neonates exposed to opioid medications *in utero* can develop dependence and manifest withdrawal symptoms in the first few days of life, known as neonatal abstinence syndrome (NAS). Characterized in mild cases by irritability and increased tone, severe neonatal withdrawal is associated with poor feeding and seizures.[44] NAS occurs in 30%–90% of infants exposed to heroin, methadone, or buprenorphine *in utero*[37,38,42,45] when mothers are treated for illicit opioid use. Patients requiring methadone to treat chronic pain tend to require lower doses of methadone, and their infants have a lower incidence of NAS, approximately 11%.[46] Most infants who have narcotic withdrawal are symptomatic by 48 hours postpartum, but there are reports of withdrawal symptoms beginning 7–14 days postpartum.[37] Neonates with prenatal exposure to opiates for long periods may require very slow weaning (as slow as a 10% reduction every third day) to prevent withdrawal symptoms.[47] The AAP considers methadone to be compatible with breastfeeding.[9]

Recognition of infants at risk for NAS and institution of appropriate supportive and medical therapy typically results in little short-term consequence to the infant.[48,49] The long-term effects of *in utero* opioid exposure are unknown. Chasnoff has considered environmental and socioeconomic factors that influence child development and concluded that no definite data exist to demonstrate long-term developmental sequelae from *in utero* opioid exposure.[50]

Buprenorphine, a partial μ-opioid agonist and κ-opioid antagonist, is currently used for office-based treatment of opioid dependence but is increasing in use for the treatment of chronic pain.[51,52] Obstetricians and anesthesiologists will encounter patients treated with buprenorphine with increasing frequency. This drug's low intrinsic receptor efficacy results in a ceiling effect and a diminished risk of overdose compared with methadone.[43] While methadone has been used for over 40 years in the treatment of opioid dependence, buprenorphine is now advocated as first line therapy.[42] The literature that reports buprenorphine in pregnancy remains limited, but buprenorphine has been found to be superior to methadone in reducing signs of withdrawal in newborns, thus requiring less medication and hospitalization time for the babies. In a randomized, double-blind trial comparing 175 women and infants treated with methadone versus buprenorphine, infants who had prenatal exposure to buprenorphine required significantly less morphine for the treatment of NAS, a significantly shorter period of NAS treatment, and significantly shorter hospitalization than those with prenatal exposure to methadone. However, there was no difference in the number of neonates requiring NAS treatment, peak NAS score, head circumference, or any other neonatal or maternal outcome.[43,53] However, in buprenorphine-maintained patients, acute pain can be challenging to treat because of the partial antagonist activity at the mu receptor. While treatment of opioid dependence requires only once-daily dosing, opioid dependent patients receiving buprenorphine with mild pain may receive analgesia simply by splitting the same daily dose into dosing intervals every 6 hours.[54]

According to the drug manufacturer insert, buprenorphine is not recommended during breastfeeding. However, it appears to be safe.[42] Because of the low levels in breast milk and the poor oral bioavailability in the infant, the infant is exposed to about 1%–1.4% of the maternal weight-adjusted dose. The risk of breast milk induced addiction appears unlikely, and there is no reason to time breastfeeding to avoid peak levels of buprenorphine. The amount of buprenorphine in the milk may not be sufficient to prevent neonatal withdrawal, and treatment of the infant may be required.[55]

Fentanyl is one of the most common parenteral opioid analgesics administered during the perioperative period. As with all opioid analgesics, administration of fentanyl to the mother immediately prior to delivery may lead to respiratory depression in the newborn.[56] Maternal administration of fentanyl or other opioids may also cause loss of the normal variability in fetal heart rate. Loss of fetal heart rate variability can signal fetal hypoxemia; thus the administration of opioids during labor may deprive obstetric caregivers of a useful tool for assessing fetal wellbeing.[57]

Meperidine undergoes extensive hepatic metabolism to normeperidine, which has a long elimination half-life (18 hours). Repeated dosing can lead to accumulation, especially in patients with renal insufficiency.[58] Normeperidine causes excitation of the central nervous system that manifests as tremors, myoclonus, and generalized seizures.[59] Significant accumulation of normeperidine is unlikely in the parturient who receives single or infrequent doses. However, meperidine offers no advantages over other parenteral opioids.

Although mixed agonist-antagonist opioid analgesic agents are widely used to provide analgesia during labor, they do not appear to offer any advantage over pure opioid agonists. In a blinded randomized comparison of meperidine and nalbuphine during labor,

the two agents appeared to provide comparable analgesic effects as well as similar neonatal Apgar and neurobehavioral scores.[60] Use of nalbuphine[61] or pentazocine[62] during pregnancy can lead to NAS. Nalbuphine may also cause a sinusoidal fetal heart rate pattern after maternal administration, thereby complicating fetal assessment.[63]

Low-affinity opioid agonists, such as tramadol (Ultram), are being used with increasing frequency, in part because of a perceived lessening of the abuse and addiction potential. There is no evidence that acute use of tramadol for labor analgesia has any advantages over more traditional opioids. According to the manufacturer's prescribing information, no drug related teratogenic effects were observed in the progeny of rats treated orally with combination tramadol and acetaminophen at 1.6 times the maximum human daily dose. However, at this dose, embryo and fetal toxicity consisted of decreased fetal weights and increased supernumerary ribs.[64] The intramuscular application of tramadol in mothers in labor reaches the neonate almost freely, confirming a high degree of placental permeability. The neonate already possesses the complete hepatic capacity for the metabolism of tramadol into its active metabolite.[65] However, the renal elimination of the active tramadol metabolite M1 is delayed, in line with the slow maturation process of renal function in neonates. Neonates born to women who are chronically receiving tramadol during pregnancy carry a risk of withdrawal. There are no studies on the relative rates of NAS comparing tramadol with other opioid analgesics.

Postoperative analgesia for most pregnant women undergoing non-obstetric surgery can be readily provided using narcotic analgesics (Tables 45.1 and 45.2). Fentanyl, morphine, and hydromorphone are all safe and effective alternatives when a potent opioid is needed for parenteral administration. There are a range of safe and effective oral analgesics. For mild pain, acetaminophen alone or in combination with hydrocodone is a good alternative. For moderate pain, oxycodone alone or in combination with acetaminophen is effective. More severe pain may require morphine or hydromorphone, both of which are available for oral administration.

Narcotic analgesics can also be administered into the intrathecal or epidural compartments to provide postoperative analgesia. Such neuraxial administration of hydrophilic agents, e.g. morphine, greatly reduces total postoperative opioid requirements while providing excellent analgesia.[66] Spinal or epidural delivery of opioids can be used to minimize maternal plasma concentrations, thereby reducing placental transfer to the fetus or exposure of the breastfeeding infant.

Maternal use of opioids can result in infant drowsiness, central nervous depression, and even death. Opioids are excreted into breast milk. Pharmacokinetic analysis has demonstrated that breast milk concentrations of codeine and morphine are equal to or somewhat higher than maternal plasma concentrations.[67] Meperidine use in breastfeeding mothers via patient-controlled analgesia (PCA) has resulted in significantly greater neurobehavioral depression of the breastfeeding newborn than equianalgesic doses of morphine.[68] After absorption from the infant's gastrointestinal tract, opioids contained in ingested breast milk undergo significant first-pass hepatic metabolism. Morphine undergoes glucuronidation to inactive metabolites.[67] Meperidine undergoes *N*-demethylation to the active metabolite normeperidine.[69] Normeperidine's half-life is markedly prolonged in the newborn,[70] so that regular breastfeeding leads to accumulation and the resultant risks of neurobehavioral depression and seizures. The AAP considers the use of many opioid analgesics, including codeine, fentanyl, methadone, morphine, and propoxyphene, to be compatible with breastfeeding.[9] There are insufficient data to determine the safety of buprenorphine with breastfeeding. However, the excretion of buprenorphine into breast milk is minimal.[71]

TABLE 45.1 Oral Analgesics for Treating Pain During Pregnancy*

Drug	How Supplied	Equianalgesic Oral Dose (Equianalgesic Oral Dose) (mg)
Acetaminophen	—	325, 500, 625 mg tabs; 500 mg/15 mL elixir
Codeine	60	15, 30, 60 mg tabs; 15 mg/5 mL elixir
Acetaminophen with codeine	—	300 • 15,300 • 30, 300 • 60 mg tabs; 120 • 12/5 mL elixir
Hydrocodone	60	—‡
Acetaminophen with hydrocodone	—	500 • 2.5, 500 • 5, 500 • 7.5, 660 • 10 mg tabs; 500 • 7.5/15 mL elixir
Oxycodone	10	5 mg tabs; 5 mg/5 mL elixir
Acetaminophen with oxycodone	—	325 • 5, 500 • 5 mg tabs; 325 • 5/5 mL elixir
Morphine	20	15, 30 mg tabs; 10, 20 mg/5 mL elixir
Hydromorphone	2	2, 4, 8 mg tabs; 5 mg/5 mL elixir

*There is wide variability in the duration of analgesic action from patient to patient. All the oral agents listed are generally started with dosing every 4–6 hours. The dosing interval can then be adjusted as needed to maintain adequate analgesia.

‡There is no oral formulation of hydrocodone alone available in the United States.

TABLE 45.2 Analgesics for Moderate to Severe Pain During Pregnancy*

Drug	Equianalgesic Parenteral Dose	Equianalgesic Oral Dose
Fentanyl	50 µg	—
Hydromorphone	1 mg	2–4 mg
Morphine	5 mg	30–60 mg
Meperidine	50 mg	150–300 mg

*There is wide variability in the duration of analgesic action from patient to patient. All the parenteral agents listed are generally started with parenteral dosing every 3–4 h and the oral agents every 4–6 h. The dosing interval can then be adjusted as needed to maintain adequate analgesia.

Local Anesthetics

Few studies have focused on the potential teratogenicity of local anesthetics. Lidocaine and bupivacaine do not appear to pose a significant developmental risk to the fetus. In the Collaborative Perinatal Project,[20] only mepivacaine had any suggestion of teratogenicity. However, the number of patient exposures was inadequate to draw conclusions. Animal studies have found that continuous exposure to lidocaine throughout pregnancy does not cause congenital anomalies but may decrease neonatal birth weight.[72] Continuous exposure to local anesthetics is unusual but might be seen with the frequent use of local anesthetic patches or creams, which are used for postherpetic neuralgia and other neuropathic pain states.

Neither lidocaine nor bupivacaine appear in measurable quantities in breast milk after epidural local anesthetic administration during labor.[7] Intravenous infusion of high doses (2–4 mg/min) of lidocaine to suppress cardiac arrhythmias has led to minimal levels in breast milk.[73] Based on these observations, continuous epidural infusion of dilute local anesthetic solutions for postoperative analgesia should result in only small quantities of drug reaching the fetus. The AAP considers local anesthetics to be safe for use in the nursing mother.[9]

Mexiletine is an orally active antiarrhythmic agent with structural and pharmacologic properties similar to those of lidocaine. This agent has shown promise in the treatment of neuropathic pain. Mexiletine is lipid-soluble and freely crosses the placenta. There are no controlled studies in humans of mexiletine use during pregnancy. However, studies in rats, mice, and rabbits using doses up to four times the maximum daily dose in humans have demonstrated an increased risk of fetal resorption but not teratogenicity.[74] Mexiletine appears to be concentrated in breast milk. However, based on expected breast milk concentrations and average daily intake of breast milk, the infant would receive only a small fraction of the usual pediatric maintenance dose of mexiletine.[75] The AAP considers mexiletine use to be compatible with breastfeeding.[9]

Steroids

Corticosteroids may be used commonly in pregnancy in patients with autoimmune disease and those with premature rupture of membranes. There is variability in placental metabolism and transplacental passage of steroids depending on the preparation.[10] Most corticosteroids cross the placenta, although prednisone and prednisolone are inactivated by the placenta,[2] while dexamethasone and betamethasone do not undergo significant metabolism.[10] Fetal serum concentrations of prednisone are less than 10% of maternal levels. No increase in malformations was seen among 145 patients exposed to corticosteroids during their first trimester of pregnancy.[20] The use of corticosteroids during a limited trial of epidural steroid therapy in the pregnant patient probably poses a minimal fetal risk (see further discussion later in this chapter).

In breastfeeding mothers, less than 1% of a maternal prednisone dose appears in the nursing infant over the next three days.[76] This amount of steroid exposure is unlikely to affect infant endogenous cortisol secretion.[76]

Benzodiazepines

Benzodiazepines are among the most frequently prescribed drugs and are often used as anxiolytic agents to treat insomnia and as skeletal muscle relaxants in patients with chronic pain.[77] First trimester exposure to benzodiazepines may be associated with an increased risk of congenital malformations. Diazepam may be associated with cleft lip or cleft palate,[78] and with congenital inguinal hernia.[79] However, epidemiologic evidence has not confirmed the association of diazepam with cleft abnormalities. The incidence of cleft lip and palate remained stable after the introduction and widespread use of diazepam.[80] Epidemiologic studies have confirmed the association of diazepam use during pregnancy with congenital inguinal hernia.[80] Benzodiazepine use immediately before delivery also increases the risk of fetal hypothermia, hyperbilirubinemia, and respiratory depression.[81]

Two other benzodiazepines have been evaluated for teratogenicity. Chlordiazepoxide has been reported to produce a four-fold increase in congenital anomalies, including spastic diplegia, duodenal atresia, and congenital heart disease.[82,83] However, a study of over 200,000 Michigan Medicaid recipients did not support these earlier findings.[84] Instead, this study found a high co-prevalence of alcohol and illicit drug use in patients receiving benzodiazepines. Benzodiazepine use alone did not appear to be a risk factor for congenital anomalies. Oxazepam use during pregnancy has also been associated with congenital anomalies, including a syndrome of dysmorphic facial features and central nervous system defects.[85] In addition to the risks of teratogenesis, neonates who are exposed to benzodiazepines *in utero* may experience withdrawal symptoms immediately after birth.[86]

Diazepam and its metabolite desmethyldiazepam in the breastfeeding mother can be detected in the infant's serum for up to 10 days after a single maternal dose. This is caused by the slower metabolism in neonates than in adults.[87] Clinically, infants who are nursing from mothers receiving diazepam may show sedation and poor feeding.[87] It appears most prudent to avoid any use of benzodiazepines during organogenesis, near the time of delivery, and during lactation.

Anti-depressants

Anti-depressants are often used in the management of migraine headaches, as well as for analgesic and anti-depressant purposes in chronic pain states. Selective serotonin reuptake inhibitors (SSRIs) have become the mainstay for the treatment of depression and are widely prescribed. As with most medications, increased use has been associated with increased reports of adverse effects in pregnancy and neonates. Although initially thought to be safe in early pregnancy, unpublished epidemiologic reports from GlaxoSmithKline have raised concern that paroxetine, one of the most widely prescribed anti-depressants, may be associated with an increase in malformations when used in the first trimester, particularly cardiovascular malformations.[88] This recent retrospective epidemiologic study of 3581 pregnant women exposed to paroxetine or other anti-depressants during the first trimester has suggested an increased risk of overall major congenital malformations for paroxetine than other anti-depressants (odds ratio [OR], 2.20; 95% CI, 1.34–3.63). There was also an increased risk for cardiovascular malformations with the use of paroxetine than other anti-depressants (OR, 2.08; 95% CI, 1.03–4.23); 10 out of 14 infants with cardiovascular malformations had ventricular septal defects. Use late in pregnancy has also recently become a concern, with reports of NAS, including jitteriness or seizures,[89] and pulmonary hypertension in the newborn.[90] While paroxetine is generally discouraged in pregnancy, citalopram, and sertraline are considered an option and have not been associated with congenital disabilities. It is important to note that although the relative risk of adverse outcomes has increased, the incidence of malformations (1%–3%)

and pulmonary hypertension (0.5%–1%) remain low, whereas the presence of severe depression in pregnant women is high (15%). As with all medications, the risk of no medication must be carefully weighed against the risk of treatment. Many women will need to remain on anti-depressants throughout pregnancy, and the low incidence of adverse outcomes remains reassuring.

Although tricyclic anti-depressants have had a more limited role in the treatment of depression, they can be of benefit in patients with chronic pain.[91] Amitriptyline is teratogenic in hamsters (encephaloceles) and rats (skeletal defects).[13] Imipramine has been associated with several congenital disabilities in rabbits but not in rats, mice, or monkeys.[92] Although there have been case reports of human neonatal limb deformities after maternal amitriptyline and imipramine use, large human population studies have not revealed association with any congenital malformation, with the possible exception of cardiovascular defects after maternal imipramine use.[13] There have been no reports linking maternal desipramine use with congenital disabilities. Withdrawal syndromes have been reported in neonates born to mothers using nortriptyline, imipramine, and desipramine, with symptoms including irritability, colic, tachypnea, and urinary retention.[13]

Amitriptyline, nortriptyline, and desipramine are all excreted into human milk. Pharmacokinetic modeling has suggested that infants are exposed to about 1% of the maternal dose.[93] In a critical review of the literature regarding the use of anti-depressants during breastfeeding, Wisner and colleagues have concluded that amitriptyline, nortriptyline, desipramine, clomipramine, and sertraline are not found in quantifiable amounts in nurslings and reported no adverse effects. They recommended the use of these agents as the anti-depressants of choice for breastfeeding women.[93] Fluoxetine is also excreted into human milk and has a milk-to-plasma ratio of about 0.3. No controlled studies are available to guide fluoxetine therapy during lactation.[13] However, colic and high infant serum levels have been reported.[94] Maternal doxepin use has also been associated with elevated plasma levels of the metabolite *N*-desmethyldoxepin and respiratory depression in a nursing infant.[95] The AAP considers all anti-depressants to have unknown risk during lactation.[9]

Duloxetine, a selective norepinephrine reuptake inhibitor (SNRI), is representative of a new class of drug that combines inhibition of serotonin and norepinephrine reuptake. Duloxetine is efficacious for depression and neuropathic pain and may have particular efficacy in diabetic neuropathy. Neonates born to mothers receiving SSRI or SNRI drugs may have a withdrawal reaction, as discussed earlier. Although the relative risks and benefits of breastfeeding when a woman is receiving duloxetine have not been fully evaluated, the manufacturer advises against its use during breastfeeding.

Anti-convulsants

Several anti-convulsant medications are used in chronic pain management. However, most data regarding the fetal risk of major malformation in women taking anti-convulsants are derived from the treatment of epilepsy. Although epilepsy itself is not associated with an increased risk of congenital malformations, some theoretical risk may exist. Despite this, data from anti-convulsant use in epileptic women is used to assess the risk of the same medications when used for pain conditions. The American Academy of Neurology and American Epilepsy Society subcommittee recently undertook a systematic review of the evidence for teratogenic potential and perinatal outcomes among pregnant women on antiepileptic medication.[96,97] The review found that valproic acid exposure, especially in the first trimester, contributes to neural tube defects, facial cleft, and possibly hypospadias. They also found that neonates of women taking anti-convulsants were also more likely to be small for gestational age and have lower Apgar scores. Treatment with valproic acid is more likely to be associated with major congenital malformation than treatment with carbamazepine or lamotrigine. There is a possible dose relationship for the development of congenital malformations for valproic acid during the first trimester. Though not consistent throughout all studies, a valproic acid dose of greater than 1000 mg daily may be associated with the greatest risk of malformations.

In the same review, carbamazepine was associated with an increased risk of cleft palate, but this was not confirmed by another study focusing specifically on carbamazepine using the European Surveillance of Congenital Anomalies (EUROCAT) database. Though this study did not find an association between carbamazepine and clefts, it did find an association with spina bifida.

Data suggests that topiramate (Topamax) and its generic version increase the risk of cleft lip and cleft palate in babies born to women who use the medication during pregnancy.[98] Its use has also been linked to low birth weight.[99]

Gabapentin is an anti-convulsant that is being used for the treatment of neuropathic pain syndromes. Little information exists about the safety of gabapentin in pregnant women, and thus far, the Gabapentin Registry Study does not show an increased risk for adverse maternal and felt events.[100] In their prescribing information, the manufacturer[101] has reported a series of nine women who received gabapentin during their pregnancies. Four women elected pregnancy termination, four had normal outcomes, and one neonate had pyloric stenosis and an inguinal hernia. Insufficient data exist to counsel patients regarding the fetal risk of gabapentin use during pregnancy.

A drug similar to gabapentin is pregabalin, which combines anti-convulsant activity and affinity to the γ-aminobutyric acid receptor. The main applications of pregabalin are for the treatment of pain associated with diabetic neuropathy and postherpetic neuralgia.

Patients contemplating childbearing who are receiving anti-convulsants should have their pharmacologic therapy critically evaluated. Those taking anti-convulsants for neuropathic pain should strongly consider discontinuation during pregnancy, particularly during the first trimester. Consultation with a perinatologist is recommended if continued use of anti-convulsants during pregnancy is being considered. Frequent monitoring of serum anti-convulsant levels and folate supplementation should be initiated, and maternal α-fetoprotein screening may be considered to detect fetal neural tube defects.

The use of anti-convulsants during lactation does not seem to be harmful to infants. Phenytoin, carbamazepine, and valproic acid appear in small amounts in breast milk, but no adverse effects have been noted.[13] There are limited data on both pregabalin and gabapentin.

Ergot Alkaloids

Ergotamine can have significant therapeutic efficacy for the episodic treatment of migraine headaches. However, even low doses of ergotamine are associated with significant teratogenic risk, and higher doses have caused uterine contractions and spontaneous abortion.[91] During lactation, ergot alkaloids are associated with neonatal convulsions and severe gastrointestinal disturbances.[13] Occasionally, methyl-ergonovine is systemically administered to treat uterine atony and maternal hemorrhage immediately after delivery. This brief exposure does not contraindicate breastfeeding.[102]

Caffeine

Caffeine is a methylxanthine often used in combination with analgesics for the management of vascular headaches. It is readily absorbed from the gastrointestinal (GI) tract and crosses the placenta such that concentrations in the fetus are similar to maternal plasma levels.[103] Early studies of caffeine ingestion during pregnancy suggested an increased risk of intrauterine growth retardation, fetal demise, and premature labor,[104] while more recent studies do not.[105] Although the data are not strongly compelling against caffeine use in pregnancy, most obstetricians recommend that pregnant women limit caffeine intake to less than 300 mg per day. To date, there is no evidence for congenital disabilities related to caffeine.[106]

Caffeine use is also associated with certain cardiovascular changes. Ingestion of modest doses of caffeine (100 mg/m^2, a dose similar to that found in two cups of brewed coffee) in caffeine-naïve subjects produces modest cardiovascular changes in mother and fetus, including increased maternal heart rate and mean arterial pressure, increased peak aortic flow velocities, and decreased fetal heart rate.[107] The modest decrease in fetal heart rate and increased frequency of fetal heart rate accelerations may confound the interpretation of fetal heart tracings. Caffeine ingestion is also associated with an increased incidence of tachyarrhythmia in the newborn, including supraventricular tachyarrhythmias, atrial flutter, and premature atrial contractions.[108] Many over-the-counter analgesic formulations contain caffeine (typically in amounts from 30–65 mg/dose), and the use of these preparations must be considered when determining total caffeine exposure.

Moderate ingestion of caffeine during lactation (up to two cups of coffee/day) does not appear to affect the infant. Breast milk usually contains less than 1% of the maternal dose of caffeine, with peak breast milk levels appearing 1 hour after maternal ingestion. Excessive caffeine use may cause increased wakefulness and irritability in the infant.

Sumatriptan

Sumatriptan is a selective serotonin agonist that has achieved widespread use because of its efficacy in the treatment of migraine headaches. It has been associated with fetal malformations in rabbits but not in rats.[109] Limited data in humans have not demonstrated any strong teratogenic effects.[91,110] Sumatriptan is advantageous in the treatment of migraine headache in pregnancy because it does not share uterine contractile properties with ergotamine and would not likely have abortifacient effects.[111] Beginning in January 1996, Glaxo Welcome established a registry to prospectively evaluate the risk of sumatriptan use during pregnancy.[112] The accumulated evidence from sumatriptan's pregnancy registry and other studies suggest that this drug is a safe therapeutic option for the treatment of migraine attacks in pregnant women.

A minimal amount of sumatriptan is excreted into breast milk, and it is considered safe in breastfeeding. The use of sumatriptan during lactation has not been well studied. One study of a single 6 mg dose of subcutaneous sumatriptan given to lactating women found total breast milk sumatriptan to be only 0.24% of the maternal dose. Because sumatriptan is poorly absorbed from the infant GI tract, only 14% of the drug ingested by the fetus would be bioavailable. Even this minor exposure could be largely avoided by expressing and discarding all milk for 8 h after injection.[113]

β-Blockers

Propranolol and other β-blockers are used for chronic prophylaxis against migraine and non-migraine vascular headaches. Most of the studies on β-blocker use during pregnancy involve women being treated for hypertension instead of migraine prophylaxis, and hypertension itself may increase the risk for SGA.[114] A 2009 Cochrane review looking at β-blocker use for mild to moderate hypertension during pregnancy found that the effect of β-blockers on the perinatal outcome is unclear.[115] There is no evidence that propranolol is teratogenic. Fetal effects noted with maternal consumption of propranolol include decreased weight, potentially because of a modest decrease in maternal cardiac output, with consequent diminished placental perfusion.[116] Patients should be aware that fetal toxicity can result in complications, including intrauterine growth retardation, hypoglycemia, bradycardia, and respiratory depression.[116] Longer acting agents should lead to less fluctuation in maternal and fetal blood concentrations and perhaps less fluctuation in the drug effects on fetal heart rate. In the lactating mother, propranolol doses of up to 240 mg/day appear to have minimal neonatal effects, resulting in subtherapeutic exposure to the infant.

Marijuana

Marijuana is the most commonly used dependent substance in pregnancy.[117] This is likely because of increased use in the generalized population for medical and recreational use and de-stigmatization of the substance. California first made marijuana legal in 1996, and its use in the United States has steadily increased since that time. At the time of writing this chapter, 33 states and the District of Columbia have medical cannabis programs, 11 states have legalized recreational use, and another 16 states have decriminalized. This increase in legalization has also increased the perception of safety, although the chemical concentration of tetrahydrocannabinol (THC) has increased dramatically. While the potency of THC was about 4% on average in marijuana in 1995, it has increased to about 12% now. Over a similar time frame, the number of women of reproductive age who believe there is no risk to regular marijuana use has increased from 4.6%–19%.[118]

The American College of Obstetricians and Gynecologists[118] and the Centers for Disease Control[117] currently recommend that all pregnant women are screened for the use of marijuana and encouraged to discontinue use during pregnancy. It is known that THC does cross the placenta and into breast milk, resulting in fetal and neonatal exposure. There is a limitation of evidence for outcomes with marijuana use during pregnancy and breastfeeding as most of the studies are retrospective and based on patient self-reporting, likely leading to underreporting. Additionally, many studies do not adjust for confounding factors such as tobacco use and socioeconomic status. However, there is enough human and animal data to suggest potential harm with the use of cannabis. Marijuana use may be associated with long-term adverse neurobehavioral outcomes, preterm birth, stillbirth, growth restriction, and neonatal intensive care admissions. Therefore women should be educated to refrain from marijuana use during pregnancy and lactation.[118]

Evaluation and Treatment of Pain During Pregnancy

Pain medicine specialists may be asked to consult on patients with uncontrolled pain during the course of pregnancy. Often, severe pain can arise from an extreme form of one of the more common

musculoskeletal pain syndromes of pregnancy, including abdominal wall and ligamentous pain, hip pain, and pelvic girdle pain. Thus working knowledge of the painful musculoskeletal conditions that occur during pregnancy is essential. Low back pain and migraine headaches are very common and will be discussed during pregnancy because these are among the most common problems encountered in practice. Finally, although sickle cell pain crisis is less common, it provides a good example of the approach to managing chronic recurrent pain during the course of pregnancy and will be discussed below

Musculoskeletal Considerations in Pregnancy

Abdominal Wall and Ligamentous Pain

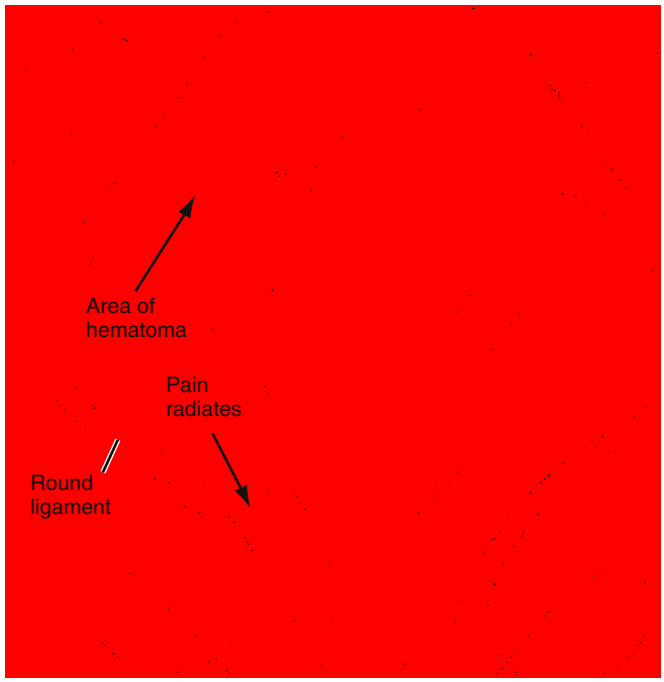
Abdominal wall pain during pregnancy typically results in prompt evaluation by an obstetrician. One of the most common causes of abdominal pain early in pregnancy is miscarriage, which presents with abdominal pain and vaginal bleeding. Unruptured ectopic pregnancy and ovarian torsion may present with vague hypogastric pain and suprapubic tenderness. Once these conditions requiring the immediate attention of an obstetrician have been ruled out, myofascial causes of abdominal pain should be considered.

The round ligaments stretch as the uterus rises in the abdomen. If the pull is too rapid, small hematomas may develop in the ligaments (Fig. 45.1). This usually begins at 16–20 weeks of gestation, with pain and tenderness localized over the round ligament, which radiates to the pubic tubercle.[119] Treatment is bed rest and local warmth, along with oral analgesics in more severe cases.

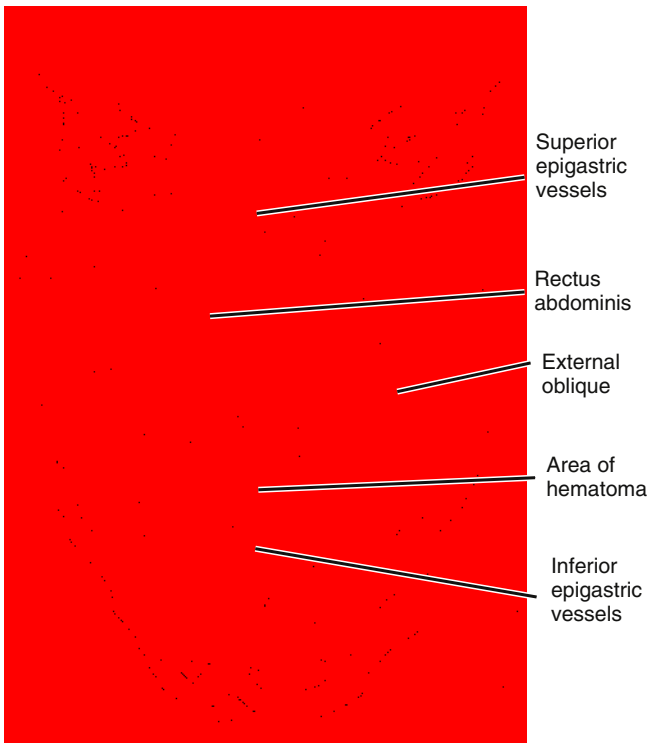
Less common is abdominal pain arising from hematoma formation within the sheath of the rectus abdominis muscle (Fig. 45.2). As the uterus expands, the muscles of the abdominal wall become greatly overstretched. Rarely, the rectus muscle may dehisce, or the inferior epigastric veins rupture behind the muscle. Severe pain localized to a single segment of the muscle often follows a bout of sneezing. Diagnosis of rectus hematoma is made when localized pain is exacerbated by tightening the abdominal muscles (raising the head in the supine position). Ultrasonography can help confirm the diagnosis. Conservative management with bed rest, local heat, and mild analgesics are often all that is needed.

Hip Pain

Two relatively rare conditions, osteonecrosis and transient osteoporosis of the hip, occur with somewhat greater frequency during pregnancy.[120] Although the exact cause is unknown, high levels of estrogen and progesterone in the maternal circulation and increased interosseous pressure may contribute to the development of osteonecrosis.[121] Transient osteoporosis of the hip is a rare disorder characterized by pain and limitation of motion of the hip and osteopenia of the femoral head.[122] Both conditions present with hip pain during the third trimester, which may be sudden or gradual in onset. Osteoporosis is easily identified, with plain radiography demonstrating osteopenia of the femoral head and preservation of the joint space. Osteonecrosis is best evaluated with magnetic resonance imaging (MRI), which will demonstrate changes before they appear on plain radiographs. Both conditions are managed symptomatically during pregnancy. Limited weight bearing is essential in transient osteoporosis of the hip to avoid fracture of the femoral neck.[122]



• **Figure 45.1** Abdominal pain arising from stretch and hematoma formation in the round ligament usually presents between 16 and 20 weeks of gestation, with pain and tenderness over the round ligament, which radiates to the pubic symphysis. (Adapted with permission from Chamberlain G. ABC of antenatal care. Abdominal pain in pregnancy. *Br Med J.* 1991;302:1390–1394.)



• **Figure 45.2** Stretch of the abdominal wall in pregnancy can tear the rectus abdominis muscle or inferior epigastric veins and form a painful hematoma within the rectus sheath. Pain is well localized and can be severe, often starting after a bout of coughing or sneezing. (Adapted with permission from Chamberlain G. ABC of antenatal care. Abdominal pain in pregnancy. *Br Med J.* 1991;302:1390–1394.)

• Box 45.2 Signs and Symptoms of the Syndrome of "Pelvic Girdle Pain"

- A history of time- and weight-bearing–related pain in the posterior pelvis, deep to the gluteal area
- A positive "posterior pelvic provocation test" (Fig. 45.5)
- A pain drawing with well defined markings of stabbing pain in the buttocks distal and lateral to the L5–S1 area, with or without radiation to the posterior thigh or knee, but not into the foot (Fig. 45.6)
- Free movements in the hips and spine and no nerve root symptoms
- Pain when turning in bed

Pelvic Girdle Pain

Causative Factors and Clinical Presentation

Pelvic girdle pain (PGP) is a clinical syndrome with pain localized from the posterior iliac crest and gluteal fold over the anterior and posterior elements of the bony pelvis. Many other terms have described the syndrome, including symphysis pubis dysfunction, pelvic joint insufficiency, pelvic girdle relaxation, and posterior pelvic pain.[123] This pain entity is distinct from pregnancy related low back pain (Box 45.2). Pain is often described as stabbing, sometimes burning in the region of the sacroiliac joints, and can extend anteriorly to the region of pubic symphysis. Radiation patterns can include the groin, perineum, and posterior thigh in a non-dermatomal pattern. The location of pain can change during the course of pregnancy. Onset can be from the first trimester to one month postpartum, though most regard the third trimester as the peak of symptoms. In most patients, symptoms subside by six months postpartum. The incidence is difficult to establish given various diagnostic criteria used. Some report the incidence to be between 16% and 25%.[124,125]

The cause of PGP remains unclear but is likely multifactorial with mechanical, hormonal, and genetic influences. Mechanical factors relate to the separation of the pubic symphysis during pregnancy. Hormonal changes include elevated levels of progesterone and relaxin. Genetic influence is based on epidemiologic findings of increased prevalence among first-degree relatives.

Back Pain

Causative Factors and Clinical Presentation

Pregnancy related low back pain (PLBP) is characterized as pain in the lumbar region. Fifty percent of women will experience low back pain during pregnancy, which is commonly looked upon as a normal part of pregnancy (Fig. 45.3).[126] In one-third of pregnant women, back pain is a severe problem that compromises everyday activity.[127] The pain resembles the low back pain of the nonpregnant state and is often described as dull and aching in nature. There can be a limitation to the range of motion of the lumbar spine, and the pain is exacerbated by both forward flexion and palpation of the erector spinae muscles.[128]

As with PGP, the cause of PLBP is likely multifactorial. To balance the anterior weight of the womb, the lumbar lordosis becomes markedly accentuated during pregnancy and may represent a mechanical cause for the pain.[129] Endocrine changes during pregnancy may also play a role in the development of back pain. Relaxin, a polypeptide secreted by the corpus luteum, softens the ligaments around the pelvic joints and cervix, accommodating the developing fetus and facilitating vaginal delivery. This laxity may cause pain by allowing an exaggerated range of motion.[130]

The onset of low back pain is usually around the 18th week of pregnancy, with the peak intensity between the 24th and 36th weeks.[128] However, the pain can start as early as the first trimester or as late as three weeks postpartum. Sixteen percent of women with PLBP report persistent pain six years later, thus representing pregnancy as a risk factor for persistent low back pain.[131] Although radicular symptoms often accompany low back pain during pregnancy, herniated nucleus pulposus (HNP) only has an incidence of 1:10,000.[132] Pregnant women do not have an increased prevalence of lumbar disc abnormalities.[133] Direct pressure of the fetus on the lumbosacral nerves or lumbar plexus has been postulated as the cause of radicular symptoms.

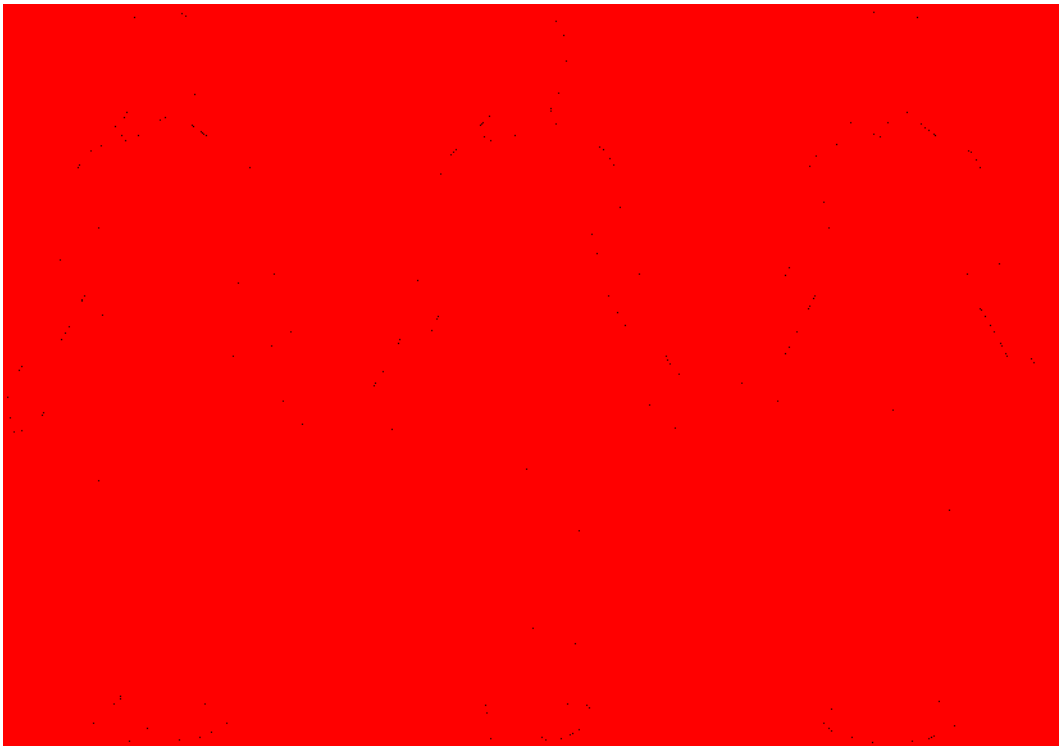
Evaluation of the Patient With Back and Pelvic Girdle Pain

Evaluation of the pregnant patient with low back pain and PGP must begin with a thorough history and physical examination.[134] The aim is to exclude other causes of pain as obstetric complications (preterm labor, abruption, degeneration of uterine fibroids, round ligament pain, and chorioamnionitis) may also present with low back pain.[135,136] Urologic disorders, including hydronephrosis, pyelonephritis, and renal calculi, may also present with low back discomfort.[137] Major morphologic changes occur in the collecting system of pregnant women, including dilation of the calices, renal pelvis, and ureters (Fig. 45.4).[138] The physical examination should include complete back and neurologic evaluations. Particular attention should be directed toward the pelvis and sacroiliac joints during the examination. Posterior pelvic pain (sacroiliac dysfunction) can often be distinguished from other causes of low back pain based on physical examination (Figs. 45.5 and 45.6; Table 45.3; Box 45.2). During the physical examination, positive straight leg raise (typical low back pain with or without radiation to the ipsilateral lower extremity) is consistent with sacroiliac subluxation or HNP. Unilateral loss of knee or ankle reflex or the presence of a sensory or motor deficit is suggestive of lumbar nerve root compression.

X-ray imaging techniques such as computed tomography are not ideal in pregnancy. However, pregnancy is not an absolute contraindication to radiographic evaluation. Radiation exposure during pregnancy leads to concerns about resultant congenital anomalies, mental retardation, and increased risk of subsequent cancers.[139] No detectable growth or mental abnormalities have been associated with fetal exposure to less than 10 rad; the dose received during a typical three-view spinal series typically does not exceed 1.5 rad.[140] Plain radiographs will contribute vital information primarily when fracture, dislocation, and destructive lesions of the bone are suspected.

MRI has revolutionized diagnostic imaging during pregnancy, proving effective and reliable in the diagnosis of many structural abnormalities.[141] Although MRI appears to be safe during pregnancy, there are no long-term studies examining the safety of fetal exposure to intense magnetic fields during gestation.[142] Schwartz[140] has presented a thorough and insightful review of neurodiagnostic imaging of the pregnant patient. Practical guidelines for the use of radiographic studies in the evaluation of pregnant patients are given in Box 45.3.

Electromyography and nerve conduction studies (collectively referred to as EMG) serve as good screening tests in patients with new onset of low back pain accompanied by sensory or motor

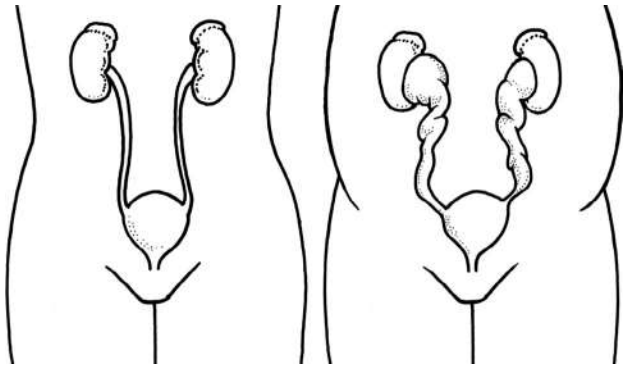


• **Figure 45.3** A group of 855 women studied between 12 menstrual weeks of pregnancy and delivery reported three types of pain. Back pain was reported by 49% of the women at some point during pregnancy. **A,** High back pain (10%). **B,** Low back pain (40%). **C,** Sacroiliac pain (50%). (Adapted with permission from Ostgaard HC, Andersson GBJ, Karlsson K. Prevalence of back pain in pregnancy. *Spine.* 1991;16:549–552.)

symptoms. When the clinical presentation is confusing, EMG can aid in differentiating peripheral nerve lesions, polyneuropathies, and plexopathies from single radiculopathies. However, false-negative EMG results are common, especially in the case of a HNP causing compression of a single nerve root.[143]

Prevention and Treatment of Back and Pelvic Girdle Pain

Few of the commonly used strategies to prevent low back pain during pregnancy are universally effective. Patients who were instructed in basic lifting techniques experienced significantly less backache than a control group who did not receive similar instruction.[144] Aerobic exercise can be prescribed safely throughout pregnancy.[144] However, maintenance of good physical conditioning may not alter the incidence of back pain during pregnancy.[145] Nonetheless, the American College of Obstetricians



• **Figure 45.4** Elevated progesterone levels and pressure from the expanding uterus lead to dilation of the ureters in pregnancy. Stasis in the urinary tract can lead to pyelonephritis. • **Figure 45.6** Areas where pain is felt when the posterior provocation test is performed in women with posterior pelvic pain. (Adapted with permission from Ostgaard HC, Zetherström G, Roos-Hanson E, et al. Reduction of back and posterior pelvic pain in pregnancy. *Spine.* 1994;19:894–900.)

and Gynecologists recommends specific muscular conditioning exercises to promote good posture and prevent low back pain during pregnancy.[146]

Treatment of pregnancy related low back and PGP begins with the education of the common causes of pain during pregnancy. Back care classes are available that focus on anatomy, ergonomics, correct posture, and relaxation techniques. If the pain remains poorly controlled, referral to a physical therapist for instruction in body mechanics and low back exercises may be beneficial. In a recent Cochrane review of the treatment of low back pain, pregnant-specific exercise programs, physiotherapy, and acupuncture added to the usual prenatal care appeared to reduce back pain more than just usual prenatal care. Moreover, acupuncture may be more effective than physiotherapy. Participation in water gymnastics programs also reduced the number of back pain related work absences.[147]

Although the incidence of HNP during pregnancy is low, radicular symptoms are common and often accompany sacroiliac subluxation and myofascial pain syndromes. The use of epidural steroids outside of pregnancy remains controversial.[148] The strongest evidence for the efficacy of epidural steroids appears to be in patients with symptoms attributable to acute disk pathology.[149] Whereas the risk to the fetus following a single dose of an epidural corticosteroid appears to be low, it is our opinion that epidural steroids should be reserved for the parturient with the new onset of signs (e.g. unilateral loss of deep tendon reflex, sensorimotor change in a dermatomal distribution) and symptoms consistent with lumbar nerve root compression. We believe that it is reasonable to proceed with epidural steroid placement prior to obtaining imaging studies in such patients. Resolution of the radicular symptoms after epidural steroid treatment may well obviate the need for imaging studies.

Guided local anesthetic injection into the sacroiliac joint or the pubic symphysis can have diagnostic and therapeutic value.

TABLE 45.3 Sacroiliac Subluxation: Criteria for Diagnosis and Common Confirmatory Signs

Criterion or Sign	Description
Diagnostic Criterion	
Sacral pain	The pain is usually unilateral and, in some cases, radiates to the buttock, lower abdomen, anterior medial thigh, groin, or posterior thigh.
Positive Piedallu's sign	Forward flexion of the lower back results in asymmetric movement of the posterior superior iliac spines (PSISs), with one PSIS becoming higher than the other.
Positive pelvic compression	Pain in the sacral area is provoked by direct bilateral downward pressure on the anterior superior iliac spines (ASISs).
Asymmetry of the ASIS	The ASISs should be examined with the patient in the supine position to eliminate the effect of leg length discrepancy; in sacroiliac subluxation, one ASIS will be higher than the other.
Confirmatory Sign	
Straight leg raise	Passive raising of the patient's leg, with the knee extended and the patient in the supine position, causes pain, usually at the end range.
Flexion block	With the patient in the supine position, the knee is flexed at 90 degrees and then passively pressed toward the chest; flexion is blocked to half the expected range on the painful side.
Positive Patrick's test	Placing one heel on the opposite knee, in the recumbent position, and simultaneously rotating the leg outward provokes pain.
Pain at Baer's point	A point of acute tenderness is found just to the side and below the umbilicus on the painful side, which is about one-third of the way between the umbilicus and ASIS.

• Box 45.3 Recommendations for the Use of Neurodiagnostic Imaging in the Pregnant Patient

- Determine the necessity of a radiologic examination and the risks involved.
- If possible, perform the examination only during the first 10 postmenses days. If the patient is pregnant, delay the examination until the third trimester, or preferably postpartum.
- Determine the most efficacious use of radiation for the problem.
- Use magnetic resonance imaging (MRI) if possible.
- Avoid direct exposure to the abdomen and pelvis.
- Avoid contrast agents.
- Do not avoid radiologic testing purely for the sake of pregnancy. Remember, you are responsible for providing the best possible care for the patient. The risk to the pregnant patient of not having an indicated radiologic examination is also an indirect risk to the fetus.
- If significant exposure is incurred by a pregnant patient, have a radiation biologist (usually stationed in the radiology department) review the radiology examination history carefully so that an accurate dose estimate can be ascertained.
- The decision to terminate pregnancy because of excessive radiation exposure is an extremely complex issue. Because any increased risk of malformations is considered negligible unless radiation doses exceed 0.1–0.15 Gy (10–15 rad). The amount of exposure that an embryo or fetus would likely receive from diagnostic procedures is well below the level for which a therapeutic abortion should be considered.
- Consent forms are neither required nor recommended. The patient should be informed verbally that any radiologic examinations ordered during pregnancy are considered necessary for her medical care. She should also be informed that the risks to the fetus from computed tomography or plain film radiography are very low and that there are no known risks to humans of MRI. Having the patient sign a consent increases the perceived risks and adds needlessly to her concerns during and after the examination.

• Figure 45.7 Proper placement of a trochanteric belt to stabilize painful pelvic joints and decrease back pain.

As mentioned previously, most clinicians wish to limit exposure to ionizing radiation during pregnancy. Surface ultrasound can be used to aid in entry into the sacroiliac joint. Relief after an intra-articular injection is indicative only of intra-articular pathology. Extra-articular pathologies contributing to PGP, such as strain of superficial long sacroiliac joint ligament, are unlikely to improve after intra-articular injection.

Treatment options during pregnancy are limited by the presence of and potential hazard to the fetus. After delivery, the majority of women have improvement of their symptoms within a few months. Non-pharmacologic treatment modalities used during pregnancy include physical therapy with pelvic tilt exercises, use of support belts (Fig. 45.7), rotational manipulation of the sacroiliac joint, water gymnastics, transcutaneous electrical nerve stimulation (TENS), and acupuncture.[147] With the use of the TENS unit during pregnancy, there is a theoretical concern about inadvertent induction of labor through the use of certain acupuncture points and fetal cardiac conduction disturbances with the passage of current through the fetal heart. Limited data suggest that TENS is safe during pregnancy. A recent Cochrane review on the use of TENS for the treatment of pain during labor found no deleterious effects on the mother or the fetus.[150] Given the theoretical concerns, one recommendation for TENS use during pregnancy is to keep the current density low and avoid certain acupuncture points.[151]

Migraine Headache During Pregnancy

Causative Factors and Clinical Presentation

The clinician is often confronted with the occurrence of headaches during pregnancy as recurring headaches happen most commonly during the childbearing years. Migraine can be a disabling disorder that is more prevalent among women than men, thought in part because of the influence of female sex hormones.[152] Migraine headaches vary with female reproductive events, including menarche, menstruation, oral contraceptives, pregnancy, and menopause.[153] Eighty percent of female migraineurs report the onset of migraine at 10–39 years, suggesting that sex hormones play a significant role in the pathogenesis.[154] They typically improve in the first trimester of pregnancy when there is a sudden and sustained increase in estradiol levels.[155] In fact, 50%–80% of patients who suffer from migraines experience a significant reduction in frequency or total cessation of migraine attacks during pregnancy. However, women with headaches persisting into the second trimester are less likely to improve after that.

Migraine headaches rarely begin during pregnancy, but if they do, they typically occur during the first trimester. Many clinicians believe that the initial presentation of headaches during pregnancy should initiate a thorough search for potentially serious causes.[91,156] One report of nine women presenting with migraine-like headaches during pregnancy found that four were severely thrombocytopenic, two met the criteria for preeclampsia,

and one had a threatened abortion.[156] The literature is replete with reports of intracranial pathology that mimicked migraines during pregnancy, including strokes, pseudotumor cerebri, tumors, aneurysms, arteriovenous malformations, and cerebral venous thrombosis.[91] Metabolic causes of headache during pregnancy include illicit drug use (most notably, cocaine[157]), anti-phospholipid antibody syndrome, and choriocarcinoma.[158]

Evaluation

Patients who present with their first severe headache during pregnancy should be aggressively evaluated. Only when secondary causes of headache in pregnancy, including head trauma, cerebral venous thrombosis, preeclampsia, ICH or subarachnoid hemorrhage, ischemic stroke, vasculitis, or dehydration, have been ruled out should pregnant women be diagnosed with a primary headache. The first step is a detailed history and neurologic examination. Focal neurologic abnormalities, papilledema, and seizures in the setting of headaches warrant further investigation. Suggested diagnostic tests for new onset headache during pregnancy include urinalysis, blood chemistries, hematologic studies, liver function tests, and coagulation studies.[154] Brain imaging is also an important component of the workup. MRI without gadolinium is safe in all trimesters and should be the modality of choice during pregnancy.[154] In the patient who presents with sudden onset of the "worst headache of my life," a subarachnoid hemorrhage should be ruled out.[91] If the brain computed tomography (CT) is negative for hemorrhage, a lumbar puncture should be performed, and the spinal fluid should be evaluated for subarachnoid blood. Progressively worsening headaches in the setting of sudden weight gain should suggest preeclampsia or pseudotumor cerebri. The triad of elevated blood pressure, proteinuria, and peripheral edema point toward preeclampsia. Furthermore, hyperreflexia and elevated serum uric acid are also found in patients with preeclampsia.

Treatment and Prevention

For pregnant women with a history of migraines prior to pregnancy and a normal neurologic examination, the therapeutic challenge is to achieve control of the headaches while minimizing the risk to the fetus. Non-pharmacologic techniques, including relaxation, biofeedback, and elimination of certain foods, often suffice for treatment. Marcus and colleagues[159] have demonstrated a significant reduction in headache that continued throughout pregnancy and at the one-year follow up using a combination of relaxation training, thermal biofeedback, and physical therapy exercises.

If pharmacologic therapy appears warranted, acetaminophen with or without caffeine is safe and effective.[160] A drawback to acetaminophen is the potential for medication overuse and rebound headache, which could lead to the development of daily chronic headaches. Ibuprofen and naproxen are the most commonly used NSAIDs for abortive management of migraines. However, as discussed in the prior section, they can have significant effects on pregnancy. The short-term use of mild opioid analgesics such as hydrocodone, alone or in combination with acetaminophen, also appears to carry little risk (Table 45.1). When oral analgesics prove ineffective, hospital admission and administration of parenteral opioids may be required (Table 45.2).

Until more information is available on the safety of sumatriptan during pregnancy, it should be used only after other strategies have failed. Triptans are the most used abortive agent in nonpregnant patients but are rarely used during pregnancy. There are pregnancy registries for both sumatriptan and naratriptan to track pregnancy outcomes after exposure to these medications. At this time, there does not seem to be an increased incidence of teratogenicity or adverse pregnancy outcomes with use in the first trimester. Ergot preparations should be avoided during pregnancy and lactation. They are known to cause prolonged and marked uterine tone and impaired placental flow leading to fetal distress or spontaneous abortion.

A history of three to four incapacitating headaches per month warrants consideration of prophylactic therapy.[160] If the frequency of the headache is less than three to four per month, but they are severe and unmanageable with acute therapies, prophylactic therapy should be considered to prevent dehydration to the mother, which could cause fetal distress. Daily oral propranolol or atenolol are reasonable choices, although patients should understand that their use is associated with small for gestational age infants. Longer acting agents should lead to less fluctuation in maternal and fetal blood concentrations and perhaps less fluctuation in the drug effects on fetal heart rate. We prefer to use long-acting agents (e.g. atenolol or sustained-release propranolol) based on this theoretical advantage.

Although anti-depressants are effective for prophylactic therapy in nonpregnant patients, the most commonly used medications of this class (imipramine, amitriptyline, and nortriptyline) are typically avoided because of insufficient information in the pregnant patient. The selective serotonin receptor inhibitors can be used with caution, especially if there is comorbid depression. Limited anecdotal experience with calcium channel blockers (verapamil, nifedipine, and diltiazem) and mini dose aspirin (81 mg/day) suggests that they may be effective prophylactic agents during pregnancy.[91,160]

Migraine and Lactation

Postpartum headache is common and can occur in 30%–40% of all women.[153] Most occur in the first week, and about 50% of those who experience relief of their migraine during pregnancy have recurrence a short time after delivery. This phenomenon may be secondary to the rapid ovarian withdrawal of progesterone and estradiol. Lactation can inhibit ovulatory cycles during the puerperium and is characterized by increased prolactin levels and low estradiol levels. In bottle-feeding women, the hormonal cycle is rapidly restored, which may contribute to it being the main risk factor for postnatal recurrence of migraine.[162]

Pain in the Pregnant Patient With Sickle Cell Disease

Causative Factors and Clinical Presentation

Sickle cell disease is an inherited multisystem disorder. The presence of abnormal hemoglobin in red blood cells leads to the cardinal features of the disease, chronic hemolytic anemia, and recurrent painful episodes. Vaso-occlusive crisis is the most common maternal complication noted in parturients with sickle cell hemoglobinopathies.[161] Vaso-occlusive crises follow a characteristic pattern of sudden, recurrent pain attacks, usually involving the abdomen, chest, vertebrae, and extremities. One prospective study has demonstrated that the clinical course of women with sickle cell disease is not adversely affected by their pregnancy, as measured by the rate of painful episodes over 100 days.[163] The rate was constant before, during, and after the first pregnancy and subsequent pregnancies. Painful episodes occurred at some time during the course of 50% of pregnancies.

Most crises during pregnancy are vaso-occlusive and are often precipitated by urinary tract infection, preeclampsia or eclampsia, thrombophlebitis, or pneumonia. Clinically, the individual will describe pain in the bones or joints but may also perceive the soft tissues as being affected. Visceral pain is also common and may be related to events in the liver or spleen. Painful episodes can be variable in severity and duration, with most episodes lasting from three to five days.[164]

Evaluation

Because laboratory evaluation is nonspecific, diagnosis of vaso-occlusive crisis begins with excluding other causes for the painful episode, particularly occult infection.[162] Complete assessment and the acute management of sickle cell crisis in pregnancy has been reviewed by Martin and coworkers.[165]

Treatment

Management of vaso-occlusive crisis during pregnancy is primarily supportive and symptomatic. A 2009 Cochrane review of intervention for treating a sickle cell crisis during pregnancy attempted to assess the effectiveness and safety of commonly used treatment regimens including red cell transfusion, oxygen therapy, intravenous hydration, analgesic drugs, and steroids. There are no randomized clinical trials on this topic, in part because pregnant women tend to be excluded from clinical trials.[166] Most clinicians begin management with aggressive hydration to increase intravascular volume and decrease blood viscosity.[165] Supplemental oxygen is essential in those patients with hypoxemia. Partial exchange transfusions to reduce polymerized hemoglobin S remain an integral part of the management of sickle cell disease.[167] Prophylactic transfusions may reduce the incidence of severe sickling complications during pregnancy.[168]

Education about how pregnancy interacts with sickle cell disease can help reduce depression or anxiety, often decreasing the pain that the patient is experiencing. Biofeedback has been shown to reduce the pain of sickle cell crises and the number of days that analgesics were taken.[169] Physical therapy techniques (e.g. exercise, splinting, local application of heat) can also be helpful.[170] TENS may be helpful when pain is isolated to a limited region.[171]

The severity of pain dictates the pharmacologic approach to managing sickle cell pain. Although non-opioid analgesics may suffice, oral or parenteral opioids are often required (Tables 45.1 and 45.2). Acetaminophen remains the non-opioid analgesic of choice during pregnancy. Although NSAIDs can be useful adjuncts, particularly for controlling bone pain, they should be used cautiously during pregnancy. Oral analgesic combinations containing acetaminophen and hydrocodone or another weak to moderate potency opioid can be added for more severe pain.

For the hospitalized patient with severe sickle cell pain, potent opioid analgesics administered intravenously may be necessary to control pain adequately (Table 45.2). Morphine sulfate is well tolerated and effective for control of severe sickle cell pain.[172] Fentanyl and hydromorphone provide reasonable alternatives for patients who cannot tolerate morphine. Administration of morphine via PCA device allows patients a sense of control over their illness. Weisman and Schecter[173] have noted that significantly higher doses of opioids may be necessary for the control of vaso-occlusive crisis pain than postoperative pain. In our practice, we aggressively treat individuals with severe sickle cell pain with potent opioids administered via PCA (most often using morphine). As the pain of vaso-occlusive crisis begins to resolve, patients are transitioned to a long-acting oral opioid (such as sustained-release morphine). This approach allows earlier ambulation and hospital discharge. All opioids are then tapered over the following 7–10 days.

The use of regional anesthesia has not been formally studied in sickle cell disease. There are case reports describing epidural analgesia to treat a sickle cell crisis during pregnancy in parturients with pain localized to the trunk or lower extremities.[174,175] This technique offers the theoretical advantage of increased microvascular blood flow while providing pain relief without opioids.

Acute Pain in Opioid Dependent Patients

Acute pain in the pregnant patient is most often encountered during labor and delivery. Both pain control and withdrawal symptoms are mediated through the μ-opioid receptor. Therefore opioid pain medication requires the availability of the μ-opioid receptor, which in opioid dependent patients is also occupied by opioid agonist therapy for dependence. No randomized or controlled studies are available to determine whether anesthetic needs differ in opioid dependent patients compared to control patients. One descriptive study has found that 24% of opioid dependent women had difficulty with labor analgesia, and 74% had difficulty with post-Cesarean analgesia.[176] These statistics may overestimate the difficulty in pain control because it was not clear that treatment of opioid dependence was adequate prior to treatment for acute pain. When opioid dependence is untreated and combined with acute pain, opioid needs reflect the combined therapies rather than treatment for pain alone. Although no randomized clinical trials have been performed, we have found that epidural analgesia with a standard dose of local anesthetic and low dose opioid (e.g. 0.0625% bupivacaine with fentanyl, 2 mg/mL) provides adequate intrapartum analgesia.

Intrathecal or epidural analgesia using only opioids may not be effective in reducing the need for systemic opioids. Sustained administration of m-opioid agonists by any route can induce both opioid tolerance and abnormal pain similar to neuropathic pain.[177] Although previously attributed to pharmacologic tolerance, patients maintained on methadone may experience opioid-induced hyperalgesia, a paradoxical effect mediated in part by the neurotransmitter *N*-methyl-D-aspartate and possibly by the novel neuropeptide dynorphin.[178] Interestingly, dynorphin may be an important mediator of chronic neuropathic pain, a common complaint among opioid dependent patients.

There are no trials that investigate opioid use and pain control after vaginal or abdominal delivery in opioid-tolerant patients. Recently published guidelines for the treatment of acute pain in patients maintained on methadone or buprenorphine provide a reasonable approach until more data are available.[54] Patients maintained on methadone for opioid dependence should have their methadone continued at the same dose in addition to standard dose opiates as needed for acute pain. The use of non-opioid analgesics should be included, but additional opioid medication should not be withheld. This additional short-acting opioid medication can be gradually discontinued as clinically indicated. If patients cannot tolerate oral medication, methadone can be administered intramuscularly or subcutaneously in two to four divided doses.

Patients maintained on buprenorphine pose a more difficult dilemma in the postoperative period. As a combined opioid agonist-antagonist, continued administration of buprenorphine can block the μ-mediated analgesic effect of additional short-acting opioids.[179] It is of note that although nonpregnant patients receive a combination of buprenorphine and naloxone, monotherapy is prescribed during pregnancy with buprenorphine to avoid naloxone exposure by the neonate.[180] Pain control options

and non-opioid analgesics include the following[54]: adding short-acting opioids with the realization that larger doses may be needed or dividing the daily dose of buprenorphine into 6 hour intervals, which can take advantage of the short-term analgesic effect of buprenorphine. Suppose buprenorphine is going to be discontinued with the initiation of another opioid, such as methadone. In that case, this approach is best attempted with the help of an addiction specialist because restarting the buprenorphine after the acute pain has been resolved can precipitate withdrawal if not carefully managed. In general, buprenorphine should be restarted only when patients have mild withdrawal symptoms (not before) to prevent antagonistic effects at the μ-opioid receptor.

Conclusion

Many physicians find themselves apprehensive about treating pain in pregnant patients. Evaluation and treatment are limited by the relative contraindication of radiography in the workup and the risks associated with pharmacologic therapy during pregnancy. Nonetheless, familiarity with common pain problems and the maternal and fetal risks of pain medications can allow the pain physician to help women achieve a more comfortable pregnancy. A single healthcare provider should be designated to coordinate specialist evaluations and integrate their suggestions into a single integrated care plan.

Key Points

- Medical management of the pregnant patient should begin with attempts to minimize the use of all medications and use non-pharmacologic therapies whenever possible.
- The most critical period for minimizing maternal drug exposure is during early development, from conception through the tenth menstrual week of pregnancy.
- Most breast milk is synthesized and excreted during and immediately following breastfeeding. Taking medications after breastfeeding or when the infant has the longest interval between feedings and avoidance of long-acting medications will minimize drug transfer via breast milk.
- There is no role for routine use of NSAIDs for pain other than that related to rheumatologic disease or uterine fibroids.
- All NSAID use for pain should be discontinued by 34 weeks gestation to prevent pulmonary hypertension in the newborn.
- All opioid analgesics carry teratogenic risk but can be used to monitor acute and chronic pain.
- For the opioid dependent parturient, buprenorphine has been found to be superior to methadone in reducing signs of withdrawal in newborns, thus requiring less medication and hospitalization time for the babies.
- Benzodiazepines should be avoided during organogenesis, near the time of delivery, and during lactation.
- Fifty percent of women will experience low back pain during their pregnancy, and it is commonly looked upon as a normal part of pregnancy.
- Although the incidence of HNP during pregnancy is low, radicular symptoms are common and often accompany sacroiliac subluxation and myofascial pain syndromes.
- Migraine headaches rarely begin during pregnancy, but if they do, they typically occur during the first trimester.
- Patients who present with their first severe headache during pregnancy should be aggressively evaluated, and only when secondary causes of headache in pregnancy have been ruled out should pregnant women be diagnosed with a primary headache.
- Postpartum headache is common and can occur in 30%–40% of all women. Most occur in the first week, and about 50% of those who experience relief of their migraine during pregnancy have recurrence a short time after delivery.
- Vaso-occlusive crisis is the most common maternal complication noted in the parturient with sickle cell hemoglobinopathies.
- Evaluation and treatment of the parturient with pain are limited by the relative contraindication of radiography in the workup and the risks associated with pharmacologic therapy during pregnancy.

Rheumatologic Conditions

DAVID ANDREW WALSH

Introduction

Rheumatology is the study of rheumatism, arthritis, and other disorders of the joints, muscles, and ligaments.[1,2] Rheumatologic conditions are highly prevalent. Nearly one-fifth of the United Kingdom population reports a chronic musculoskeletal system condition. Rheumatologic conditions commonly begin during working life, with the peak incidence of gout and rheumatoid arthritis in late working life, although many people are afflicted by inflammatory arthritis in early adulthood or even childhood. Rheumatologic conditions are complex and heterogeneous and require multi-disciplinary approaches to their management. Health systems across the world structure rheumatologic care in different ways, often involving physicians with rheumatologic and general medical expertise, orthopedic surgeons, experts in metabolic bone disease, nurses, physiotherapists, occupational therapists, orthotists, podiatrists, and others. The patient should always be at the center of the team. Pain is the main, although not the only, problem described by people with rheumatologic conditions. Rheumatologic pain management depends on principles and research from other disciplines, incorporating both pharmacologic and non-pharmacologic approaches. Specific aspects of the function of the musculoskeletal system and the nature of rheumatologic conditions may require disease-specific approaches to pain management. Pain and function are closely integrated, and physiotherapy and occupational therapy aim to address both concurrently. Common chronic conditions such as osteoarthritis, rheumatoid arthritis, and gout illustrate persistent chronic and episodic acute pain associated with musculoskeletal disease.

Osteoarthritis is the most common form of arthritis, and its prevalence increases with age. Osteoarthritis subgroups may be defined based on the joint distribution (e.g. knees, hips, or small joints of the hands) or precipitating factors (e.g. primary, post-traumatic, or secondary to inflammatory arthritis). Osteoarthritis affecting major weight-bearing joints substantially impacts mobility and function, although small joint osteoarthritis in the hands or feet can also cause substantial distress and disability.

Rheumatoid arthritis is the most common form of inflammatory arthritis, affecting approximately 1%-2% of the Western population. People with inflammatory arthritis report pain as their highest priority for improvement.[3,4] Inflammatory arthritis is an autoimmune condition characterized by immune-mediated inflammation of the joint lining (synovitis) and, if inadequately controlled, consequent joint damage and secondary osteoarthritis. Seronegative inflammatory arthritis may be associated with psoriasis, colitis, ankylosing spondylitis, or reactive arthritis that may follow infection, and each has its own specific genetic and immunologic characteristics. Rheumatoid arthritis has a predilection for small joints of the hands and feet and often affects the knees, shoulders, ankles, or wrists in a symmetrical polyarticular distribution. Seronegative spondyloarthropathies often affect small numbers of weight-bearing joints (oligoarthritis) and/or the axial skeleton, although polyarticular distributions are not uncommon. Seronegative spondyloarthropathies are characterized by enthesopathy (inflammation at ligament insertions) and tendon sheath inflammation. Therefore inflammatory pain might not always be associated with localized joint swelling, and "tender points" because of inflammation might overlap with those associated with fibromyalgia. Pain and stiffness in inflammatory arthritis vary during the day, with the most pronounced symptoms usually in the morning, explained in part by diurnal variation in endogenous glucocorticoids. Disease onset may be acute or insidious, and early disease may be difficult to diagnose. Classifying these conditions as "inflammatory" does not deny the important contributions of inflammation to joint pain in osteoarthritis and gout.

Crystal diseases are characterized by acute, severe episodes of pain caused by the innate inflammatory responses triggered by crystal deposits. High circulating uric acid concentrations because of inadequate renal clearance or increased production (e.g. during chemotherapy) may favor urate crystal deposition and attacks of gout. In calcium pyrophosphate deposition (CPPD), crystals may trigger attacks that are indistinguishable from gout and are therefore called pseudogout. Calcium pyrophosphate deposition in articular cartilage may be detected radiologically as chondrocalcinosis, even in the absence of acute attacks. In CPPD, crystal formation may be associated with various metabolic disorders involving divalent cations (e.g. Wilson's disease). Gout and pseudogout may be associated with OA. Attacks typically affect a single joint, such as the knee, or, particularly in gout, first metatarsophalangeal, or interphalangeal joint. However, any synovial joint may be affected, and oligoarthritis or even polyarticular acute presentations may occur.

Non-inflammatory genetic connective tissue disorders associated with hypermobility are commonly associated with chronic musculoskeletal pain. Hypermobility syndromes include Marfan syndrome, Ehlers-Danlos syndrome, and Stickler syndrome, associated with genetic variation in fibrillin-1, collagen Col3/Col5, or Col2/9/11, respectively.[5] However, most people with joint hypermobility (perhaps 10% of the population) have a medically benign condition on a polygenetic background.

The Experience of Rheumatologic Pain

Pain is rarely a single experience, and people with rheumatologic conditions may report multiple qualities of pain. Rheumatologic pain may be described using any of the terms embedded within the McGill pain questionnaire, both those commonly associated with nociceptive and those characteristic of neuropathic pain.[6] The characteristics of osteoarthritis, inflammatory arthritis, and crystal disease often overlap, and these conditions may be comorbid. Evidence and experience from one rheumatologic condition may sometimes be generalizable to others, although caution should be exercised when such generalizations are not based on sound evidence.

In osteoarthritis, pain may occur only on weight-bearing or during joint movement or may be persistent at rest. Intermittent pain may be short-lived but severe, interspersed with periods that are pain-free or with less intense but constant pain.[7] Acute flares may be spontaneous and unexplained or may be attributed to unaccustomed activity. Periods of exacerbation might last weeks or months, and the unpredictability of intermittent pain can prevent forward planning. Pain may be progressive or may subside or resolve.

In rheumatoid arthritis, pain is often associated with joint inflammation, as evidenced by soft tissue swelling, synovial effusion, increased local temperature, and tenderness. Each of these features typically varies over time, either spontaneously or with treatment. However, such variations in inflammation and pain are not always concurrent. An increase in pain may herald an imminent inflammatory flare, and reductions in acute phase reactants on blood tests may precede symptomatic improvement.

Episodic and severe pain characterizes crystal arthropathies, such as gout or pseudogout. During an attack, the affected joint becomes red, hot, and swollen and is exquisitely tender to the extent that movement or weight-bearing might be impossible, and the weight of bed clothes can be intolerable. These signs resemble acute infection, which is an important differential diagnosis that must be excluded. However, between attacks, the joint is typically pain-free.

Pain is not the only symptom of rheumatologic disease, and people differ in how they understand or separate their pain from comorbid symptoms. Pain exists alongside fatigue, stiffness, and disability. Sleep disturbance and depressive symptoms are more common in people with inflammatory arthritis than in the general population.[8] Joint stiffness is particularly a feature of inflammatory joint diseases such as rheumatoid arthritis when it characteristically varies during the day and increases with increased inflammatory disease activity. Morning stiffness lasting more than an hour is not unusual during active synovitis, even though it may ease joint movement and activity. People with osteoarthritis also describe stiffness, which may reflect the inflammatory components of their disease. The reduced movement might also be because of structural changes, such as loss of articular cartilage, bony outgrowths at joint margins (osteophytes), or joint capsule fibrosis and tendon contracture. This type of stiffness, unlike stiffness associated with inflammation, displays slight diurnal variation.

Stiffness is a symptom rather than a sign, and the feeling that a joint does not move freely results from multiple mechanisms in and around the joint and in the central nervous system. Central mechanisms contribute to stiffness. People with rheumatoid arthritis who have undergone limb amputation may describe phantom stiffness, which varies during the day, and with generalized inflammatory flares of their arthritis.[9] People often find it difficult to disentangle their experiences of pain and stiffness. Indeed "stiffness," which is unpleasant and associated with tissue damage, would satisfy the International Association for the Study of Pain (IASP) definition of pain[10] and might therefore be considered a component of the pain experience.

Fatigue is a common accompaniment of rheumatologic pain and has been reported as the second most troublesome symptom in people with rheumatoid arthritis. People may attribute their fatigue to sleep disturbance, for example, being woken by joint pain when turning during the night. However, sleep disturbance, unpleasant in its own right, is not an inevitable cause of fatigue, and additional biopsychosocial factors are important. Sleep disturbance and fatigue may be associated with evidence of central sensitization in osteoarthritis or rheumatoid arthritis,[11] as it is also associated with widespread chronic pain. Circulating cytokines may contribute to fatigue in people with systemic inflammation.[12] Fatigue is associated with a low mood, even in the absence of chronic musculoskeletal pain. Regardless of its underlying mechanisms, fatigue is associated with chronic musculoskeletal pain, is an important symptom in its own right, and can be a barrier to effective pain management. Overwhelming fatigue challenges the individual's ability to cope with their pain and limits their ability to exercise as a form of therapy.

Difficulties with acceptance, psychological distress (anxiety and depression), catastrophizing, and cognitive impact are key components of rheumatologic pain, not less than in other chronic pain states. Patients may have difficulty accepting their rheumatologic condition, which in most cases will not be amenable to cure, but instead, require lifelong treatment with associated risks and inconvenience. When newly diagnosed, people often display psychological reactions comparable to grieving, reflecting their permanent loss of good health. Persistent pain may be interpreted (both by patient and clinician) to indicate persistent inflammation, treatment failure, and ongoing joint damage, even when inflammation has been completely suppressed. Fear that pain on activity inevitably indicates ongoing joint damage can be a barrier to rehabilitation and exacerbates declining function.

In addition to constituting the key emotional components of pain, psychological distress may be associated with central sensitization,[13] augmenting nociceptive signaling, and the sensory dimensions of pain. Pain's ability to distract attention and impair cognitive processing can compromise both work and leisure. With modern immunosuppressive therapy, people now developing rheumatoid arthritis might expect to live normal lives, engage in work, sports, and other activities alongside those without disease. However, the unpredictability of flares can prevent the planning of valued activities, including work and vacations, and undermine an individual's self-esteem. Self-efficacy and successful self-management require control over persistent and intermittent symptoms and suppression of the underlying pathology.

Suppressing pain in people with rheumatologic conditions is urgently needed. Furthermore, delays in effective pain management can lead to disability and loss of gainful employment, which may be difficult to reverse. Inadequate pain management in people with rheumatologic conditions is a risk factor for future pain, psychological distress, lost work productivity, healthcare utilization, and poor response to later definitive interventions such as joint replacement surgery.[6,14] Pain management aims to improve symptoms and modify a key risk for future adverse outcomes, both for the patient and society.

Why Are Rheumatologic Conditions Painful?

Mechanisms of rheumatologic pain include changes in the peripheral musculoskeletal system, sensitization of peripheral and central nociceptive pathways, changes in brain connectivity, experience, and interpretation within a psychosocial context. Each pain mechanism is modulated by constitutional risk factors and comorbidities. Mechanisms may be shared or may differ between diseases, between individuals, and across time within an individual. Different mechanisms underlie different aspects of the pain experience, including pain quality, periodicity, associated symptoms, impact, and response to treatment.

The musculoskeletal system is designed for weight-bearing and movement, and biomechanical factors contribute significantly to rheumatologic pain. Pain on normal movement might indicate sensitization within either the peripheral or central nervous system. Sensitization might result from actions on peripheral nerves by chemical mediators, including growth factors or cytokines. Structural changes may redistribute forces within the joint. Thinned, irregular, or inelastic articular cartilage may be unable to adequately dissipate force, thereby activating nerves that are normally present in the subchondral bone. Hypermobility, for example, may be associated with patellar maltracking and consequent anterior knee pain. Nociceptive transduction may be increased by abnormal interactions between sensory nerve terminals and adjacent connective tissue molecules.

Loss of osteochondral integrity can expose subchondral nerves to molecules generated by the synovium, which may further stimulate subchondral inflammation and neuronal sensitization. Normal forces may activate nerves that have grown into the articular cartilage or knee menisci during structural disease progression.[15,16] These joint structures were not innervated in the normal joints.

Peripheral sensitization is a key component of rheumatologic pain. Inflamed or damaged tissues generate cyclo-oxygenase products, bradykinin, and nerve growth factor (NGF). These may either activate or sensitize the peripheral terminals of the primary nociceptive afferents. Urate (gout) or calcium pyrophosphate dihydrate (pseudogout) crystals trigger leukocyte degranulation and an acute innate immune response. In chronic rheumatoid arthritis or osteoarthritis, NGF, cytokines such as interleukin (IL)-1 and tumor necrosis factor (TNF)α, and chemokines may be upregulated in the synovium and subchondral bone.[17] NGF has been identified as a key cause of peripheral sensitization in osteoarthritis[18] and may also contribute to pain in rheumatoid arthritis.[19] NGF induces phosphorylation of transient receptor potential cation channel subfamily V member 1 (TRPV1). It increases the expression of substance P, calcitonin gene-related peptide (CGRP), and brain-derived neurotrophic factor in the dorsal root ganglion and increases the levels of transmitters and modulators at the first synapse within the dorsal horn. Systemic factors, such as circulating autoantibodies or immune complexes, might also interact with primary afferent nociceptors to increase sensitization in rheumatologic conditions.[20]

Persistent nociceptive barrage, the release of growth factors, and glial cell activation within the central nervous system, and changes in descending nociceptive control, contribute to central sensitization in rheumatologic conditions. With persistent joint pathology and nociceptive drive, central pain mechanisms become increasingly important. Functional connectivity may be enhanced between brain areas involved in sensory and emotional experiences, aggravating the emotional component of pain.[21]

Pain experience depends on psychosocial context. An increased understanding of the underlying mechanisms of rheumatologic disease has led to major advances in immunologic treatments in recent decades. However, pain and inflammation can be discordant.[22] A patient who is informed that their inflammatory disease is well controlled may feel that their pain experience is invalidated or not believed. Pain does not even need to be present in order to be a problem, for example, if a patient fears future severe or unpredictable flares.

Different individuals experience pain differently, despite apparently similar rheumatologic pathologies. Such diversity depends, in part, on genetic heterogeneity. Genotyping studies in painful osteoarthritis have identified polymorphisms in genes that are anticipated to influence joint shape and structure, but also in genes that regulate neuronal function or analgesic responses. Sex differences in rheumatologic pain similarly reflect both the propensity for joint pathology and differences in nociceptive processing.[23]

Assessment of Painful Rheumatologic Conditions

Pain is the dominant symptom in most rheumatologic conditions, and patient-centered assessment should include evaluation of the nature, severity, and consequences of pain. Assessment should also address pain mechanisms, such as using biomarkers linked to diagnosis or pathology, to demystify this most bothersome symptom and help select treatments most likely to be of benefit. Careful attention to multimorbidity can inform prognosis, maximize health benefits, and reduce risks from pain treatments. Understanding and informing patients' expectations and preferences facilitates treatment convergence

Rheumatologic Pain

Pain assessment aims to identify its nature, severity, and importance to the patient and is essential for evaluating treatment response. Where pain is the presenting problem, assessment is inevitably incomplete without a detailed pain assessment. Pain is a subjective experience, and only patients can provide the gold standard measurement.

Tools for evaluating pain may be generic or disease-specific. Assessment tools used in clinical practice often differ from those used in research because of the different requirements of validity, feasibility, and sensitivity to change. In the clinic, we are interested in the individual's pain, whereas research often seeks to understand the average effects across populations. Research might seek to explore mechanistic subgroups for whom there is currently no effective treatment, whereas clinical practice aims to identify problems for which interventions may be helpful. Pain is a subjective experience whose mechanisms are complex and are often unknown. Therefore assessment should embrace the patient's subjectivity rather than seek objective indices that might bear little relevance to the patient's problem.

In general, patient-centered pain outcome measures focus on the impact of pain on function (physical, psychological, sleep). Putative mechanistic tools, such as measuring neuropathic-like qualities, may inadequately address the problems of people with rheumatologic conditions.[24] Pain rarely occurs as a symptom in isolation, such that rheumatologic-specific outcome measures often include pain alongside other factors such as stiffness and fatigue.[25,26] Pain outcome measures might be incorporated into the more generic quality of life tools such as the medical outcomes study short form 36 (SF36) and EuroQol questionnaires. These

quality of life measures lack focus on individual joints but instead address the overall burden of commonly comorbid painful conditions. More specific outcome tools might be more able to detect responses to treatments that target a single joint or pain mechanism.

Osteoarthritis pain may be measured using self-report tools such as the intermittent and constant osteoarthritis pain (ICOAP) questionnaire,[7] pain subscales of the Western Ontario and McMaster Universities arthritis index (WOMAC),[27] or knee injury, and osteoarthritis outcome score (KOOS).[28] WOMAC contains five items related to weight-bearing or non-weight-bearing pain and has demonstrated a two factor structure through which weight-bearing and non-weight-bearing OA pain may be associated with different pathologic mechanisms. For example, weight-bearing pain was specifically associated with bone marrow lesions in weight-bearing joint compartments on MRI.[29] KOOS extends the WOMAC items to improve targeting for people with lower pain intensities or musculoskeletal injuries. The ICOAP was developed following qualitative assessment of pain in people with knee or hip OA and displayed a two factor structure corresponding to the intermittent or constant pain. People with early disease may experience predominantly intermittent pain, whereas those with advanced OA report intermittent on a background of constant pain, suggesting changes in pain mechanisms when the structural disease progresses.

The management of rheumatoid arthritis has traditionally focused on suppressing joint inflammation. Pain is assessed as one of the cardinal features of inflammation. However, pain in rheumatoid arthritis may also involve non-inflammatory mechanisms. The 28 joint disease activity score (DAS28) is a frequently used outcome measure in clinical trials of immunomodulatory treatments and clinical practice.[6] This composite tool incorporates tender joint counts (TJC) and swollen joint counts (SJC) based on a standardized set of 28 joints that are relatively frequent and specific for rheumatoid arthritis. TJC is classified by the application of standardized pressure (to blanch the assessor's nail bed) over each joint line. SJC is determined by the soft tissue swelling observed by a clinician. TJC and SJC are combined with a 100 mm visual analog scale of general health over the past week (VAS-GH) and a laboratory measure of an acute phase response (erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP]). VAS-GH is highly correlated with patient-reported pain. Therefore DAS28 comprises self-reported (VAS-GH and TJC) and observed (ESR/CRP and SJC) components. Synovitis may increase ratings for each component, whereas central sensitization may selectively increase VAS-GH and TJC. Therefore the difference between TJC and SJC has been proposed as an index of non-inflammatory pain mechanisms in rheumatoid arthritis.[30] High DAS28 is used in several countries as a criterion for commencing or continuing immunomodulatory treatments. The use of DAS28 in this way depends on a clear understanding of the contribution of pain to inflammatory disease assessment. Inappropriate escalation of immunomodulatory treatments in people whose pain is attributable to non-inflammatory mechanisms exposes them to risks with little likelihood of benefit.

Pain-Related Biomarkers

Biomarkers can help direct the treatment of rheumatologic conditions by indicating diagnosis and identifying and measuring peripheral or central pain mechanisms. Biomarkers may predict the prognosis or treatment outcomes. In general, those who have suffered worse pain in the past may have a worse pain prognosis, and those whose pain will persist or deteriorate stand to gain the most benefit from treatment. Treatments that target a particular mechanism might be expected to work best for those in whom this mechanism drives pain. Biomarker levels might change before patient-reported outcomes deteriorate or improve, opening opportunities for early intervention and accelerating the development of new treatments. Biomarkers may enable early discontinuation to minimize the risk of treatment in those destined to not respond and those who will suffer adverse events.

Diagnostic Biomarkers and Genetic Risk

Despite the overlap in pain mechanisms across diseases, the nature and responses to treatment of rheumatologic pain may vary between diagnoses. Biomarkers may be used to aid diagnosis. Specific connective tissue genetic variants directly cause hypermobility syndromes, such as Ehrlers' Danlos syndrome. Other genetic variants may predispose to rheumatologic conditions (for example, human leukocyte antigen B27 [HLA-B27] in spondyloarthropathies). Genetic variants encoding neuronal proteins, such as ion channels, may either predispose to or protect against rheumatologic pain. Other genetic variants, such as μ-opioid receptors, might influence the responsiveness to analgesic drugs.

Circulating autoantibodies to citrullinated peptides or double-stranded DNA have moderate to high specificity for rheumatoid arthritis and systemic lupus erythematosus, respectively. Radiographic features contribute to diagnostic classification, such as osteophytes for osteoarthritis, bony erosions at joints affected by inflammatory arthritis, and spinal syndesmophytes or sacroiliac joint fusion in ankylosing spondylitis. Hyperuricemia is a risk factor for gout and radiographic chondrocalcinosis for pseudogout, although the definitive diagnosis of these conditions requires the identification of crystals in joint fluid aspirates. Diagnostic biomarkers might be particularly important in early disease when the link between diagnosis and pain mechanism may be the strongest. Comorbid osteoarthritis or fibromyalgia may reflect increasing mechanistic complexity of pain with increasing time from disease onset.

Diagnostic classification may help predict pain prognosis and treatment response. Radiographic evidence of osteoarthritis predicts pain persistence and persistent pain severity in people with knee pain.[31] Diagnosis may also predict the response to treatment. However, diagnostic uncertainty may prevail, particularly in cases of early disease. The earliest stages of osteoarthritis might not be reliably classified by plain radiographs, and early rheumatoid arthritis may be mimicked by self-limiting parvovirus infection. Diagnostic uncertainty should not prevent adequate pain management.

Biomarkers of Peripheral Pain Mechanisms

Biomarkers that may point to pain mechanisms within the joint and are amenable to intervention include indices of inflammation and joint structural pathology.

Acute phase reactants such as ESR or CRP and ultrasound or MRI evidence of inflammation are useful indicators of peripheral drives to rheumatologic pain across multiple diagnoses, such as rheumatoid arthritis, psoriatic arthritis, and ankylosing spondylitis. Raised acute phase in rheumatoid arthritis predicts worse structural outcomes, but not pain outcomes,[32] perhaps because modern treatments can effectively suppress the inflammatory components of the disease. Similarly, raised acute phase or MRI evidence of spinal inflammation in ankylosing spondylitis predicts better outcomes on biologic therapy.[33] However, precise

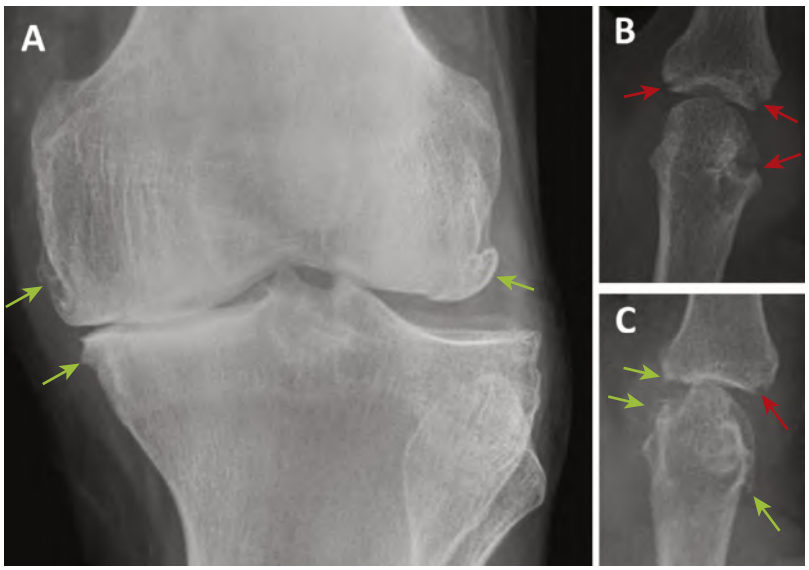
mechanisms of rheumatologic pain often remain ill-defined, and these "indices" should not be over-interpreted as direct causes of pain. For example, CRP production in the liver is dependent on IL-6, and IL-6 blocking antibodies reduce circulating CRP concentrations irrespective of their effect on pain. Shortly after the onset of polyarthritis, the high acute phase might paradoxically be associated with a good prognosis if, rather than rheumatoid arthritis, the patient has an acute synovitic response to viral infection.

Greater joint space narrowing on weight-bearing knee radiographs is associated with greater pain severity in cross-sectional studies and predicts worse pain outcomes in longitudinal community studies of osteoarthritis but better outcomes from joint replacement surgery (Fig. 46.1). However, the association between radiographic changes and pain in osteoarthritis is weak. Radiographic erosive joint damage or comorbid hand osteoarthritis at presentation with rheumatoid arthritis may be only weakly associated with pain and does not predict chronic pain with long term treatment,[34] consistent with a predominant drive to pain from non-structural mechanisms. MRI may provide more detailed biomarkers of the peripheral pain mechanisms. In osteoarthritis, subchondral bone marrow lesions and synovitis have consistently been associated with pain, both in cross-sectional and longitudinal studies.[35] Other MRI features, including knee meniscal extrusion or cartilage defects, may also be associated with pain, and close associations between different aspects of osteoarthritis structural pathology raise uncertainty about which features directly cause pain.

Biomarkers of Central Pain Mechanisms

Quantitative sensory testing (QST) evidence of sensitization is associated with higher concurrent pain severity in osteoarthritis,[36] and rheumatoid arthritis.[37] Mechanical stimulation modalities such as blunt or cuff-induced pressure or punctate stimulation of the skin may be more relevant to rheumatologic pain than thermal modalities, although it is uncertain whether sensitization mechanisms are specific to particular nociceptor subtypes. Baseline QST evidence of sensitization predicts worse pain at follow up and worse pain progression.[38] Much evidence has been derived from static mechanical QST modalities, such as pressure pain detection thresholds (PPT). PPT distal or remote from affected joints has been taken as an indication of central sensitization, whereas PPT at the joint may reflect a combination of peripheral and central sensitization.[39] Dynamic QST modalities such as temporal summation (TS) and conditioned pain modulation (CPM) more directly reflect central sensitization. Greater TS may indicate sensitization at the spinal cord, whereas lower CPM may indicate supraspinal deficiencies in endogenous analgesic mechanisms. Dynamic QST modalities may better predict pain outcomes in rheumatologic diseases than does PPT.[37,38] Evidence of central sensitization might predict worse pain outcomes in rheumatologic conditions by indicating resistance to treatments directed at the peripheral nociceptive drive.

Several phenotypic characteristics have been associated with QST evidence of central sensitization, leading to the proposal that self-report questionnaires might be used to indicate central sensitization in people with rheumatologic conditions.[13] In people with knee pain, psychological distress (depressive or anxiety symptoms), catastrophizing, sleep disturbance, fatigue, cognitive interference, neuropathic-like symptoms, and more widespread pain were each associated with lower PPT distal to the affected knee. These eight characteristics each contributed to a single factor, the central mechanisms trait, which was more strongly associated with PPT than was any one of the eight characteristics alone. Higher central mechanisms trait scores were associated with more severe pain and predicted worse pain outcomes in community dwellers with knee pain.[40] Similar self-report characteristics predict poor pain outcomes in other rheumatologic and non-rheumatologic conditions,[41] and contribute to the diagnostic classification of fibromyalgia.



• **Figure 46.1** Radiographic change in osteoarthritis and rheumatoid arthritis. (A) Posteroanterior radiograph of the knee of a person with structural changes of tibiofemoral osteoarthritis. The lateral joint compartment can be identified by the localization of the fibula. The medial tibiofemoral joint space is narrowed, with marginal osteophytes (*green arrows*) and subchondral sclerosis. (B and C) Plain radiographs of second metacarpophalangeal joints of two people with rheumatoid arthritis. B shows erosive damage (*red arrows*) at joint margins. C displays erosive change also, and more severe joint space narrowing plus marginal osteophytes. It is not possible from plain radiographs to determine whether the individuals concerned were experiencing pain, nor how severe any pain was. The osteoarthritic changes in C may represent comorbid osteoarthritis that preceded the onset of rheumatoid arthritis or may show secondary osteoarthritis following earlier erosive damage. Disease modifying treatments may reduce the progression of erosive damage in rheumatoid arthritis but do not always eliminate pain.

Comorbidities and Multimorbidity

Comorbid conditions may be associated with rheumatologic disease. Rheumatoid arthritis is associated with cardiovascular diseases, diabetes mellitus, and fibromyalgia. Rheumatologic conditions increase in prevalence with age. Therefore multimorbidity is common, with or without causal association between diseases. Multimorbidity is associated with increased pain severity and worse pain prognosis,[6] and contributes to frailty and loss of resilience to future health challenges. Concurrent morbidities might augment pain from rheumatologic conditions. Therefore treatment of comorbidities might improve pain outcomes. Morbidities or risk factors for future development may influence the choice of pain management strategy. Some, but not all, immunosuppressive therapies help with both cutaneous psoriasis and psoriatic arthritis. Comorbidities might be risk factors for adverse events from treatment, such as gastrointestinal bleeding on nonsteroidal anti-inflammatory drugs (NSAIDs) or analgesic medication abuse. Morbidities that pose an anesthetic or surgical risk, such as hypertension or obesity, should be addressed before elective surgical intervention should be considered. A holistic approach is required to avoid interruption of pain management by intervening in acute medical needs. Morbidities may be painful or non-painful.

Rheumatologic conditions coexist with comorbidities, which further influence the pain experience. Fibromyalgia is a common accompaniment of both inflammatory and non-inflammatory rheumatologic conditions. The extent to which phenotypic similarities between rheumatologic conditions and fibromyalgia reflect shared mechanisms remains uncertain. Chronic widespread pain in people with hypermobility might be associated with comorbid fibromyalgia or central sensitization but might also be an indication of widespread abnormalities in peripheral nerve function. Fibromyalgia may be considered as a comorbid diagnosis, and also fibromyalgianess may be viewed as a continuous trait linked to pain mechanisms. Each may be classified or measured in people with rheumatologic conditions by questionnaires; the Symptom Severity Scale, which addresses fatigue, cognitive, and somatic symptoms, together with WideSpread Pain Index.[42]

Osteoarthritis is a common accompaniment of other rheumatologic conditions. Primary osteoarthritis (OA) is a prevalent condition. Similar to all non-fatal, incurable conditions, osteoarthritis increases in prevalence with age. Rheumatologic conditions may predispose patients to osteoarthritis. Hypermobility may be associated with joint trauma and inflammatory arthritis with erosive joint damage, each of which is a risk factor for secondary osteoarthritis.

Obesity is associated with osteoarthritis and increased pain. The association of body weight with osteoarthritis is multifactorial, partly based on genetic and biomechanical factors. Adipokines may contribute to augmented pain processing.[43] Reciprocally, where arthritis pain is a barrier to exercise, weight reduction may be difficult to achieve. Diabetes mellitus may be associated with obesity and is an autoimmune condition associated with inflammatory rheumatologic conditions. Diabetes mellitus is associated with increased pain, even in the absence of demonstrable neuropathy.[44] A negative association between osteoarthritis pain and hypertension has been attributed to the use of β-blocking medications,[45] although causality awaits demonstration by a randomized controlled trial.

Rheumatoid arthritis and systemic lupus erythematosus are associated with an increased risk of cardiovascular disease, which might be attributed to the effects of systemic inflammation or the adverse effects of treatments such as glucocorticoids or NSAIDs. Cardiovascular risk assessment tools incorporate rheumatoid conditions, including age, sex, smoking status, diabetes mellitus, hypertension, ischemic heart disease, and chronic kidney disease.[46]

Treatment History, Expectations, and Preferences

Assessment should include detailed documentation of treatment expectations and preferences. Expectations influence concordance with treatment plans and may contribute to analgesic efficacy or adverse events. A high expectation of benefit might facilitate placebo analgesia, whereas anticipating adverse events might contribute to nocebo responses. Expectations may be driven by the patient's understanding of the natural history and mechanisms of their disease and its treatment. The threat of pain is greater if pain is beyond an individual's comprehension or control. It is important to link the current biomechanical, structural, inflammatory, and neuronal mechanistic understanding of pain to the patient's experience. Explanations that clearly align treatments with the patient's informed understanding of the underlying mechanisms can enhance the therapeutic context and improve patient satisfaction.

A patient's previous treatment experience of pain strongly will influence their expectations from future treatment. In this respect, the patient's recollection may be the most important. Pain recollection might be unreliable beyond one week, whereas immunomodulatory drugs used for inflammatory arthritis often have a slow (several weeks) onset of specific analgesic benefits. Pain relief from high dose glucocorticoids may be rapid and easily appreciated by people with inflammatory arthritis. However, prospective pain documentation may be needed to understand the analgesic benefits of slower acting disease modifying anti-rheumatic drugs (DMARDs). Long term efficacy and side effect profiles might be preferable for DMARDs compared to glucocorticoids, even though the rapid analgesic benefit from glucocorticoids may be more easily appreciated. Previous treatment failure may create expectations of similar future treatment failure, and repeated treatment failure may lower expectations for all future treatments, not only those that have failed in the past. Treatments that are most likely to help and are least likely to cause adverse events should be selected for an individual. Patient expectations may differ from predictions from evidence-based prognostic tools, and this should be addressed to help patients choose optimal treatment.

Different individuals place different emphasis on treatment characteristics when making choices. Someone whose husband has just died from myocardial infarction may be averse to commencing an NSAID irrespective of their own personal risk. People with moderate to severe knee osteoarthritis generally place more emphasis on the likely analgesic efficacy rather than known adverse events.[47] Holistic assessment is needed to ensure that patients can make the best treatment decisions based not only on statistical models but also accounting for personal values and perspectives.

Pain Prognosis and Treatment Outcomes

Those people at the highest risk of poor outcomes stand to gain most from changes to their treatment. Assessment of a patient with a rheumatologic condition should lead to an understanding of likely pain prognosis, the likely impact of treatment on future pain, and the risk of treatment-related adverse events. Pain risk assessment overlaps with but does not equate to the risks of other outcomes, such as the risk of joint structural damage.

In populations undergoing usual care, worse knee pain at follow up may be predicted by a range of general and disease-specific risk factors. Across rheumatologic and non-rheumatologic conditions, being female, older age, higher body mass index (BMI), anxiety, depression, catastrophizing, and more widespread pain at baseline predicted worse pain outcomes, and indices of central sensitization, either using QST or questionnaires, also predict worse pain outcomes.[38,40] The average outcomes in a population conceal diverse pain trajectories in individuals. In osteoarthritis, pain progression is not inevitable, with pain deteriorating over time in some individuals but improving in others.[48] In people with early or established rheumatoid arthritis, subgroups have been identified whose pain may return to levels observed in non-diseased populations, whereas for others, pain may persist unchanged over several years.[32] Factors that predict the pain trajectory that an individual will follow overlap with those that predict persistent pain at follow up.

Specific interventions for rheumatologic conditions can change an individual's pain trajectory and outcome. Predictors of treatment response may differ, therefore, from predictors of pain outcomes in untreated populations. The raised acute phase might predict poor outcome in the absence of treatment for rheumatoid arthritis but predicts a more favorable pain trajectory on immunomodulatory treatment.[32] Joint space narrowing predicts worse outcomes in people with knee pain but predicts better outcomes in response to arthroplasty. Risk is therefore dependent on the treatment context, and we can anticipate that the adverse risk factors of today will become positive prognostic factors with treatments in the future.

Joint inflammation indices predict the analgesic benefits of immunomodulatory therapies in rheumatoid arthritis. DAS28 scores have been recommended by some for the selection of people who may be offered biologic immunomodulatory therapy. DAS28 requires careful interpretation because of the influence of non-inflammatory pain mechanisms. Randomized controlled trials in rheumatoid arthritis often require minimum thresholds of acute phase reactants and SJC to be met prior to treatment initiation.

An individual's risk factors and pain mechanisms may vary over time. This helps explain why a previously effective treatment might no longer be so, whereas another treatment that has previously failed might now help. For example, pain in early rheumatoid arthritis might respond well to immunomodulatory therapy, whereas in later disease, if central sensitization or joint damage becomes dominant, continuing to suppress inflammation might not relieve pain.

A single risk factor might make only a small contribution to pain outcomes, even if it displays highly significant associations in large cohort studies. For example, a high BMI predicts worse outcomes from joint replacement surgery, but people with high BMI can still gain important clinical benefits and should not be denied surgery.[49] Combinations of multiple risk factors may only explain a small proportion of treatment outcomes. For example, less than one-fifth of people destined to have poor outcomes from arthroplasty can be identified by a combination of currently known pre-surgical risk factors.[50] Risk factors should be discussed with the patient to help them minimize their risks while selecting what is appropriate for their care.

The analgesic response is not entirely attributable to specific effects and depends on contextual factors that might also be observed with placebo treatments. Only half of the total analgesic benefit experienced by the patient may be attributable to the specific effects of treatment.[51] The predictors of placebo response may differ from those of specific pharmacologic effects. This mixed mode of analgesic action challenges outcome prediction. For example, ultrasound evidence of synovitis may predict pain in people with knee pain,[31] but has little ability to predict the response to intra-articular glucocorticoid injection. Improved biomarkers of pain mechanisms are required to determine the effective targeting of mechanism-specific treatments.

Central mechanisms may predict worse pain outcomes in part by posing barriers to treatment response. A low mood might reduce treatment uptake or persistence, where the future seems hopeless. Anxiety and catastrophizing may reduce concordance with medical or physiotherapeutic interventions, where adverse events are feared, or where patients are concerned that by masking their pain, they will damage their joint. Sleep disturbance and chronic fatigue reduce motivation and the ability to engage in physical activity and therapies or to travel and attend to health care. Cognitive interference may impair the understanding or adherence to therapeutic plans. Multisite pain may compromise therapies targeting a particular joint, for example, by limiting mobility. Treating one joint may unmask the limitations of another. Identifying risk factors for poor outcomes as barriers to treatment benefit can reveal targets for interventions that might synergize with pain management.

Pain in rheumatologic conditions may persist for years, and long term benefits from analgesic medications are often unproven. Continued use of medications in those gaining little benefit exposes them to unnecessary risk of adverse events. Response to treatment should be assessed after an adequate therapeutic trial and should be confirmed before considering its continuation. What constitutes an adequate trial may vary between interventions. Two weeks might be adequate to evaluate response to an NSAID, whereas treatment with biologic DMARDs might be continued for up to six months before the benefit can be excluded, particularly if there are concomitant changes to glucocorticoid doses. Where treatment aims to reduce the frequency of pain flares, the duration of an adequate trial of treatment will depend on baseline flare frequency. For acute gout attacks, treatment should be titrated to achieve serum urate levels in the lower half of the normal range, and equivalent biomarkers are needed to satisfactorily reduce the risk of pain flares in inflammatory arthritis or osteoarthritis.

New treatments with different efficacy and risk profiles will increase the choices available to patients and their clinicians and increase the range of risk factors that need to be assessed. Pharmaceutical development of NGF inhibitors for osteoarthritis pain, for example, has identified risks from drug-induced rapidly progressive osteoarthritis, leading to the incorporation of risk screening tools such as large joint radiography into developmental treatment pathways.[18]

Management

General Principles

Box 46.1 summarizes the key management recommendations from recent guidelines for health professional contributions to rheumatologic pain management.[52–54] Guidelines recommend holistic patient assessment and a stepped care approach, incorporating steps of increasing treatment intensity and cost from education and self-management through specialist and multi-disciplinary care. A personalized approach depends on an individual's risk factors, needs, and values. Not all treatments are necessary or appropriate for all patients. A personalized management plan guided by shared decisions can help in implementing this approach.

• BOX 46.1 Health Professional Management of Pain in Rheumatologic Conditions

Education:

- Educational materials, brochures/online resources encouraging to stay active, sleep hygiene guidelines
- Psychoeducation by a health professional
- Self-management interventions; online/face to face

Physical activity and exercise:

- Advice to stay active
- Physiotherapy; individually tailored graded physical exercise or strength training
- Multi-disciplinary intervention; cognitive behavior therapy addressing fear of movement and catastrophizing

Occupational therapy, orthotist, orthopedic shoemaker:

- Splints, braces, gloves, sleeves, insoles, and shoes
- Daily living aids: e.g. tin openers
- Assistive devices: e.g. cane, rollator
- Ergonomic adaptation at home/workplace

Psychological or social interventions:

- Basic social and psychological management support
- Referral to a psychologist, social worker, self-management support program, cognitive behavior therapy

Sleep interventions:

- Basic education; sleep hygiene
- Referral to sleep therapist/program or specialized sleep clinic

Weight management:

- Dietitian, psychologist, community lifestyle services, or bariatric clinic/surgery

Pharmacologic and joint-specific pain:

- Advice on prescribed and over-the-counter pain relief
- Refer for medical advice if concerns about safe/effective use or if additional pharmacologic treatment may be indicated

Multi-disciplinary treatment:

- If more than one treatment option is indicated or if monotherapy failed

Box 46.1 summarizes the key management recommendations from the EULAR guidelines for health professional contributions to rheumatologic pain management.[52] Comparable guidelines have been issued by the American College of Rheumatology.[53] The Osteoarthritis Research Society International (OARSI) has published guidelines using evidence for knee, hip, or generalized osteoarthritis, including benefits in outcomes additional to pain.[54] All patients should be offered personalized advice and guidance, beyond which a stepped care approach provides treatment access to those who may most benefit. Individuals or professional groups may have particular skills in specific treatment areas, although treatment may be delivered by a range of professional and non-professional team members.

Optimal management requires consideration of the nature and impact of rheumatologic pain alongside other symptoms that the patient seeks to address and risk factors for future pain progression. Realistic expectations should be encouraged based on evidence-based information on likely outcomes for individuals with or without treatment. Decisions to initiate treatment depend on individual benefits balanced against adverse events and risks, focusing on the patient's perspective. Response to any single treatment may vary between individuals, and treatment should be continued where benefits outweigh the risk. Modifiable risk factors such as low mood, anxiety, or obesity might be indications for treatment in their own right and improve pain prognosis. The risk of gastrointestinal bleeding on NSAIDs can be reduced by co-prescription of proton pump inhibitors, and that of osteoporosis on glucocorticoids can be reduced by bisphosphonates in the context of adequate calcium and vitamin D intake.

Different pain mechanisms and qualities in an individual may demand a combination treatment. Interventions might aim to suppress constant, ongoing pain or to prevent, suppress, or abort intermittent pain episodes. Oral NSAIDs can relieve rheumatologic pain, but their use may be limited by the patient's baseline cardiovascular, gastrointestinal, or renal risks. Opiate analgesics may acutely relieve rheumatologic pain. However, despite the absence of evidence of sustained analgesic benefits from opioids in inflammatory arthritis, their use progressively increased from 2002 to 2015.[55] Many patients choose to use analgesic medications on an "as required" basis, according to hour-to-hour variations in symptoms, pre-emptively to facilitate a specific activity or to help manage a pain flare. Such intermittent treatment might help optimize the balance between benefit and risk, and randomized controlled trials have not demonstrated clear superiority of regular over "as required" analgesic use. However, "as required" usage should be strongly discouraged for slow-acting treatments, such as DMARDs, urate-lowering therapies, or antineuropathic analgesics.

Some treatments might effectively reduce pain across multiple diagnoses, whereas others have demonstrable efficacy only for a single disease. Intra-articular glucocorticoid injections may reduce pain in rheumatoid arthritis or osteoarthritis. Systemic glucocorticoids might reduce pain in rheumatoid arthritis,[56] but are not recommended for osteoarthritis. TNFα blocking antibodies might reduce pain from rheumatoid arthritis or psoriatic arthritis, whereas IL-6 blockade might reduce pain only in RA, and IL-17 blockade only in psoriatic arthritis (Table 46.1).[57] For some conditions, specific treatments are not available, and generic pain management approaches should be adopted. Hypermobility syndrome is determined by genetic variants that cannot be modified by specific treatments. Quadriceps strengthening may improve hypermobility-associated anterior knee pain, and strategies developed for people with fibromyalgia may be helpful, although exercises aimed at *increasing* mobility should be avoided by these people.

Exercise therapies are commonly prescribed and may reduce rheumatologic pain, improve strength, balance, and endurance, reduce frailty and falls, and improve general health outcomes. Exercises may need to be individualized based on patient comorbidities. Formal knee exercises may need to be performed in the presence of significant hip disease. Aerobic exercise might be precluded in patients with unstable angina, although increasing aerobic fitness might ultimately reduce cardiovascular risk. Rheumatologic treatments are often complex and might be challenging for people with cognitive impairment or if motivation is compromised by a low mood. Attendance in group exercise may be precluded by agoraphobia or personality disorders.

Osteoarthritis

Randomized controlled trials in osteoarthritis have focused predominantly on major weight-bearing joints such as the knee or hip. Evidence may be less robust for the management of hand OA pain, and although shared principles of analgesia and exercise might be valid, therapies may need adaptation to the particular

TABLE 46.1 Targeted Immunologic Therapies for Inflammatory Arthritis

Molecular Target	Pharmaceutical Agent	Rheumatologic Condition	Direct Actions on Peripheral Sensory Nerves
Tumor Necrosis Factor-α	infliximab, etanercept, adalimumab, certolizumab, golimumab	Rheumatoid arthritis, Psoriatic arthritis, Ankylosing spondylitis	Sensitizes voltage gated sodium channels[70] Upregulates NaV1.7 currents[71] Increases gene expression; CGRP, adrenomedullin, CCL2, MMP9,[72] Nav1.6,[73] Nav1.7,[74] BDNF[75] Increases neurite outgrowth[76]
Interleukin-1 β	anakinra	Rheumatoid arthritis	Increases CGRP expression[77] Increases CGRP,[77] and SP release[78]
Interleukin-6	tocilizumab, sarilumab	Rheumatoid arthritis	Increases TRPV1 and NK1 receptor expression[79]
Interleukin-17	secinumab, ixekizumab, brodalumab	Psoriatic arthritis, Ankylosing spondylitis	Increases axonal outgrowth and mitochondrial function[80]
Interleukin-12/23	ustekinumab, guselkumab	Psoriatic arthritis	Unknown
CD20 (B cell depletion)	rituximab	Rheumatoid arthritis, Systemic lupus erythematosus	Unknown
CD80/86 (T cell costimulator)	abatacept	Rheumatoid arthritis	Unknown
JAK kinase/STAT3	baricitinib, tofacitinib	Rheumatoid arthritis, Psoriatic arthritis	Mediates TNFα induced gene expression[73]

Direct effects on dorsal root ganglion neurons of molecular targets for biologic DMARDs (bDMARDs) and targeted immunomodulatory agents. The predominant analgesic action of bDMARDs is because of the suppression of peripheral inflammation and may be attributed to the suppression of the release of other sensitizing agents. However, molecular targets may themselves sensitize peripheral nociceptors, and direct effects on nerve function may precede the secondary effects of immune suppression. Biologic agents have very low penetration across the blood-brain barrier, such that their analgesic actions are likely to be peripherally mediated. Inhibitors of JAK kinase/STAT3 might have additional effects, for example, on glial cells within the central nervous system.

needs of different joint groups. International guidelines on the management of OA recommend core treatments for arthritis education and structured land-based exercise programs comprising strengthening, cardiovascular fitness, balance training, and neuromuscular control, or mind-body exercises such as tai chi or yoga.[54] These core treatments aim to improve both pain and functional capacity. Meta-analysis of exercise trials suggests that mind-body exercise might be more effective than muscle strengthening exercises for improving knee pain.[58] However, further research is required to determine whether different treatment approaches may be more acceptable or effective for different individuals.

Core exercise therapies may be supplemented by aquatic exercise, gait aids, or self-management programs in people at high risk of poor outcomes. In addition, they might be offered analgesic medications such as topical NSAIDs or oral NSAIDs, if these are not contraindicated, together with proton pump inhibitors for gastroprotection. Topical capsaicin may also provide clinically important pain relief from knee or hand OA, with similar overall efficacy as topical NSAIDs, although different people might respond better to one or other of these medications.[59] Current evidence does not allow accurate prediction of which analgesic medications will best help which patient, and if the first tried intervention is ineffective, a second treatment should be considered. Intra-articular corticosteroid injection may reduce OA pain, often for some weeks, but cannot be self-administered and can rarely be associated with important adverse events, such as accelerated structural damage.[60] Other analgesic medications have limited specific benefits for osteoarthritis pain. Randomized controlled trials have not unequivocally demonstrated the benefit of paracetamol in osteoarthritis, which is less effective for OA pain than are NSAIDs. Paracetamol has a narrow therapeutic window above which liver toxicity may be significant as well as other adverse events comparable to those observed with NSAIDs.[61] Oral or transdermal opioids do not have evidence of sustained benefits for OA pain, and risks of nausea, constipation, cognitive impact, falls, and dependency may outweigh any benefit. There is an urgent need for more effective medical treatments for OA pain, several of which are in development.[18]

Where core and supplemental interventions do not adequately control osteoarthritis pain, intra-articular hyaluronic acid injections might be considered as also may combination of exercise with cognitive behavior therapy.[54] However, failure of conservative pain management approaches may indicate a need for surgical intervention. Better pre- and perioperative pain control, lack of musculoskeletal comorbidities including fibromyalgia, low indices of central sensitization, low BMI, more joint space narrowing, good mental health, and low catastrophizing predicted better outcomes from large joint arthroplasty. However, these factors explain only a small proportion of the variation in outcome and should be viewed as targets to improve outcome rather than hurdles that must be overcome before surgery is offered. For appropriately selected

patients, pain improvement following arthroplasty is usually pronounced, particularly with hip replacement surgery. However, up to 20% of people undergoing total knee arthroplasty continue to suffer from pain.[62] Relieving pain alone might not be sufficient to enable people to return to their valued activities. Adjunctive therapies, addressing fear avoidance, low mood, and comorbidities, play important roles.

Inflammatory Arthritis

Optimal management of pain in inflammatory arthritis can reduce the burden of symptoms and enable patients to better manage their inflammatory disease. People with inflammatory arthritis report major concerns with pain, fatigue, stiffness, and disability, whereas physicians often pay more attention to biomarkers of inflammation or joint damage. This discrepancy has been associated with worse outcomes after treatment.[63] The aim of modern DMARDs is to induce and maintain inflammatory disease remission, but many patients continue to experience intermittent flares or persistent low-grade inflammation. Non-inflammatory pain mechanisms may persist despite resolution of inflammation, and improvements in pain on treatment, although clinically important, may not be complete, even when inflammation is completely suppressed.[32]

Rheumatoid Arthritis

Suppressing inflammation can reduce pain in active rheumatoid arthritis,[6] and reduce stiffness and joint swelling. Immunosuppressive therapies can slow or stop structural damage and are referred to as DMARDs. A wide variety of DMARDs are available, with high-quality randomized controlled trial evidence of clinically important benefits for pain. These include conventional synthetic DMARDs such as methotrexate and targeted biologic agents including TNF-α blockers, B cells (rituximab) or T cells (abatacept) directed therapies, IL-6 blocking antibodies (tocilizumab, sarilumab), and small molecule JAK/STAT kinase inhibitors (e.g. baricitinib, tofacitinib; Table 46.1).[64] Each significantly increases the risk of infection, and several may have potential liver or hematologic toxicity. Regular blood monitoring during treatment may reduce risks by detecting adverse events before they become clinically apparent. The requirement for subcutaneous or intravenous delivery of biologic agents, need for monitoring, and cost may necessitate provision through secondary care services. Immunosuppressive therapies usually do not have immediate benefit, and depending on the chosen agent, treatment for up to six months may be required to definitively assess the benefit. Pain may be severe, and there is both a practical and ethical imperative to relieve pain before these slow-acting treatments can take effect.

More rapid suppression of inflammation at disease onset or during flares might be achieved by glucocorticoids. These may be administered by local (e.g. intra-articular) injection or systemically by tablet, intramuscular injection, or intravenous infusion. Systemic glucocorticoids administered by any of several routes may provide effective analgesia for inflammatory pain in rheumatoid arthritis and reduce stiffness, joint swelling, and fatigue. Adverse events with short-duration treatment are usually not troublesome, although high doses of glucocorticoids can precipitate or destabilize diabetes mellitus or induce psychosis. Short courses of low dose systemic glucocorticoids, such as prednisolone (7.5 mg daily or less), may be less likely to cause problems but might be less effective at reducing pain. Long term glucocorticoid use is associated with reduced symptomatic benefit and increased risk of adverse events, some of which can be mitigated by concomitant medication (e.g. bisphosphonates to reduce osteoporosis risk). Patients who experience a good symptomatic response to high dose glucocorticoids shortly after disease onset might be reluctant to engage with maintenance DMARD treatment in light of the latter's slow onset of (and therefore less noticeable) symptomatic benefit and potential for adverse events. However, long term glucocorticoid use itself has high risk and low efficacy and does not retard structural damage in established inflammatory arthritis. DMARDs should be introduced to permit the eventual withdrawal of any initial glucocorticoid therapy.

NSAIDs may also reduce inflammatory pain in rheumatoid arthritis and improve joint stiffness. They have the advantage of ready availability and may be used "as required." Topical NSAIDs or topical capsaicin may be beneficial in rheumatoid arthritis, even in the absence of concurrent osteoarthritis, although evidence is less robust than in osteoarthritis. Glucocorticoids also inhibit cyclo-oxygenases, and concurrent use of NSAIDs with glucocorticoids substantially increases the risk of gastrointestinal bleeding. However, concurrent NSAIDs may provide analgesic benefits over and above the analgesia from low dose glucocorticoids below 7.5 mg prednisolone daily. The peak age of onset of rheumatoid arthritis is now >50 years, and comorbid cardiovascular or renal disease or anticoagulant treatment may limit the number of people who can benefit from oral NSAIDs.

Other Forms of Inflammatory Arthritis

Pain in psoriatic, enteropathic (e.g. ulcerative colitis and Crohn's disease), reactive arthritis, and ankylosing spondylitis displays similar characteristics, periodicity, and responds to many similar treatments as rheumatoid arthritis pain, although with some important differences (Table 46.1). The molecular pathways of inflammatory pain differ between diseases. For example, IL-17 blockade may effectively reduce pain in psoriatic arthritis but is not currently recommended for rheumatoid arthritis.[64] Different forms of inflammatory arthritis may have different comorbidities, and treatments should be selected to reduce the symptoms and impact of comorbidities. For example, TNF-α inhibitors may improve spinal and peripheral joint pain and improve skin disease in psoriatic arthritis. Seronegative inflammatory arthritis may be associated with uveitis, sometimes sight threatening, and a difficult balance may be needed between symptomatic benefit from some biologic agents and their potential to precipitate or aggravate ocular disease. TNF-α inhibition has not been conclusively shown to slow the progression of bone structural changes in inflammatory spinal disease, but excellent symptomatic benefit alone justifies the associated risks of immunosuppressant therapies.

Non-inflammatory Pain and Inflammation Nonselective Interventions in Inflammatory Arthritis

Even when inflammatory disease is in remission, people with inflammatory arthritis may continue to experience unacceptable pain. An acutely painful joint in someone whose arthritis is otherwise well controlled should always raise the relatively rare possibilities of other diagnoses, such as infection or insufficiency fracture. Chronically persistent and disabling pain is reported by up to 30% of patients with rheumatoid arthritis,[32] or psoriatic arthritis[65] despite objective evidence of inflammatory disease remission. This disappointing average outcome conceals subgroups in which pain remits to levels reported by normal populations, but also other subgroups who appear to gain little analgesic benefit from the introduction of DMARD treatment.[32] Persistent non-inflammatory

pain is, therefore, a major problem for these patients. Furthermore, the assessment of inflammatory disease activity and clinical scores used to determine the response to immunomodulatory treatments are strongly influenced by pain.[26,30] Pain improvement may be necessary to persuade patients and clinicians that inflammatory diseases are adequately controlled and avoid unnecessary escalation and risks from immunosuppression.

Persistent "non-inflammatory" pain may be because of pre-existing morbidities or be a consequence of earlier active inflammatory disease. Half of the patients presenting to secondary care with early rheumatoid arthritis already have radiographic osteoarthritis of the hands or feet.[66] Up to a third of people with established rheumatoid arthritis, psoriatic arthritis, or spondylarthritis may satisfy the classification criteria for the diagnosis of fibromyalgia.[67] Fibromyalgia diagnosis may be only the tip of the iceberg, and fibromyalgianess affects many people who do not meet the fibromyalgia classification criteria for a formal diagnosis.

Treatments recommended for primary fibromyalgia or osteoarthritis should be offered to people with inflammatory arthritis when diagnosed with these comorbidities. Indeed, pain management strategies used in non-inflammatory pain conditions can be helpful for people with inflammatory arthritis, even in the absence of a comorbid diagnosis. Care from health professionals should use a patient-centered framework with a personalized management plan, pharmacologic and joint pain-specific treatments, and a multi-disciplinary approach.[52,53] Strong research evidence supports the use of education, aerobic exercise, cognitive behavior therapy, and weight loss in obese individuals. In addition, there is some evidence for benefit from strength training, hypnotherapy, biofeedback, balneotherapy, yoga, tai chi, neuromodulation, acupuncture, chiropractic, manual, and massage therapy.

Comorbid inflammatory arthritis raises additional concerns in people with fibromyalgia or osteoarthritis. Each of these conditions may be associated with "pain flares," and patients and clinicians may struggle to understand whether any particular flare indicates a need to escalate anti-inflammatory treatment or to pursue more intensive pain management strategies. Misattribution of pain to non-inflammatory causes might prevent access to effective treatments, whereas repeated courses of high dose glucocorticoids are inappropriate for fibromyalgia or osteoarthritis pain flares. Engagement with chronic pain management interventions may be limited if patients believe that their pain will resolve once they are established on effective DMARD treatment. Graded physiotherapy may be helpful for osteoarthritis and fibromyalgia, but an increase in pain during an exercise program may indicate a need for further individual assessment of inflammatory disease activity.

In summary, treatments for fibromyalgia and osteoarthritis are not contraindicated in patients with inflammatory arthritis, and many modalities have benefits for both inflammatory and non-inflammatory pain. Many patients require many months of DMARD treatment adjustments before inflammatory disease enters remission. Early and effective management of non-inflammatory pain should aim to minimize suffering during this period, reduce the risk of chronic pain and equip the patient for effective self-management in the long term.

Gout and Pseudogout

The key aims of gout management are to relieve acute pain during an attack and prevent future attacks by controlling serum urate levels.[68] Prevention is not currently possible for pseudogout, for which management focuses on treating acute attacks.[69] Gout is associated with significant renal, cardiovascular, and metabolic comorbidities that may complicate treatment and require management in their own right.

Rapid pain reduction during acute attacks of gout or pseudogout may be achieved using colchicine, NSAIDs, and/or glucocorticosteroids. Colchicine inhibits microtubule function, thereby reducing leukocyte degranulation. Microtubules also regulate gastrointestinal epithelial and neuronal function, such that colchicine may also often cause diarrhea, with neuropathy, if use is prolonged. NSAIDs are similarly effective for treating acute crystal-induced pain. However, NSAIDs may be contraindicated for people whose gout is associated with significant renal disease, a cause of hyperuricemia, or metabolic syndrome and associated cardiovascular disease. By intra-articular injection or systemic administration, glucocorticoids may also rapidly reduce pain during an acute crystal attack. However, their use requires the prior exclusion of joint infections. Despite the severity of pain during crystal attacks, strong opioids are usually unnecessary because more effective analgesia can be achieved with specific therapies directed at inflammatory mechanisms.

In addition, to acute gout attacks, management aims to reduce the risk of recurrence. Recognized precipitants of gout attacks may be avoided, such as alcohol intake or medication changes such as thiazide diuretics. However, long term urate-lowering treatments, such as allopurinol, should be considered for those at high risk of future attacks, such as those who have experienced more than a single attack or those with very high serum urate levels. With effective urate-lowering therapy, complete prevention of acute attacks is possible. Disappointingly, many patients continue to experience repeated attacks of gout over many years. The reasons for this are complex. A lack of understanding that treatment offers control rather than cure might lead people to discontinue once the patient feels well. Reduction in serum uric acid concentrations on medication may vary considerably between individuals, and dosage titration is required to achieve serum urate concentrations in the lower half of the normal range if acute attacks are to be prevented. Acute attacks may be triggered by either increasing or *decreasing* urate levels, and patients may not understand that an attack shortly after starting treatment, while serum urate levels are decreasing, does not predict long term treatment failure.

Conclusions

Rheumatologic conditions are commonly associated with both acute and chronic pain. Many have clearly defined pathologic mechanisms, enabling specific treatments to offer rapid and effective pain relief. However, pain in rheumatologic conditions is multifactorial and complex, and suppression of underlying disease often does not eliminate pain. Advances in targeted immunosuppressive therapy have made inflammatory disease remission a realistic goal for most patients with rheumatoid arthritis. However, non-inflammatory pain mechanisms remain resistant to treatment, and new treatments are urgently needed. More could be gained from existing therapies by careful and timely selection and targeted access for those most likely to benefit. The multitude of potentially useful pain management strategies offers hope to those seeking help, but some feel lost and unable to find the best way forward. This journey is shared by patients, family members, friends, and professionals. Rheumatologic pain management demands a personalized approach based on the individual's values and aspirations and a clear explanation from healthcare professionals regarding their evidence-based understanding of pain mechanisms, treatment benefits, and risks.

Key Points

- People with rheumatologic conditions suffer from diverse pains, which may vary in severity, quality, and impact over time, and between individuals.
- Multiple and changing mechanisms underlie rheumatologic pain, including peripheral nociception and nociplastic pain associated with mechanisms in the central nervous system.
- Pain in rheumatologic conditions is often linked to comorbid symptoms of fatigue, stiffness, disability, low mood, and anxiety. Pain should be managed alongside these other symptoms to maximally improve the quality of life.
- Pain mechanisms and, therefore, some treatment recommendations overlap between inflammatory and non-inflammatory rheumatologic conditions and with other non-rheumatologic chronic pain.
- General principles of rheumatologic pain management reflect those in other chronic pain conditions, benefiting from a personalized, multi-disciplinary approach proportionate to the needs of the patient.
- Treatments targeting molecular pathways of specific immunity can effectively reduce pain in inflammatory rheumatic conditions such as rheumatoid arthritis, but residual non-inflammatory pain remains a major treatment challenge.
- Intermittent pain, often severe and unpredictable, has a major impact on people with rheumatologic conditions. In gout, maintenance urate-lowering therapy can prevent flares if adequately implemented, but adequate flare prevention in other rheumatologic conditions requires further research.
- Painful and non-painful comorbidities are common in people with rheumatologic conditions and should inform treatment choices to maximize benefits for the person as a whole and to minimize the risks of adverse events.
- Individuals have diverse values and might place more or less emphasis on pain and its relief, other symptoms, cost and inconvenience of treatment, and other potential or experienced adverse events. Treatment should be tailored to the individual's needs and values.
- Pain management is a moral and personal necessity that should not be delayed while establishing optimal disease modification, which may take several months.

Pain Management in Patients With Comorbidities

NATALIE H. STRAND, ANDREA L. CHADWICK

Introduction

Pain is defined by the International Association of Pain (IASP) as "an unpleasant sensory and emotional experience associated with, or resembling that associated with actual or potential tissue damage."[1] Given that pain is not only a symptom but also an independent disease, it is highly likely that patients with chronic pain may also have other medical comorbidities and disorders that will influence the scope of treatments that are recommended. In any patient with chronic pain, the severity, frequency, and tolerance to the condition are variable and are influenced by a variety of factors, including one's cultural background, expectations, behaviors, and physical and emotional health. In patients with comorbid conditions such as renal and hepatic diseases, diabetes, and the elderly, an understanding of how these conditions may influence pain treatment is of utmost importance. The appropriate selection of non-pharmacologic, pharmacologic, and interventional treatments based on the underlying comorbid conditions has the potential to improve physical functioning, emotional wellbeing, and overall quality of life. The scope of this chapter is to understand how pain management strategies need to be understood and tailored to specific comorbid medical conditions, including renal disease, liver disease, diabetes, and the frail/elderly population.

Renal Disease

Prevalence

Chronic kidney disease (CKD) is a global public health problem that is increasing in incidence and prevalence and is associated with poor patient outcomes and high medical costs.[2] CKD is defined as the progressive and gradual loss of the kidneys to concentrate urine, excrete wastes and metabolites, secrete hormones, and conserve electrolytes. There is a distinction between CKD and end stage renal disease (ESRD), which is the deterioration of kidney function to the point where renal dialysis or transplantation is required for survival. Patients with CKD and ESRD experience a high severity and prevalence of physical symptoms related to their diseases. The symptom burden in these populations is greater than that of the general population, and despite this well-described complication, many patients have underrecognized, underestimated, and undertreated symptoms related to their CKD and ESRD.[3–5] Pain is one of the most common symptoms encountered in CKD and ESRD, with the reported prevalence of pain ranging from 30 to over 58%.[6–9] In patients with ESRD who are on hemodialysis (HD) or peritoneal dialysis (PD), the prevalence of acute and chronic pain has recently been shown to be up to 80%.[10] Of these patients who report pain, it has been shown that over half report pain as moderate to severe in intensity.[8,9,11,12]

Etiologies

Similar to the underlying disease processes present in CKD and ESRD, the pain experienced by patients with kidney disease is often multifactorial. Etiologies of pain can be either straightforward or complex and related to a multitude of issues (Table 47.1). Symptoms can be caused as a direct result of the primary underlying kidney disease process, such as pain related to autosomal dominant polycystic kidney disease, or they can be related to associated underlying systemic and comorbid diseases such as diabetes, peripheral vascular disease, and various musculoskeletal processes.[7] Pain may also be experienced as a direct result of HD or PD procedure itself.[10,12] It is also important to remember that additional pain related diagnoses such as anxiety, depression, and sleep problems may coexist with the chronic pain syndromes experienced by CKD/ESRD patients and that these conditions may feed into the challenges that coincide with treating chronic pain in these populations.

As in any patient with acute or chronic pain, determining the type and severity of the pain can provide an excellent roadmap for outlining treatment plans. Listening to the patient about their symptoms and experiences surrounding their pain provides a great opportunity to provide them with compassion and validation of the significance of their problem and is an important piece of the therapeutic relationship.

Acute and chronic pain can be classified as nociceptive, neuropathic, nociplastic, or mixed pain. By definition, nociceptive pain arises from actual or threatened damage to non-neural tissue and results from the activation of nociceptors, while neuropathic pain is a clinical description that requires a definite lesion or a specific disease process that affects the somatosensory nervous system. The persistence of nociceptive stimuli can lead to several functional and structural changes in the central nervous system, known as central sensitization.[13] Many chronic pain conditions are characterized by central sensitization, widespread pain, and altered descending pain modulation.[14] The IASP has recently introduced a new term, nociplastic pain, defined as conditions that arise from altered nociception, without clear evidence of actual or threatened

TABLE 47.1 Pain Origins in Chronic Kidney Disease and End Stage Renal Disease

Pain Origin	Examples
Intrinsic Kidney Pathologies	Calciphylaxis Renal osteodystrophy (bone pain) Limb ischemia because of dialysis access steal syndrome Dialysis related amyloid arthropathy
Underlying or Comorbid Disease Processes	Autosomal dominant polycystic kidney disease Urinary tract infections Vascular peripheral neuropathy Diabetic peripheral neuropathy Amyloidosis Phantom limb pain Dermatologic conditions Malignancy Osteoporosis
Dialysis Related	AV fistula/graft surgical creation Needlestick cannulation of HD AV access Instillation of PD fluid PD associated peritonitis, low back pain Muscle cramping from dialysis ultrafiltration Pruritis Headache Chest pain associated with intradialytic hypotension Dyspnea Infected HD catheter
Pain Unrelated to Kidney Disease	Osteoarthritis Malignancy Degenerative disc disease Radiculopathies Migraines Gout Fibromyalgia Restless leg syndrome Entrapment neuropathies

Clinical Presentation and Assessment of Pain in CKD/ESRD.

tissue damage or lesions, or disease of the somatosensory nervous system. Patients with ESRD may suffer from nociceptive, neuropathic, nociplastic, or mixed pain states. Ascertaining the mechanism of chronic pain is essential in the choice of mechanism-based analgesic therapies.[15,16]

A thorough and complete pain assessment includes determining several attributes that contribute to acute and chronic pain, such as pain severity, pain quality (described in the previous paragraph), eliciting and attenuating factors, impact of pain on daily activities and physical functioning, pain interference with mood and sleep, and effects of pain on quality of life. No instruments have been specifically designed and validated for pain assessment in CKD/ESRD patients. However, several approaches can be used. One-dimensional scales are instruments used to identify pain severity, while multidimensional scales can be utilized to reflect the biopsychosocial model of pain that integrates social and psychological paradigms with the biologic mechanisms of pain.

The most commonly used one-dimensional scale for pain assessment is the 11 point numeric rating scale (NRS), where zero indicates no pain and ten is the worst imaginable pain, and the 10 cm (100 mm) continuous visual analog scale (VAS), which is anchored by the two verbal descriptors for each extreme ("no pain" and "pain as bad as it could be"). Many of the same assessment tools that exist for patients with non-kidney disease pain are valid and reliable in the CKD/ESRD population. The McGill pain questionnaire (MPQ) and the brief pain inventory (BPI) are the most common multidimensional scales used to assess pain. The MPQ has been in use since 1975 and is a widely used instrument to evaluate pain and helps determine both quantitative and qualitative aspects of pain, such as location, grade, temporal characteristics, and intensity.[17] The BPI, initially developed for cancer patients but validated for use in chronic non-cancer pain, uses an 11 point NRS for pain intensity, requests the patient to draw the site(s) of pain on a body diagram, and uses an 11 point NRS to assess pain interference in seven domains, including general activity, mood, walking ability, work, relations with other people, sleep, and enjoyment of life.[18]

Assessment tools such as the modified Edmonton symptom assessment system (m-ESAS v. 2),[19] and palliative care outcome scale-renal (POS-renal)[20] are renal-specific screening tools that may be more appropriate for routine clinical screening for pain in renal patients. These assessments identify the presence of pain and provide opportunities for discussions about appropriate palliative and supportive care treatment options.

Barriers to Pain Management in Kidney Disease

As mentioned previously, chronic pain is very common in patients with CKD and ESRD. However, it has historically been underrecognized and often poorly managed. It is well known that poorly controlled pain leads to decreased quality of life, poor physical functioning, reduced mobility, increased healthcare utilization, and longer hospital stays.[16] Numerous reasons have been reported for insufficient pain management in CKD and ESRD, including inadequate pain assessment, concerns about analgesic-related adverse effects, and misconceptions.[3,5,16]

As described in the previous section, an adequate pain assessment requires an accurate medical history, thorough physical examination, and the application of validated tools for the identification of pain intensity and quality. The presence and severity of pain should be regularly assessed in patients with CKD and ESRD, and if applicable, during each HD session. Pain is generally undertreated in patients with CKD and ESRD because of the fear of the potential toxicity of analgesic drugs. Overtreatment, overdose, and inadequate analgesia can result from inappropriate dosing of non-opioid and opioid analgesics. Unfortunately, quality data or guidelines on the pharmacokinetics, clinical efficacy and safety of many common analgesics in this population are lacking. Indeed, the translation of pharmacologic pain management methods used in non-CKD/ESRD populations can be dangerous, as patients with CKD and ESRD have reduced renal function and altered pharmacokinetics.[21] Alterations in metabolism and excretion may lead to significant adverse toxicities and side effects. Renal dose adjustments are required for most analgesics.

Setting Expectations

At the initiation of any pain management treatment program, the provider must discuss with the patient the expectations of therapy. These expectations should include the identification of reasonable therapeutic goals, including the level of pain that is acceptable for

a patient's quality of life, the risks and benefits of the treatment(s), the potential duration of pharmacologic therapy, and if applicable, the components of a pain contract for continued care. The overall goal of both immediate and long term pain management should be to improve the functional status. Moreover, a discussion that the patient should not expect to be pain-free is of importance and that a reasonable expectation should be that pain may not be completely resolved or controlled and that a 30% reduction in pain symptomology is often identified as clinically meaningful.[22]

Pain Management Approach in Patients With CKD and ESRD With or Without Hemodialysis

General Principles

Pain treatment should be tailored to each individual according to the type and severity of pain. In general, non-pharmacologic options should be used first. Non-pharmacologic treatment options can be broadly categorized as psychosocial/behavioral interventions (e.g. cognitive behavior therapy (CBT), mindfulness) and physical interventions (e.g. exercise, physical therapy, yoga, acupuncture, electrical stimulation). Although most of these have not been specifically tested in CKD/ESRD, they have been proven to be effective in other chronic pain states and thus provide an encouraging approach for the treatment of pain in this population, either alone or as an adjunct to pharmacologic treatment.

Pharmacologic analgesic therapy should be based on the type of pain, severity of pain, and when the benefits of medications are cautiously weighed against possible side effects, drug-drug interactions, and coexisting medical morbidities. It is recommended that patients initiate therapy on a minimal dose of an analgesic medication and up-titrated slowly based on response and tolerance with very close monitoring for side effects or adverse events. An opioid-sparing approach is recommended in most cases.

Non-pharmacologic Therapies

The non-pharmacologic approach is the first step in pain management. In particular, in patients where drugs are not free of risks, non-pharmacologic techniques should be encouraged. Non-pharmacologic interventions include biofeedback, CBT, massage, and physical therapy/exercise programs.

CBT has become a well-established and accepted treatment for chronic pain in the general population. Robust evidence from a meta-analysis of 35 trials (>4700 patients) supports its efficacy for improving chronic pain symptoms and pain related physical disability in the general population. However, the effect size may be small, and the long term effects are not durable.[23] In the CKD/ESRD population, CBT is effective in improving depression, but its effect on pain has not been tested.[24] CBT has been shown to be effective in the general non-cancer chronic pain population and is based on concepts surrounding poor self-management skills, self-efficacy, and coping skills, which typically exist in this patient population. There is a strong premise that CBT may be a successful non-pharmacologic pain management strategy.

The potential benefits of complementary and alternative medicine have not been adequately investigated in patients with CKD/ESRD. These interventions include relaxation techniques, mindfulness, and acupuncture. A systematic review of randomized control trials investigating the effect of relaxation techniques in >400 patients with chronic pain in the general population found no significant benefit in reducing pain. However, the studies were of low quality, and thus the data are not conclusive at this time.[25] In HD patients, two small studies have shown that relaxation techniques may improve pain intensity and health-related quality of life.[26,27] Mindfulness-based techniques including meditation, which involves focusing the mind on experiences (e.g. sensations, emotions, thoughts) in the present moment, have shown some promise in improving pain in the non-ESRD population.[28] Moreover, a recent pilot study demonstrated that a brief, individualized, chairside mindfulness meditation intervention was feasible and acceptable for HD patients.[29] A recent Cochrane analysis evaluated 24 studies on various types of acupuncture in patients with CKD. There is a paucity of evidence on the efficacy of acupuncture for fatigue, depression, sleep disturbance, and uremic pruritus in HD patients. Moreover, data on possible acupuncture-related harm are lacking. Therefore no conclusions may be drawn on its safety.[30]

In the multimodal approach to chronic pain, invasive interventional pain techniques may potentially play a role in treating pain refractory to conventional pharmacologic treatment or to reduce the dose of analgesics in patients with CKD/ESRD. There is a paucity of literature on this topic. However, spinal cord stimulation (SCS) could be useful in HD patients suffering from peripheral vascular disease, stump pain after amputation, and painful diabetic neuropathy (PDN), but current guidelines only support a weak recommendation.[31]

Pharmacologic Therapies

The World Health Organization ladder for analgesic pain control, originally created for cancer pain treatment, has been validated for use in the CKD/ESRD population.[32] The modified ladder uses a three-step approach for pain management. Mild pain is generally treated in step 1 using non-opioid analgesics, such as acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs). Step 2 treats moderate pain with the addition of mild or weak opioids such as tramadol, low dose oxycodone, and low dose hydromorphone. Step 3 initiates higher-dose opioids, such as higher doses of oxycodone/hydromorphone, fentanyl, methadone, and buprenorphine to treat severe pain. Adjunctive medications, such as gabapentin, pregabalin, tricyclic anti-depressants (TCAs), and serotonin norepinephrine reuptake inhibitors (SNRIs), can be added at any step of the ladder.[33]

When pharmacologic interventions for pain management in CKD/ESRD are being implemented, it is best to identify the level of current renal function. Moreover, special emphasis should be placed when choosing pharmacologic therapies to prevent further deterioration of renal function and protection of existing renal function in patients with moderate to severe impairment. Therefore, drug adjustments may be required for CKD/ESRD. Two methods of dosing regimen adjustment have been recommended: (1) extending the time between doses while maintaining the same dose size (reducing the number of daily doses) or (2) to reduce the size of the individual prescribed dose at the same dosing interval.[16] Sometimes, a combination method can be needed when both these methods (interval extension and dose reduction) are used. The interval extension method is generally not indicated for drugs with a short half-life because of the risk of a prolonged period with a subtherapeutic drug concentration. However, it is recommended for drugs with a relatively long half-life.[16]

Non-opioid Medications

Acetaminophen is the most commonly used non-opioid analgesic for ESRD.[34] Notably, the National Kidney Foundation promotes acetaminophen as the non-narcotic analgesic of choice for mild

to moderate pain in CKD/ESRD.[8] The proposed adjustment in HD patients suggests dosing every 8 h.[35] Clinical studies have shown the effective removal of acetaminophen and its metabolites by HD.[36]

NSAIDs are commonly prescribed for their inflammatory and analgesic properties. However, they are known to have gastrointestinal, cardiovascular, and renal toxicity. Clinical investigations on NSAIDs in patients with CKD/ESRD are typically single-dose studies or trials conducted for short periods and were not designed to evaluate efficacy and safety.[16] Limited information is currently available regarding the use of NSAIDs in patients undergoing HD. Considering the potential for nephrotoxicity, it is strongly recommended to avoid NSAIDs in patients with CKD/ESRD.[16] Despite this, the literature suggests that they continue to be commonly prescribed in this population. In a cohort study of 972 subjects with CKD, 16.9% used NSAIDs every day or several times a week, which increased to 35% among those on HD.[37] In 46.7% of these cases, the CKD/ESRD patients used NSAIDs without being advised to do so by a medical professional and were unaware of the potential side effects of the painkillers, and the remaining were prescribed by physicians or pharmacists. Over 40% of the exposed patients experienced renal function deterioration in this cohort, 37.6% experienced peptic ulcer disease, and 18.2% experienced altered blood pressure control.[37] Thus if NSAID use is considered in patients with kidney disease, a full description of risks and benefits should be discussed with the patient, and ongoing monitoring of renal function throughout treatment should be performed. Topical NSAIDs, such as diclofenac gel, can be effectively used without significant systemic adverse effects.[38]

Anti-convulsants, particularly gabapentinoids, are strongly recommended as first line treatment for the management of neuropathic pain conditions, which are common in CKD/ESRD patients.[39] Gabapentin and pregabalin have been specifically evaluated in patients with CKD/ESRD. Dose adjustment is required in terms of dose reduction and interval extension with these medications. Gabapentin has a favorable pharmacokinetic profile. It is excreted unchanged by the kidneys in urine, and plasma concentrations and toxicity correlate with impaired renal function. Its half-life, 6 to 8 h in healthy subjects, decreases to 4 h after HD and increases to 132 h without HD in ESRD patients.[40] The low protein binding makes gabapentin easy to dialyze (approximately 35%). The recommended dose in HD patients is up to 300 mg daily, with a supplemental 200 to 300 mg dose after each HD session.[41]

Similarly, pregabalin is easily dialyzable because it has a low molecular weight, a low volume of distribution (0.5 L/kg), and is not bound to plasma protein.[42] The maximum recommended dose of pregabalin in ESRD patients is reduced to 25 to 75 mg/day, with mental doses after HD. However, a recent prospective, open-label, single-arm study on pregabalin for neuropathic pain in patients undergoing HD evaluated 45 patients carefully titrated to 150 mg during a 12 week study period.[43] The authors reported a 22.2% withdrawal rate because of side effects (mainly drowsiness and dizziness) without serious drug-related adverse events. Pregabalin has been shown to be effective in reducing pain scores and improving QoL.[43] These medications are associated with an increased risk of falls, cognitive impairment, and altered mental status in a dose-dependent fashion.[44] These effects may be more pronounced in the elderly population.

Alternative neuropathic analgesics such as SNRI and tricyclic anti-depressants (TCA) have been extensively studied and are reported to be efficacious in non-CKD/ESRD populations and are recommended as first or second line treatment in many neuropathic chronic pain conditions. However, data supporting the safety and efficacy of these medications in CKD/ESRD are not available. These medications are not removed by HD, and the anticholinergic and serotonergic effects of these medications may be intensified in patients with ESRD. A recent systematic review concluded that most studies on anti-depressants for depression in ESRD patients involved a small number of subjects and were observational, leading to possible bias. Dose reduction is currently recommended for duloxetine, amitriptyline, venlafaxine, desvenlafaxine, and milnacipran.[45] In general, anti-depressants should be started at lower doses and carefully titrated to the effective dose to reduce the risk of side effects.[46]

Opioid Medications

Opioids are widely used in chronic pain management and historically have been the mainstay of pharmacologic treatment for severe and refractory chronic pain. However, there is no high-quality clinical evidence for their long term use in chronic non-cancer pain, and systematic reviews have only reported a moderate benefit.[47] The Centers for Disease Control and Prevention (CDC) current guidelines recommend a cautious opioid prescription for chronic pain in which non-opioid therapy is indicated as the preferred treatment for chronic pain and opioid use is suggested only when the benefits for pain and function are expected to outweigh the risks.[48] Compared with the general population, patients with CKD and ESRD are likely to be undertreated with opioids because of provider concerns about decreased metabolism and clearance and the increased risk of adverse events.[49] Should opioid use be initiated in CKD/ESRD patients, it is recommended that they be started with the lowest possible dose and using immediate release formulations (instead of extended release).[50] If the pain does not respond with an improvement in pain using a low dose, the pain may not be opioid-responsive. If the pain responds slightly, for either a lower degree or a shorter period than desired, it may be reasonable to increase the dose or frequency. Prescribers should be cautious with opioids at a morphine milligram equivalent daily dose (MME) above 50 mg. Concurrent benzodiazepines and other sedatives should be avoided in line with the current CDC guidelines.

The therapeutic window for opioid medications is narrow, even in a generally healthy population. Individuals with CKD or ESRD have not been included in many trials of opioid use in chronic pain, so the specific analgesic impact of opioids is not known in this population. However, individuals with CKD and ESRD likely experience many known side effects of opioids, including sedation, confusion, and constipation. While the literature on these specific adverse effects is limited in populations with CKD/ESRD, they are well documented in the elderly, which represents a high proportion of individuals with CKD/ESRD. Even low dose opioids are associated with increased morbidity and mortality in the context of ESRD.[51,52]

ESRD and HD lead to additional complications related to the metabolism and dialyzability of opioid medications. Most naturally occurring opioids have active metabolites, which may lead to increased toxicity in patients with CKD/ESRD. For example, morphine and codeine are metabolized in the liver to the active metabolites morphine-6-glucuronide (M6G) and morphine-3-glucuronide (M3G), respectively.[33,53] These metabolites are known to accumulate in patients with impaired kidney function,

and their accumulation can lead to potential neurotoxicity and other adverse reactions, such as nausea, vomiting, and respiratory depression. The active metabolite of meperidine, normeperidine, is renally excreted and highly neurotoxic.[33,53] When it accumulates in patients with CKD and ESRD, it places them at a high risk of seizures. Morphine, codeine, and meperidine are generally avoided in patients with decreased kidney function, similar to a few other opioids (Table 47.2).

Semi-synthetic opioids such as hydromorphone, synthetic opioids (e.g. fentanyl and methadone), and the semi-synthetic opioid buprenorphine do not have active metabolites and are reported to have a higher safety profile in patients with CKD and ESRD.[16,50] Although oxycodone is metabolized by the liver into active metabolites that may accumulate in CKD/ESRD, it may be used cautiously in these patients. However, sustained-release formulations should be avoided because of the risk of accumulation and toxicity.[16,50] Buprenorphine has a lower risk profile and can be utilized with either split dosing or a continuous transdermal patch.[54] Tramadol belongs to a class of medications with a dual mode of action, both as an agonist of the μ-opioid receptor and as an SNRI. Since its metabolism depends on an individual's cytochrome P450 profile, its opioid metabolism and resultant potency are highly variable and unpredictable.[55] It is generally considered safe in the general population and in CKD and ESRD in its immediate release formulation.[8,56] However, given the variability in effect, it should be used cautiously, starting with the smallest dose in patients with ESRD. Limited data exist for the safety of extended release tramadol in CKD and ESRD, and as such, its use in this population is not recommended.[8,56]

As in any patient population, when prescribing opioids, providers should educate patients on the risks of opioid overdose and incorporate risk mitigation strategies into the treatment plan. This includes considering a prescription for naloxone, an opioid antagonist, when risk factors for opioid overdose, such as a history of overdose, history of substance use disorder, higher opioid dosages (≥50 MME/d), or concurrent benzodiazepine use, are present.[48]

Liver Disease

Prevalence

Liver disease is a major public health problem, accounting for over 700,000 deaths annually.[57] Pain is very common in patients with liver disease, and it is often difficult for practitioners to manage because of underlying medical comorbidities. Pain has been reported in up to 82% of patients with liver cirrhosis and is chronic in over half of the patients with liver it.[58] Despite the high prevalence of pain in this population and its potential for adverse consequences, there is limited research, knowledge, and guidance on the management of pain in liver disease and cirrhosis, with most available literature focusing on pain assessment and treatment in cirrhotic disease.

Assessment of Pain in Liver Disease and Cirrhosis

An evaluation of pain in patients with liver disease or cirrhosis can be accomplished via standard screening assessments, such as numeric or visual analog rating scales. As with the general population, as discussed in detail in the previous section on renal disease, once pain has been identified as being present, the next step is to determine the nature and likely mechanism of the pain, including location, quality, and duration, and perform a physical examination to assess underlying etiology.[58]

TABLE 47.2 Opioid Medications to be Avoided in Chronic Kidney Disease/End Stage Renal Disease

Medication	Pharmacokinetics in CKD and ESRD	Known Observed Toxicities
Morphine	Active metabolite morphine-6-glucuronide (M6G) is renally cleared M6G accumulates in renal insufficiency M6G concentrations are 15 times higher in HD patients than those with normal renal function	Respiratory depression Central nervous system depression Seizures Myoclonus Lethal overdose
Codeine	Hepatic metabolism into active metabolites Reduced clearance of parent drug and metabolites in renal insufficiency Risk for drug accumulation in HD patients	Nausea and vomiting Hypotension Respiratory depression or arrest CNS depression
Hydrocodone	Limited data in renal disease and failure 85% of an oral dose is excreted as parent drug or metabolite in the urine within 24 h Risks of adverse effects are increased with renal insufficiency and drug accumulation	
Tapentadol	Limited data on use in renal insufficiency and failure Undergoes first pass metabolism into inactive metabolites, 99% of which are excreted in the urine AUC of the metabolite is increased 5.5 times in severe renal insufficiency	
Meperidine	Hepatic metabolism into active metabolite normeperidine, which is renally excreted Half-life of normeperidine is increased in renal insufficiency HD has been reported in case of overdose, suggesting the drug can be dialyzed	Mental status changes, seizures
Tramadol (especially Extended Release)	Limited data - Has not been studied in renal disease	Seizures Serotonin syndrome

Special Considerations in Patients With Liver Disease and Cirrhosis

Most patients with liver disease and cirrhosis reporting pain describe abdominal pain as their primary pain area. However, a large proportion of patients also report pain in the lower back, large joints, and diffusely.[59] As non-alcoholic fatty liver disease increases in prevalence, it may overlap with other common non-hepatic painful conditions, such as osteoarthritis, which is a common etiologic factor of obesity. As with renal disease, specific considerations should be noted that are intrinsic and related to the disease process itself. The high prevalence of abdominal pain in patients with liver disease and cirrhosis is likely related to several factors, including liver capsular distension, ascites, peritonitis, and splenomegaly.[58,59] Notably, cirrhosis is a pro-inflammatory state, and the same cytokines associated with cirrhosis are also associated with pain. Fibromyalgia-like syndrome has been found in both hepatitis C virus (HCV) and non-HCV-related liver disease, which may be related to this systemic inflammation.[60]

Pain Management Approach in Patients With Liver Disease

General Principles

The management of pain in patients with liver disease and cirrhosis is complex, and the risk of an adverse event related to pain treatment is high.[61] Similar to the treatment of pain in any patient, the pain management plan for patients with liver disease or cirrhosis should focus on improving physical and other functional outcomes. The treatment plan should be individualized with consideration of physical, behavioral, pharmacologic, and procedural approaches and is best accomplished with a multi-disciplinary approach, including behavioral health, palliative care, or chronic pain specialists.[61]

Much of the apprehension and barriers to treatment of pain in liver disease and cirrhosis stems from the risk of encephalopathy, bleeding, hepatorenal syndrome, and the association of many analgesic agents, such as acetaminophen and NSAIDs, with additional drug-induced liver injury. Furthermore, there is also an increased risk of adverse drug reactions, including over-sedation or overdose, constipation, and altered drug metabolism and pharmacokinetics in patients with chronic liver disease. As such, to provide effective analgesia and reduce the risk of adverse events or side effects, it is important to consider how severe liver disease can alter the metabolism and action of analgesic agents. There is a considerable paucity of literature to guide physicians in this area, given the public health impact of liver disease.[62,63]

Drug Metabolism in Liver Disease and Cirrhosis

The liver plays an important role in the distribution and elimination of most drugs, including analgesic therapies. Generally, drug metabolism in the liver occurs through 1) conjugation; 2) oxidation, reduction, or hydrolysis reactions via hepatic cytochrome P450 (CYP) enzymes; and 3) biliary excretion and elimination.[57] The efficiency of removal of the analgesic drug relies on a variety of factors, including blood flow, plasma protein binding, and intrinsic activity of CYP enzymes. Liver disease and cirrhosis affect all these processes and can alter the metabolism and elimination of many drugs. Generally speaking, the more advanced the liver disease, the greater the impairment of these processes. Unlike renal disease, there is no accurate measure of liver disease severity that can be used to guide dose adjustment. It is recommended that in patients with more advanced or decompensated liver disease, who are at greater risk of adverse drug reactions, close monitoring is employed, and gradual dose uptitration be utilized while balancing side effects such as sedation.[61]

Nonpharmacologic Pain Management in Patients With Liver Disease or Cirrhosis

As described previously, in patients with renal disease, a biopsychosocial approach to pain includes nonpharmacologic options such as simple heat and cold therapy, weight loss, physical therapy, massage therapy, acupuncture/acupressure, CBT, and meditation. Unfortunately, there are no data regarding the efficacy or use of these modalities in patients with liver disease or cirrhosis.

Pharmacologic Pain Management in Patients With Liver Disease or Cirrhosis

As discussed previously, the pharmacologic approach to pain management is particularly challenging in patients with liver disease and cirrhosis because of altered and often unpredictable drug metabolism.

Non-opioid Medications

Although commonly used by the general public for analgesia, acetaminophen is often avoided in patients with liver disease because of its well-described and potentially fatal hepatotoxicity at higher doses. However, although limited data exist regarding the use of chronic daily acetaminophen in liver disease, it has been reported that a reduced dose of 2 g/day is generally considered safe in patients with cirrhosis.[61–63] This was a double-blind study in which 20 patients with chronic liver disease (of undocumented severity) were treated with acetaminophen (4 g/day) or placebo for 13 days followed by crossover to the alternative treatment for 13 days with no resultant significant changes in liver function laboratory tests.[64] As such, low dose acetaminophen (≤2 gm/day) has been recommended as a first line analgesic for patients with cirrhosis.[58]

Given concerns about hepatic damage with acetaminophen use, patients with liver disease and cirrhosis often take or are prescribed NSAIDs. NSAIDs are likely to be more dangerous in this population.[58] NSAIDs are primarily metabolized by CYP enzymes and are heavily protein-bound. As such, patients with liver disease and cirrhosis are at a much higher risk of renal dysfunction and bleeding complications when using NSAIDs. One case-control study reported an association between NSAID use and an increase in variceal bleeding.[65] Given these significant risks, NSAIDs have been reported as contraindicated in patients with cirrhosis and advanced liver disease.[58]

Non-opioid adjuvant analgesic agents are occasionally required for neuropathic pain from peripheral neuropathy secondary to comorbid diabetes, alcohol use, or HCV-associated cryoglobulinemia.[66] As described previously, gabapentin and pregabalin play a prominent role in the treatment of neuropathic pain. Gabapentin and pregabalin undergo minimal hepatic metabolism with unchanged drug excretion from the kidney.[67] Gabapentin has no significant effects on hepatotoxicity and has been recommended as a first line agent to treat neuropathic pain with a maximum dose of 3600 mg/day, assuming normal renal function. Pregabalin has rare reports of idiopathic liver injury and, although rare, should thus be considered and used as a second line agent to treat gabapentin.[68] Gabapentin and pregabalin are both reasonable first line medications for the treatment of neuropathic pain. However, they can cause sedation and have the potential to lead to cognitive or

mental status depression. As with many other analgesics, the doses should again be slowly initiated and carefully up-titrated with preferential dosing before bed.

Anti-depressants have also been frequently used with moderate success in the treatment of chronic pain, especially neuropathic pain. Tricyclic anti-depressants (TCAs) are commonly used for the treatment of neuropathic pain, are metabolized by CYP enzymes, and rely on renal elimination. As a result, drug accumulation can be observed in progressive liver disease. However, its use in patients with liver disease and cirrhosis has been reported to be relatively safe at low doses and in the short term.[69] Starting TCA therapy at the lowest dose with slow titration is suggested with co-administration of laxatives to prevent constipation-induced encephalopathy.[61]

SNRIs, including venlafaxine and duloxetine, have also been used in the treatment of neuropathic pain but have been reported to not be good options for patients with severe liver disease or cirrhosis. Duloxetine carries a manufacturer warning of hepatotoxicity, given its implication in numerous cases of drug-induced liver injury, and is not recommended in patients with chronic liver disease.[70] Concerning venlafaxine, significant dose reduction is recommended, which relies heavily on hepatic CYP.[71] Selective serotonin reuptake inhibitors (SSRIs) have generally not been shown to be recommended for the treatment of neuropathic pain in the general population as they have a lower efficacy than TCAs. However, given the risks outlined previously for TCAs and SNRIs, SSRIs could be considered, although more work is needed to determine the effectiveness of SSRIs for chronic pain in this population.

Opioid Medications

Opioid pharmacotherapy needs to be approached with caution in patients with liver disease or cirrhosis, as they are known to cause sedation, constipation, and encephalopathy. Opioid medications are primarily metabolized via CYP450 (CYP2D6 and CYP3A4) and glucuronidation, and both are affected by liver disease.[61,72] Liver disease and cirrhosis are risk factors for prescription opioid toxicity and/or overdose, and it has been reported that opioid use is associated with poor liver transplant outcomes.[73,74] Furthermore, a history of substance abuse is common in patients with liver disease and cirrhosis. As such, prescription opioids can lead to dependence, addiction, and use disorder, particularly among those with a history of addiction; in general, opioids should not be administered as first line analgesic therapy to the extent possible in this population. The decision making process for the use of opioids for the treatment of chronic pain is difficult even in the general population and should only be employed when all non-pharmacologic and non-opioid treatment options have been exhausted. The potential gain in patient function and quality of life is felt to outweigh the significant risks of long term opioids.

To date, no "safe" prescribing limits of opioid medications have been established in the context of liver disease and cirrhosis. However, they are likely much lower than those of the general population. Total daily doses of >50 MME per day have been shown to lead to an increased overdose risk in the general population.[75] However, pre-liver transplant opioid doses as low as 10 MME per day were shown to be associated with significant increases in post-transplant mortality in one study.[74] Extended or sustained-release opioids should be avoided because of the risk of a toxic drug or metabolite accumulation in liver disease or cirrhosis. The combination of opioid-acetaminophen pills should be avoided in patients with cirrhosis because of the potential for additional liver toxicity because of acetaminophen. The metabolism and data regarding the different opioid types are outlined in Table 47.3, based on recent systematic and narrative reviews on opioid use in liver disease.[57,58,61,76] It is highly recommended to ensure that constipation is mitigated through the use of lactulose or other laxatives, as hepatic encephalopathy can occur.[62]

Diabetes

Diabetes is a metabolic disorder that results in impaired glucose tolerance because of deficiency or absence of insulin. According to the American Diabetes Association, approximately 34 million Americans live with type 1 or type 2 diabetes, which accounts for more than 10% of the United States population. It is worth noting that in pain medicine, we will be treating many patients with diabetes for ailments related to and unrelated to diabetes. Chronic pain is the most common complication of diabetes.[77] This pain syndrome is discussed in more detail in Chapter 34.

Diabetic Peripheral Neuropathy

Diabetic peripheral neuropathy is the most common type of pain syndrome related to diabetes. Like other peripheral neuropathies, it presents as a length-dependent neuropathy in the typical stocking and glove distribution. As many as 26% of patients with diabetes develop diabetic peripheral neuropathy.[78] Glycemic control is seen as an important preventative measure and may help slow the progression of neuropathy after it has been presented.

Painful diabetic peripheral neuropathy can have severe effects on a patient's wellbeing. Patients often experience mood disturbances, decreased quality of sleep, increased levels of pain, and reduced quality of life.[79]

Painful diabetic peripheral neuropathy (PDPN) is a difficult to treat condition, and many of the medications used to treat this condition are only mildly helpful, leaving the patient in continued distress despite treatment. First line therapies include medications such as tricyclic anti-depressants, serotonin-noradrenaline reuptake inhibitors, and anti-convulsants. Opioids are often reserved for second or third line therapies because of their limited effect on neuropathic pain and the risk of side effects.

Other Painful Conditions Related to Diabetes

While diabetic peripheral neuropathy is the most common and well known painful condition related to diabetes, there are several other diagnoses that the pain medicine practitioner should be familiar with as approximately 50% of people with diabetes will experience a clinically significant neuropathy.[80] Painful neuropathies include mononeuropathy, cranial neuropathy, and plexus neuropathy.

Mononeuropathy: This is characterized by pain and motor dysfunction in the distribution of a single nerve. This can be because of ischemic damage and compressive lesions.[81] The most common nerves affected are the oculomotor and median nerves.

Cranial neuropathy: The most common cranial neuropathy in diabetic patients is oculomotor neuropathy and typically presents as a third nerve palsy with pupillary sparing.[82]

Radiculopathy: Patients with diabetes can have radiculopathy without degenerative spine changes or disc herniation.[81] This is important to avoid unnecessary decompression surgery, as diabetes is a cause of non-compressive radiculopathy.

TABLE 47.3 Opioids Medications in Liver Disease

Medication	Metabolism	Recommendation
Oxycodone	Metabolized into α and β oxycodone metabolites by CYP3A4 and CYP2D6 In advanced liver disease, plasma concentration is increased up to 40%, and the half-life of the IR formulation is increased from 6.4 to 24.6 h (average 14 h, normal half-life is 3.5 h) Bioavailability is dramatically increased	The initial dose should be reduced to 30%-50% of the usual starting dose The interval between doses should be lengthened
Codeine	Prodrug, which is converted to morphine by CYP2D6 Limited metabolism may lead to poor analgesic effects Morphinemia because of delayed clearance of metabolite may lead to significant respiratory depression and overdose	Not recommended for use in liver disease or cirrhosis
Meperidine	Converted to normeperidine through hydrolysis by CYP3A4 and CYP2B6 Clearance is reduced, and half-life prolonged Accumulation can lead to respiratory depression, seizures, CNS depression, and encephalopathy	Not recommended for use in liver disease or cirrhosis
Methadone	Metabolized by CYP3A4 and CYP12A Clearance is reduced in liver disease, and the compound has a long half-life Does not produce toxic metabolites High affinity for binding to proteins	In mild hepatic disease, may use with caution and start low/go slow as data has shown no change in dose is required with mild impairment In patients with moderate liver disease with or without hypoalbuminemia, caution is advised with dose reduction and less frequent dosing Contraindicated in severe liver disease
Tramadol	Metabolized by CYP3A4 and CYP2D6 Metabolism to active metabolites may be reduced, thus decreasing analgesic efficacy	More research needed, alternative therapies are recommended Caution advised if used in patients with a seizure disorder or concomitant SNRI, TCA, or SSRI use
Morphine	Undergoes significant first pass metabolism via glucuronidation Liver disease decreases glucuronidation and therefore leads to increased bioavailability, decreased clearance, and a prolonged half-life	Caution advised Decreased dosing with an increased time between dosing and slow titration
Hydromorphone	Does not require metabolism to an active metabolite Undergoes significant first pass metabolism via glucuronidation, which is decreased in liver disease Leads to higher bioavailability Metabolites not known to be neurotoxic	Decrease usual start dose by 50%-75%, titrate slowly
Fentanyl	Metabolized by CYP3A4 Clearance can be decreased in liver disease with decreased hepatic blood flow Heavily protein-bound Pharmacokinetics of single intravenous dose similar to healthy controls in well-compensated liver disease with preserved hepatic blood flow These findings cannot be extrapolated to transdermal fentanyl preparations	Transdermal preparation not adequately studied can assume decreased absorption, metabolism, and clearance. Should be avoided in patients with severe hepatic impairment
Hydrocodone	Pre-drug that is metabolized into hydromorphone and oxymorphone by CYP2D6 Half-life is increased in liver disease	Decrease initial dose by at least 50% and titrate slowly, with a possible increase in time between dosing

Mononeuritis multiplex affects multiple nerve trunks that cause dysesthesia and paresthesia, likely related to ischemia.[83]

Insulin neuritis/treatment-induced neuropathy. Secondary to aggressive control of glucose levels in a previously hyperglycemic patient, insulin neuritis presents as a symmetric distal neuropathy combined with autonomic dysfunction and acute pain after rapid glucose regulation, such as initiation of insulin therapy.[84] The condition is often reversible, but the pain can be persistent and is often difficult to treat and refractory to typical neuropathic pain medication therapy.

Medication Management

Tricyclic Anti-depressants

Originally designed for mood disorders, it is common to utilize this class of medications for neuropathic pain within the pain medicine community. Commonly used medications in this class include nortriptyline, amitriptyline, and desipramine. Dosing is initiated at a low nightly dose, such as 10 to 25 mg per night. The dose was then increased every five to seven days until a goal dose was attained, pain relief was achieved, or adverse effects were encountered. Compared to the SSRI and SNRI type of medications, pain

relief with TCAs is similarly delayed in onset.[85] Unfortunately, adverse effects are not uncommon and include somnolence, dizziness, urinary retention, and increased risk of falls.[86] Extra caution should be exercised in patients with urinary retention, baseline increased fall risk, and underlying cardiac disease. Typically, the first medication trialed in this category is amitriptyline, with nortriptyline as a secondary alternative if amitriptyline is ineffective or poorly tolerated. Desipramine is often not utilized because of the increased risk of adverse effects compared to amitriptyline and nortriptyline.

Serotonin-Norepinephrine Reuptake Inhibitors/Selective Serotonin Reuptake Inhibitors

Serotonin agonists are another category of medications that are frequently used for the treatment of PDPN. One of the most commonly used agent is duloxetine.

This is initiated at 30 mg daily for two weeks and then increased to 60 mg daily for most patients. This medication can take up to 12 weeks to take full effect, and studies have shown that while the 60 mg and 120 mg daily doses are successful in treating PDN, the 20 mg daily dose is not.[87] Patients must be counseled about this delayed onset to encourage compliance. Common adverse effects include nausea, dry mouth, sweating, and constipation. Many of these can be abated by starting the medication at a lower dose to develop tolerance to serotonin effects. SNRIs may help treat pain when there is also a mood disorder.

Anti-convulsants

To date, the most common anti-convulsants utilized for neuropathic pain are gabapentin and pregabalin, and they have both been shown to be effective for PDPN.[88,89] Gabapentinoids, which include both gabapentin and pregabalin, act by inhibiting calcium currents by binding with the alpha two δ subunit of voltage-gated calcium channels.[90] The benefit of gabapentin is that it is inexpensive, typically well tolerated, and has proven efficacy. This medication was started at a low dose and titrated to effect as tolerated. Many times for neuropathic pain, patients will need to titrate up to 2700 mg/day or higher. While some patients will experience substantial pain relief with pregabalin, most will have moderate pain relief, and many will have no relief at all.[91]

Opioids

Opioids are not the first line therapeutic agents for PDPN. However, some are more successful in treating neuropathic pain than others. Medications that combine activity at the NMDA receptor and the opioid receptor may have a higher likelihood of treating neuropathic pain than pure mu agonists. Examples of these opioids include tramadol and methadone. Low dose naltrexone, a reversible competitive antagonist of μ-opioid and κ-opioid receptors, is also gaining popularity. When used at low doses of 1 to 5 mg daily, naltrexone acts as a glial modulator with a neuroprotective effect via inhibition of microglial activation.[92]

Topical Agents

Often, topical agents are used for PDPN with mixed results. The efficacy of 0.075% capsaicin lotion was similar to that of placebo in one study, but it was well tolerated.[93] In another study, a single 30 min application of the capsaicin 8% dermal patch provided 12 weeks of pain relief and improved quality of sleep.[94] In this scenario, patients can undergo repeat treatment with the capsaicin 8% dermal patch as needed.

In summary, many medications are options for the treatment of PDPN and other diabetes-related painful conditions. They must all be tailored to each patient's specific needs and risk factors to create a personalized approach that maximizes the response and minimizes the side effect profile.[95] In the United Kingdom, the National Institute for Health and Care Excellence (NICE) recommends amitriptyline, duloxetine, pregabalin, and gabapentin as the initial treatment for PDPN. If this is not effective, combination therapy will be the next step.[96] If medication management is ineffective, other strategies for pain control should be considered.

Botulinum Toxin

Botulinum toxin A has been shown to significantly improve PDPN.[97] Botulinum toxin A has long been known to decrease neuropathic pain by preventing the fusion of synaptic vesicles with the cell membrane, thus halting the release of neurotransmitters.[98] With peripheral neuropathy, BTa is injected in the area of pain, utilizing a grid-like pattern. Pain relief typically presents within one to two weeks of injection and can last for up to 12 weeks.

Scrambler Therapy

When PDPN fails to respond to conventional first and second line treatments, scrambler therapy may be an option for otherwise intractable neuropathy.[99] Scrambler therapy is similar to TENS in that the electrodes are placed on the skin. However, in scrambler therapy, electrodes are placed in the non-painful area. During treatment, the patient perceives non-painful sensations, such as itching or pressure, in the previously painful area. The proposed analgesic mechanism of scrambler therapy includes the electrodes sending non-painful impulses to the peripheral receptors, with the A δ and C fibers relaying the stimuli to the CNS. Scrambler therapy has been shown to be effective in some neuropathic pain syndromes.[99]

Integrative therapies, including mindfulness and progressive relaxation, have been shown to reduce chronic pain in women with diabetes.[77] In addition, Rozworska et al. demonstrated that participation in mindfulness-based stress reduction leads to an improvement in pain related outcomes.[100] Acupuncture has also been shown to improve symptoms of PDPN symptoms.[101] Exercise has also been considered to reduce pain interference in this patient population without actually decreasing the pain score itself.[102]

Regenerative Medicine

Growing evidence suggests that increased inflammatory factors, combined with a deficiency of angiogenic factors, contribute to the underlying pathology of PDPN. Studies have shown that bone marrow-derived stem cells (BMCs) may be a promising strategy for tissue repair.[103] Known to inhibit inflammation and promote angiogenesis, BMCs may be a novel therapeutic option for patients with PDPN.

Spinal Cord Stimulation

SCS has been shown to reduce pain experienced by PDPN.[104] As peripheral blood flow is a fundamental part of the pathophysiology of PDPN, peripheral vasodilation, and improved blood flow are potentially beneficial secondary effects of SCS is peripheral vasodilation and improved blood flow.[105]

Surgery

Surgery can be utilized for the treatment of superimposed peripheral nerve entrapment syndrome in patients with diabetic peripheral

neuropathy, sometimes with pain relief and restored sensation. One study evaluated the effects of microsurgical decompression of multiple entrapped peripheral nerves in patients with refractory PDPN of the lower limbs. Bodily pain was significantly reduced two weeks after the procedure.[106]

Conclusion

For pain medicine practitioners treating patients with diabetes, it is important to consider their overall health when initiating therapy for painful conditions. Opioid medications may lead to increased nausea in patients with diabetes-related gastroparesis. Steroid injections may also lead to hyperglycemia. The dosing of medications may need to be adjusted in the setting of renal failure or dialysis. With comprehensive analysis and attention to detail, we can treat these patients safely and offer them the full spectrum of multi-disciplinary pain management in hopes of restoring function and improving their quality of life.

Pain Management in Older Adults

Background

An estimated 51 million Americans are over the age of 65 years, which is about 16% of the American population (United States Census Bureau, population projections). Up to 65% of people over the age of 65 years experience pain, and up to 30% have chronic pain (painconsortium.nih.gov). Older adults are more likely to experience pain than younger individuals.[107] Diagnosing and treating pain in older individuals can be difficult because of differences in patient reporting, communication barriers, and underlying comorbidities. The most common chronic pain conditions are arthritis, back or neck pain, and joint pain, which are present in 48%, 45%, and 41% of older Americans, respectively.[108,109] Up to 50% of patients in nursing homes use analgesic therapy for the treatment of pain, and some sources report that up to 80% of nursing home patients suffer from pain.[110] Hence, this is a significant problem in the aging population. Pain physicians need to have a thorough understanding of the mechanisms underlying pain in this population and the physiologic changes that affect the efficacy and side effect profile of our treatment options. For many reasons, both provider-related and patient-related pain is significantly under treatment in this patient population.[111] The importance of pain management in this population cannot be overstated. Poor pain control can lead to a lack of socialization, poor sleep, depression, increased healthcare costs, and reduced quality of life.[112,113]

Evaluation: Assessment and Physical Examination

Assessment

Understand that the older patient population may not present in the same way as younger individuals, and failure to recognize pain leads to an inability to treat pain. Older adults often present with multiple painful conditions. Therefore there is a need for comprehensive evaluation.[114] In addition, multiple comorbidities may make it difficult to determine the underlying cause of pain. A careful history, thorough physical examination, and diagnostic studies, including imaging and nerve conduction studies, can all help identify the source of pain. Prior to obtaining the patient's history, the ability of the patient to report pain should be assessed. If the patient cannot provide history, the provider should supplement the history with other proxies for self-reporting. The history should detail the onset of pain, the location of the pain, the character of the pain, and any recent changes in the way the pain is present. Be mindful to use words other than pain, as patients in this cohort may identify with words like "ache" or "discomfort" more than pain. Methods to understand baseline pain and determine the response to pain-directed treatments are similar to those of younger patients. However, self-reported pain relief may need to be supplemented by behavioral observation, data from caregivers and family members, and pain behavior tools. The lack of appropriate assessment tools can be a barrier to appropriate pain assessment.[115] Our most common pain assessment tool, the VAS, does not work well for older patients with pain.[116] A variety of other pain assessment tools are used to include the faces pain scale, NRS, verbal descriptor scale, pain thermometer, pictorial pain scales.[112,116] In addition, cultural beliefs about the importance of stoicism in this age group may lead to underreporting by the patient.[117] Therefore rewording questions are useful. A patient may report low levels of pain, but when questioned about discomfort or aches, significant findings will be reported. It is helpful to take note of nonverbal cues during history and physical examination to assess for pain that is underreported or not effectively communicated. The checklist of nonverbal pain indicators (CNPI) and the pain assessment in advanced dementia are two behavioral observation tools available.[118] These tools are discussed in Chapters 43 (geriatric pain management), 79 (pain evaluation in patients with limited ability to communicate), and 84 (outcome domains in chronic and acute pain). In addition to pain severity, it is crucial to understand the level of interference pain that may affect individuals' function and quality of life. The level of interference can be evaluated by asking about fatigue, disturbed sleep, activity level, mental health, and quality of life.[119]

Physical Examination

Physical examination should be comprehensive, focusing mostly on the musculoskeletal and neurologic systems. When assessing neurologic function, it is important to evaluate the strength, response to light touch and pinprick, and sensation. When assessing musculoskeletal function, examining joint swelling, range of motion, tenderness to palpation, muscular pain, and straight leg raise are all useful.[112] Deconditioning, reduced flexibility, and reduced muscle mass were observed. In addition, age-related loss of tendon reflexes is important to note, and attention should be paid to asymmetric changes instead of a global decrease in reflexes.[120]

Evaluation of Common Painful Syndromes

Osteoarthritis

Osteoarthritis (OA) is a very common condition in geriatric patients and can significantly affect the quality of life and ability to be active. Symptoms of OA include stiffness, pain, decreased range of motion, and disability. Age is an independent risk factor for OA, along with obesity, metabolic disease, gender, genetics, and ethnicity.[121]

Neck Pain

Neck pain is common in the geriatric population and is often multifactorial with pain generators, including osteoarthritis, disc degeneration, myofascial pain, cervical spondylosis, and trauma.[122] Neck pain is the fourth leading cause of disability in adults.[123] Available imaging includes plain film (X-ray), computed tomography (CT), magnetic resonance imaging (MRI), and CT myelography.[124] The differential diagnosis and imaging workup of neck pain was determined based on relevant pieces of the patient's history and physical examination. Common indications for cervical imaging include trauma, neurologic deficits, myelopathy or "red flag symptoms," radiculopathy, and persistence of symptoms.[125]

Back Pain

Chronic low back pain is exceedingly common in the elderly population, with up to 25% of those 65 years and older with chronic low back pain.[126] Chronic low back pain is currently the most common cause of disability worldwide.[127] Common causes of low back pain include osteoarthritis, facet joint arthropathy, myofascial pain, lumbar spondylosis, lumbar stenosis, and vertebral compression fractures. Less common causes include infection and tumors. Available imaging includes plain film (X-ray), CT, MRI, and CT myelography. The differential diagnosis and imaging workup of low back pain are determined based on relevant pieces of the patient's history and physical examination. Common indications for lumbar imaging include trauma, neurologic deficits, myelopathy or "red flag symptoms," radiculopathy, and persistence of symptoms.

Medication Considerations for Use in Older Adults

One of the most concerning aspects of pain management in older adults is concerns about the adverse effects of medication therapy. This is a valid concern and may also lead to the treatment of pain in this population. Rather than avoiding medication usage in elderly patients, the pain physician should focus on having a detailed understanding of the differences in dosing and adverse effects in this population to create a sense of security in treating pain and efficiency in recognizing potential adverse effects.

Renal: Avoid medications that can affect renal function, as this is already reduced in elderly patients. In addition, underlying renal issues need to be considered when determining the appropriate dosage to avoid the buildup of toxic metabolites. While NSAIDs are effective agents for inflammatory processes, they are associated with renal toxicity, and severe side effects from NSAIDs are more common among elderly patients.[128]

Hepatic metabolism: Secondary to decreased liver mass and decreased liver perfusion, the first pass effect on medications that are highly cleared by the liver may have increased bioavailability.[129] Dosing decreases should be considered for medications that undergo p450 dependent metabolism.

Pharmacokinetic and pharmacodynamic changes: With advanced age, we know that a reduction in renal and hepatic clearance occurs. In addition, there is an increased volume of distribution of lipid-soluble drugs that can lead to a prolonged elimination half-life.[130] Pharmacodynamic changes lead to increased sensitivity to several classes of medications.[130]

Conclusion

In summary, the evaluation and management of elderly patients requires a thorough understanding of how to assess pain in this population, various pain scales to compensate for possible changes in cognition, the most common pain syndromes, and the management of medications in a population that may have pharmacodynamic and pharmacokinetic differences related to aging. Pain should not be undertreated because of barriers in communication, difficulty in physical examination, or a bias that pain is just a part of getting older. With proper care, many elderly patients can have a higher quality of life with minimal interference from their daily activities because of chronic pain.

Summary and Conclusions

When treating patients with chronic pain, it is important to consider their overall health and potential complications when initiating medications and considering interventions. Many of these patients with renal or liver disease, diabetes, and the elderly are often excellent candidates for multi-disciplinary pain management, including psychology/behavioral health services, functional restoration programs, physical therapy, occupational therapy, and advanced interventional procedures to include neuromodulation. Treatment requires a thorough understanding of the unique characteristics of these patient populations, including altered pharmacokinetics, metabolism, and clearance. Understanding that history and physical evaluation may require different assessments than patients without these chronic conditions or non-elderly patients. Pain medicine providers should be familiar with the most common pain syndromes in these populations and how to treat them. In addition, it is of paramount importance to remember that pain is often undertreated in these patient populations and that with proper care, patients can have increased function and improved quality of life.

Key Points

- Common medical comorbidities that can be encountered in chronic pain conditions are kidney disease, liver disease, diabetes, and the care of elderly patients.
- Pain is one of the most common symptoms of CKD, ESRD, and liver disease.
- The pain experienced by patients with kidney and liver disease is often multifactorial and can be because of the underlying organ-related disease process, hemodialysis, or comorbid diseases.
- Many non-pharmacologic and non-opioid pain management strategies have been shown to be helpful for pain in kidney and liver disease patients. However, further research is needed to establish the efficacy of many of the behavioral and complementary therapies specifically for these populations.
- When pharmacologic interventions for pain management in kidney and liver disease patients are being implemented, it is best to identify the level of current kidney and liver function,

and the focus should be on preventing further damage and adjusting the drug dosage as indicated.
- While diabetic peripheral neuropathy is the most common and well known painful condition related to diabetes, there are several other diagnoses that pain medicine practitioners should be familiar with, as approximately 50% of people with diabetes will experience clinically significant neuropathy.
- The most common anti-convulsants utilized for neuropathic pain are gabapentin and pregabalin, both of which have been shown to be effective for PDPN.
- Opioids are not first line therapeutic agents for PDPN.
- Pain is often undertreated in elderly patients.
- Pain should not be undertreated because of barriers in communication, difficulty in physical examination, or a bias that pain is just a part of getting older.
- The older population may have pharmacodynamic and pharmacokinetic differences related to aging, which should be considered when managing medication therapy.

Major Opioids and Chronic Opioid Therapy

DAVID COPENHAVER, REBECCA HOSS, MEGAN H. CORTAZZO, IRIS VUONG, SCOTT M. FISHMAN

General Considerations of Opioid Administration

Derivatives from the opium plant have been described as analgesics and used for pain control since 3500 BC. It was not until 1806 that a pure opioid substance was isolated. This substance was called "morphine," named after the Greek god Morpheus.[1] Since then, the opium plant has yielded other byproducts, and synthetic analogs of morphine have been produced for medicinal use. The use of opioid medications in the United States has fluctuated because of various factors, including but not limited to production, availability, governmental regulation, and physician and societal attitudes. Fluctuations have also occurred because of guidelines that have shifted their positions. Over the last 20 years, the prescription pattern of opioids has escalated significantly for several reasons. The increasing trend in prescription writing has been accompanied by a concordant rise in the incidence of diversion and abuse, as well as an increase in the incidence of complications, including overdose and death. Over the past several decades, evidence for a sustained benefit of opioids in alleviating chronic pain has remained weak and inadequate, either with results that are not substantially positive or negative or have poor scientific quality. However, evidence of the risk associated with the use of opioid drugs has been increasingly elucidated in the literature and from public health agencies. This change in which evidence of the efficacy of opioids has not changed, whereas risk has increased, should significantly impact treatment decisions based on a critical analysis of risks and benefits. This chapter aims to review clinically relevant aspects of selected opioids, including side effects and pharmacology, and review the current consensus on rational opioid prescription.

Opioid Receptors

Endogenous opioids, in addition to multiple other endogenous systems, are involved in the modulation of pain perception. Natural endogenous opioids include the endogenous peptides β-endorphins, enkephalins, and dynorphins. Since the discovery of opioid receptors in the central nervous system (CNS) in 1973, the body of literature describing their function and location has grown immensely.[2,3] Opioid receptors play integral roles in the endogenous antinociceptive system and, accordingly, are located throughout the central and peripheral nervous systems. The best-described opioid receptors are labeled μ, κ, and δ and are prominently located in the CNS, particularly in the dorsal horn of the spinal cord,[4] as well as in the dorsal root ganglia and peripheral nerves.[5,6] The three opioid receptors identified, μ, κ, and δ, belong to a superfamily of guanine (G) protein-coupled receptors located at pre-synaptic and post-synaptic sites in the CNS and peripheral tissues.[7]

The μ-opioid receptor modulates input from mechanical, chemical, and thermal stimuli at the supraspinal level. The κ receptor is similar to the μ receptor in that it influences thermal nociception. However, it also modulates chemical visceral pain. The δ receptor influences mechanical and inflammatory pain.[8] An opioid agonist, such as morphine, binds primarily to the μ opioid receptor to produce analgesia, as well as undesired side effects, such as respiratory depression and constipation. In a study using knockout mice that lacked the μ receptor, it was found that they did not respond to morphine with respect to analgesia, respiratory depression, constipation, or physical dependence.[9]

Distribution, Metabolism, and Excretion

The amount of opioids required to produce analgesia has significant interindividual variability. The factors responsible for this variability include opioid receptor individuality and variations in opioid absorption and clearance. Such individual variability requires careful titration of opioids to the desired response. The onset, duration, and intensity of analgesia depend on the delivery of the drug to the target and the length of time that the receptor is occupied. The number of receptors occupied and the length of time that the opioid activates its target receptor depends on the perfusion, plasma concentration, pH, and permeability coefficient of the drug.[10]

The metabolic pathway for each opioid is based on the molecular variables of a specific opioid. Opioids with hydroxyl groups, such as morphine and hydromorphone, undergo hepatic metabolism via uridine diphosphate glucuronosyltransferase (UGT) enzymes. UGT adds a glucuronic acid moiety to form glucuronide metabolites such as hydromorphone 3-glucuronide (H3G), morphine 6-glucuronide (M6G), and morphine 3-glucuronide (M3G)). These metabolites

are excreted through the kidneys. Patients with renal impairment are particularly prone to the deleterious effects of metabolite accumulation.[11]

The cytochrome P-450 (CYP) system contains two polymorphic isoforms that metabolize certain opioids. The first CYP isoform responsible for the biotransformation of codeine, oxycodone, and hydrocodone is 2D6. It is estimated that up to 10% of white individuals lack this enzyme, thus making them "poor metabolizers" of certain opioids and providing another cause for the high interindividual variability seen in patients treated with opioids.[11] The 3A4 isoform of the CYP system is involved in the biotransformation of fentanyl and methadone to their inactive forms.[12] Because other drugs also interact with 3A4 isoenzymes, the metabolism of methadone and fentanyl can be problematically decelerated or accelerated. For example, macrolide antibiotics inhibit the enzyme, which decreases the clearance of methadone and fentanyl, whereas anti-convulsants such as phenytoin induce the activation of this enzyme system and increase the clearance of methadone and fentanyl.[13,14] The excretion of most opioid metabolites occurs via the kidneys, but some of the glucuronide conjugates are excreted in bile, and methadone is excreted primarily in feces.[11]

The study of pharmacogenomic polymorphisms is important in understanding the interindividual variability in analgesic effects [the reader is directed to Chapter 13 on pharmacogenetics]. Opioid related therapies have a multiplicity of genetic factors that influence the metabolism and clearance of specified opioids. In the future, the use of regulator-approved pharmacogenomic assays may be advantageous for identifying many of these variant alleles. Understanding pharmacogenomic polymorphisms will most likely play a role in everyday clinical decision making to manage acute and chronic pain. As for safety and patient care benefit from detailed knowledge of specified polymorphisms, this science will most likely be incorporated into the standard of care for physicians.[15]

Administration

Multiple routes of administration are among the many clinically useful characteristics of opioids. Administration can range from intrathecal, intravenous, or oral to rectal, sublingual, buccal, intranasal, or transdermal. Depending on the clinical situation, one route may be more advantageous than the other. For example, a patient who requires continuous opioid delivery but is unable to take medications orally may benefit from a transdermal delivery system, such as is currently available in a transdermal patch containing fentanyl and, more recently, the Food and Drug Administration (FDA) approved transdermal patch containing buprenorphine, which, in appropriate settings, has potential safety advantages over fentanyl. Fentanyl is also available as a rapid onset transmucosal delivery product. Neuraxial routes of opioid delivery are widely used in perioperative and postoperative care, as well as in terminally ill patients.

The pharmacologic goal of effective opioid therapy for chronic pain is to provide sustained analgesia over regular intervals.[16] This requires consideration of several factors, including knowledge of equianalgesic dosages between opioids and the pharmacologic properties and side effects of specific opioid agents. Pain in opioid tolerant patients is particularly challenging because typical dosages for opioid-naïve patients do not apply, and exact opioid requirements may require careful titration.

Whether fixed dosing is better than as-needed (PRN) dosing is controversial, with each method having advantages in specific patient settings. With fixed dosing, there is consistent opioid delivery, which can theoretically reach steady state levels.[17] Presumably, this avoids the peak-and-trough effect that can be associated with on-demand dosing and may prevent delays in delivery that can occur with on-demand schedules. One problem for opioid-naïve patients who receive fixed doses of opioids with longer half-lives is that they may experience excessive side effects or toxicity because of the difficulty in predicting the exact opioid requirement and potential accumulation. For example, morphine may take less than 24 h to reach steady state levels, whereas methadone can take up to one week. When there is a need to assess a patient's analgesia threshold, PRN dosing of an opioid with a short half-life may be used, or conservative fixed dosing of opioids with a short half-life, supplemented by PRN "rescue" dosing, may be used.

Analgesic therapy with long-acting opioids (LAOs) offers convenient dose intervals to attain safe, effective, and steady state levels. Several controlled-release opioids are available, including morphine (MS Contin, Oramorph SR, Kadian), hydrocodone (Hysingla), oxycodone (OxyContin, Xtampza), fentanyl (Duragesic patch), hydromorphone (Exalgo), tapentadol (Nucynta ER), and oxymorphone. Methadone may be used as a relatively LAO (longer effect than short-acting opioids [SAO] but shorter than most LAOs), but it poses specific issues and concerns for clinicians that are distinct from those of other opioids (see later discussion). Methadone has a faster onset and longer analgesic effect than many other SAOs and may be ideal in some situations. However, other properties and adverse effects may limit their use. Methadone is not specifically formulated for a sustained release like other LAOs, which essentially release an SAO throughout the drug's passage through the gastrointestinal (GI) tract. Methadone has an intrinsically longer plasma half-life than other typical opioids, such as hydromorphone (Dilaudid) and morphine, and can therefore be advantageous in patients with GI motility issues such as short gut syndrome.

Although sustained- and immediate-release opioid preparations have made the oral route a practical option, some patients cannot tolerate oral delivery.[18] In such cases, transdermal, buccal, rectal, intravenous, or subcutaneous infusions are often a practical alternative option. With infusion, the first-pass effect is eliminated, potentially offering some advantages. There may be a faster onset of analgesia with less complicated access when compared with the oral route. Compared with the intramuscular route, the administration is often less painful and may be safer in patients with bleeding disorders or reduced muscle mass.

Adverse Effects

The most commonly encountered side effects associated with opioids include constipation, nausea, vomiting, sedation, urinary retention, pruritus, and hypogonadism. Although respiratory depression may not be as common, its potentially devastating effects make it a heightened concern. Any of these side effects can significantly limit therapy, but the resolution of most adverse effects may occur shortly after the initiation of opioids. However, constipation is a major exception because it does not resolve with the prolonged use of opioids. Particular attention should be given to older adults and patients with hepatic or renal insufficiency. Tolerance (drug effect wears off

over time or higher dosage is needed to achieve the same effect) and physical dependency (sudden discontinuation produces withdrawal effects) are also commonly associated with opioid therapy. These are pharmacologic properties related to opioids that are frequently misinterpreted as indicators of addiction. Addiction is also a potential risk associated with opioid use (see later discussion). Physicians should anticipate any or all of these adverse effects, remain vigilant throughout therapy, and monitor patients closely, particularly when initiating therapy and escalating opioid doses.

Constipation

The most common side effect of opioid administration is constipation; unfortunately, tolerance to it does not generally develop. Constipation can cause significant discomfort, nausea, and emesis. One of the underlying mechanisms of opioid-induced constipation is thought to be decreased gastric motility because of opioid binding to highly concentrated μ-opioid receptors located in the antrum of the stomach and the proximal part of the small bowel.[19,20] There is limited evidence that certain opioids at equianalgesic doses produce more or less constipation than others. Because the transdermal route bypasses initial exposure to the GI tract, transdermal fentanyl has been postulated to produce less constipation than orally administered opioids.[21–23] However, current data are not convincing and transdermal opioids are well-known to result in significant constipation, such as that associated with oral opioids, which may require aggressive management.

When initiating any opioid, it is important to prescribe medications to maintain regular bowel motility concomitantly. Treatment of opioid-induced constipation should include an active laxative such as senna, lactulose, or bisacodyl or osmotic agents such as polyethylene glycol; passive agents such as stool softeners or fiber-based bulking agents may be ineffective because they rely on triggering gastric motility, which in the case of opioids may be inhibited. Alternatively, the use of an adjunctive agent with a side effect profile that includes diarrhea, such as misoprostol, can coexist well with constipation. However, misoprostol should be used with caution in women of childbearing age because it can initiate uterine contractions and miscarriage.[24,25]

Peripheral opioid receptor antagonists have also been shown to be effective in refractory cases of opioid-induced constipation. Methylnaltrexone, a quaternary derivative of naltrexone, contains a permanently charged tetravalent nitrogen atom and cannot cross the blood-brain barrier.[26,27] Methylnaltrexone is an antagonist of the μ receptor. It blocks the peripheral actions of opioids while sparing their central analgesic effects and reverses the slowing of bowel motility, which often occurs with opioid related therapy. Methylnaltrexone was approved by the United States FDA in 2008 as an indication of opioid-induced constipation. Alvimopan, which was also approved in 2008 by the FDA, functions as a peripherally acting μ-opioid antagonist with limited ability to cross the blood-brain barrier. Alvimopan, naloxegol, and naldemedine are opioid receptor antagonists that can treat constipation without, in most cases, affecting analgesia or precipitating withdrawal. The primary indication for this medication is the avoidance of postoperative ileus following partial large or small bowel resection with primary anastomosis.[26,27] In addition to the opioid receptor antagonists, lubiprostone is approved by the FDA for the treatment of opioid-induced constipation. However, these options are currently proprietary and costly and are usually reserved specifically for refractory opioid-induced constipation.

Nausea and Emesis

Nausea and vomiting are frequently seen in patients who are treated with opioids, but it is usually a transient side effect that often lasts only two to three days. The underlying mechanisms of nausea and vomiting appear to be related to several causative factors. One is the activation of receptors in the brainstem, which produces afferent input to the medullary chemoreceptor trigger zone, which is responsible for afferent input to the emetic center of the brain. These areas are dense in neurotransmitter receptors, which correspond to the antiemetic agents used clinically. A potential cause of nausea is the stimulation of receptors in the vestibular apparatus.[28,29] Another underappreciated cause of opioid related nausea is constipation, which often responds to treatments that increase motility.

In evaluating a patient who reports nausea and vomiting while taking opioids, one should determine important history-related factors involved in the genesis of nausea, such as the time of the last bowel movement, whether it worsens with movement, or whether there is a temporal relationship between opioid ingestion and the onset of nausea. The choice of antiemetic agent depends on the historical aspects of the reported side effects. Patients who experience nausea when they are more ambulatory may be more likely to experience vestibule-related nausea. In such cases, drugs such as meclizine, promethazine, or scopolamine may be useful in relieving this type of induced nausea. Droperidol, prochlorperazine, ondansetron, or hydroxyzine may have greater benefit for nausea that is not associated with movement, a type of nausea thought to be related to chemoreceptor trigger zone-associated activation.[30,31] However, cardiac adverse effects may be reflected on the electrocardiogram in QTc elongation. One should also ensure that reversible metabolic causes, intracranial pathology, or other factors such as medications are not the origin of nausea or emesis before it is attributed solely to opioids.

Several approaches can be used to treat opioid-induced nausea and vomiting. An antiemetic may be added, often choosing an agent that offers secondary benefits such as promotility, sedative, antipruritic, anxiolytic, or antipsychotic effects, depending on the needs of the individual patient. Another option to reduce the frequency and severity of side effects is to decrease the opioid dose to the minimum acceptable dose that will still achieve adequate analgesia. Based on the observation that tolerance to opioid-induced nausea accrues rapidly, the dose that had previously been reduced may be titrated upward slowly to increase analgesia without inducing nausea. If nausea is protracted, one may consider changing to a different opioid. The emetogenic response to opioids is idiosyncratic. Therefore a different opioid may not produce nausea.[32]

Pruritus

Opioid-induced pruritus occurs more frequently with opioids delivered via the intravenous or neuraxial route than with oral administration. Tolerance to pruritus usually develops reasonably quickly, but in rare cases, it can be more persistent. The underlying mechanism of pruritus appears to be related to the release of histamine, which activates C-fiber itch receptors on C fibers that are distinct from pain-transmitting C fibers. Clinically, pruritus is often limited to the face and perineum but can become generalized and severe. Treatment includes antihistamines, but the therapeutic effect may be related more to sedation than a direct antihistaminergic effect.[32] In patients receiving intrathecal or intravenous

morphine with significant pruritus that is unresponsive to antihistamines, low dosages of nalbuphine, a μ-receptor antagonist and κ-receptor agonist, may effectively reduce pruritus without reversing the analgesia.[33,34]

Sedation

Opioid-naïve patients or those chronically taking opioids who are undergoing dose escalation often experience sedation and drowsiness. Sedation is usually temporary as patients accommodate a new medication or dose, and it has been demonstrated that patients maintained on a stable dose of opioids for seven days rarely have psychomotor impairment.[35–37] The importance of this fact cannot be overemphasized because the opioid prescription for patients with cancer- and non-cancer-related pain remains substantial, if not decreasing, since the recognition of the opioid crisis. Patients and others may question whether it is safe to operate a motor vehicle while taking opioids. This is a controversial issue, and strong arguments can be made on both sides. Some physicians may recommend taking no precautions, whereas others may counsel their patients to never drive while taking opioids. Emerging evidence is not completely clear on this issue, but some studies have suggested that patients managed with long-term opioid therapy may be alert enough to drive safely.[38,39] However, it seems prudent to restrict driving, at least for one week or longer at the onset or with dose escalation of an opioid regimen.

Despite an adequate adjustment period to the opioid dose, sedation that persists can become as problematic as the pain itself. In such cases, lowering the dose of opioid to the minimally acceptable analgesic level, increasing (widening) the dosing interval, or changing to another opioid that may not be as sedating may be considered.[32] If the sedation is thought to be secondary to accumulating levels of the drug or its metabolites, changing to a different agent that is not as dependent on renal clearance or does not have active metabolites, such as fentanyl, may reduce the sedation. In patients with continued unremitting sedation after limiting CNS depressants, attempting opioid dose reduction, and excluding all other underlying causes, psychostimulants may be useful (e.g. amphetamines, modafinil).

Recent attention has raised the importance of considering sedation associated with other medication-related causes (e.g. benzodiazepines, antiemetics, tricyclics, and anti-convulsants such as gabapentin and pregabalin), renal or hepatic dysfunction leading to accumulation or progression of the patient's primary disease state itself. Gabapentinoids are commonly prescribed for pain, and there are rising concerns that drugs such as gabapentin are abusable and, in conjunction with co-prescribed opioids, may increase the risk of respiratory depression. A 2017 study by Gomes et al. found that concomitant use of gabapentin and opioids was associated with a substantially increased risk of opioid related death.[40] Perioperative use of gabapentinoids may increase the risk of opioid overdose and other opioid related adverse events. There are also increasing concerns that, although gabapentin does not appear to have great addiction potential, it is abused and has illicit use street value.[41] An FDA advisory from 2019 [https://www.fda.gov/news-events/fda-brief/fda-brief-fda-requires-new-warnings-gabapentinoids-about-risk-respiratory-depression] stated "Reports of gabapentinoid abuse alone, and with opioids, have emerged, and there are serious consequences of this co-use, including respiratory depression and increased risk of opioid overdose death." In light of this, the FDA has required updated labeling for gabapentinoids to warn against potential respiratory depression. According to the federal government, some states have scheduled gabapentin as a potential drug of abuse, and pregabalin is schedule 4.

Respiratory Depression

Respiratory depression is one of the most serious concerns and feared complications of opioid prescription. The underlying mechanism of respiratory depression is μ-receptor induced depression of brainstem centers that subserve respiratory drive.[42] It has long been recognized to occur more rapidly in patients who have received combined intrathecal-epidural and oral or intravenous opioids. Although there is minimal evidence to support this claim, recognizing that this is a possible risk often supports an acceptable risk management-oriented approach to opioid administration. In addition, combining opioids with other sedating drugs can hasten respiratory depression. This is particularly important because of the escalating rates of unintended overdose deaths associated with opioids, many involving multiple drugs that include additional respiratory depressants such as benzodiazepines. Clinically, the patient manifests sedation as the first sign of respiratory depression, which can pose a problem in detection during the evening hours when the patient is sleeping. Because respiratory depression can occur after the administration of epidural and intrathecal opioids and is often delayed and does not appear until approximately 12 h after injection, the signs of sedation may be lost during sleep. Therefore it is advisable to use alarmed pulse oximetry in patients in whom clinical suspicion is warranted.[32]

Pain is a powerful physiologic stimulant of the respiratory drive and opposes the respiratory depressant effects of opioids. In patients in whom pain relief is anticipated from a non-opioid analgesic treatment (e.g. neurolytic procedure, radiation therapy, adjuvant analgesics, surgery), a reduction in opioid dose may be required.[42]

If a patient cannot be aroused and opioid-induced respiratory depression is suspected, the specific opioid receptor antagonist naloxone should be administered. Care must be taken when administering naloxone to patients who have been taking opioids for longer than one week or older adult patients because severe withdrawal symptoms, seizures, and severe pain can be induced. The administration of naloxone has also led to congestive heart failure in susceptible patients. Naloxone is often packaged in an ampule containing 0.4 mg for intravenous administration, which can then be diluted in 10 mL of normal saline and administered as 0.5 mL boluses (0.02 mg/0.5 mL) every 2 min.[42]

Opioids and Immunologic Effects

Opioids have been suggested to play a role in the incidence of infection in heroin users and contribute to the pathogenesis of human immunodeficiency virus.[27] Of note, despite the suggestion that exogenous opioids may cause immunosuppression, endogenous opioids such as endorphins promote immunoactivation.[27] Inhibitory effects on antibody and cellular immune responses, natural killer cell activity, cytokine expression, and phagocytic activity have all been implicated in acute and chronic opioid administration.[27,41] Furthermore, it has been noted that peripheral immune cells express opioid receptors, which allows intricate communication between cells and cytokines.[27,43] Opioid-induced alteration of immune function can be categorized into central and peripheral components. It has been postulated that central opioid receptors mediate peripheral immunosuppression via the hypothalamic-pituitary-adrenal axis and autonomic nervous system.[27,41,44] Interestingly, severe chronic pain has been suggested to be associated with a reduction in immune function.[27,41,43]

Opioids and Hormonal Changes

The oral, intravenous, and intrathecal routes of administration of chronic opioid therapy have been well-described to alter hormonal effects in both men and women.[27] In illicit drug users, serum hormones that are altered by opioid administration subsequently return to normal following suspension of the drug.[44] Hormones disrupted by opioids are not relegated to testosterone (both total and free) but also include estrogen (estradiol), luteinizing hormone, gonadotropin-releasing hormone, dehydroepiandrosterone, adrenocorticotropin, corticotropin-releasing hormone, and cortisol.[27,45–49] Opioid related endocrinology research focuses on androgen hormones because of the well-described symptomatic side effects. Sexual dysfunction (erectile dysfunction, decreased libido), depression, and fatigue are some of the many side effects that men may experience when prescribed chronic opioid therapy.[27,45,46] Many of the side effects mentioned above have been correlated with hypogonadism. Symptoms such as depression and sexual dysfunction are not relegated to men; women can experience such side effects as well.[27,45,46] Women also experience dysmenorrhea and potentially reduce bone mineral density. Testosterone levels appear to be reduced in women and may be correlated with body mass index.[27,47–48]

Opioid-Induced Sleep Disturbances

A considerable number of studies on the effects of chronic opioid therapy on sleep are still needed. Despite the paucity of data, some studies suggest that opioids increase the number of shifts in sleep-waking states and reduce total sleep time, sleep efficiency, δ sleep, and rapid eye movement (REM) sleep.[27,50–52] In various studies, it is difficult to separate the effect of opioids on sleep from those of comorbid conditions (e.g. cancer, addiction or dependence, postoperative pain). Research suggests that γ-aminobutyric acid (GABAergic) signaling via inhibition of acetylcholine release in the medial pontine reticular formation is the primary focus for the disruption of sleep by opioids.[27,50–52] Morphine has been demonstrated to reduce REM sleep. The resulting disruption in sleep architecture affects the state of arousal during wakefulness.[27,50–52]

Opioid Tolerance and Physical Dependence

Substantial differences that distinguish tolerance, dependence, and addiction from each other. Unfortunately, these concepts are frequently misunderstood. In 2001, the American Pain Society, American Academy of Pain Medicine, and American Society of Addiction Medicine approved definitions of addiction, physical dependence, and tolerance in the hope of reducing misguided treatment of patients who require opioids for pain treatment. In patients who are chronically administered opioids, it should be anticipated that physical dependence and tolerance will develop, but clinicians should remain vigilant for maladaptive changes in behavior witnessed in patients with addiction (see later discussion) while recognizing that these changes only occur in a minority of cases.[53]

Tolerance

The term *opioid tolerance* is often used to describe the phenomenon that occurs when a fixed dose of an opioid results in decreasing analgesia, thus requiring higher doses of medication to achieve the same or less effect over time.[32] Because some opioids are only appropriate for use in opioid tolerant patients, for practical purposes, the FDA has defined a patient who is opioid tolerant as one who has received at least 60 mg oral morphine equivalents for at least seven days. The mechanisms responsible for this phenomenon are not entirely understood, but the *N*-methyl-D-aspartate (NMDA) receptor has been demonstrated to be involved.[54,55] The clinical usefulness of NMDA receptor involvement has yet to be determined fully, but nonhuman studies have continued to promulgate the potential for using NMDA receptor antagonists in conjunction with opioids to attenuate tolerance and physical dependence.[56,57] A subpopulation of dorsal horn neurons expressing NMDA receptors and treated with high-dose morphine have been shown to have enhanced NMDA receptor-mediated activity.[56] Furthermore, μ-receptor antagonist and NMDA receptor antagonist treatment of this subpopulation have attenuated the increased activity.[56] Another study has demonstrated that in "morphine-tolerant" rats treated with an NMDA receptor antagonist, the morphine-induced tolerance reversed.[57] The relevance of these findings at the bedside have, to date, not been clear.

Human studies on the effects of NMDA receptors on tolerance have been less promising. There has been great hope that NMDA receptor antagonists such as ketamine or dextromethorphan might potentiate the analgesic effect of opioids, but no convincing evidence has emerged from replicated trials.[58,59] In a double-blind controlled clinical trial comparing morphine and a combination of morphine and dextromethorphan, statistical differences in analgesia or dose were not seen between groups.[60] Nonetheless, basic concepts continue to support the understanding that the NMDA receptor is a key component in the development of opioid-induced tolerance. In particular, ketamine continues to be a drug of major interest because of its potential to improve opioid performance by preventing tolerance and enhancing opioid-induced analgesia.[61–63]

When a patient is suspected of having become tolerant to one medication, the cause may be that the pain is not sensitive to opioids, the patient has become opioid tolerant, or it may be related to increased pain, which requires adjustment in dosing. The need for dose escalation in patients treated with chronic opioids should constantly stimulate consideration of the progression of the underlying disease. Opioid rotation can be performed when opioid-induced tolerance is present. This is based on the clinical observation that patients often have intraindividual analgesic responses to different opioids and that improved analgesia with fewer side effects may occur when a different opioid is used.[64] Although the full mechanism of this phenomenon is not completely understood, it is usually thought to occur because of incomplete tolerance, possibly related to differing μ-opioid and other opioid receptor affinities of one opioid versus another. When opioid rotation is performed in opioid tolerant patients as opposed to opioid-naïve patients, equal analgesic doses may not be necessary. The patient may respond with analgesia to half the equianalgesic dose, and if not, the dose may be titrated to an adequate analgesic effect that is less than would be expected by calculation of equianalgesic conversion from standard formulas. This is a potentially useful phenomenon whereby the overall opioid requirement of the patient may be reduced, thereby achieving an opioid-sparing effect.

Physical Dependence and Withdrawal

Physical dependence is a physiologic state that occurs when a medication is abruptly stopped and withdrawal syndrome results. This is *not* synonymous with addiction. This separation of physical dependence and addiction is supported by evidence of two distinct anatomic areas within the CNS that are involved in physical

dependence versus addiction. Noradrenergic neurons within the locus coeruleus are implicated in the maintenance of dependence and development of withdrawal, whereas the ventral tegmental dopaminergic area and orbitofrontal glutamatergic projections to the nucleus accumbens are thought to subserve addiction.[61,65] It has been shown that drugs of abuse such as heroin, cocaine, nicotine, alcohol, phencyclidine, and cannabis initiate habit-forming actions by activating a common reward pathway in the brain.[66] There is also well as the involvement of noradrenergic neurons in the development of withdrawal. Not only do norepinephrine levels change in the brain following opioid dependence, but the administration of an α_2-agonist such as clonidine or a β-antagonist such as propranolol also attenuates many of the symptoms of opioid withdrawal but does not reverse addiction.[67]

The clinical manifestations of opioid withdrawal usually begin with irritability, anxiety, insomnia, diaphoresis, yawning, rhinorrhea, and lacrimation. If it progresses without intervention, a flu-like condition develops, with chills, myalgia, fever, abdominal cramping, nausea, diarrhea, tachycardia, and other features of a heightened adrenergic state. Although uncomfortable for patients, it is self-limited and lasts approximately three to seven days. Opioid withdrawal may occur in patients who abruptly discontinue opioids or who have relative discontinuation because of taking SAOs after accommodating the longer plasma half-life of LAOs.[32]

It is usually possible to taper patients from opioids without inducing withdrawal symptoms. Although faster tapering can be accomplished without the advent of withdrawal symptoms, if time allows, few patients will be symptomatic if the dose is decreased by 10%–20% every 48–72 h over a prolonged period (usually two to three weeks, depending on the dose).[68] If withdrawal symptoms develop during discontinuation or taper, clonidine, 0.2–0.4 mg/day, may be used to decrease discomfort.[69] Clonidine is often maintained for four days during taper of an SAO and 14 days during taper of an LAO. Once opioids have been discontinued, clonidine can be tapered for approximately one week.[32]

Other medications are also used for managing withdrawal symptoms, often drugs with GABA B receptor antagonism (i.e. tizanidine) and/or α_{2A} adrenergic receptor agonists (i.e. lofexidine or tizanidine).

Opioid Use Disorder

Opioids are associated with substance abuse at a rate that is high enough to be a significant concern. However, the exact rate of opioid use disorder as a result of therapeutic opioid use is controversial. Opioid use disorder (OUD) is characterized by opioid use that results in physical, psychological, or social dysfunction (or a combination of these) and continued use of opioids despite the dysfunction. The DSM-5 defines OUD as a problematic pattern of opioid use leading to clinically significant impairment or distress, with at least a 12-month period of at least two of the 11 symptoms (Box 48.1).

Neurobiologic evidence has suggested that OUD may be subserved by positive reinforcement and sensitization of the dopaminergic system in the brain, which may explain the continued seeking of a substance destructive to the patient's life.[70] Patients who are receiving an inadequate dose of opioid medication may engage in drug-seeking behavior to obtain more pain medication for the relief of pain, which can be mistaken for the drug-seeking behavior associated with OUD. Physicians are often challenged to distinguish true use disorder from undertreated pain because undertreated pain may appear similar to OUD because of features such as drug-seeking and self-escalation. However, unlike OUD, undertreated patients experience pain relief and improved function with increased doses of opioids. OUD directly contrasts with what is seen in a patient with undertreated pain who goes through dose escalation. With OUD, aberrant behavior not only continues despite an increase in opioids but is also usually further stimulated and promoted by increased exposure to the addicting drug. The Committee on Pain of the American Society of Addiction Medicine has defined OUD in the context of pain treatment with opioids as a persistent pattern of dysfunctional opioid use based on a comprehensive clinical assessment that includes history, physical examination, validated clinical scales that measure withdrawal symptoms, and urine drug testing.[71] Patient behavior may be used cumulatively to support the diagnosis of addiction, but absolute conclusions cannot always be made, particularly without longitudinal information over extended periods. Many types of behavior may indicate the possibility of addiction (Box 48.2).

• BOX 48.1 Eleven Symptoms in Opioid Use Disorder

Taking opioids in larger amounts or over longer periods than intended
Having a persistent desire to control opioid use
Sending excess time obtaining, using, or recovering from opioid use
Having opioid cravings
Inability to fulfill work, home, or school responsibilities from continued opioid use
Continued opioid use despite persistent interpersonal problems
Lack of involvement in social, occupational, or recreational activities
Opioid use in physically hazardous situations
Continued opioid use despite persistent physical or psychological problems
Tolerance, including the need for increased amounts of opioids
Opioid withdrawal syndrome
The DSM-5 defines OUD as a problematic pattern of opioid use leading to clinically significant impairment or distress, with at least a 12-month period of at least two of the 11 symptoms.

Nonadherence to opioid therapy may be related to many possibilities, including adverse effects, forgetfulness, incompatibility with lifestyle, and confusion about the drug regimen. It may rarely be related to aberrant behavior such as diversion or drug abuse, and an astute physician will maintain a position of vigilance without feeling compelled to reach immediate conclusions. If a physician chooses to pursue pain treatment with an abusable drug in a patient at risk for addiction, collaboration with an addiction specialist or addiction psychiatrist is advised to ensure that the necessary resources to support an appropriate risk management program are available. Such resources are usually far greater than those available to the average prescriber, and without the necessary resources to ensure safety, prescribing should not begin. High vigilance and tempered judgments are always required.

The exact rates of opioid misuse and abuse in patients with chronic pain are not exactly known. However, estimates range from 1%–40%.[72] Treating chronic pain in a person with a history of substance use disorder is challenging and highly risky, but it is not absolutely contraindicated. Nonetheless, responsible prescribers of opioids must ensure that the appropriate resources for safe use are in place before initiating treatment. If appropriate risk management is not available, treatment should not be initiated. Moreover, treatment should not be initiated unless it can be terminated when necessary.

Although a low percentage of the population with chronic pain appears to experience addiction, the remainder of the population has been shown to be at risk for receiving suboptimal analgesia because of prescribers' fears of patient abuse of the opioid.[73] A

• Box 48.2 Aberrant Behavior Indicative of Addiction

Behavior *Less* Indicative of Addiction

Expresses anxiety or desperation over recurrent symptoms
Hoards medications
Takes someone else's pain medications
Aggressively complains to the physician for more drugs
Requests a specific drug or medication
Uses more opioids than recommended
Drinks more alcohol when in pain
Expresses worry over changing to a new drug, even if it offers potentially fewer side effects
Takes (with permission) someone else's prescription opioids
Raises the dose of opioids on one's own
Expresses concern to the physician or family members that pain might lead to the use of street drugs
Asks for a second opinion about pain medications
Smokes cigarettes to relieve pain
Has used opioids to treat other symptoms

Behavior *More* Indicative of Addiction

Buys pain medications from a street dealer
Steals money to obtain drugs
Tries to get opioids from more than one source
Performs sex for drugs
Sees two physicians at once without them knowing
Performs sex for money to buy drugs
Steals drugs from others
Prostitutes others for money to obtain drugs
Prostitutes others for drugs
Forges prescriptions
Sells prescription drugs

From Passik SD, Kirsh KL, Donaghy KB, et al. Pain and aberrant drug-related behaviors in medically ill patients with and without a history of substance abuse. *Clin J Pain* 2006;22:173–181.

growing debate has emerged that focuses on understanding how opioids should be used in the setting of substantial rates of chronic pain while balancing the imperative for vigilant use of opioids with sufficient risk management for acceptable safety.

If the decision is made to prescribe opioids, it is imperative to prescribe an opioid antagonist, most commonly intranasal naloxone, as a potentially life-saving antidote for patients with OUD. The United States FDA recommends making naloxone available to all patients with opioids. However, it is especially important to prescribe naloxone for those at increased risk of opioid overdose (patients with a history of OUD, patients with concomitant use of other CNS depressants, and patients with a history of opioid overdose).

Selected Opioids

Although therapeutic options to provide analgesia continue to emerge, opioids remain the "gold standard" of currently available analgesics**.** Despite the widespread use of opioids to treat acute and chronic pain, controversy exists regarding the use of opioids for the treatment of chronic nonmalignant pain. There are proponents on each side of the controversy, and part of the fear of prescribing opioids stems from an inaccurate understanding of appropriate outcomes for prescribing opioids and the risk of abuse or side effects. Although opioids can be a useful tool to provide adequate analgesia for patients, fear of the development of OUD, dependence, or untoward side effects often precludes physicians from prescribing opioids.[74] If it is decided to initiate opioid therapy in patients with chronic nonmalignant pain, the decision should be based on a well-thought-out rationale for treatment, with clear end points in mind.

If the decision is made to initiate opioid therapy, SAOs are generally preferred for the initial phase of management of chronic and non-cancer acute pain. LAOs are typically reserved for patients on well-established dosing and amounts of opioids. SAOs should be titrated slowly to the lowest effective dose, in increments of 25%–50% of the total daily dose. Generally, in treating chronic pain, expert guidelines generally suggest avoiding dosages above 90 mg or morphine mg equivalents given the increased risk of overdose and other adverse effects with higher dosages and lack of evidence for increased analgesia with excessive dosages. Guidelines now suggest avoiding high doses or quantities of opioids given the increase in the prevalence of OUD among the general population. SAOs are often initially prescribed for patients with chronic pain syndromes because they have relatively brief peak serum blood levels of active analgesic metabolites. However, the use of SAOs to treat persistent baseline chronic pain may require frequent dosing. This roller coaster effect is thought to promote nonoptimal pain related behavior, which is why LAOs have been used once the total opioid dose requirement is well-established in such cases. Nonetheless, science has not clearly demonstrated this advantage.

SAOs are often combined with other analgesics, such as acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or aspirin, which may offer drug-sparing effects because less medication may be used. Although combination opioids may help reduce opioid related side effects and toxicity, there is a potential for harm to major organs from non-opioid components (e.g. acetaminophen, NSAIDs, aspirin). When using combination opioids, physicians must be aware of renal and liver function problems, as well as the potential harm that could occur in the GI system. Patients must be educated about the risks of taking other analgesics, such as acetaminophen, NSAIDs, and aspirin, in conjunction with the combination opioids. Moreover, physicians must also consider that non-opioid drugs are likely to have a ceiling effect beyond which they are no longer efficacious. Because opioids induce tolerance and have no ceiling effect, the pharmacologically appropriate need for increased opioids may inadvertently push the dose of a combination drug to appropriate levels of the opioid component but to toxic levels of the non-opioid agent. Although reviewing all available opioids is beyond the scope of this chapter, we will review some of the most commonly used opioids for pain management. Minor opioids, such as hydrocodone, are discussed in Chapter 49.

Codeine

Codeine is an alkaloid found in very low concentrations in opium. It is now derived from morphine. Codeine is frequently administered in combination with acetaminophen, butalbital, and caffeine.[69] It has been shown to be an effective analgesic for chronic nonmalignant pain but has limitations.[75] It is a weak μ-opioid agonist and has a half-life of 2.5–3 h. The major metabolic pathway leads to glucuronidation of codeine to codeine 6-glucuronide, with a minor metabolic pathway catalyzed by the polymorphically expressed enzyme CYP2D6 through *N*-demethylation of codeine to norcodeine and *O*-demethylation of codeine to morphine.[10] Evidence has suggested that the analgesic effects of codeine rely on its conversion to morphine, and patients with genetic variations in the enzymes needed to make this conversion may find codeine to be less effective.[76] The genetic polymorphism of

CYP2D6 is responsible for the variable response to the medication. Patients with the genotype CYP2D6 PM (poor metabolizers) do not achieve adequate analgesia with codeine. In addition, certain medications that inhibit CYP2D6, such as quinidine, paroxetine, fluoxetine, and bupropion, can alter the phenotype of normal patients with normal genetics and thus decrease the therapeutic analgesic effect of codeine.[77] Urinary excretory products of codeine include codeine (70%), norcodeine (10%), morphine (10%), normorphine (4%), and hydrocodone (1%).[69] This may be important to remember when interpreting the urine toxicology screens of patients taking codeine.

Morphine

Morphine, a hydrophilic phenanthrene derivative, is a prototypical opioid against which all other opioids are compared for equianalgesic potency. Because of its hydrophilic nature, it exhibits delayed transport across the blood-brain barrier, thus delaying its onset of action. Conversely, it has a longer duration of action, 4–5 h, than its plasma half-life of 2–3 h.[25] Metabolism of morphine to its two major metabolites, morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G), occurs mainly in the liver (see Table 48.1). Although the parent compound produces analgesia and side effects, M6G may also produce some analgesia along with some adverse effects. M6G accounts for 5%–15% of morphine metabolites and is a μ- and δ-agonist, which accounts for its analgesic effects. It has been demonstrated that M6G does not exert antinociceptive effects in knockout mice lacking the μ-receptor.[78]

M3G, which accounts for 50% of morphine metabolites, does not appear to possess opioid agonism but may produce effects that oppose morphine's analgesic actions, such as allodynia, hyperalgesia, myoclonus, and seizures.[10] Oral administration of morphine has been shown to result in higher levels of M3G and M6G than those achieved with the intravenous, intramuscular, or rectal routes, which bypass hepatic metabolism.[79] Chronic administration of morphine ultimately results in higher circulating levels of M3G and M6G metabolites than the parent compound.[80] It has been found that patients receiving chronically high morphine doses metabolize morphine to hydromorphone and test positive for hydromorphone on urine toxicology screens.[81] This is of critical importance in patients using morphine for chronic pain who undergo urine drug screening.

Although extrahepatic metabolism of morphine has been shown to occur in gastric and intestinal epithelia, morphine should be used with caution in patients with decreased hepatic function, such as those with cirrhosis.[10] In addition, glucuronides have been shown to undergo deconjugation back to the parent compound by colonic flora and reabsorbed as morphine.[10] Morphine metabolites are excreted by the kidneys, so caution should also be taken when prescribing morphine to patients with renal impairment because the accumulation of M6G and M3G can be toxic. Available forms of morphine include short- and long-acting preparations. Short-acting agents may be compounded for almost any route of administration, and long-acting preparations generally use specialized sustained release matrix technologies, such as those found in MS Contin, Kadian, Oramorph SR, and Avinza.

Oxycodone

Oxycodone is a semisynthetic opioid that is closely related to morphine. It has been available for analgesia since 1917 when it was introduced into clinical practice in Germany.[82] It is processed from thebaine, an organic compound found in opium. Similar to morphine, currently available forms of oxycodone include short- and long-acting preparations. Short-acting oxycodone may be used alone (e.g. Roxicodone) or may be compounded with acetaminophen (e.g. Percocet, Roxicet, Endocet) or aspirin (e.g. Percodan). Long-acting oxycodone preparations are designed for oral administration and involve the use of specialized sustained release technology (e.g. OxyContin, Xtampza, and similar generics).

Oxycodone has a bioavailability of 60% compared with morphine, which has a bioavailability of 33%, thus making oxycodone almost twice as potent as morphine.[70] Oxycodone is a prodrug that undergoes hepatic metabolism via the CYP2D6 isoenzyme, whereby it is converted into its active metabolite oxymorphone, a μ-opioid agonist, and its inactive metabolite noroxycodone. Oxymorphone is reportedly often undetectable and is 14 times more potent than the parent compound.

Similar to codeine, there is genetic polymorphism in 10% of the population, which accounts for significant variation in the metabolism of oxycodone. This variation explains why some patients require higher than usual doses of oxycodone to achieve analgesia. Another factor to be considered when prescribing oxycodone is whether other potential competitors of the CYP2D6 isoenzyme are being prescribed. Such interacting medications include neuroleptics, tricyclic anti-depressants, and selective serotonin reuptake inhibitors (SSRIs). Cases of serotonin syndrome have been described in the literature when SSRIs and oxycodone were used concomitantly.[83,84]

TABLE 48.1 Selected Opioids: Oral Bioavailability, Half-lives, Duration of Action, and Metabolites

Opioid	Availability (%)	Half-life (h)	Duration of Action (h)	Metabolites
Morphine	10–45	2–3	4–5	M6G, M3G
Oxycodone (OxyContin)	60–80	4.5	12	Oxymorphone, noroxycodone
Methadone	60–95	8–80 (average, 27)	6–8	—
Hydromorphone	24	2.3	3–4	H3G
Oxymorphone (Opana ER)	10	9 ± 3	12	O3G, 6-hydroxyoxymorphone

H3G, Hydromorphone 3-glucuronide; *M3G*, morphine 3-glucuronide; *M6G*, morphine 6-glucuronide; *O3G*, oxymorphone 3-glucuronide.

Meperidine

The use of meperidine for analgesia has been declining recently because of its potential neurotoxicity. It is a weaker μ-opioid agonist than morphine with 10% potency, more rapid onset, and a shorter duration of action,[85] with a half-life of 3 h, and it is hepatically demethylated to its neurotoxic metabolite normeperidine, which has a half-life of 12–16 h. Normeperidine has been well-documented to cause CNS hyperactivity and seizures.[25] Its excretion occurs via the kidneys. Therefore caution should be taken when administering meperidine to patients with renal impairment or those prone to CNS hyperactivity. Initially, the toxic effects may be seen as subtle changes in mood that can progress to naloxone-irreversible tremors, myoclonus, and seizures. Chronic administration of meperidine to patients with normal renal function and administration of meperidine in conjunction with SSRIs, monoamine oxidase inhibitors, tramadol, and methadone can also result in neurotoxic side effects.

Hydromorphone

Hydromorphone has a strong affinity for the μ receptor. It is a hydrogenated ketone analog of morphine and can be formed by *N*-demethylation of hydrocodone.[85] Hydromorphone is similar to morphine in that it is hydrophilic and has a comparable duration of analgesia, but it differs regarding side effects and potency. Pruritus, sedation, nausea, and vomiting occur frequently. Hydromorphone is five times more potent than morphine when administered orally (see Table 48.2) and seven times more potent when administered parenterally. Though essentially hydrophilic, it is ten times more lipophilic than morphine. This lipophilicity may be advantageous when treating patients who cannot take oral medications and cannot maintain intravenous access, such as in hospice environments. It can be administered subcutaneously at a dose of 10–20 mg/mL; this route delivers approximately 80% of the dose absorbed through intravenous delivery.[85] The onset of analgesia occurs within 30 min after oral administration and 5 min after intravenous administration, with peak analgesic effects occurring within 8–20 min.[85]

TABLE 48.2 Equianalgesic Doses of Opioids

Opioid	Oral Equianalgesic Dose (mg)
Buprenorphine	0.3
Oxymorphone	1.5
Butorphanol	2
Hydromorphone	2
Oxycodone	7
Hydrocodone	10
Morphine	10
Methadone	10–20
Tramadol	40
Codeine	80
Meperidine	100

Hydromorphone is metabolized in the liver to H3G, and like its parent compound, it is excreted renally. Like M3G, H3G lacks an analgesic effect but may be an active metabolite that potentiates neurotoxic effects such as allodynia, myoclonus, and seizures.[10] The production of H3G is relatively low. Hence, the risk of neurotoxic side effects is relatively low, except in patients with renal insufficiency, in whom H3G may accumulate.[81]

Fentanyl

Fentanyl is a highly lipophilic agent with a high affinity for the μ-opioid receptor. It is 75–125 times more potent than morphine and has a faster onset of action.[80] Because of its higher potency, smaller quantities of the medication can be delivered to the patient relative to other opioids. Although fentanyl is considered a short-acting medication, its lipophilic nature allows long-acting transdermal and very rapid onset transmucosal administration to treat chronic and acute pain, respectively.[86,87] Although there are other minor pathways, fentanyl undergoes hepatic biotransformation via CYP3A4 *N*-dealkylation to norfentanyl. Its half-life and onset of action vary greatly depending on the route of administration. (Transmucosal fentanyl undergoes first-pass metabolism and has an onset of action within 5–10 min.)[88]

A transdermal fentanyl patch is used in some patients with chronic pain or pain related to cancer. Transdermal fentanyl has been used for acute postoperative pain but may be associated with hypoventilation.[87] Transdermal patches are typically placed on a hairless part of the body that is flat and free of any defects that could interfere with patch adherence. Patients should be advised to avoid submerging the patch in hot water or placing a heating pad over the area because this influences absorption. Patients report local skin erythema or irritation as the most common side effect.[87]

Transdermal fentanyl is an alternative choice for patients with significant GI issues, such as persistent emesis, chronic nausea, or "short gut" syndrome, or for those believed to be at risk of diverting oral medications. The use of the patch offers the opportunity to allow patients to return the old patches for inspection at the time of prescription refill. Theoretically, transdermal delivery may induce less constipation than oral opioids because it avoids direct exposure to the GI tract, but this is questionable in light of the common finding of significant constipation in almost all patients who use transdermal opioids.

Unlike other LAOs, transdermal fentanyl may be challenging to titrate because of variations in individual patient characteristics, such as skin perspiration, skin temperature, fat stores, and muscle bulk.[10] The rate of achieving therapeutic serum levels can vary (ranging from 1–30 h with a mean of 13 h). Because of the wide variation in reaching therapeutic levels, a short-acting oral analgesic or intravenous patient-controlled analgesia may be necessary to address breakthrough pain, while the transdermal opioid effect is ramping up or to prevent withdrawal symptoms if rotation from another opioid has occurred. Achieving steady state levels may require up to six days, and the amount of SAO needed after a steady state is attained will help determine whether the dose of fentanyl must be increased.[10] However, if the patch is removed, it may take up to 16 h for serum fentanyl concentrations to drop by 50%.

Oral transmucosal fentanyl has a more rapid onset of analgesia than other SAOs and offers some advantages. Because it is transmucosal, it avoids the GI tract and first-pass hepatic metabolism and has a rapid onset of action within 10–15 min. One study

compared intravenous morphine with transmucosal fentanyl in an acute postoperative setting and demonstrated a similar onset of analgesia.[88] Transmucosal fentanyl can be beneficial for patients with acute breakthrough pain. To date, a major limitation in using this route is the cost.

Methadone

Methadone may be an attractive choice for analgesia because of its unique properties, but it also has many features distinguishing it from other opioids that have raised its potential for adverse outcomes. Methadone has become the most common opioid found to be related to unintended overdose deaths in the United States. Thus caution should be exercised with this drug. On the positive side of the methadone risk-benefit profile, its attributes include no known neurotoxic or active metabolites, high absorption and bioavailability, and multiple receptor activities, including μ- and δ-opioid agonism, NMDA antagonism, and serotonin reuptake blockade. Methadone has been shown to have a bioavailability that is approximately threefold that of morphine.[89,90] In patients who require high-dose LAOs, methadone appears to be a theoretical second-line choice despite the lack of accumulation of neurotoxic metabolites that induce myoclonus, hallucinations, seizures, sedation, and confusion. Unfortunately, the unique pharmacokinetics and pharmacodynamics of methadone render its effects somewhat unpredictable.

Methadone is structurally unrelated to other opioid-derived alkaloids. It is a racemic mixture of two enantiomers, the D-ISOMER (*S*-methadone) and THE L isomer (*R*-methadone). *R*-Methadone accounts for its opioid receptor affinity and thus its opioid effect. Animal studies have demonstrated that methadone has a lower affinity than morphine for the μ-receptor.[91] This may explain why methadone may have fewer μ-opioid related side effects than morphine. However, methadone has a higher affinity for the δ receptor than morphine.

Methadone has a slow but variable elimination half-life that averages approximately 27 h, which may be related to its lipophilicity and extensive tissue distribution.[91] The delayed clearance of methadone is the basis for its use in maintenance therapy. Surprisingly, although methadone may be efficacious for the purpose of opioid maintenance therapy because it potentially prevents withdrawal symptoms for 24 h or longer, its analgesic half-life is shorter than 24 h, usually found to range from 6–8 h. This discrepancy is related to the biphasic elimination. The α elimination phase lasts 8–12 h and correlates with the period of analgesia, which lasts approximately 6–8 h. The β elimination phase ranges from 30–60 h and is responsible for preventing withdrawal symptoms; this property is exploited in maintenance therapy.[91]

Methadone has multiple drug interactions related to inducers or inhibitors of the CYP system, particularly the 2D6 and 3A4 subtypes.[92] Because these interactions rarely are seen with other opioids, drug interactions with methadone may not be as readily anticipated or detected. Besides interacting with drugs, 3A4 is an auto-inducible enzyme, which accounts for the fact that methadone can bring about its own metabolism and increase its clearance with prolonged use.[91,92]

Other issues affecting methadone absorption and accumulation are gastric and urinary pH. Decreased gastric pH, such as in patients taking proton pump inhibitors, results in increased rates of methadone absorption. Renal failure and hemodialysis do not alter the excretion of methadone. However, as urinary pH increases, methadone clearance in urine decreases. Urine pH higher than six can reduce methadone clearance from 30% to almost 0%, thereby resulting in increased circulating levels. Most methadone is eliminated in feces.[10] Another source of methadone's potential metabolic instability relates to its avid protein binding. Acute changes in protein binding may lead to sudden increases or decreases in circulating methadone levels.

The difference between methadone and other LAOs is that the duration of the effect of methadone is intrinsically long-acting, whereas most other LAOs are sustained-released forms based on compounding technology. This is beneficial for patients with impaired GI absorption. In addition, methadone is available as a powder, allowing it to be formulated for almost any route of administration. Methadone pills can be broken and cut in half, and it is also available as a liquid elixir (1 or 10 mg/mL). This avoids the need to crush pills, which offers a potential advantage in patients with gastrostomy tubes. In addition, because methadone elixir has a low-concentration formulation, careful and precise titration of methadone can be performed to achieve adequate analgesia.

One of the most disturbing aspects of methadone use in the United States has been the reported increase in methadone-related deaths.[93,94,95] Although the mechanism for these deaths is not exactly clear, many appear to be related to overdose and drug interactions. In some cases, an overdose may be related to misunderstanding the standard conversion rates of methadone from other opioids. Contrary to conventional wisdom, methadone appears to be more potent (milligram for milligram) in patients whose treatment is being switched to methadone from high doses of other opioids. Although standard conversion tables may suggest that the ratio of conversion from morphine to methadone may be from 1:1 to 1:3, these ratios were taken from studies on acute pain or normal controls. Many of these conversion tables were developed over 20 years ago, far before recent increases in methadone use as a chronic analgesic. If much higher pre-switch dosages are converted to methadone, the appropriate morphine to methadone ratio may range from 1:5 to 1:20 or higher. Such a counterintuitive dosing phenomenon leads to the potential for overdose.

Another possible source of methadone-related mortality includes torsade's de pointes arrhythmias, which have been reported in some patients.[96] Although a prospective study has demonstrated QT prolongation on electrocardiogram in patients taking methadone, it was also concluded that the magnitude of the increase is less than that with other antiarrhythmic drugs and is not higher than the QT widening caused by other drugs, such as tricyclic anti-depressants.[96] The use of methadone requires awareness of possible QT prolongation and the possible additive effect that other QT-prolonging agents may have when combined with methadone. Table 48.1 shows the oral bioavailability, half-life, duration of action, and metabolites of selected opioids. Table 48.2 shows the equianalgesic doses of the different opioids.

Methadone must be used with significant knowledge of the special properties that predispose it to substantial risk. Slow-dosing titration and careful monitoring are essential for safe use. If this and all other elements of safe prescription of opioids are not possible, the drug should not be prescribed.

Buprenorphine

Buprenorphine demonstrates a high binding affinity and mixed agonist-antagonist activity at opioid receptors. A derivative of the morphine alkaloid thebaine, a semisynthetic opioid, possesses unique pharmacologic characteristics compared to traditional opioids, making it an appealing first choice option for chronic pain.

Buprenorphine is a μ-opioid receptor agonist, a κ-opioid receptor antagonist, and is thought to act as a mild antagonist of the δ-opioid receptor. Antagonistic activity at the κ-receptor is believed to explain buprenorphine-associated anti-hyperalgesia, lessened sedation, euphoria, cravings, and dysphoria compared with conventional opioids, and its potential to act as an antidepressant. Distinctively, buprenorphine has been shown to activate the opioid receptor-like (ORL-1) receptor, which may account for a reduction in the development of opioid tolerance. Acting as a "chaperone" ligand, buprenorphine demonstrates the ability to boost μ-opioid receptor expression on cell membranes.

Buprenorphine is a Schedule III controlled substance available in multiple dosage forms, including injection (IV, depo-SC, subdermal implant), transdermal, buccal, and sublingual routes. Buprenorphine is available independently or combined with naloxone in a 4:1 ratio. The addition of naloxone (an opioid receptor antagonist) to sublingual routes is intended to deter misuse and blunt opioid agonist effects if injected. The oral bioavailability of buprenorphine is poor (10%) because of high first-pass hepatic clearance. Buprenorphine is metabolized in the liver through cytochrome CYP3A4 to norbuprenorphine and is excreted primarily through feces. For patients with renal failure, buprenorphine is a preferred opioid analgesic; drug clearance is unchanged with renal impairment and is not removed by dialysis.

Compared to traditional opioids, buprenorphine has an advantageous safety profile. Most notably, when used alone, buprenorphine exhibited a ceiling effect related to respiratory depression. It is essential to understand that when combined with respiratory depressants such as alcohol or benzodiazepines, this protective effect is diminished. Adverse effects such as constipation, sedation, hypogonadism, and tolerance are also seen to be less of a degree with buprenorphine than with other opioids.

Similar to methadone, buprenorphine is an effective treatment for OUDs and opioid dependence. Buprenorphine exhibits slow dissipation from opioid receptors, and sublingual formulations have a prolonged plasma half-life (24–72 h). Delayed drug clearance and high lipophilicity make buprenorphine an ideal agent to prevent withdrawal symptoms, often for a period of up to three days. Interestingly, similar to methadone, buprenorphine displays a shorter analgesic half-life (6–8 h) and is often dosed two to four times daily for pain. It should be clarified that a Data-2000 waiver (additional prescriber training for addiction medicine) is needed to prescribe buprenorphine for OUD but is not required to prescribe buprenorphine for pain.

As attractive as buprenorphine may be for chronic pain as a first choice opioid, compared with a full agonist opioid, logistical limitations exist around prescribing the drug itself. Challenges include a lack of coverage and reimbursement by third-party payers and hospital formularies, as well as a lack of education on the proper usage of buprenorphine. Clinical experience is recommended when transitioning a patient from a full-opioid agonist to buprenorphine. Careful timing of the window of clearance of the initial full-opioid agonist is necessary to prevent abrupt displacement by buprenorphine. The absence of this consideration may lead to severe precipitated withdrawal. Additionally, the equianalgesic data for buprenorphine are conflicting and incomplete.

Conflict exists in the literature on whether to maintain the classification of buprenorphine as a "partial agonist" opioid. Buprenorphine displays low intrinsic activity *in vitro*, leading to a ceiling effect on analgesia in animal models and a ceiling effect on respiratory depression in humans. The question remains as to how this translates clinically. Some studies have shown bell-curve antinociception, while others have observed similar analgesic values to full μ-opioid agonists, such as morphine and fentanyl. The variability of interindividual responses to different opioids remains reliable. The clinical decision to utilize one opioid over another should be made with patient-specific circumstances in mind.

Rational Opioid Prescribing

Opioids work for some pain but not all. They may be problematic for many and even life-threatening for some but knowing who is susceptible is not always clear. Treatment of substantial pain may necessitate the use of opioid related medications. Opioids are not the first choice, nor should they necessarily be the last choice in the pain management armamentarium. A detailed diagnosis with a thorough history and physical examination and an essential focus on risks and benefits will drive the selection of specified analgesic treatments. Non-opioid treatments will often be the initial choice. The decision to use opioid therapy has undergone intense scrutiny as the public health epidemic of prescription drug abuse has been elevated to a national discussion. The importance of risk management with focal attention to the risk-benefit ratio for safe use of opioids underscores the serious potential for opioid abuse and overdose death that has been well documented through approximately 15 years of retrospective data. A history of psychiatric comorbidity and a history of substance abuse are known variables suggestive of increased risk for abuse and unintentional overdose death. A full discussion of the safe prescribing of opioids is beyond the scope of this chapter but can be found in other resources, such as from the Department of Health and Human Services [https://www.hhs.gov/opioids/prevention/safe-opioid-prescribing/index.html], from the CDC Guideline for Prescribing Opioids for Chronic Pain [https://www.cdc.gov/drugoverdose/prescribing/guideline.html], and from the FDA [https://www.fda.gov/consumers/consumer-updates/guide-safe-use-pain-medicine].

Before initiating opioid therapy, a detailed evaluation is necessary. This evaluation must include risk stratification, assessment of functional activity, a thorough review of the patient's medical history with special attention paid to previous experience with opioid analgesics, and a review of other related comorbid factors, including previous substance abuse, mental illness, hepatic, renal, or pulmonary dysfunction, or sleep apnea. Informed consent is a critical element of opioid treatment that requires patient education regarding the benefits and risks associated with treatment. The expectations and responsibilities of patients must be clarified early. Monitoring and management of opioid-induced side effects are imperative. The use of opioid agreements, urine drug screens, and well-defined boundaries of care must be considered before initiating treatment, as well as an exit strategy if treatment fails to be successful for a variety of reasons.

If the patient is opioid-naïve and the benefits outweigh the risks, low-dose SAOs such as hydrocodone or oxycodone may be initiated and carefully titrated to establish an opioid requirement. Because of the rapid clearance and brief half-life of SAOs, toxic accumulation of the medications is less likely than with LAOs. The severity and duration of the patient's pain should help guide whether PRN or fixed dosing is required. In patients with acute pain secondary to an injury or surgery for which rapid healing is expected, PRN dosing is reasonable. However, in patients with the expectation of prolonged recovery or with chronic pain and significant baseline or persistent pain, opioids may be administered in fixed dosing intervals and PRN intervals for breakthrough pain.

Scheduled dosing decreases clock-watching anxiety and reinforcement of pain behavior. However, it may cause drug accumulation. If a patient can tolerate an SAO and its side effects, consolidation of the daily opioid requirement into an equianalgesic LAO regimen may be an appropriate step.

Although opioids may be excellent analgesics, they are often used as a second-line treatment for chronic pain, mainly because chronic pain may respond to non-opioid treatments that might carry fewer risks. When other pharmacologic, rehabilitative, or interventional procedures are not appropriate or are unsuccessful, chronic opioid therapy should be considered. It is not uncommon to combine opioid treatment with other modalities, including psychological and physical rehabilitation. Simultaneously, interventional pain procedures and adjunctive analgesics may be useful.

The effectiveness of opioid therapy for certain types of chronic pain, such as neuropathic pain, remains controversial. Because anti-depressants and anti-convulsants have been shown to provide less than 50% pain relief on average, opioids have been used to treat chronic neuropathic pain despite their narrow therapeutic window.[97] When treating neuropathic pain, it has been shown that opioid potency may be relatively lower than that for other conditions. This seems to be secondary to the changes that occur in the endogenous opioid system after nerve injury. It appears that endogenous peptide levels and opioid receptor density decrease in nociceptive pathways.[97] It also appears that GABAergic tone decreases after nerve injury and that the inhibitory effect of morphine on dorsal horn neuron projections after nerve injury is reduced compared to its effect on non-injured nerves.[98] Despite these findings, there is evidence in the literature that opioids are efficacious for neuropathic pain; a trial demonstrated that combining gabapentin and morphine for the treatment of neuropathic pain was superior to either alone.[99.] Nonetheless, gabapentinoids may also pose a risk for respiratory depression, drug abuse, and other adverse effects, particularly well established for gabapentin in the postoperative setting.[100,101]

In the form of chronic pain unrelated to nerve injury that does not respond well to other treatments, opioid therapy has been shown to be more effective than placebo or anti-inflammatory medications alone in reducing pain. However, studies have struggled to show substantial improvements in overall functioning with opioid therapy. Although opioids may be effective if used as the sole agent for changing all the primary and secondary effects of chronic pain, they may not be effective enough. The importance of a multi-disciplinary approach to the treatment of chronic pain syndromes cannot be overstated.

The use of opioids requires a comprehensive risk-to-benefit-based strategy, including the consideration of other potentially effective therapies that have less risk. Rational prescription also requires consideration of all potential risks associated with the treatment and should include a plan to avoid or deal with these risks.

Considerations for Opioid Prescribers

In response to a surging public health crisis regarding the misuse of prescription drugs, the Obama Administration in 2011 developed a prescription drug abuse prevention plan through the Office of National Drug Control Policy (ONDCP). The ONDCP plan entails specialized efforts concerning monitoring, proper medication disposal, enforcement, and education. Education of patients, parents, and youth is a key element of focus for the White House-implemented drug misuse prevention plan. Equally important is the education of prescribing physicians and care providers. In 2014, the Federation of State Medical Boards (FSMB) of the United States revised and expanded the book *Responsible Opioid Prescribing: A Clinician's Guide*.[102] The revised guide reviews the new data on opioid risk and toxicity, including high rates of unintended overdose deaths, which were not available when the first edition was written in 2006. It offers clinicians examples of current federal guidelines and strategies to reduce the risk of addiction, abuse, and diversion of opioids. Moreover, the revised edition includes, but is not limited to, defined strategies for patient evaluation that include risk assessment, treatment plans that incorporate functional goals, periodic review and monitoring of patients, documentation, informed consent, and termination strategies for chronic opioid therapy. It also emphasizes the special care that is needed when using methadone and treating children and adolescents, as well as prescriber responsibilities for consumer education on the safe use of opioids. The use of defined risk stratification methods by prescribers of chronic opioid therapy has become paramount. In 2016, the CDC released its *Guideline for Prescribing Opioids for Chronic Pain*, and in 2017, the FSMB published its *Guidelines for the Chronic Use of Opioid Analgesics*. These guidelines offered granular details on the expectations of opioid prescriptions that have been well-received. However, overreactions to the intent of the CDC guidelines resulted in some clinicians leading to rapid and involuntary discontinuation of long-standing opioid prescription, which resulted in increased risks for some patients, including increased illicit drug use and suicide. As a result, the CDC reframed its recommendations in 2019 (see the suggested readings and Chapter 50). However, the risks of chronic opioid therapy, including toxicity, overdose, and OUD, are well-supported by data. However, the benefits of chronic opioid therapy for chronic nonmalignant pain remain weak and inadequate. Therefore the analysis of risks and benefits must shift accordingly and is a critical basis for deciding whether opioids should be initiated. Gourlay and colleagues endorsed a universal precautions approach and suggested that addiction can only be elucidated on a behavioral prospective basis.[103]

Treatment End Points

Pain is a subjective experience, using "pain relief" as a treatment endpoint is a subjective and untestable marker of therapeutic success or failure. One of the most feared consequences of chronic opioid therapy is OUD, which, as discussed earlier, involves compulsive use of an opioid that causes dysfunction and continued use of the opioid despite the dysfunction (i.e. negative impact on or harm to the patient's life). Because effective analgesia should improve function and because of the risk of the side effect of OUD, which hinges on dysfunction, a major focus of chronic opioid therapy should be on functional improvement as an objective endpoint. It is expected that patients who are treated carefully and judiciously with opioids and achieve analgesia should have functional gains. This contrasts with those struggling with an OUD who becomes impaired by substance misuse as manifested by dysfunction. The challenge for physicians treating chronic pain with opioids is to devise a system of objective markers that distinguish function from dysfunction and emphasize a wide spectrum of therapeutic goals.

Several markers of functional improvement can be used in patients chronically treated with opioids. Several standardized

functional measurements (e.g. the 36-item short-form health survey [SF-36] and Oswestry disability index [ODI]) can be used to subjectively measure the reduction in pain with supportive and objective evidence of improvement in functional status and effect on the quality of life. However, psychological and social factors, as well as the status of coexistent disease, may influence the perception of pain, suffering, and entitlement and can alter the overall assessment. Unfortunately, not all of these parameters will improve concomitantly or proportionately following the initiation of opioid therapy. If factors related to psychological and physical reconditioning have not been addressed, pain perception and reduction of pain after a trial of an opioid may be less than optimal.

Determining effective treatment end points during an opioid trial may require flexibility in considering the many possible variations in efficacy and functional gain. A central question that may be useful at the beginning of an opioid trial is, "What do you need to do with this treatment that you cannot do now?" What follows should be the creation of a list of reasonably attainable functional goals that cover multiple domains of the patient's life. Equally important in documenting this list is the process by which the goals will be attained and how the patient plans to document progress toward each functional goal for the clinician on every subsequent follow-up visit, which may include but are not limited to the use of non-opioid pain medicine, physical therapy, acupuncture, injections, and surgery. Each goal was monitored regularly and adjusted based on progress. Expectations may need to be reduced if goals are not met or may be advanced as the patient improves.

One part of determining whether a patient is benefiting from opioid therapy is to gather collateral information from others involved in the patient's care and life. Input from physical and occupational therapists, psychologists, family members, and caregivers may prove invaluable. Evidence of improved function may include gains in employment, increased activities of daily living, and socializing with family and friends. On the contrary, if a patient becomes dysfunctional in employment or social or private life, concerns about possible medication-related deterioration, including addiction, should be raised. However, a decreased function is not pathognomonic of OUD. This may be related to factors other than patient control, such as sedation, cognitive impairment, or other external causes. Suppose these or other external problems are not the cause of a patient's deteriorating mental or physical health. In that case, it may help to consider seeking additional support in the form of a multi-disciplinary program or referral to other specialty providers, such as psychologists, social workers, psychiatrists, or addiction specialists.

It remains controversial whether subjective relief without objective evidence of the improved quality of life is sufficient to justify the chronic use of opioids. Pain reduction is a subjective variable. Its use as an assessment tool for therapeutic success represents only a single aspect of adequate chronic opioid therapy. For example, consider a patient with significant disability related to pain rated six on a pain severity scale of one to ten. Although opioid therapy may not significantly reduce subjective pain scores, this does not signify treatment failure. In fact, despite no reported reduction in pain scores, objective signs of a return to work and increased physical activity clearly demonstrate that treatment has improved the patient's quality of life. Conversely, suppose an opioid trial is characterized by subjective reports of marked pain relief. In that case, there are no observable functional gains and possibly even signs of persistent sedation with decreased physical activity, voluntary unemployment, dysfunctional interpersonal relationships, or diminished physical activity; the physician must consider why the patient would regard this as a positive outcome and attempt to resolve any underlying conditions or misunderstandings.

As noted by the FSMB, a critical aspect of safe opioid management is documentation of a patient's care, including current functional status on initial evaluation and throughout follow up.[104] Documentation not only requires clarity of events but should also offer transparency about the physician's decision process, particularly concerning risk-benefit considerations, choices, and plans for risk management. Vigilance in detecting decreased function is important; this may help reveal problems such as OUD, progressive disease, or pain unresponsive to opioids.

Another critical issue to consider before and during the course of treatment is the discontinuation of opioid therapy if the treatment is deemed ineffective. Many factors must be considered before treatment is considered to be a failure, including inadequate dosing, inappropriate dosing schedule, improper drug delivery route, opioid-insensitive pain, side effects limiting dose escalation, and social and psychological issues.

The appropriate duration of effective opioid therapy remains controversial. Currently, there are no clear guidelines or consensus regarding this issue. The efficacy of treatment, adverse effects of opioid therapy, and progression of the underlying disease must be considered thoroughly when formulating decisions regarding the length of treatment, and these factors must be reconsidered regularly. Once opioid therapy has been initiated, it may be challenging to determine whether pain would be present without opioid therapy unless opioids are tapered.

Key Points

- Opioid drugs have been used to control pain for thousands of years as reliable and potent analgesics, but they do not work for all pain, for everyone, or every condition and may pose serious risks.
- Opioid therapy has undergone intense scrutiny as the opioid crisis, and public health epidemic of excessive prescription drug abuse has been elevated to a national discussion.
- The evidence for sustained benefits of opioids in relieving chronic pain is weak and inadequate, whereas evidence of risk associated with the use of these drugs is clear and substantial.
- Focal attention on the risk-benefit ratio for safe use of opioids underscores the serious potential for opioid abuse and overdose death, which has been well documented through approximately 15 years of retrospective data.
- There is increasing concern about opioid and gabapentinoid related respiratory depression.
- The exact rate of addiction because of prescription opioid use is relatively low but a significant concern.
- Sudden or involuntary discontinuation of opioids may be associated with adverse effects and morbidity.
- Methadone has many features that distinguish it from other opioids, including heightened risk and significant life-threatening adverse outcomes.

- A detailed diagnostic assessment with a thorough history and physical examination, as well as an essential focus on risks and benefits, will drive the selection of specific analgesic treatments.
- The increased risk for abuse and unintentional overdose death requires increased risk management, including risk assessment, treatment plans that incorporate functional goals, periodic review and monitoring of patients, documentation, informed consent, and termination strategies for chronic opioid therapy.
- A thorough history of comorbid psychiatric conditions and a history of substance abuse are important elements of safe prescription.
- Once opioid therapy has been initiated, it may be challenging to determine whether pain would be present without opioid therapy unless opioids are tapered.

Minor Analgesics: Non-Opioid and Opioid Formulations

STEVEN P. STANOS, MARK D. TYBURSKI, SAGAR S. PARIKH

The use of naturally occurring plant material for the relief of pain dates back to early times. Advances in antipyretic and analgesic medications began in the late 1800s with the development of salicylic acid, antipyrine, phenacetin, and acetaminophen (APAP).[1] These basic medications are still used today to various degrees in both over-the-counter (OTC) and prescription preparations—the minor analgesics salicylic acid and APAP are widely marketed and heavily consumed. Minor analgesics for acute and chronic pain include several prescription and OTC agents, which may be useful in isolation or as adjuvants in a more comprehensive multimodal pharmacologic approach. Many including minor analgesics, OTC medicines include a growing market area for managing acute and chronic pain conditions. Research has demonstrated that at least 80% of adults use OTC medicines as a first response to minor ailments, with great availability of OTCs in the approximately 54,000 pharmacies in the United States and more than 750,000 retail stores that carry these products.[2] A population survey has reported that the use of OTC medications, many of which include minor analgesics, account for the most common method of relieving pain (53%). This is closely followed by physical exercise (52%) and prescription medications (35%).[3]

The minor analgesics reviewed in this chapter include oral APAP, opioid combination preparations (i.e. codeine, propoxyphene, hydrocodone, oxycodone, and tramadol), tapentadol, and buprenorphine products for chronic pain (buccal films and transdermal patch systems), steroids, and caffeine, as well as topical compounds and delivery systems. See the chapters in this text that discuss opioids, anti-convulsants, anti-depressants, and nonsteroidal anti-inflammatory drugs (NSAIDs) for complete information on these topics (Chapters 48, 53, 54, 55, 56, and 57). Additional combination OTC formulations with minor analgesics include convenience combinations—those that contain aspirin, APAP, or ibuprofen plus other remedies such as nasal decongestants, antihistamines, cough suppressants, or antacids. These medications help treat the sequelae of a primary illness (e.g. cold and flu symptoms, insomnia, cough) and any pain symptoms that may coexist.[4]

Prescribing habits regarding the use of analgesics for the treatment of various musculoskeletal conditions continue to evolve. Caudill-Slosberg and colleagues[5] compared prescribing habits between 1980 and 1981 with those between 1999 and 2000 and demonstrated a significant increase in patients receiving prescriptions for acute and chronic musculoskeletal pain. Increases were seen in the use of NSAIDs and cyclooxygenase-2 (COX-2) agents, as well as more potent opioids, including combination opioid preparations containing APAP and NSAIDs.

Minor analgesics are used widely, with reported prevalence rates of twice-weekly use of approximately 8.7% for prescription drugs and 8.8% for OTC analgesics. Analgesics are usually the largest selling group of OTC medications in several population studies. Daily use was more common for prescribed analgesics, whereas OTC analgesics were used a few times per week.[6,7] Among prescription and OTC medications, APAP, ibuprofen, and aspirin were the most commonly used (17%–23% of the population).[8] Use of analgesics, many of which include minor agents, accounts for a significant amount of healthcare dollars. In a population study, analgesic cost ranked second behind diagnostic imaging in expenditures for the treatment of acute low back pain.[7] Chronic use of prescription and OTC analgesics (i.e. aspirin, non-aspirin-containing NSAIDs, and APAP) may continue for longer than one year. In the same survey, approximately 2.3 million adults reported using non-aspirin-containing NSAIDs, and 2.6 million used APAP on a frequent basis for longer than five years.[9] This widespread use occurs despite general knowledge of the increased risk for gastrointestinal (GI), renal, and cardiac toxicity with short-term and chronic use. Unfortunately, the perception remains that as a class of medications, OTC and prescription NSAIDs are relatively safe. This misbelief leads to frequent inappropriate use and the potential for serious adverse events.[10] The increased availability and marketing of OTC agents have probably contributed to patient misuse, with consumers still being unaware of the potentially catastrophic risks associated with their use: 60% of people cannot identify the active ingredient in their analgesics, and 40% of Americans believe that OTC drugs are too weak to cause significant harm.[11]

The use of OTC and prescription analgesics is not only confined to the outpatient setting. Significant use of these agents in nursing home facilities was reported in a group of Medicare beneficiaries during 2001. Patients averaged 8.8 unique medications per month, including 2.9 OTC medications. Of these subjects, 70% used non-opioid OTC analgesics and 19.0% used non-opioid prescription analgesics.[12]

Specific Drugs

Minor Opioids

Minor opioids are defined as analgesic combination products with codeine, propoxyphene, hydrocodone, or oxycodone, and dual-mechanism opioid products, including tramadol and tapentadol. Additionally, the chapter will also review buprenorphine

formulations for the management of chronic pain, including buccal and transdermal systems or patches. These products continue to account for a large percentage of prescriptions written for chronic and persistent pain conditions. Combination opioid analgesics—compounds containing APAP or anti-inflammatory medications—make up a significant number of opioids prescribed by primary care physicians and pain specialists. Combination analgesics are advocated in several treatment guidelines, including the three-step analgesic ladder of the World Health Organization (WHO) (step 2; Fig. 49.1).[13,14]

Opioid therapy increased dramatically between 1999 and 2010 with a decrease in prescribing in 2013, preceding the Centers for Disease Control and Prevention (CDC) Guideline on prescribing opioids for acute and chronic pain. Within that period, a substitution of opioids for non-opioid analgesics between 2003 and 2006 may have emerged in response to the emerging evidence of cardiovascular risks associated with non-opioid analgesics, primarily NSAIDs.[15] Since the 1990s, the use of minor analgesic combinations containing oxycodone and hydrocodone continued to increase, whereas the use of those containing codeine declined. Clinic type (e.g. primary care, spine center, pain center), geographic, and socioeconomic variables may also affect prescribing practices.[16]

Opioid analgesics as a class can be categorized into three chemical groups: (1) synthetic phenylpiperidines (e.g. meperidine, fentanyl), (2) synthetic pseudopiperidines (e.g. methadone, propoxyphene), and (3) naturally occurring alkaloids derived directly from the poppy seed (e.g. morphine, codeine, thebaine) and their semisynthetic derivatives (e.g. hydromorphone, oxycodone, oxymorphone).[17] This chapter reviews codeine, oxycodone, hydrocodone, and tramadol combination products, as well as formulations of tapentadol and buprenorphine products indicated for the treatment of chronic pain (Tables 49.1 and 49.2).

TABLE 49.1 Minor and Short-Acting Opioids

Class	Name	Adult Dose	Half-Life (Onset)	Mechanism of Action	Other
Natural opium alkaloids	Codeine with acetaminophen (APAP) or acetylsalicylic acid (ASA) (Tylenol No. 2, No. 3, No. 4; Empirin No. 3, No. 4; Capital with Codeine; Aceta with Codeine; Fioricet with Codeine; Fiorinal with Codeine)	PO: 15–60 mg q4h (max daily APAP-ASA dose, 4 g)	2.5–3.5 h (30–60 min)	Opioid agonist activity at multiple receptors—μ (supraspinal analgesia, euphoria), κ (spinal analgesia and sedation), δ (dysphoria, psychotomimetic effects)	Compared with morphine—decreased analgesia, constipation, respiratory distress, sedation, emesis, and physical dependence; increased antitussive effects
Phenanthrene derivatives	Hydrocodone plus ASA or APAP (Lortab, Lortab ASA, Vicodin, Norco, Vicoprofen, ZTuss, P-V-Tussin, Tussafed HC)	PO: 5–10 mg q4–6h (max dose, 4 g)	3.8 h (10–30 min)	Opioid agonist activity at multiple receptors—μ (supraspinal analgesia, euphoria), κ (spinal analgesia and sedation), δ (dysphoria, psychotomimetic effects)	Compared with morphine equivalent analgesia—respiratory depression and physical dependency; equivalent antitussive effects
	Oxycodone (with or without APAP or ASA) (OxyIR, Roxicodone); Oxycodone plus ASA (Percodan, Endodan, Roxiprin); Oxycodone plus APAP (Percocet, Endocet, Tylox, Roxicet, Roxilox)	PO: 5–30 mg q4–6h (4 g max dose of ASA/APAP); sustained-release: 10/10–160 mg q12h	2–5 h (10-15 min)	Opioid agonist activity at multiple receptors: μ (supraspinal analgesia, euphoria), κ (spinal analgesia and sedation), δ (dysphoria, psychotomimetic effects)	Compared with morphine— more potent analgesia, constipation, antitussive effects, respiratory depression, sedation, emesis, and physical dependence
Diphenylheptane derivative	Propoxyphene, with or without APAP (Darvon, Darvon-N); Propoxyphene plus APAP (Darvocet A500, Propacet 100)	PO: 65 mg q4h (max, 390 mg/day); napsylate, 100 mg q4h (max, 600 mg/day)	6–12 h (15–60 min)	Opioid agonist activity at multiple receptors: μ (supraspinal analgesia, euphoria), κ (spinal analgesia and sedation), δ (dysphoria, psychotomimetic effects)	Compared with morphine — less analgesia, sedation, emesis, respiratory depression, and physical dependence

TABLE 49.2 Opioid Combination Products

Drug Class	Drug Name	Trade Name	Available Dose	Typical Dose	Comments	Half-Life
Para-aminophenol derivatives/ natural opium alkaloids	Acetaminophen/ codeine phosphate	Tylenol with Codeine elixir; Tylenol with Codeine No. 2, No. 3, No. 4	(120/12 mg)/5 mL liquid; 300/15 mg, 300/30 mg, 300/60 mg (tablets)	Elixir—children <three years, safe dose not established; three to six years, 5 mL (1 tsp) three to four times daily; seven to 12 years, 10 mL three to four times daily; adults, 15 mL q4h; tablets and capsules, 15–60 mg codeine q4–6h	Codeine phosphate, max, 360 mg daily; acetaminophen, max, 4000 mg daily	Acetaminophen, 1–4 h; codeine, 2.5–3 h
			650/30 mg (tablets)	30–60 mg codeine q4–6h	Codeine phosphate, max, 360 mg daily; acetaminophen, max, 4000 mg daily	Acetaminophen, 1–4 h; codeine, 2.5–3 h
Acetylsalicylic acid/natural opium alkaloids	Aspirin/codeine phosphate	Empirin with Codeine No. 3, No. 4	325/30 mg, 325/60 mg (tablets)	One to two tablets q4h	Codeine phosphate, max, 360 mg daily	Aspirin, 2.5–3.5 h; codeine, 2.5–3 h
Para-aminophenol derivatives/ phenanthrene derivatives	Hydrocodone bitartrate/ acetaminophen	Vicodin, Lorcet-HD, Lortab, Norco, Maxidone, Anexsia	2.5/500 mg, 5/500 mg, 7.5/325 mg, 7.5/500 mg, 7.5/650 mg, 7.5/750 mg, 10/325 mg, 10/500 mg, 10/650 mg, 10/660 mg, 10/750 mg (tablets)	One to two tablets q4–6h	Dosage typically limited by acetaminophen, max, 4000 mg daily	Hydrocodone, 3.5–4.1 h
	Oxycodone/ acetaminophen	Percocet, Endocet, Tylox, Roxicet, Roxilox	5/325 mg, 7.5/325 mg, 5/500 mg (Tylox), 7.5/500 mg, 10/325 mg, 10/650 mg (tablets); 5/500 mg (caplets; Roxicet); 5/325 mg/5 mL (solution) (Roxicet)	One to two tablets q4–6h	Acetaminophen, max, 4000 mg daily	Acetaminophen, 1–4 h; oxycodone, 3.1–3.7 h
Acetylsalicylic acid/phenanthrene derivates	Oxycodone/ aspirin	Percodan, Endodan, Roxiprin	4.8/325 mg (tablet)	One tablet q4–6h	Aspirin, max, 4000 mg daily	Aspirin, 2.5–3.5 h; oxycodone, 3.1–3.7 h
Propionic acid/ phenanthrene derivatives	Hydrocodone bitartrate/ ibuprofen	Vicoprofen	7.5/200 mg (tablet)	One tablet q4–6h	Marketed for short-term management of acute pain; NSAIDs may increase the risk for serious cardiovascular thrombotic events, myocardial infarction, stroke	Hydrocodone, 3.5–4.1 h; ibuprofen, 4–6 h
	Oxycodone/ ibuprofen	Combunox	5/400 mg (tablet)	One to two tablets q4–6h	Max dosage of ibuprofen, 2400–3200 mg daily	Oxycodone, 3.1–3.7 h; ibuprofen, 1.8–2.6 h
Diphenylheptane derivatives	Propoxyphene HC1/APAP		65/650 mg (tablet)	One tablet q4–6h	Structurally related to methadone; propoxyphene HC1, max, 390 mg daily	Propoxyphene, 6–12 h; norpropoxyphene, 30–36 h; acetaminophen, 1–4 h
	Propoxyphene HC1/aspirin/ caffeine	Darvon Compound 65	65/389/32.4 mg (tablet)	One to two tablets q4–6h	Structurally related to methadone; propoxyphene HC1, max, 390 mg daily	Propoxyphene, 6–12 h; norpropoxyphene, 30–36 h; aspirin, 2.5–3.5 h; caffeine, 3–6 h
	Propoxyphene napsylate/ acetaminophen	Darvocet-N 50, Darvocet-N 100, Darvocet A500, Propacet 100	50/325 mg (N 50), 100/650 mg (N 100), 100/500 mg (A500) (tablets)	One to two tablets q4–6h	Structurally related to methadone; propoxyphene napsylate, max, 600 mg daily	Propoxyphene, 6–12 h; norpropoxyphene, 30–36 h; acetaminophen, 1–4 h

NSAIDs, Nonsteroidal anti-inflammatory drugs.

Pharmacokinetics and Pharmacodynamics

Understanding pharmacokinetics and pharmacodynamics is essential for appropriately prescribing minor opioid analgesics, interpreting related toxicology screens, and appreciating the potential mechanisms for adverse side effects. In general, medications are primarily metabolized by the cytochrome P-450 (CYP) and glucuronidation pathways. Opioid analgesics, like any medication, may be metabolized by the CYP drug-metabolizing enzyme system 2D6. Genetic polymorphism of CYP2D6 may lead to variability in enzyme breakdown and clinical effectiveness of the medication. Deficiency of CYP2D6 may be seen in whites (7%) and those of Asian descent (1%).[18] These enzyme systems can be induced (activated) or inhibited by various agents, including drugs, alcohol, and cigarette smoke, as well as by endogenous substances. Inducers are agents that activate the CYP enzyme system and thereby lead to increased metabolism and reduced drug effect. Inhibitors may impair the CYP enzyme system and thus limit the metabolism of the drug and increase the effect of the drug. Although pharmacokinetic drug-drug interactions may affect serum levels of a drug, this may be subclinical in most patients, with significant interactions rarely occurring *in vivo* in only about 10%–15% of patients.[19] Patients' response to individual opioids may vary markedly. Recent evidence has supported more than one mechanism for μ-opioid analgesic reactions, which may be related to receptor polymorphism.[20]

Morphine, hydromorphone, and oxymorphone are not metabolized by CYP but are metabolized by uridine diphosphate glucuronosyltransferase (UGT) enzymes. Except for morphine and codeine, UGT enzymes metabolize medications primarily to inactive metabolites. Morphine is converted into large quantities of relatively inactive morphine-3-glucuronide (M3G) and smaller quantities of the active metabolite morphine-6-glucuronide (M6G). M6G is 50 times more potent than morphine. M3G may account for central nervous system (CNS) toxicity, including lowering of seizure thresholds.[21] Equianalgesic oral doses of the various minor opioid combination products and morphine are listed in Table 49.3.

Codeine

Along with morphine and thebaine, codeine (methylmorphine) is a naturally occurring opium alkaloid derivative. A weak analgesic, codeine is similar in structure to morphine but has an affinity for the μ-opioid receptor 300 times lower. Classically, codeine is thought to be metabolized by *O*-demethylation to its primary active metabolite morphine by the CYP2D6 enzyme.[22] Studies have demonstrated that only a small percentage of the total dose (3%)[23] is converted by CYP2D6 to morphine. Approximately 80% is directly glucuronidated by uridine diphosphate glucuronosyltransferase 2B7 (UGT2B7) enzyme to codeine-6-glucuronide (C6G), an additional active metabolite. The remaining inactive metabolites are primarily norcodeine (2%) and normorphine (2.4%).[24] Nonfunctional CYP2D6 renders codeine ineffective, perhaps because of genetic mutations or deletions[25] or pharmacologic inhibition.[26] Effects of codeine not related to the formation of morphine include cognitive impairment,[27] sedation, dizziness, euphoria and dysphoria, headache, blurred vision,[28] and prolongation of GI transit time. The average half-life of codeine is 2.5 h. Poor metabolizers, based on CYP2D6 genotypes, are present in 7%–10% of the white population and show a decreased metabolism of codeine to morphine and a diminished analgesic effect compared to normal or extensive metabolizers. Ultrarapid metabolism occurring in 1%–7% of the white population versus 3%–10% of Europeans may have an increased formation of morphine and a potential for adverse effects at recommended doses of codeine.[29] Because of the unpredictable metabolism of codeine as an analgesic, codeine is often replaced by other opioids or combination products.

Efficacy

When used alone, codeine is typically prescribed in doses of 30–60 mg every 4–6 h, with the onset of analgesia taking place in 30–60 min and the duration of effect lasting 4–6 h. Codeine has been shown to be an effective cough suppressant (10–120 mg/day) and is present in several OTC cold and cough convenience preparations.[30] However, codeine's potential opioid analgesic effect has long been questioned. Houde's classic study in the 1960s reported the analgesic effects of codeine (32 mg) to be no more than that of 650 mg of aspirin, although both were more effective than placebo.[31] The number needed to treat (NNT), or the number of patients needed to receive the medication to achieve at least 50% pain relief, with 60 mg codeine, has been reported to be 16.7,[32] which has led to its widespread use as a combination analgesic.

TABLE 49.3 Combination Analgesics for Mild to Moderate Pain

Agent	Onset (min)	Duration of Action (h)	Equianalgesic Oral Dose (mg)*	DEA Schedule
Oxycodone combinations	10–15	4–6	30†	II
Hydrocodone combinations	30–60	4–6	30	III
Codeine combinations	30–60	4–6	130	III
Propoxyphene combinations	15–60	4–6	130	IV
Tramadol combinations	60	6–7	100	III

DEA, United States Drug Enforcement Agency.

*Doses reflect the opioid component only and are equianalgesic to 30 mg morphine.

†Doses for moderate to severe pain not necessarily equivalent to 30 mg morphine.

From Gutstein HB, Akil H. Opioid analgesics. In: JG Hardman, LE Limbird, AG Gilman (eds). *Goodman and Gilman's the Pharmacological Basis of Therapeutics,*. 10th ed. New York: McGraw-Hill; 2001: 569–619.

Codeine (10–60 mg) is more commonly prescribed in combination with APAP (400–1000 mg), aspirin, or NSAIDs such as ibuprofen (400 mg). A systematic review of codeine and APAP trials for acute non-cancer-related pain concluded that the benefit over codeine alone is only modest (5%).[33] A systematic review of trials of APAP alone or in combination with codeine noted efficacy in patients prescribed APAP plus 60 mg codeine versus APAP alone. At doses higher than 60 mg, incremental analgesia was diminishing with increasing doses and a higher incidence of side effects (e.g. constipation, nausea, and sedation).[34] A head-to-head study of codeine (30 mg) plus APAP (300 mg) and hydrocodone (7.5 mg) plus APAP (500 mg) showed significant relief of moderate to severe acute (6 h) postoperative pain than placebo, but the analgesia was no greater than that achieved with hydrocodone-APAP.[35]

Propoxyphene (Dextropropoxyphene)

Propoxyphene (dextropropoxyphene) is a mild synthetic opioid originally synthesized in the 1950s and at one point marketed in its hydrochloride form as Darvon (65 mg; maximum, 400 mg/day), as propoxyphene napsylate (Darvocet-N 50, Darvocet-N 100), and in Europe, as co-proxamol (32.5 mg dextropropoxyphene plus 325 mg paracetamol). By the late 1960s, propoxyphene was the most widely prescribed analgesic in the United States.[36] Reports of propoxyphene overdoses led to warnings by the United States Food and Drug Administration (FDA) in 1978 and a subsequent reduction in use.[37] Propoxyphene's major metabolite norpropoxyphene has fewer CNS effects than propoxyphene does but accumulates in cardiac tissue, thereby leading to a local anesthetic effect and prolongation of action potentials, in some cases fatal torsades de pointes.[38] Because of the increasing number of fatal overdoses of co-proxamol and limited evidence supporting its efficacy versus APAP for acute and chronic pain, the British government announced the gradual withdrawal of co-proxamol from British markets in January 2005.[39] As a result of increasing public outcry from patient advocacy groups and recommendations by an FDA advisory board group, propoxyphene was voluntarily removed from the United States market in 2011 and India in 2013.[40,41] It is interesting to note that at the time of its withdrawal from the market, a survey showed that 68% of pain medicine practitioners saw patients who were prescribed propoxyphene by their primary care physicians.[42] Propoxyphene is still allowed in some countries, although with prescription.

Oxycodone

Oxycodone is a semisynthetic opioid analgesic derived from the opium alkaloid thebaine. Human studies have demonstrated it to have analgesic potency 1.5 times that of morphine after oral administration.[43] Several active metabolites have been proposed to contribute to the clinical pharmacokinetics of oxycodone. One theory supports 3-*O*-demethylation by CYP2D6 to oxymorphone. Oxymorphone is a potent μ-opioid ligand with two to five times higher receptor affinity than morphine has. Though potent, oxymorphone accounts for only 10% of oxycodone metabolites. Oxymorphone has been available for several years for parenteral and rectal use and was reformulated and released in an immediate-release (IR) and extended-release (ER) schedule II formulation. *In vitro* studies have shown that *O*-demethylation of oxycodone accounts for 13% of its oxidative metabolism. Oxidation of oxycodone primarily occurs via *N*-demethylation by CYP3A4/5 to noroxycodone, which is the most abundant circulating metabolite in human studies. Unfortunately, noroxycodone has a weak affinity for μ-opioid receptors.[44]

In vivo, oxycodone has potent μ-opioid receptor effects, but data suggest that the intrinsic antinociceptive effects may be additionally mediated by κ-opioid receptors.[45] This has led some to consider oxycodone an ideal medication for opioid rotation in patients not responsive to morphine, a classic μ-opioid receptor agonist.[46,47] Recent studies have proposed non-CYP2D6 metabolites (noroxycodone, noroxymorphone, noroxycodols, oxycodols) as additional substances responsible for its μ-opioid receptor binding and analgesic effects.[48] Animal studies have recently demonstrated conflicting gender-related differences in female versus male rats when examining the antinociceptive effects of oxycodone.[49]

Hydrocodone

Hydrocodone is similar in structure to codeine but is six to eight times more potent.[50] Hydrocodone is a prodrug and undergoes CYP2D6 metabolism to hydromorphone and CYP3A4 metabolism to noroxycodone. Hydrocodone is less potent than morphine by receptor affinity and demonstrates a relative analgesic potency of 0.59 compared to morphine. The discrepancy between hydrocodone's binding affinity and potency versus that of morphine is possibly the result of active hydrocodone metabolites or the intrinsic efficacy of receptor activation, which is more efficient for hydrocodone than for morphine.[51] Hydrocodone is marketed as a combination product with APAP, ibuprofen, and aspirin (HCPs).

Efficacy

The hydrocodone-ibuprofen combination product was introduced in the United States in 1997 as a fixed dose of hydrocodone (7.5 mg) and ibuprofen (200 mg) and has demonstrated efficacy for acute postoperative pain.[52] Neither hydrocodone (7.5 mg) nor ibuprofen (200 mg) given alone was superior to placebo, thus supporting the concept of analgesic synergy between the two agents. Similar findings were demonstrated in patients with acute low back pain,[53] and postoperative obstetric and gynecologic pain.[54] Hydrocodone-APAP (7.5, 200 mg), one and two tablets, compared to a fixed dose combination of codeine (30 mg) and APAP (300 mg). The two tablet dose of combination hydrocodone-APAP was more effective than the one tablet dose and one or two tablets of the fixed codeine-APAP combination.[55]

In 2014, to counter the increasing prevalence of opioid misuse, over-prescribing, and growing number of overdose deaths, the Drug Enforcement Agency (DEA) rescheduled hydrocodone combination products from DEA Schedule III to DEA Schedule II, leading to a reduction in prescribing of HCPs for acute and chronic pain, with a subsequent increase in other minor opioids including codeine-containing products and tramadol.[56-58] Commonly prescribed hydrocodone-APAP combination products presently include 10, 7.5, and 5 mg hydrocodone and 325, 500, 750 mg APAP, with ranges between 5 and 10 mg hydrocodone and 325 and 750 mg APAP (Hydrocodone Bitartrate/Acetaminophen Tablets, package insert, Mallinckrodt, Inc., St. Louis).

Long-acting and extended-release hydrocodone formulations entered the United States market in 2013 and include an ER hydrocodone product (hydrocodone bitartrate ER capsules [Zohydro], Zogenix, Inc., San Diego.), followed in 2014 by approval of hydrocodone bitartrate (Hysingla ER) [Purdue Pharma] (Hysingla ER [package insert]. Stamford, CT: Purdue Pharma LP, February 2015), a once-daily formulation. Both formulations are categorized with abuse deterrent properties and are indicated for pain severe enough to require around-the-clock, long-term treatment and for which alternative treatment options are inadequate. The two ER

hydrocodone products also include drug interaction warnings related to possible cytochrome P450 interactions, including the role of CYP3A4 isoenzymes impacting hydrocodone clearance. CYP3A4 inhibitors, such as ketoconazole, macrolide antibiotics, and protease inhibitors (e.g. ritonavir), may cause increased levels of hydrocodone because of a decrease in drug clearance. CYP3A4 inducers, such as rifampin, carbamazepine, and phenytoin, may lead to a lack of efficacy or withdrawal syndrome in patients with physical dependence on hydrocodone. A third ER hydrocodone product, hydrocodone bitartrate (Vantrela ER, Teva) (Vantrela ER, Hydrocodone Bitartrate PI, Teva, 2017) was approved in 2017 with abuse deterrent technologies to reduce the risk of oral, intranasal, and intravenous abuse via manipulation of the tablets, but is currently not available.

Tapentadol

Tapentadol, 3-((1R,2R)-3-(dimethylamino)-1-ethyl-2-methylpropyl) phenol hydrochloride, is a non-racemic molecule used to treat moderate degrees of chronic or central pain syndromes.[59] Tapentadol (Nucynta) was approved in 2008 (Nucynta PI, Ortho-McNeil-Janssen Pharmaceuticals, 2008) and is available in 50, 75, and 100 mg doses. An extended-release formulation, tapentadol ER, was approved in 2011 for chronic pain uniquely for the management of neuropathic pain associated with diabetic peripheral neuropathy with recommended dosing BID (50 mg, 100 mg, 150 mg, 200 mg, and 250 mg strengths) (Nucynta ER PI, Janssen Pharmaceuticals, Inc, Titusville, NJ, 2014).

Tapentadol has a dual action with both opioid and neuropathic properties, given it is opioid receptor affinity and monoamine reuptake inhibition and is considered a strong synthetic opioid. In clinical trials, tapentadol has been shown to have higher tolerability and comparable efficacy to oxycodone. Tapentadol is a μ-opioid receptor agonist and a norepinephrine reuptake inhibitor.[60] It also possesses serotonin reuptake inhibitor properties; however, not enough to contribute significantly to its analgesic profile. It binds to the μ-opioid receptor selectively, and its affinity is 44-fold lower than morphine.[57] Despite this lower affinity, tapentadol is only two to three times less potent than morphine as an analgesic. This is mainly because of the dual-analgesic mechanisms of action. Tapentadol's neuropathic properties increase levels of norepinephrine which leads to analgesia through activation of inhibitory alpha-2 receptors. Its mechanism of action on the μ-opioid receptor and norepinephrine reuptake both independently and synergistically contribute to the analgesic effect. However, this synergistic quality is not evident in the drug's side effect profile.[61] Thus with a lesser adverse effect profile than typical opioid medication, tapentadol has higher tolerability. Tapentadol is available as IR and ER formulations. Regarding the conversion of tapentadol IR to ER, a direct milligram to milligram conversion on a total daily dose basis is appropriate.

Tapentadol has an oral bioavailability of 32% because of first pass metabolism. When taken orally, the medication is absorbed rapidly and reaches a plasma steady-state concentration in approximately 25–30 h when taken regularly. Close to 97% of the drug is metabolized to inactive metabolites by glucuronic acid significantly and to a lesser degree by CYP enzymes. Once metabolized, the resultant molecule does not have analgesic properties. All metabolites and parent compounds are renally excreted.

Buprenorphine

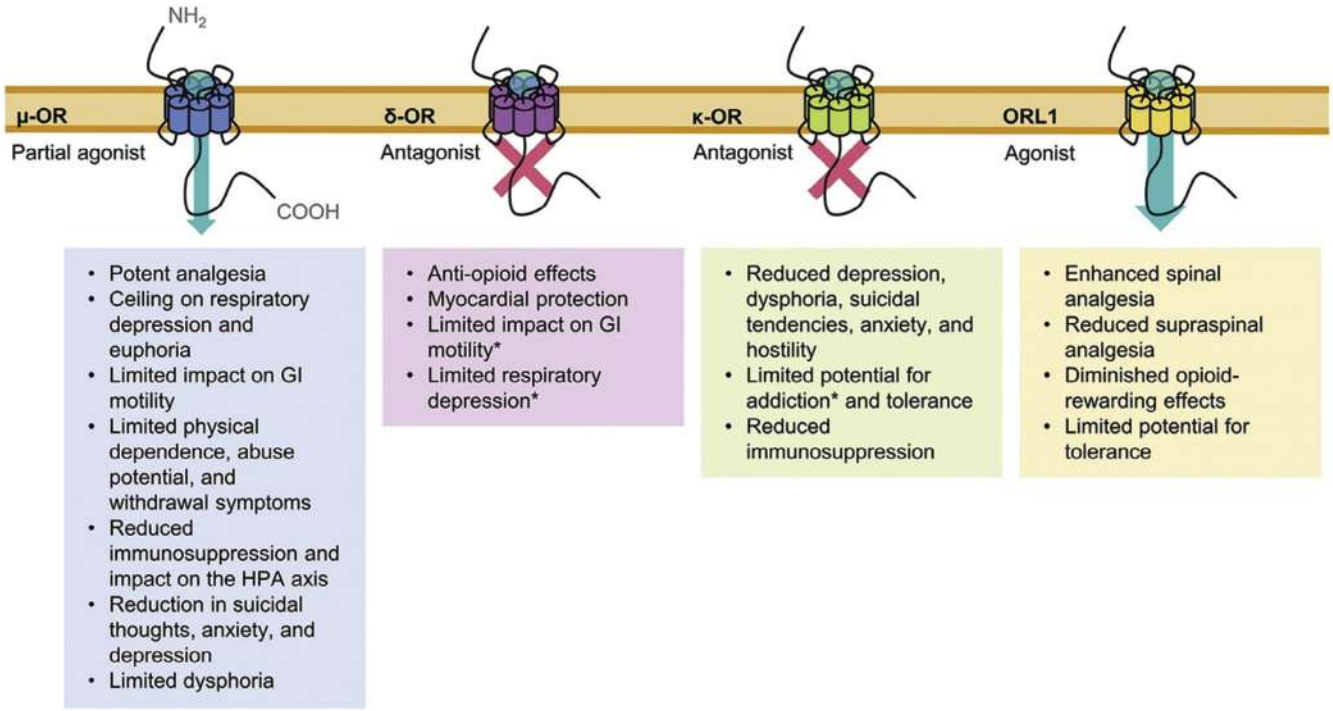
Buprenorphine is a schedule III lipophilic semisynthetic derivative of thebaine and possesses unique opioid activity compared to traditional opioids, including partial μ-opioid agonist and multiple nonselective mixed agonist-antagonist opioid receptor activity (κ-opioid, δ-opioid), opioid receptor-like 1 [ORL1]). Buprenorphine's unique characteristics as an opioid include a bell-shaped analgesic dose-response curve related to unique binding affinity,[62] and ceiling effect for respiratory depression, making it an attractive option for clinical settings because of reduced potential for toxicity and overdose.[63] The FDA indications for the use of buprenorphine include opioid detoxification, opioid maintenance treatment, and management of pain severe enough to require daily, around-the-clock, long-term opioid treatment.[64]

Buprenorphine has multiple agonist-antagonist properties. It is a partial agonist of the μ-opioid receptor, with high binding affinity and slower dissociation from the μ-opioid receptor, which may contribute to prolonged analgesia and less potential for withdrawal.[65] It is an antagonist of the κ-opioid and an agonist at δ-opioid receptors and also shows to have weak affinity for the ORL-1 receptor, an opioid subfamily of G protein-coupled receptors. It also possesses a strong local anesthetic effect, given that it also blocks voltage-gated sodium channels. See Figure 49.2 for a description of the unique pharmacodynamic properties of buprenorphine related to opioid receptor multi-mechanistic activity that may result in enhanced analgesia and decreased side effects.[66]

Buprenorphine is hepatically metabolized via the CYP3A4 enzyme into norbuprenorphine and undergoes glucuronidation by UGT1A1 and UGT2B7 before being eliminated through bile excretion. The compound is thus relatively safe in those with renal compromise. Although possessing a higher degree of respiratory depression properties, the metabolite norbuprenorphine does not pass the blood–brain barrier easily and thus does not exact this side effect to the same degree as other opioid compounds. Nevertheless, respiratory depression can still be a factor to monitor.

Buprenorphine formulations include intravenous, sublingual, buccal, and transdermal systems (patch). There are two sublingual/buccal formulations of buprenorphine indicated for maintenance treatment of opioid dependence and during induction. One formulation of sublingual buprenorphine (Subutex Package Insert, Indivior UK Ltd., 2018)), available in 2 mg and 8 mg pills, is indicated for opioid dependence and is preferred for initiation of treatment. Suboxone is a combination product of buprenorphine and naloxone (Suboxone Package Insert, Indivior, Inc, 2018), formulated in a 4:1 ratio of buprenorphine to naloxone, is indicated for maintenance treatment of opioid dependence (2 mg/0.5 mg; 4 mg/1 mg; 8 mg/2 mg, 12 mg/3 mg). Naloxone is an opioid receptor antagonist, and its addition is meant to deter abuse by crushing, which could precipitate severe opioid withdrawal.

Two buprenorphine formulations FDA approved for chronic pain include a buccal film (Belbuca) and transdermal patch (Butrans). Buprenorphine buccal film (Belbuca, Endo Pharmaceuticals, Inc, 2015) is a schedule III opioid long-acting medication indicated for chronic pain (the management of pain severe enough to require daily, around-the-clock, long-term opioid treatment and for which alternative treatment options are inadequate). Conversion to the buccal film from other opioids includes for those patients opioid naïve or on <30 morphine equivalent doses (MED) start at 75 mcg film every 12 h; 30–89 MED, 150 mcg every 12 h; and 90–160 MED, 300 mcg every 12 h. Incremental titrations should not be done more frequently than every four days. This medication is not indicated for patients currently on >160 MED. The dissolvable film is placed against inside the check, holding for 5 s, to allow the film to stick, and usually dissolves within 30 min. Buprenorphine buccal film includes a range of doses (75, 150, 300, 450, 600,



• **Figure 49.2** Pharmacodynamic properties of buprenorphine: multi-mechanistic regulation of opioid receptors (Gudin J, Fudin J. A narrative pharmacological review of buprenorphine: a unique opioid for the treatment of chronic pain. *Pain Ther.* 2020;9:41–54.)

750, and 900 mcg). Patients being converted from other opioids should have their MED decreased to less than 30 MED prior to initiating therapy.[67]

Buprenorphine formulated in a transdermal system or patch (Butrans Package Insert, Purdue Pharma LP 2019) provides lower serum blood levels compared to oral formulations and is indicated for chronic pain in opioid naïve and patients on relatively lower MED. This formulation is not indicated for opioid use disorder, maintenance, or detoxification.

Buprenorphine transdermal patch system (Butrans Package Insert, Purdue Pharma, 2019) provides continuous systemic delivery of buprenorphine for seven days. Dosage strengths include 5, 7.5, 10, 15, and 20 mcg/h patch systems. The product is also FDA approved for the management of pain severe enough to require around-the-clock, long-term opioid treatment and has demonstrated efficacy in chronic osteoarthritis pain and chronic low back pain.[68,69] For opioid naïve patients, treatment is initiated at 5 mcg/h every seven days, with dose titrating to the next higher level after a minimum of 72 h. When converting patients taking other opioids to a buprenorphine patch system, it is recommended to taper the patient's current opioids for up to seven days to no more than 30 mg of MED before initiating therapy at 5 mcg/h for seven days. Patients on 30–80 MED can be converted with the initiation of a 10 mcg/h patch. In the United States, the maximum buprenorphine transdermal system dose is 20 mcg/h because of a potential risk of QTc interval prolongation, which was noted in clinical trials used to obtain FDA approval. Patients are advised to avoid exposing the patch site to direct external heat sources while wearing the patch because of the potential dose-dependent increase in buprenorphine release and possible opioid toxicity and overdose. The most common adverse events reported in clinical trials included nausea, dizziness, headache, and application site pruritus (Butrans Package Insert, Purdue Pharma LP 2019).

Acetaminophen

APAP (paracetamol) and APAP combination products (i.e. containing opioids) are commonly prescribed as a minor analgesic for acute and chronic pain (Table 49.2). The 2000 American College of Rheumatology and similar European professional colleges have recommended it as first line pharmacologic therapy for osteoarthritis (OA).[70,71] Prescription APAP is available as an opioid-containing combination product (e.g. codeine, hydrocodone, oxycodone), whereas OTC preparations may be combined with pseudoephedrine or dextromethorphan as convenience drugs.

Mechanism of Action and Description

APAP (paracetamol) is a *p*-aminophenol analgesic that was introduced in the late 1800s in Germany, a product of the rapidly developing chemical industry. Newly synthesized compounds included synthetic antipyretics and analgesics such as acetophenetidin (phenacetin), antipyrine (phenazone), and acetylsalicylic acid (ASA; aspirin).[72] Paracetamol, the active metabolite of phenacetin, was found to demonstrate less intense GI side effects, which led to its use as an analgesic. Paracetamol was formally introduced in the United States in the 1950s, and although it was found in the 1960s to have hepatotoxic effects with unintentional misuse and overdose, it became one of the most widely used OTC and combination prescription analgesics worldwide.

The pharmacologic mechanism of action of paracetamol remains unclear. Generally, it has known analgesic and antipyretic activity with no known peripheral anti-inflammatory or platelet effects. Its antipyretic activity may be secondary to blockade of prostaglandin (PG) production and inhibition of PG endoperoxide H_2 synthase and COX centrally. APAP may block COX activity by reducing the active form of COX to an inactive form, but with only limited effects in the GI tract and peripherally at sites of

inflammation, thus contributing to a lower GI side effect profile than that of NSAIDs.[73] Further, recent studies have suggested that its central analgesic qualities may be related to decreased activation of a subtype of endogenous opioid peptide, β-endorphin.[74]

APAP is available in oral and rectal formulations and is rapidly absorbed from the GI tract, mainly the small intestine.[75] APAP has a half-life ($t_{½}$) of between 1.25 and 3 h and therapeutic serum levels of 10–30 μg/mL. Twenty-five percent of the dose undergoes first pass metabolism in the liver. Up to 90% of APAP is metabolized in the liver via glucuronidation and sulfate conjugation to nontoxic metabolites. The remaining 10% undergoes oxidative metabolism via the CYP system (CYP-450 2E1 and CYP-450 1A2), which is responsible for the formation of the potentially hepatotoxic and nephrotoxic metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI; Fig. 49.3). This minor pathway becomes more critical when the enzyme system responsible for sulfonation and glucuronidation becomes saturated with doses higher than 150 mg/kg, thereby increasing the total fraction of NAPQI. Approximately 85% of the dose is excreted in urine within 24 h of oral dosing. NAPQI is itself detoxified by conjugation with glutathione.[76] Case reports have suggested that clinical situations characterized by low glutathione levels (e.g. chronic hepatitis C, malnourishment, human immunodeficiency virus infection, cirrhosis) may place these patients at greater risk for adverse events from APAP. However, one study found no significant evidence that these populations are at higher risk for APAP toxicity.[77] There are few clinically significant pharmacokinetic interactions with therapeutic doses of APAP. Although case reports have attributed an elevated international normalized ratio (INR) to APAP and oral anticoagulant drug interactions,[78] randomized controlled studies have found no evidence of clinically significant changes in the INR.[79] Even though studies have demonstrated an association, there is no clear evidence of cause and effect.[80]

Risks and Precautions

APAP-induced toxicity is often associated with liver and renal dysfunction. APAP hypersensitivity reactions are rare, but severe reactions are possible. In general, chronic administration of APAP may cause depletion of glutathione stores and hence lead to greater production of the hepatotoxic and nephrotoxic metabolite NAPQI. Current recommendations for a maximum daily dosage of APAP are approximately 4 g/day in adults and 75 mg/kg/day in infants and children (Box 49.1).[81] Unintentional liver injury, such as hepatic necrosis or acute liver failure from self-medication with OTC and prescription APAP products, can develop with dosages exceeding 4 g/day.

The serum alanine transaminase (ALT) level may be elevated with the acute use of recommended doses of APAP. Watkins and Seeff[82] studied healthy adults given 4 g of APAP for 14 days. They found that 31%–44% of the study subjects, including patients taking APAP and various opioid-APAP combination products, demonstrated elevations to three times the upper limit of normal (typically considered clinically significant). Opioids were found to have no additional effect on ALT levels. Elevated liver function is not routinely seen with chronic use and is thought to occur because of cellular adaptation.[82] This APAP tolerance may be characterized by possible downregulation of CYP bioactivation and increased glutathione production by liver hepatocytes.[83]

The concomitant use of alcohol and APAP resulting in increased risk, lower threshold for hepatic and renal toxicity, or both remain controversial and reported primarily in retrospective reviews and case reports.[84] Acute and chronic alcohol use contribute to drug-induced hepatotoxicity via induction of CYP2E1 and NAPQI formation.[85] Enhanced ethanol-related toxicity was demonstrated only in patients at high risk with APAP levels above 300 mg/mL, a level far above the package insert recommendation for no more than three alcoholic beverages daily.[86] When consumed with APAP, ethanol may block the formation of NAPQI.[87] Other inducers of hepatic isoenzymes CYP2E1 and CYP1A2 that are commonly used for pain management include carbamazepine, oxcarbazepine, barbiturates, and phenytoin (Box 49.2).[88] Most importantly, the risk for APAP-induced hepatotoxicity may be increased in patients with alcoholic hepatic disease, viral hepatitis, or alcoholism because of a reduction in glucuronide conjugation and subsequent depletion of glutathione reserves.

Chronic APAP prescribing should be avoided in patients with renal disease, although the exact mechanism of injury is unknown

• Box 49.1 Acetaminophen Dosing Considerations

Dosing for Mild Pain

- 325–1000 mg PO, per rectum, q4–6h
- Maximum dose: 1 g/dose; 4 g/24 h
- American Liver Foundation: patients should not exceed 3 g/day for any prolonged period*

Renal Impairment

- Adjust dose frequency
- Creatine clearance (CrCl) = 10–50 mL/min, q6h; CrCl <10 mL/min, q8h

Hepatic Impairment

- Use with caution
- Consider decreasing the dose, monitor liver function, avoid chronic use

Counseling Patients

Acetaminophen (APAP) in over-the-counter products:

- Regular strength APAP products commonly contain 325 mg/tablet
- Extra strength APAP products commonly contain 500 mg/tablet

*Based on a study by Watkins and Seef.[82]

and may be relevant only in patients with preexisting renal compromise or systemic disease.[89] Patients with a history of salicylate hypersensitivity characterized by drug-induced urticaria have demonstrated 11% cross-reactivity to APAP.[90] APAP use has been shown to be associated with hypertension in two large prospective studies in women.[91,92] Similar studies in healthy men failed to show an association between the use of APAP and hypertension.[93] Analgesics, in general, may modestly affect blood pressure via several mechanisms, primarily through the kidney or systemic COX-2 inhibition of PGs, which leads to an imbalance between the vasodilators PGI_2 and PGE_2 and the vasoconstrictors $PGF_2\alpha$ and thromboxane A_2. These effects on PG synthesis are greater with NSAIDs than with APAP.[94]

Clinical Use

Although several guidelines traditionally recommended APAP as a first line agent, its advantages over NSAIDs in managing OA-related pain remain controversial. A double-blind trial of paracetamol, 4 g/day, for one month found it to be as effective as both analgesic and anti-inflammatory doses of ibuprofen in patients with knee OA.[95] The 2019 American College of Rheumatology (ACR) guideline for hand, hip, and knee osteoarthritis conditionally recommended acetaminophen for patients with knee, hip, and/or hand OA.[96] A "conditional recommendation" is given when the quality of evidence is low or very low and/or the balance of benefits versus harms and burdens was sufficiently close that shared decision making press between the patient and clinician is necessary. This recommendation was based on clinical trials where the effect sizes are small, and meta-analysis suggests that APAP as monotherapy may be ineffective.[97] The latest ACR osteoarthritis guideline recommended APAP consideration for those with limited medication options because of intolerance or contraindications to the use of NSAIDs for short-term or episodic use.[96]

Studies have demonstrated the efficacy of both a traditional NSAID (diclofenac)[98] and a COX-2 inhibitor (celecoxib)[99] versus APAP in hip and knee OA cohorts. A Cochrane database review of the use of APAP for the chronic pain of OA found the drug to be less effective than NSAIDs in terms of pain reduction scores, although the superiority of NSAIDs over APAP appeared to be more evident in OA patients with more severe pain. Both the NSAID and APAP groups had similar efficacy concerning functional status.[100] APAP may retain anti-inflammatory action comparable to that of NSAIDs in patients with knee OA. Brandt and associates[101] performed a pilot study of 30 subjects in whom OA of the knee was diagnosed and showed that treatment with APAP results in similar significant decreases in mean total knee effusion volume (measured by magnetic resonance imaging) as does treatment with NSAIDs. A systematic review on the efficacy of acetaminophen for chronic pain demonstrated no or little efficacy for the treatment of chronic pain conditions and recommended assessment of continuous efficacy with patient use.[102]

Tramadol

Tramadol, (±)cis-2-[(dimethylamino)methyl]-1-(3-methoxyphenyl)-cyclohexanol hydrochloride, is a synthetic racemic mixture typically used for its centrally acting analgesic properties. Clinical and basic science studies have described numerous mechanisms of action at central and peripheral sites. Tramadol is classified as a weak synthetic opioid with mild serotonin and norepinephrine reuptake-inhibiting effects.[103]

Mechanism of Action and Description

The most well-studied mechanism of action of tramadol is its weak affinity for opioid receptors, the most significant of which involves the μ receptor. Tramadol-induced analgesia is only partially inhibited by the opiate antagonist naloxone, thus suggesting additional non-opioid-related analgesic mechanisms.[104] Tramadol also displays an inhibitory effect on the central neuronal norepinephrine and serotonin (5-HT) reuptake systems. Additional actions include a local anesthetic effect, anti-inflammatory effects in experimental rat models, and reduction of substance P levels in human synovial fluid.[105,106] Although α_2-agonist activity has also been reported, concentrations in the range of 10–100 μmol/L do not bind significantly to α_2-adrenergic receptors.

Tramadol's affinity for the μ receptor appears to be approximately ten times weaker than that of codeine, 60 times weaker than that of dextropropoxyphene, and 6000 times weaker than morphine (Table 49.4).[104] The active *O*-demethylated metabolite

M1 has 300 times higher affinity for the μ receptor than the parent compound does and is up to six times more potent in producing analgesia.[107]

Central Neuronal Actions

Multiple actions affecting the descending inhibitory pain pathways have been reported.[108,109] The first system involves neurons originating in the periaqueductal gray matter in the midbrain that synapse at the nucleus raphe magnus, from which fibers then project to the spinal cord. Inhibition of 5-HT reuptake may contribute to inhibition of pain. Another pathway originates at the locus coeruleus in the pons, with fibers projecting to the spinal cord. The norepinephrine released from this pathway inhibits pain responses at the spinal cord via an α-adrenergic mechanism.

Activation of these descending pain inhibition pathways stimulates interneurons that inhibit the transmission of painful stimuli in the dorsal horn by the action of endogenous opioids. Opioid receptor activity has been proposed to be mediated by the dextrorotatory (+) enantiomer instead of the levorotatory (–) enantiomer.[110] The (–) enantiomer is approximately ten times more potent than its (+) counterpart in the inhibition of norepinephrine uptake, and the (+) enantiomer is approximately four times more potent than the (–) enantiomer in the inhibition of 5-HT uptake. M1 retains a higher affinity for the μ-opioid receptor (300–400 times) and possesses greater analgesic activity than the parent compound does. The M1 (+) enantiomer acts at the μ receptor, whereas the M1 (–) enantiomer mainly inhibits the reuptake of norepinephrine (Table 49.5).[108,109]

Formulations include IR and sustained-release (SR) oral forms (SR, dosing every 12 h; ER, dosing every 24 h); injectable solutions for subcutaneous, intravenous, or intramuscular administration; and a rectal formulation. SR formulations are available in several countries worldwide, but only the ER formulation is currently available in the United States. In addition, an orally disintegrating tablet version of tramadol (Ralivia FlashDose) for the treatment of moderate to moderately severe pain is under development.[111] Tramadol is currently recommended for the treatment of moderate to moderately severe pain in patients unresponsive to previous oral therapies or who have a contraindication to COX-2-selective or COX-2-nonselective NSAIDs.

History

Tramadol has been available in Germany since 1977, where it remains one of the most widely prescribed analgesics. Before its United States release in 1995, clinical[112] and epidemiologic studies[113] suggested that tramadol demonstrates low abuse potential, which led the Drug Abuse Advisory Committee to recommend FDA approval of tramadol as a nonscheduled analgesic. Current studies continue to support the low abuse potential of tramadol. A post-marketing survey has demonstrated limited evidence of tramadol use-related dependence, withdrawal, and abuse.[114] Another study assessing the prevalence of abuse compared tramadol with NSAIDs and hydrocodone-containing analgesics in patients with chronic non-cancer-related pain.[115] This study used an abuse index that identified subjects according to the following behavior: (1) increased doses without physician approval, (2) used for purposes other than intended, (3) demonstrated an inability to stop use, and (4) experienced withdrawal. The percentage of subjects who scored positive (at least one of the four types of behavior) during 12 months was 2.5% for NSAIDs, 2.7% for tramadol, and 4.9% for hydrocodone.

Formulations

Currently available oral formulations of tramadol include 50 mg scored IR tablets, SR tablets and capsules (every 12 h dosing available worldwide but not in the United States), two ER once-daily tablets (Ultram ER and Ryzolt [Purdue Pharma]), and combination tablets consisting of tramadol, 37.5 mg, plus APAP, 325 mg.[116] The SR preparations are available in strengths of 50, 100, 150, and 200 mg taken twice daily. ER tramadol hydrochloride tablets (Ultram ER) are available in 100, 200, and 300 mg strengths taken once-daily. The bioavailability of Ultram ER, 200 mg, relative to tramadol, 50 mg IR formulation every 6 h, is approximately 85%–90%. Steady-state plasma concentrations of tramadol and M1 are achieved within four days of once-daily dosing. Important pharmacokinetic parameters of the 200 mg ER formulation include a time of maximum concentration (T_{max}) of 12 and 15 h for tramadol and the M1 metabolite, respectively, compared to a T_{max} of 1.5 and 1.9 h for tramadol and the M1 metabolite, respectively, with the 50 mg IR formulation (Table 49.6).[116]

Once-daily ER Ultram was formulated to counter the need for doses of IR tramadol hydrochloride (Ultram) every 6 h, improve

T_{max} (h)	12	1.5	15	1.9

compliance, and decrease sleep interruptions because of more stable serum concentrations. The bioavailability of ER tramadol is comparable to that of IR tramadol and demonstrates steady-state bioequivalence (area under the plasma drug concentration versus time curve and maximum concentration [C_{max}] values) compared to IR tramadol administered four times daily.[116] ER tramadol (200 mg) has a longer T_{max} (tramadol, 12 h; M1 metabolite, 15 h) than IR tramadol does (tramadol, 1.5 h; M1 metabolite, 1.9 h) but reaches steady-state plasma concentrations (tramadol and M1) within four days with once-daily dosing.

ER tramadol (100, 200, 300 mg) was found to be superior to placebo in average change from baseline pain from one through 12 weeks in a randomized trial of OA of the knee. The average ER tramadol dose was 276 mg/day.[117]

Tramadol hydrochloride ER tablets (Ryzolt, Purdue Pharma LP, Stamford, Conn, 2009) contain both IR and ER characteristics (100, 200, and 300 mg). Ryzolt is indicated for the management of moderate to moderately severe chronic pain in adults who require around-the-clock treatment of their pain for an extended period. The median time to peak plasma concentrations of tramadol and M1 after multiple doses of 200 mg tablets is about 4 and 5 h, respectively. Steady-state is achieved after two days with a relative bioavailability of approximately 95% with 200 mg of Ryzolt versus IR tramadol, 50 mg every 6 h (Ryzolt Package Insert, Purdue Pharma LP, 2009).

Pharmacokinetics

The maximum serum concentration of oral tramadol is reached in approximately 2 h.[118] Its mean bioavailability after a single dose is 68%,[119] and this increases to 90%–100% after multiple doses. Mean bioavailability after intramuscular administration is 100%, and after rectal administration is 78%. Tramadol is 20% bound to plasma proteins and crosses the placenta.[120] Metabolism is primarily hepatic via the CYP enzyme system. Tramadol is excreted by the kidneys (90%) and in feces (10%). Biotransformation in the liver creates 23 metabolites; the primary metabolite is *O*-desmethyltramadol (M1).[121] Polymorphism of the CYP2D6 isoenzyme in the liver (present in approximately 7%–10% of whites) may cause attenuation of analgesia in poor metabolizers. Such patients may require higher loading doses and more rescue analgesia.[122] The elimination $t_{½}$ of tramadol is 5–6 h, and that of M1 is approximately 8 h. Adjustments in dosage are required for patients with hepatic and renal failure and geriatric patients (Table 49.7).[123] Bioequivalence has been demonstrated between IR and SR-ER formulations.[107]

Management Considerations

For improved tolerability of tramadol, various titration regimens have been proposed. An alternative example of a titration schedule for the IR 50 mg tablets in patients with moderate to moderately severe chronic pain is as follows:

1. Start at 25 mg/day and titrate in 25 mg increments as separate doses every three days to reach 100 mg/day (25 mg four times daily).
2. Increase the total daily dose by 50 mg as tolerated every three days to reach 200 mg/day (50 mg four times daily).
3. After titration, tramadol, 50–100 mg, can be administered as needed for pain relief every 4–6 h, not to exceed 400 mg/day.

Patients with moderately severe pain who need more immediate pain control may benefit from a more aggressive dosing schedule. In this case, the increased risk for adverse events associated with higher initial doses must be discussed and acceptable. In this subset of patients, tramadol, 50–100 mg, may be administered as needed every 4–6 h, not to exceed 400 mg total per 24 h period.

The initial recommended dose of tramadol SR formulations is 50–100 mg twice daily. Titration to doses of 150–200 mg twice daily pending side effect tolerability and efficacy of pain relief as needed may be carried out. Tramadol ER dosage recommendations include an initial dose of 100 mg daily, with upward titration by 100 mg every five days to a maximum daily dosage of 300 mg.

Risks and Precautions

When compared to traditional opioid analgesics, tramadol retains a more favorable side effect profile and may be associated with a lower risk for addiction with chronic use.[124]

Common Side Effects

The most commonly reported side effects include nausea, vomiting, dizziness, fatigue, sweating, dry mouth, drowsiness, sedation, and orthostatic hypotension. The incidence of side effects has been reported to be as high as 16.8% in patients with chronic pain complaints. Controlled-release formulations may produce a lower incidence of side effects (6.5%).[125]

Despite its improved side effect profile and early consideration as an alternative to pure μ-opioid receptor agonist medications, reports of overdose and fatality have led to a change in the package insert information that includes a contraindication in patients with a past or present history of addiction or dependence on opioids.[113] Other more severe side effects include angioedema,[126] bleeding complications because of the increased effect of oral anticoagulants,[127] and serotonin toxicity.[128–130]

Tramadol and Serotonin Toxicity (Serotonin Syndrome)

Concomitant use of tramadol with other serotonergic medications (e.g. selective serotonin reuptake inhibitors [SSRIs], monoamine oxidase inhibitors [MAOIs], and serotonin-norepinephrine reuptake inhibitors [SNRIs]; Box 49.3) has been associated with case reports of serotonin toxicity.[131] Given that several medication classes commonly used for pain management may predispose patients to be mild to severe symptoms of serotonin toxicity, a review to gain a clearer understanding of serotonin toxicity and serotonin syndrome is in order.

Definition

Serotonin toxicity is an iatrogenic drug-induced toxidrome, a group of signs and symptoms occurring together with a particular type of chemical poisoning. Life-threatening serotonin toxicity, though rare, is usually precipitated by ingestion of MAOIs and SSRIs and leads, in some cases, to hyperpyrexia and death.[132] The pathophysiology remains unclear but may involve overstimulation of 5-HT_{1A} and 5-HT_2 receptors in the brain. Serotonin toxicity has been described by Gillman and Whyte as a triad involving neuromuscular hyperactivity, autonomic hyperactivity, and altered mental status (Table 49.8).[130]

Sternbach proposed criteria for serotonin syndrome is one of the earlier published comprehensive reviews of serotonin syndrome.[128]

Parameter	Manifestations
Neuromuscular hyperactivity	Tremor, clonus, myoclonus, hyperreflexia
Autonomic hyperactivity	Diaphoresis, fever, tachycardia, tachypnea, mydriasis
Altered mental status	Agitation, excitement, confusion

In 2000 Radomski and associates[129] published an updated review of the subject with revised diagnostic criteria (Table 49.9).

Mechanisms of Serotonin Toxicity. Serotonin toxicity may be related to the mechanisms of action and potency of drugs. Tricyclic anti-depressants (TCAs) exhibit a 100-fold variability in affinity for the serotonin transporter in humans. Overdose of amitriptyline alone does not precipitate serotonin toxicity.[133] More potent TCAs, such as clomipramine, may have more potent serotonergic effects clinically and in overdose. In overdoses of SSRIs or SNRIs such as with venlafaxine alone, 15% of individuals exhibit moderate serotonin toxicity without life-threatening symptoms or pyrexia.[134] Although venlafaxine has less potency than amitriptyline at the receptor level, it precipitates serotonin toxicity more frequently than SSRIs do (30% vs. 15%). This may be related to mechanisms other than inhibition of serotonin reuptake.[135] Trazodone and nefazodone differ from TCAs and SSRIs in that they are primarily 5-HT_{2A} antagonists. Neither exhibit serotonergic side effects, nor do they induce signs of serotonin toxicity in overdose.[132]

Several other pharmacologic agents, including illicit substances, enhance 5-HT activity and must be considered in the workup for possible serotonin toxicity (e.g. buspirone, ergot alkaloids, amphetamine, cocaine, TCAs, MAOIs; Box 49.3).[136]

Clinical Use of Tramadol Formulations

Earlier reports evaluating the effectiveness of tramadol for varied painful conditions yielded conflicting results. In comparative studies of acute pain, oral tramadol was found to have efficacy similar to that of propoxyphene in a postoperative pain study and comparable efficacy as codeine for pain related to dental surgery.[137] However, tramadol hydrochloride, 50 and 100 mg, was found to have efficacy similar to that of placebo for pain after total hip arthroplasty,[138] but provided analgesia inferior to that of hydrocodone-APAP in an emergency room acute musculoskeletal pain cohort consisting of fracture, sprain-strain, and contusion.[139]

More recent clinical and evidence-based practice has found tramadol useful for a wide range of painful conditions, including OA, postamputation phantom limb and residual limb pain,[140] postoperative pain reduction after arthroscopic knee surgery,[142] and cancer-related pain.[142] Guidelines for the pharmacologic management of OA have recommended tramadol for patients who fail to achieve analgesia with APAP, COX-2 inhibitors, or NSAIDs.[143]

A 2004 Cochrane collaboration review of tramadol for neuropathic pain identified several eligible trials, including two comparing tramadol with placebo,[144,145] one comparing tramadol with clomipramine,[146] and one comparing tramadol with morphine for cancer pain.[147] Tramadol was found to be effective for the treatment of neuropathic pain based on this limited number of short-term studies (four to six weeks). The NNT for tramadol in relieving neuropathic

TABLE 49.9 Spectrum of Serotonin Syndrome

Mild State of Serotonin-Related Symptoms	Serotonin Syndrome (Full-Blown Form)		Toxic States
Single symptom may predominate	At least four major or three major and two minor of the following:		Coma
Most common are	Major	Minor	Generalized tonic-clonic seizures
Tremor Myoclonus Diaphoresis and shivering	Mental symptoms: Impaired consciousness, Elevated mood Neurologic symptoms: Myoclonus Tremor, Shivering, Rigidity, Hyperreflexia Vegetative symptoms: Fever, Sweating	Restlessness, Insomnia, Incoordination, Dilated pupils, Akathisia, Tachycardia, Tachypnea, Dyspnea, Diarrhea, Hypertension, Hypotension	Fever (may exceed 40°C) Disseminated intravascular coagulation and renal failure

Coincident with the addition of or an increase in a known serotonergic agent. Clinical features were not an integral part of the underlying psychiatric disorder before commencing the serotonergic agent. Other causes (e.g. infectious, metabolic or endocrine, substance abuse, or withdrawal) have been ruled out. A neuroleptic drug has not been started or increased in dosage before the onset of the signs and symptoms listed.

From Gnanadesigan N, Espinoza RT, Smith R, et al. Interaction of serotonergic antidepressants and opioid analgesics: is serotonin syndrome going undetected? J Am Med Dir Assoc 2005;6:265-269.

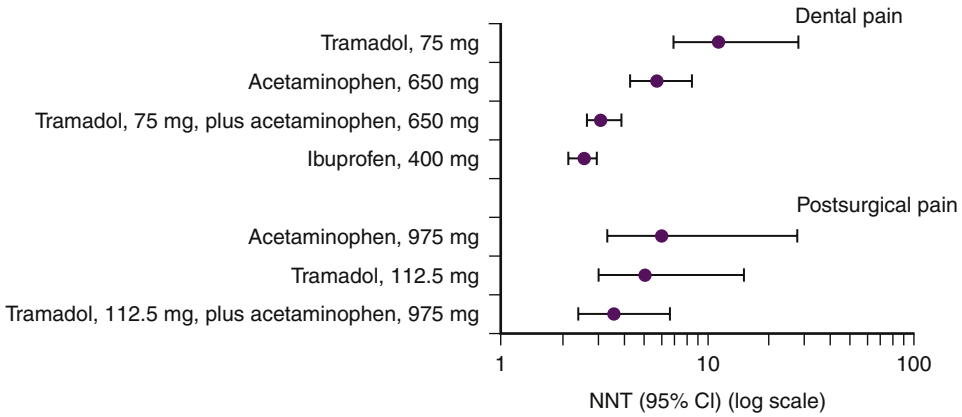
pain states (3.5) was similar to that for other commonly used medications: 2.4 for TCAs, 2.5 for carbamazepine, and 3.7 for gabapentin.

Tramadol-Acetaminophen

Several different strengths of combination tramadol and APAP compounds are available in the United States and Europe. The combination takes advantage of the potential synergy between the two compounds demonstrated in animal and human models, with an initial onset of analgesia with APAP (20 min) followed by tramadol (approximately 50 min).[148] A meta-analysis of dental pain has demonstrated that the combination of APAP plus tramadol has a similar rapid onset of efficacy as paracetamol alone, but levels of analgesia are maintained for a longer period than with tramadol alone.[149] Tramadol-APAP combination products contain less tramadol by dose (in the United States, 37.5 vs. 50 mg) and relatively less APAP (325 vs. 500 mg [extra strength APAP]) and thus may lower the potential incidence of organ toxicity (liver) when taken within the range of recommended doses.[107] Tramadol-APAP combination products have demonstrated efficacy for acute and chronic pain conditions.[150] Combination tramadol, 37.5 mg, plus APAP, 325 mg, may provide analgesia equivalent to codeine and APAP in patients with chronic OA, but with greater tolerability.[151] The most common treatment-related adverse events include somnolence, nausea, and constipation with a mean dosage of 4.1 tablets daily.[152] Figure 49.4 illustrates NNT data from a meta-analysis evaluating the efficacy of a tramadol-APAP combination for moderate to severe postoperative pain.[153]

Oral Steroids

The first glucocorticoid was isolated in 1935. This naturally occurring corticosteroid, cortisone, was later synthesized in the laboratory in 1944. Four years later, Hench and colleagues at the Mayo Clinic could obtain a portion of the synthetic cortisone available from Merck for clinical trial use. They injected the "compound E" (cortisone) into patients with rheumatoid arthritis. The patients experienced dramatic pain reduction and remarkable improvement in their functional mobility. However, when the supplies ran out just one week later, all the treated patients went into remission.[154] This report led not only to the widespread use of cortisone for the treatment of rheumatologic conditions but also earned Hench a joint award (along with Kendall and Reichstein) of the Nobel Prize in Medicine and Physiology in 1950. As oral steroid preparations evolved, their use increased in addition to injection therapy to produce systemic levels for chronic treatment regimens. Pulsed dosing schedules are now routinely used for disease



• **Figure 49.4** Meta-analysis evaluating a tramadol-acetaminophen combination for moderate to severe postoperative pain. *CI,* Confidence interval; *NNT,* number needed to treat. Combination analgesic efficacy: individual patient data meta-analysis of single-dose oral tramadol plus acetaminophen in acute postoperative pain. *J Pain Symptom Manage.* 2002;23:121–130.)

management and episodic flares of various conditions, including rheumatic, pulmonary, dermatologic, neurologic, ophthalmologic, hematologic, and endocrine disorders. Exogenous glucocorticoid administration has been shown to have a suppressive effect on the hypothalamic-pituitary-adrenal (HPA) axis. Some believe that this can occur in as few as five days when using high supraphysiologic doses, whereas at physiologic doses, this may not occur for three to four weeks. Thus a tapered dosing schedule is typically recommended when treatment exceeds two to three weeks.[155] The use of steroids for the treatment of painful conditions is largely based on the premise that there is an inflammatory role in the mediation of pain.[156] Chronic oral steroid therapy is used for the treatment of rheumatologic inflammatory conditions (e.g. rheumatoid arthritis, polymyalgia rheumatica, Crohn's disease) and cancer pain. In addition, oral steroids are commonly used in short-term or pulsed dosing schedules for conditions such as complex regional pain syndrome (CRPS), rheumatoid arthritis flares, gouty or OA flares, painful radiculopathy, bursitis, carpal tunnel syndrome, and other acute or chronic musculoskeletal conditions.[157-159]

Mechanism of Action and Description

Adrenocortical steroids such as prednisone, methylprednisolone, and dexamethasone act by inhibiting multiple cellular mechanisms, including accumulation of inflammatory cells at sites of inflammation, macrophage phagocytosis, lysosomal enzyme release and synthesis, and release of mediators of inflammation. Regarding their ability to attenuate pain responses, this action is probably related to their strong anti-inflammatory action. Steroids suppress or prevent cell-mediated immune responses and decrease or prevent tissue response to the inflammatory process. The mechanisms for reduction of cancer pain are thought to be secondary to inhibition of PG synthesis and reduction in peritumor and perineural edema by decreasing capillary permeability.[156]

Oral prednisone is readily absorbed in the GI tract. It is highly protein-bound (up to 70%–90%) and is distributed widely in various tissues. The plasma $t_{½}$ of prednisone is 3.4–4 h, with a biologic $t_{½}$ of 18–36 h. It is metabolized in the liver to its active metabolite prednisolone, which is further metabolized to inactive compounds. The active metabolite and inactive compounds are excreted in urine, and the drug is not removed by hemodialysis.[160]

The pharmacodynamics of commonly used glucocorticoids is presented in Table 49.10.

Prednisone tablets are available in multiple dosage forms ranging from 2.5–50 mg tablets. Other glucocorticoids commonly prescribed for painful conditions include methylprednisolone (Medrol Dosepak) and dexamethasone (Table 49.11). The Medrol Dosepak consists of 21 × 4 mg tablets taken in a tapering fashion from six tablets on day one to one tablet on day six. See Box 49.4 for common glucocorticoid dosing schedules.

Risks and Precautions

In general, long-term administration at physiologic replacement doses does not lead to adverse effects. Similarly, short-term dosing at supraphysiologic levels typically does not cause adverse effects. Many have recommended a tapering dose schedule to avoid glucocorticoid withdrawal, which can occur in as few as five days at high supraphysiologic doses or in three to four weeks at physiologic doses.[155] Suppression of the HPA axis can persist for up to 12 months after cessation of prolonged corticosteroid therapy, and supplementation may be required during periods of physiologic stress such as surgery, acute blood loss, or infection. Because of the depression and prevention of cell-mediated immune responses, oral corticosteroids are not well tolerated by patients with immunocompromised states, whether acute or chronic. However, they do play an adjuvant role in the management of cancer pain.[162] In such cases, new pain complaints in cancer patients or palliative care patients must be monitored vigilantly because, in the presence of opioid analgesics and corticosteroid therapy, symptoms may be less severe and related to a new diagnosis, such as appendicitis.[162]

A population-based study examining more than 2400 patients maintained on long-term oral glucocorticoid therapy found that side effects are associated with cumulative and average doses in a dose-dependent fashion.[163] The study allowed the use of varied glucocorticoid preparations and converted them into a prednisone-equivalent dose. The most common side effects, with approximate prevalence, included weight gain (70%), skin bruising (53%), sleep disturbance (45%), mood symptoms (42%), cataracts (15%), acne (15%), and fractures (12%). An increasing daily dosage was more significantly associated with fractures and sleep disturbance than was an increased duration of use.[163]

TABLE 49.10 Pharmacodynamics of Common Glucocorticoids

Agent	Equivalent Glucocorticoid Dose (mg)	Relative Glucocorticoid Activity	Relative Mineralocorticoid Activity*	Relative Half-Life in Plasma (h)	Biologic Half-Life (h)
Cortisone	25	0.8	0.8	0.5	8–12
Cortisol	20	1	1	1.5–2	8–12
Methylprednisolone	4	5	0.5	>3.5	18–36
Prednisolone	5	4	0.6	2.1–3.5	18–36
Prednisone	5	4	0.6	3.4–3.8	18–36
Triamcinolone	4	5	0	2–5	18–36
Dexamethasone	0.75	20–30	0	3–4.5	36–54
Betamethasone	0.6	20–30	0	3–5	36–54

TABLE 49.11 Commonly Prescribed Oral Glucocorticoids

Agent	Trade Name	Available Dose Form
Methylprednisolone	Medrol	2, 4, 8, 16, 24, 32 mg tablets
Prednisone	Deltasone, Sterapred	2.5, 5, 10, 20, 50 mg tablets
	Prednisone Intensol (oral concentrate)	5 mg/mL
Dexamethasone	Decadron	0.25, 0.5, 0.75, 1.5, 4, 8 mg tablets
	Decadron elixir (oral concentrate)	0.5 mg/5 mL

• Box 49.4 Common Glucocorticoid Dosing Schedules

- Prednisone taper—prednisone, 10 mg tablets
  - Three tablets PO bid × four days, two tablets PO bid × three days, one tablet PO bid × three days
- Medrol Dosepak—methylprednisolone, 4 mg tablets
  - Day one: two tablets before breakfast, one tablet after lunch and dinner, and two tablets at bedtime (total = six tablets). If given later in the day, may take all six tablets at once or in divided doses
  - Day two: one tablet before breakfast, one tablet after lunch and dinner, and two tablets at bedtime
  - Day three: same as day two, except one tablet at bedtime
  - Day four: one tablet before breakfast, after lunch, and at bedtime
  - Day five: one tablet after breakfast and at bedtime
  - Day six: one tablet after breakfast
- Dexamethasone taper—dexamethasone, 8 mg tablets
  - Tapering schedule over seven days: 64, 32, 24, 16, 8, 8, 8 mg

Prednisone use during pregnancy is schedule D during the first trimester and schedule C in the second and third trimesters. First trimester exposure to systemic corticosteroids (category C) has been associated with intrauterine growth retardation and an increased incidence of cleft lip, with or without cleft palate. If necessary, the maternal benefits of short courses of oral corticosteroids may outweigh the fetal risks when given beyond the first trimester.[165]

Clinical Use

Oral corticosteroids have a limited role in the treatment of painful conditions. They may be useful in the treatment of acute painful inflammatory conditions, including CRPS, carpal tunnel syndrome, rotator cuff arthropathy-adhesive capsulitis, and painful cervical or lumbar radiculopathy. Steroids have been and continue to be administered by multiple routes for the treatment of CRPS.

An animal study of the effects of chronic methylprednisolone treatment on the rat CRPS type 1 model (tibia fracture) has revealed that glucocorticoids reverse hind paw edema and warmth after fracture, with persistent effects occurring after discontinuation of treatment. However, glucocorticoid treatment does not affect the allodynia, hind paw unweighting, or periarticular bone loss observed after tibia fracture.[166] Early reports reported success with systemic steroids.[167] Christensen and coworkers[160] studied 23 patients and reported that 30 mg/day of oral prednisone is significantly better than placebo based on their stated clinical outcome measures. Braus and colleagues[167] studied the effects of methylprednisolone, 32 mg/day for two weeks, followed by a taper over two weeks, for the treatment of CRPS in post-stroke patients. This randomized study showed a significant clinical improvement in the steroid-treated patients at four weeks. More recent studies showed the efficacy of oral steroids in CRPS. Jamroz et al. treated CRPS patients with a typical prednisone regimen (60 mg followed by a taper of 5 mg per day until 20 mg, 40 mg before the taper was used in elderly, adolescent, and diabetic patients).[168] Of the 39 patients, 19 (49%) reported complete pain relief, and 17 patients reported functional recovery. They noted that earlier treatment resulted in better outcomes, confirming an earlier study that showed limited efficacy of steroids in treating CRPS of more than three months.[169] It appears that a low dose oral steroid regimen (200 mg total dose: 30 mg for three days, 20 mg over three days, 10 mg for three days, 5 mg from day ten to day 14, then discontinued) is comparable to that of a high-dose regimen (450 mg total dose) in alleviating symptoms in patients with CRPS I.[170]

The use of minor analgesics in the cancer pain population is common. The most commonly used opioid co-analgesics are NSAIDs and APAP, but up to 39% of cancer patients take various types of corticosteroids, with dexamethasone being the most common formulation. Conditions being treated include breast, lung, and colorectal cancer. Studies have documented the usefulness of corticosteroids for the rational polypharmacy of cancer pain management.[161,171,172] Efficacy has been demonstrated for neuropathic pain caused by tumor compression (malignant compression of the spinal cord or brachial or lumbosacral plexus), tumor-induced bone pain, and hepatic capsule distention secondary to liver metastases.[156,173] In addition to NSAIDs and disease-modifying antirheumatic drugs, low dose oral corticosteroids may also help manage joint symptoms caused by chemotherapy-induced arthropathy.[174]

Recruitment of cancer pain patients can be difficult.[175] Despite the lack of controlled clinical trials, corticosteroids are frequently prescribed in an adjunctive role for palliation and control of the side effects of chemotherapy. Therefore these agents may play a dual role in selected patients. Many believe that corticosteroids may help in preventing chemotherapy-induced nausea and emesis and hypersensitivity reactions. In addition, they may also help ameliorate asthenic symptoms and fatigue, as well as stimulate appetite.[158,176] Any effect of oral steroids on cancer-related dyspnea is limited by the low quality of published studies.[177]

The use of oral glucocorticoids in the form of methylprednisolone or prednisone burst or taper is common practice in the acute treatment of disk herniation with radicular pain complaints. Despite a significant increase in studies evaluating the efficacy of fluoroscopically guided epidural steroid injections (see Chapter 65), there is a paucity of reports on the usefulness of oral or systemic corticosteroids in this pain population. In a prospective, double-blind, randomized controlled trial evaluating the use of oral corticosteroids for the treatment of radicular pain, a tapering dose of dexamethasone over seven days was not superior to a placebo for early or long-term relief of lumbosacral radicular pain.[178] However, dexamethasone was superior to placebo in reducing stretch-invoked pain during the straight-leg raise test. This study did allow the concurrent use of meperidine, oxycodone, and APAP for analgesia.[178] Systemic dexamethasone taper via the intramuscular route has been studied to a limited degree, with conflicting results.[179,180] The rationale for the use of oral corticosteroids is based on the observance that pro-inflammatory

mediators and neurosensitizing chemicals are released from the damaged intervertebral disk.[181,182]

There is a close relationship between injury and pain with most musculoskeletal injuries. Therefore individual treatments in a comprehensive management program may serve dual purposes—reducing inflammation to control local damage and concurrently reducing pain. Although few trials have evaluated the efficacy of oral corticosteroids for musculoskeletal injuries, clinical practice reveals that their use is widespread. A questionnaire-based study at a national sports medicine conference found that 59% of the physicians prescribe oral corticosteroids for musculoskeletal injuries, with prednisone being the most commonly used.[183] The study did not differentiate whether the medication was prescribed specifically for pain or its anti-inflammatory properties, but prescriptions were written equally for acute and chronic conditions.

Although the mainstays of treatment of carpal tunnel syndrome include neutral wrist splints, ergonomic evaluation and modification of biomechanics, oral NSAIDs, steroid injections, and surgical release of the transverse carpal ligament, there is evidence to suggest that oral corticosteroids may play a role in the short-term management of patients with mild to moderate symptoms and in those not interested in or awaiting surgical release of the transverse carpal ligament. Studies have examined varied dosing and duration-of-treatment regimens with prednisolone (ten days to three weeks, doses of up to 25 mg daily). The results suggest that regardless of dosing, the global symptom score is improved in patients treated with oral corticosteroid versus placebo.[157]

Short-term dosing of oral prednisolone at variable doses has been studied for adhesive capsulitis. Binder and associates[184] used 10 mg daily for four weeks, followed by 5 mg daily for two weeks. Night pain was significantly lower in the treatment group at eight weeks. However, by five months, this difference had resolved. Over the total eight-month period, no difference was found in pain at rest or with movement, range of motion, or the cumulative recovery curve between the oral steroid group and the control group, which received no specific therapy. Other studies have evaluated a three-week course of 30 mg prednisolone daily and reported a significant reduction in pain and disability, improved active range of motion, and better participant-rated improvement at three weeks. The improvements were still evident by six weeks, but none of the values were statistically significant. At 12 weeks, the placebo group was favored.[158] A review of the treatments for adhesive capsulitis showed steroids as a component of the multimodal management that includes intraarticular steroid injection, physical therapy, manipulation under anesthesia, and arthroscopic capsular release.[185]

The use of oral corticosteroids for the treatment of rheumatoid arthritis has been studied since 1949 when Hench and coworkers[186] showed the efficacy of the treatment in an uncontrolled trial. Although oral corticosteroids may show beneficial effects concerning the radiologic progress of the disease,[187] they are more commonly used during episodes of symptomatic flares to control pain or as bridge therapy with slower-acting agents.[188,189] A meta-analysis evaluating the effectiveness of low dose prednisolone versus placebo and NSAIDs found that low dose prednisolone (<15 mg daily) has greater effect than placebo and NSAIDs on joint tenderness and pain.[189] Presently, an oral steroid (prednisone) is an adjuvant treatment for rheumatoid arthritis, the main pharmacologic agent being a conventional disease-modifying agent (DMARD), either methotrexate or sulfasalazine and/or a biologic DMARD (e.g. adalimumab).[190]

Caffeine

Caffeine is an important adjuvant compound used in combination with OTC and prescription analgesics. Caffeine exhibits antinociceptive effects and analgesic properties when used in combination with opioid analgesics.[191] Caffeine combination products have been studied for several pain conditions, including headache,[192] low back pain,[193] and postpartum-related pain.[194] Caffeine (65–130 mg) was shown to increase the potency of other analgesics by 40%.[195] OTC headache medications typically include 65 or 32.5 mg caffeine combined with APAP, 250–500 mg, and/or ASA, 250–520 mg (Table 49.12).

Mechanism of Action and Description

Caffeine, a methylxanthine, is a nonselective adenosine receptor antagonist that blocks multiple adenosine receptors (A1, A2A, A2B, and A3) in peripheral tissues and the CNS.[196,197] Centrally, caffeine may increase dopamine and norepinephrine, as well as act as a vasoconstrictor of vessels, thereby contributing to its analgesic effect in certain headache conditions.[198] An animal study using a fixed dose of aspirin, APAP (paracetamol), and caffeine demonstrated increased secretion of norepinephrine and a reduction in dopamine in rat striatal tissue.[199]

Clinical Use

Older studies examining the relationship between dietary caffeine intake and chronic low back pain have yielded conflicting results.[200,201] One retrospective study showed higher consumption in patients with chronic low back pain[201] while a retrospective review showed no significant differences among the low, medium, and high caffeine consumer groups on pain severity, anxiety, distress, or sleeping patterns.[200] Caffeine, by itself, is not used to treat low back pain. Instead, it can be a component of combination therapy. A recent study showed small doses of a combination product (aspirin, acetaminophen, caffeine, and chlorpheniramine) to be as effective as 500 mg acetaminophen.[202]

Caffeinated medications, either alone or in combination, are widely used by patients in the treatment of headaches. A review showed that combinations of caffeine with analgesics (acetaminophen, ASA, ibuprofen) showed improved efficacy in tension-type headaches or migraines over analgesic medication alone.[203] Caffeine has also been recommended in the management of mild postdural puncture headaches.[204]

TABLE 49.12 Components of Caffeine-Containing Over-the-Counter Medications

Name	Caffeine (mg)	Acetaminophen (mg)	NSAID (mg)
Excedrin Tension Headache	65	500	N/A
Excedrin Migraine	65	250	250 ASA
Goody's Extra Strength Headache Powder	32.5	260	520 ASA

ASA, Acetylsalicylic acid; *N/A*, not applicable; *NSAID*, nonsteroidal anti-inflammatory drug.

Conclusion

Analgesics play an important role in the treatment of many acute and chronic pain conditions. Classically, many minor analgesics represent the first line of agents in the WHO analgesic ladder and range from OTC convenience medications to opioids, and adjuvants to treat musculoskeletal, arthritis, spine-related, and cancer pain conditions. The class of "minor analgesics" has broadened from the original WHO ladder to include tapentadol and buprenorphine products indicated for chronic pain. Though considered relatively safe compared to many other prescription-strength medications and stronger μ-opioid agonists, minor analgesics must be used with caution and require close patient monitoring. Side effects and adverse events related to common use and misuse of the medications include liver toxicity (APAP); GI, renal, and cardiac toxicity (NSAIDs and COX-2 inhibitors); and physiologic dependence, tolerance, and addiction (combination opioid analgesics, tramadol, tapentadol, and buprenorphine products).

Key Points

- Regular use of OTC analgesic medications is a common method used by patients to relieve various pain related conditions.
- Minor opioid analgesics include propoxyphene, hydrocodone, oxycodone, and tramadol, individually and in combination products.
- Two buprenorphine formulations, including a seven-day transdermal patch system and an oral buccal film, are additional minor opioid analgesics and are indicated for chronic pain and differ from sublingual formulations indicated for opioid use disorder. Buprenorphine has unique opioid receptor agonist-antagonist properties contributing to it is multi-mechanistic pharmacologic activity.
- Patients' responses to individual opioids and opioid combination products may vary significantly. This is probably explained by opioid receptor polymorphisms, differences in pharmacokinetics, and genetic variation related to enzymatic breakdown by hepatic metabolic systems.
- True serotonin toxicity and serotonin syndrome are rare but potentially deadly conditions seen in the field of pain management. They are characterized clinically by changes in mental status and autonomic and neuromuscular hyperactivity.
- Although conflicting clinical evidence exists, oral corticosteroids may be helpful for spine, musculoskeletal, and rheumatologic conditions. Prescribers should be aware of differences in specific types of steroid preparations and related variability in dosing.
- Combining caffeine with analgesics (acetaminophen, ASA, ibuprofen) results in improved efficacy in tension-type headaches or migraines over analgesic medication alone. Caffeine has also been recommended in the management of mild postdural puncture headaches.

The U.S. Opioid Crisis and the Legal and Legislative Implications

JORDAN STARR, MOHAMMED A. ISSA, AJAY WASAN

Introduction

The opioid crisis has had a dramatic impact on medical care in the United States, affecting all medical providers, especially pain physicians and their patients. From 1999 to 2011, oxycodone use increased by 500%, with the quadrupling of opioid-related overdose deaths during the same period.[1,2] Despite formal recognition of the opioid crisis in 2011 and subsequently reduced opioid prescriptions, 10.3 million Americans still misused opioids in 2018, 9.9 million of which inappropriately used prescription pain medications.[3] This was associated with over 48,000 opioid-related overdose deaths that year alone.[4] Clearly, despite the efforts of numerous stakeholders in the United States government and medicine, combating the opioid epidemic is still necessary. As one of these stakeholder groups, pain physicians must not only understand ongoing efforts to contend with the opioid epidemic but also their specific roles in these efforts. Additionally, pain physicians have unique concerns about the initiation or limitation of prescription opioids, as well as public perception and backlash. In this context, this chapter reviews the history of the opioid crisis, current efforts, and the legal background that underlies these interventions.

Historical Perspective

Opium use has been recorded since at least 3400 B.C. by the Sumerians in lower Mesopotamia, and its addictive properties were likely appreciated soon after.[5] While opium use spread throughout Asia and Europe during the following millennia, the first recorded "opium epidemic" occurred in China from the end of the 18th century to the beginning of the 20th century.[6] This was sparked by the introduction of smoking opium, rather than ingestion and dramatic increases in production and trade by the British.[6] By 1906, it is estimated that 13.4% of the Chinese population was addicted to opium.[6]

The United States dealt with its own opioid epidemic in the late 19th and early 20th centuries.[7] Morphine dependence increased after battlefield exposures during the civil war.[7] This was exacerbated by the release of heroin in 1898, which was purported to carry no "danger of acquiring the habit."[8] Increasing opioid use in the United States and other Western countries, along with the unprecedented crisis in China, ultimately led to the formation of an international drug control system and widespread reforms, including the criminalization of non-clinical opioid use in the United States in 1915.[6,7,9]

The next wave of United States opioid use began in the 1960s–70s, as approximately 20% of service members returned from the Vietnam War addicted to heroin.[10,11] This was followed by a period of "opiophobia," during which both patients and doctors limited prescription opioid use due to fears of iatrogenic opioid addiction.[11,12]

Recent History

The modern opioid crisis can be traced back to the publication of two now infamous scientific articles in the 1980s. The first was a letter to the editor published in the New England Journal of Medicine in 1980 by Porter and Jick, which stated the following:

> *Recently, we examined our current files to determine the incidence of narcotic addiction in 39,946 hospitalized medical patients who were monitored consecutively. Although there were 11,882 patients who received at least one narcotic preparation, there were only four cases of reasonably well-documented addiction in patients who had no history of addiction. Addiction was considered to be major in only one instance. The drugs implicated were meperidine in two patients, percodan in one, and hydromorphone in one. We conclude that despite the widespread use of narcotic drugs in hospitals, the development of addiction is rare in medical patients with no history of addiction.*[13]

The second was a retrospective review published in the International Association for the Study of Pain journal *Pain* in 1986 by Portenoy and Foley, which included 38 chronic pain patients managed with chronic opioid therapy. It concluded, "that opioid maintenance therapy can be a safe, salutary, and more humane alternative to the options of surgery or no treatment in patients with intractable non-malignant pain and no history of drug abuse."[14] These articles were widely presented and cited to support claims about the safety of chronic opioid therapy by physicians and the pharmaceutical industry.[15,16]

As "opiophobia" was being assuaged by the medical literature, the pharmaceutical industry was concurrently innovating to create theoretically less addictive opioids, leading to the introduction of OxyContin, an extended-release formulation of oxycodone, in 1995 by Purdue Pharma. This medication, an extensive advertising campaign, and sponsorship of more than 20,000 medical educational programs were associated with an acceleration in opioid prescribing beginning in 1996.[17,18] Purdue Pharma also provided financial support to multiple professional societies that

subsequently advocated for increased attention to the treatment of pain and opioid use for chronic non-cancer pain.[1,19,20] For example, the American Pain Society introduced the "pain is the Fifth Vital Sign" campaign in 1995.[21] Beyond providing education, this campaign impacted policy among the major hospital accrediting bodies: the Department of Veterans' Affairs in 1999 and the Joint Commission in 2001.[22,23] These efforts were associated with a dramatic acceleration in opioid prescribing in the inpatient and outpatient setting in the following years (Fig. 50.1).[24]

Well-meaning physicians, pharmacists, and patients who previously minimized opioids due to fears of dependence and addiction were now utilizing opioids more liberally to avoid undertreatment of pain and be concordant with contemporary guidelines. Not all parties were found to be well-meaning. However, exacerbating the growth in opioid prescriptions during this period without resulting in patient benefit. For example, Purdue Pharma paid an $8.3 billion settlement in 2020 as part of a plea deal on three felony counts of criminal wrongdoing.[25] They are not the only pharmaceutical companies to face penalties, as settlements have been reached involving Johnson & Johnson, Mallinckrodt, and Teva Pharmaceuticals.[26]

Physicians, pharmacists, physician assistants, nurses, organized crime, and street-level drug dealers have also been implicated in the spread of prescription opioids during this time.[27] For example, one "pill mill" scheme in Arkansas involved recruiters who found patients to be inappropriately prescribed large amounts of opioids by a clinic. These patients would fill these prescriptions at the pharmacy involved in the scheme. The patients would then deliver the pills to drug dealers, and all parties involved received portions of the profits.[27] Irregular, high-volume controlled substance prescription fills could theoretically be detected and reported by drug distribution companies, but this mechanism proved to be inadequate, leading to legal settlements involving the three largest drug distribution companies: AmerisourceBergen Corp., Cardinal Health Inc., and McKesson Corp.[26]

The influx of prescription opioids in the market led to a large increase in opioid exposure in the United States. Between 1988 and 1994, the prescription opioid use rate in the past 30 days among medical and non-medical users aged 20 and over was 3.4%.[28] Between 1999 and 2002, this number grew to 5.0%, and from 2003 to 2006, this rate peaked at 6.9% and persisted until at least 2012,[29] with increased opioid usage increased opioid overdose deaths among medical and non-medical users during the first wave of the opioid crisis from 1999 to 2010 (Fig. 50.2).[30]

The second wave of the opioid crisis began in 2010, with a dramatic inflection in opioid overdose deaths involving heroin.[30] The rise in heroin use and deaths has been attributed to several factors: increased availability of high-purity heroin, prescription drug abusers turning to heroin, and heroin use beginning at a younger age.[31] As a measure of availability, heroin seizures at the Southwest border increased 352% from 2008 to 2015, according to the United States Drug Enforcement Agency.[31] Additionally, as law enforcement focused on limiting the distribution of illicit prescription opioids, an unintended consequence was opioid users being shunted to cheaper and readily available heroin. Prescription pain pill abusers were 19 times more likely to start using heroin than the general public.[32] Furthermore, the average age of heroin users dropped to as low as 21.4 years old, which was associated with higher rates of polysubstance abuse and alcohol binge drinking.[32]

In 2011, the Obama administration formally addressed the prescription opioid epidemic and revealed a plan to combat the crisis.[33] This plan detailed broad reforms involving many governmental agencies. Most notably, it initiated diverse education efforts, invested in prescription drug monitoring programs (PDMPs), encouraged appropriate drug disposal, and removed law enforcement barriers.[33] Around this time, prescribed opioid overdose deaths stabilized, and morphine equivalents dispensed began to decline.[24,30] However, heroin use continued to grow.

In the setting of stable prescription opioid overdose deaths but increasing heroin associated deaths, the third wave of the opioid crisis began in 2013 with a rise in the use of fentanyl and other synthetic opioids.[30] Increased law enforcement efforts made the production and shipment of heroin more difficult, which may have shifted drug production toward fentanyl. Fentanyl does not require harvesting poppies, and small shipments are profitable. Furthermore, fentanyl is found to be mixed with non-opioids such as cocaine and methamphetamine, suggesting that dealers

may add fentanyl to non-opioids attempting to leverage its addictiveness.[34,35]

As the opioid crisis persisted, several professional organizations, states, and federal agencies began releasing opioid prescribing guidelines, but these guidelines varied in their use of evidence, methods of addressing conflicts of interest, and ultimately their specific recommendations.[36] This motivated the creation of the Centers for Disease Control and Prevention (CDC) Guidelines for Prescribing Opioids for Chronic Pain released in 2016, which intended to advise primary care clinicians on how to avoid problematic prescribing habits for adults with chronic, non-cancer pain.[36] Although all pain medicine clinicians should be familiar with the full text of the CDC guidelines, the 12 primary recommendations are listed in Box 50.1.[36]

This guideline with explicit morphine milligram equivalent thresholds has had a dramatic impact on opioid prescriptions.[37] High-dose opioid prescriptions, concurrent opioid, and benzodiazepine prescriptions, and overall opioid prescription rates all declined more rapidly after the publication of the guideline.[37]

Before the end of his second term, President Obama signed two additional pieces of legislation into law to further combat the opioid crisis, the Comprehensive Addiction and Recovery Act (CARA) of 2016, followed by the 21st Century Cures Act.[38,39] CARA dedicated new funding toward the opioid epidemic and focused on prevention, overdose reversal, treatment, recovery, law enforcement, and criminal justice reform.[39] The 21st Century Cures Act supplemented this work with grant funding for substance abuse and mental health treatment.[38]

Current State

In January 2017, Donald Trump was inaugurated as president of the United States. By October 2017, President Trump declared the opioid crisis a public health emergency, which remained designated as an emergency until October 2018.[40] The emergency status led to reduced paperwork and wait times for several governmental efforts to address the crisis. However, the overall impact of this emergency declaration is a matter of debate.[41]

In November 2017, the President's Commission on Combating Drug Addiction and the Opioid Crisis released its final report with 56 recommendations.[42] This was followed in March 2018 by the release of President Donald J. Trump's initiative to stop opioid abuse and reduce drug supply and demand.[43] These two reports outline a variety of priorities and continue to impact actions by the administration. For example, they advocate increased funding of opioid-related government activities, a mass media prevention campaign, increasing access to treatment for substance use disorder, drug court rather than prison, legislation to assist former felons in finding work, and expanding law enforcement resources.[42,43] A progress update published in May 2019 by the Trump administration touted examples of its progress toward the goals of these reports: $6 billion in funding over two years to fight the opioid crisis, a large ad campaign, a reduction in opioids dispensed, increased arrests and seizures by law enforcement, increased use of medication-assisted treatment (MAT), increased naloxone prescription, and several other reported measures of success.[44]

• BOX 50.1 Recommendations From the Centers for Disease Control and Prevention Guideline for Prescribing Opioids for Chronic Pain - United States, 2016

1. Nonpharmacologic therapy and non-opioid pharmacologic therapy are preferred for chronic pain. Clinicians should consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, they should be combined with nonpharmacologic therapy and non-opioid pharmacologic therapy, as appropriate.
2. Before starting opioid therapy for chronic pain, clinicians should establish treatment goals with all patients, including realistic goals for pain and function, and should consider how opioid therapy will be discontinued if the benefits do not outweigh the risks. Clinicians should continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
3. Before starting and periodically during opioid therapy, clinicians should discuss with patients known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.
4. When starting opioid therapy for chronic pain, clinicians should prescribe immediate-release opioids instead of extended-release/long-acting (ER/LA) opioids.
5. When opioids are started, clinicians should prescribe the lowest effective dosage. Clinicians should use caution when prescribing opioids at any dosage, should carefully reassess evidence of individual benefits and risks when considering increasing dosage to ≥50 morphine milligram equivalents (MME)/day, and should avoid increasing dosage to ≥90 MME/day or carefully justify a decision to titrate dosage to ≥90 MME/day.
6. Long term opioid use often begins with the treatment of acute pain. When opioids are used for acute pain, clinicians should prescribe the lowest effective dose of immediate-release opioids and should prescribe no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than seven days will rarely be needed.
7. Clinicians should evaluate benefits and harms with patients within one to four weeks of starting opioid therapy for chronic pain or of dose escalation. Clinicians should evaluate the benefits and harms of continued therapy with patients every three months or more frequently. If benefits do not outweigh the harms of continued opioid therapy, clinicians should optimize other therapies and work with patients to taper opioids to lower dosages or taper and discontinue opioids.
8. Before starting and periodically during the continuation of opioid therapy, clinicians should evaluate risk factors for opioid-related harms. Clinicians should incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase the risk for opioid overdose, such as a history of overdose, history of a substance use disorder, higher opioid dosages (≥50 MME/day), or concurrent benzodiazepine use, are present.
9. Clinicians should review the patient's history of controlled substance prescriptions using state prescription drug monitoring program (PDMP) data to determine whether the patient is receiving opioid dosages or dangerous combinations that put him or her at high risk for overdose. Clinicians should review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every three months.
10. When prescribing opioids for chronic pain, clinicians should use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications and other controlled prescription drugs and illicit drugs.
11. Clinicians should avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
12. Clinicians should offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone combined with behavioral therapies) for patients with opioid use disorder.

Another effort by the Trump administration to combat the opioid crisis, the Prescription Interdiction and Litigation Task Force, was announced in February 2018. This task force aims to support local jurisdictions with the filing of lawsuits against prescription drug producers and distributors.[45] For example, the task force filed a statement of interest in a federal court case that combined over 600 lawsuits lodged by disparate government entities against opioid manufacturers.[46]

In addition to efforts to reduce opioid use, another development in the opioid crisis is a "swing of the opioid pendulum" back toward rational but slightly more liberal opioid prescribing.[47–49] Though the CDC guideline was in many respects a success, it also led to the creation of some inflexible policies and practices that were inconsistent with the original guidelines.[47–49] For example, misapplication of the guidelines affected the care of patients with cancer, sickle cell crises, and opioid use disorders.[47,50] The guidelines were also used to justify rapid tapers or complete discontinuation of opioids in some patients.[47,49] Such practices are not only difficult for patients but can also be associated with an increased risk of overdose death in high risk populations.[51] These concerns prompted several of the authors of the CDC guideline to provide further guidance regarding the proper application of the guidelines in April 2019.[47,48] Individualized approaches were emphasized, and hard limits, abrupt tapering, and sudden discontinuation of opioids were discouraged.[47,48]

At the time of writing, there is room for optimism in the current state of the opioid crisis. Prescription opioid dispensing has been declining every year since its peak in 2011, and it declined by 17% in 2018 alone.[24] Deaths from opioid-related overdoses may have also plateaued since the peak of 48,580 deaths in November 2017, although deaths from synthetic opioids continue to rise.[52] Overall life expectancy rose in 2018 for the first time since 2014. The CDC attributed this partially to decreased unintentional injuries, which includes opioid-related overdose deaths.[53] Part of the decline in opioid-related overdose deaths may be due to increased use of MAT for opioid use disorder. From 2014 to 2018, MAT prescriptions increased 47%, from 11 to 16.2 million.[24] Opioid misuse among youth in the United States is also trending down. For example, 2.7% of 12th-graders reported illicit prescription opioid use, the lowest percentage ever recorded since surveying began in 1991.[54] Despite these encouraging trends, the opioid crisis remains a significant problem. More people die from opioid-related overdoses than car accidents in the United States, and the number of opioid-related overdose deaths has remained essentially unchanged from November 2017 to August 2019.[52,55]

Legal Landscape

All past and present efforts to combat the opioid crisis are founded on a host of international treaties, federal and state laws, and legal precedent set by case law. While a full account of these influences is beyond the scope of this chapter, some of the most impactful are described in the following sections to provide context and a working understanding for the practicing pain clinician.

International

The most important international treaty affecting prescription opioid distribution is the Single Convention on Narcotic Drugs of 1961, which was signed by 186 countries.[56–58] The Single Convention encourages a balance between the dual obligations of minimizing opioid abuse and ensuring opioids are available for legitimate medical and scientific purposes.[57,58] These requirements stipulate the authorization and licensing of all parties involved in the medical distribution of opioids, a valid prescription for patients to receive opioids, and barriers to abuse that are not so high as to limit reasonable use.[57,58] Interestingly, much of the global work of the International Narcotics Control Board, the United Nations agency responsible for monitoring compliance with the Single Convention, has been focused on increasing access to opioids for appropriate medical needs.[59] While the United States battles the opioid crisis, approximately 75% of the world population is without adequate access to medications containing opioids.[59]

Federal

Until the early 20th century, opioid use was effectively unregulated in the United States.[60] Opium, morphine, or heroin could be widely obtained.[60] This changed with the passage of the Harrison Narcotics Tax Act of 1914.[9,60] Initially intended as a law to regulate the opioid market, it became interpreted by law enforcement as a prohibition of all opioid use except for the medical treatment of pain.[60] Non-prescription opioid use was outlawed within weeks, and MAT of opioid addiction was discontinued by 1924 due to interpretation of the Harrison Act.[60]

The next major piece of legislation to impact prescription opioid use in the United States was the Federal Food, Drug, and Cosmetic Act of 1962, which provided new authorities and teeth to the Food and Drug Administration (FDA).[61] Prior to this, the FDA had no authority to enforce proper manufacturing processes or regulate all marketing, for example.[62] This was eventually followed by the Food and Drug Administration Amendments Act of 2007, which was particularly relevant to opioid prescribing.[63] It gave the FDA the authority to determine if drug manufacturers must submit risk evaluation and mitigation strategies (REMS) for medications with anticipated harms.[63] Since then REMS programs have been established for a variety of opioid formulations, including transmucosal immediate-release fentanyl (TIRF) products and long-acting (LA) and extended-release (ER) products.[64,65] REMS programs involve educating patients and providers, and they may increase knowledge and reduce harm.[66] However, they also create a barrier to prescribing for some clinicians, thus limiting access for some patients.[67]

Between 1914 and 1970, 55 federal laws were passed to strengthen the Harrison Narcotics Tax Act.[60] In the context of the Single Convention, modernization of the FDA, the rise of methadone maintenance in the mid-to-late 1960s under legal ambiguity, increasing recreational drug use in the late 1960s, and the subsequent "War on Drugs," preexisting federal laws were consolidated into the Comprehensive Drug Abuse Prevention and Control Act of 1970, which included the Controlled Substances Act (CSA).[60,68–70]

The CSA is now the primary law dictating prescription opioid distribution in the United States, and it is primarily enforced by the Drug Enforcement Administration (DEA).[68,71] Importantly, while trying to prevent the illicit distribution of opioids and other controlled substances, the CSA aims to conform to the Single Convention and ensure the availability of opioids for legitimate medical purposes.[68,72] Furthermore, while controlling the distribution of prescription opioids, the CSA does not define or give the DEA the authority to define appropriate medical practices. This responsibility is left to the state.[68,71]

The CSA is responsible for establishing the one through five scheduling classification schema of controlled substances.[68] Controlled substances are placed into one of the schedules based on medical usefulness and abuse potential (Box 50.2).[68] Briefly, Schedule I drugs are those with no accepted medical use and a high abuse potential.[68] However, there is debate about which substances should belong in this class.[73] For example, it includes "marijuana," which has established medical value for a variety of conditions.[68,73] Schedule II drugs are those with medical use and high abuse potential, which includes most opioids.[68] Notably, Schedule II drugs can only be prescribed for up to 30 days and cannot be refilled, though they can be prescribed sequentially for up to 90 days.[68,74] Schedule III medications have less abuse potential and include codeine combination products as well as buprenorphine.[71] Schedule IV medications have even lower abuse potential and include tramadol.[71] Both Schedule III and IV prescriptions can be refilled up to five times.[68] Lastly, Schedule V includes the least abusable substances, like compounds with very low doses of opioids used for cough suppression or as antidiarrheals.[71]

Another significant component of the CSA was the explicit legalization of opioid prescription for addiction treatment, not just for pain.[68] Opioid maintenance for addiction was distinguished from prescribing for pain. However, all sites must register as opioid treatment programs to be allowed to prescribe opioid detoxification or maintenance.[68]

State

The power to regulate medical practice lies with states and their medical licensing boards, either through legislation or regulations. These regulatory powers must comply with federal law and the Single Convention.[71] Though each states' laws differ, nearly every state has adopted some form of the Federation of State Medical Boards' 2017 Guidelines for the Chronic Use of Opioid Analgesics.[71,76] These guidelines are intended as a resource for state medical boards in assessing physician use of opioids in a "medically appropriate manner."[76] Every clinician who manages pain should be aware of the laws and regulations specific to his or her state. Nevertheless, a variety of legal issues apply to all states.[77]

Maintaining a balance between the availability and regulation of opioids remains important, especially in the age of the opioid epidemic.[77] For example, primary care providers in Washington must consult a pain physician for patients who receive a morphine equivalent dose (MED) greater than 120 mg.[78] However, if pain physician consultations are not accessible due to distance or insurance coverage, this requirement could create an imbalance. Imbalance can also be created by overly restrictive prescription limitations in terms of quantities or days.[77]

Another issue is state classifications of addiction.[77] Defining addiction by physiologic dependence or tolerance, without the necessary behavioral components, can falsely label patients on chronic opioid therapy as "addicts."[77,79] Beyond being incorrect, this can have other legal ramifications depending on opioid prescribing laws targeted toward those with true substance abuse disorders.[71,77] Furthermore, for those with substance abuse disorders, laws should aim to limit abuse, but they should not prevent patients with substance abuse disorders from receiving adequate treatment for pain.[71,77]

Of equal importance to how laws and regulations are written is how they are interpreted. Regardless of what is intended,

• BOX 50.2 The United States Drug Enforcement Administration Drug Scheduling[75]

Schedule I

Schedule I drugs, substances, or chemicals are defined as drugs with no currently accepted medical use and a high potential for abuse. Examples of Schedule I drugs are as follows:

Heroin, lysergic acid diethylamide (LSD), marijuana (cannabis), 3,4-methylenedioxymethamphetamine (ecstasy), methaqualone, and peyote.

Schedule II

Schedule II drugs, substances, or chemicals are defined as drugs with a high potential for abuse, potentially leading to severe psychological or physical dependence. These drugs are considered dangerous. Some examples of Schedule II drugs are as follows:

Combination products with less than 15 mg of hydrocodone per dosage unit (Vicodin), cocaine, methamphetamine, methadone, hydromorphone (Dilaudid), meperidine (Demerol), oxycodone (OxyContin), fentanyl, Dexedrine, Adderall, and Ritalin.

Schedule III

Schedule III drugs, substances, or chemicals are defined as drugs with moderate to low potential for physical and psychological dependence. Schedule III drug abuse potential is less than that of Schedule I and Schedule II drugs but more than Schedule IV. Some examples of Schedule III drugs are as follows:

Products containing less than 90 mg of codeine per dosage unit (Tylenol with codeine), ketamine, anabolic steroids, testosterone.

Schedule IV

Schedule IV drugs, substances, or chemicals are defined as drugs with a low potential for abuse and a low risk of dependence. Some examples of Schedule IV drugs are as follows:

Xanax, Soma, Darvon, Darvocet, Valium, Ativan, Talwin, Ambien, Tramadol.

Schedule V

Schedule V drugs, substances, or chemicals are defined as drugs with a lower potential for abuse than Schedule IV and consist of preparations containing limited quantities of certain narcotics. Schedule V drugs are generally used for antidiarrheal, antitussive, and analgesic purposes. Some examples of Schedule V drugs are as follows:

Cough preparations with less than 200 mg of codeine or per 100 mL (Robitussin AC), Lomotil, Motofen, Lyrica, Parepectolin.

practitioner misperceptions of policy can lead to reluctance to prescribe opioids, potentially limiting access.[71] In this sense, legal ambiguity itself is an issue within state control.

Beyond laws and regulations, states also play a critical role in maintaining PDMPs. Forty-nine states, the District of Columbia, and Guam have operational PDMPs.[80] The lone missing state is Missouri, though it has several city-level and county-level PDMPs.[81] Ideally, all PDMPs would provide near-real-time information, be readily accessible by clinicians at the time of prescription writing, and extract information from neighboring jurisdictions, if not all jurisdictions.[76]

Legal Decisions

In addition to adopted legislation, there is a host of litigation that has set precedents relevant to opioid prescriptions. While many could be discussed, three illustrative cases are presented. The binding nature of case law depends on the jurisdiction of pending litigation, but these cases demonstrate the range of perspectives adopted by the courts.

The first is *the Estate of Henry James v. Hillhaven Corporation*, which was decided in North Carolina in 1991. In this case, a patient with metastatic cancer achieved pain control in the hospital with opioid therapy. However, when he was admitted to a skilled nursing facility, a nurse determined that he was addicted to morphine and completely replaced his opioid with a sedative. After his stay, his estate sued the facility, arguing that a standard of care existed, was not met, and led to suffering. His estate won this case at $15 million. This case suggests that patients have the right to effective pain relief.[82]

United States v. Rosen is a case decided by the United States Court of Appeal for the Fifth Circuit in 1978 on the opposite end of the prescribing spectrum. Dr. Rosen heavily prescribed medications as part of a weight loss practice, and he was charged with 25 counts of distribution of controlled substances, leading to a five-year prison sentence.[83] To be convicted of these charges, the prosecution had to prove that he prescribed these medications without a legitimate medical purpose. By showing that his behavior was far outside standard medical practice, he was not treated as just a negligent physician who would be liable to malpractice or revocation of his license. Instead, he was prosecuted as a drug dealer and subject to criminal penalties. This case suggests that prescribing physicians can be treated as criminals if their behavior is far from the standard of care.[71]

An additional notable case was the DEA administrative decision to grant a DEA certificate of registration to Dr. David Gillis in 1993. The DEA initially attempted to deny Dr. Gillis the opportunity to register for a DEA license because they claimed he was prescribing opioids to known drug abusers. However, because it was shown that the physician was prescribing to treat pain, the physician's actions were deemed legitimate by an administrative decision.[84] This clarified the ability to prescribe to treat pain regardless of addiction. Ultimately, the purpose of prescribing is most relevant, not the patient himself/herself.[71]

Conclusions

Opioids play a complex role in human history. They are undoubtedly essential tools in a physician's toolbox, especially when treating acute pain. However, their addictive nature and lethality have plagued humanity. To remedy the current opioid crisis, a broad swath of stakeholders is actively working under an evolving legal and regulatory landscape. As clinicians, we must understand and assist these efforts for the betterment of our patients, as well as the community at large.

Key Points

- Opioids are an essential tool in a physician's toolbox, but their addictive nature and lethality have also plagued humanity throughout history.
- The development of OxyContin in 1996, combined with an advertising campaign and sponsorship of more than 20,000 educational programs, led to an acceleration in opioid prescription.
- The first wave of the opioid epidemic began in 1999, with a large increase in prescription opioid overdose deaths. The second wave of the opioid epidemic began in 2010, as former prescription opioid users transitioned to heroin. The third wave of the opioid epidemic started in 2013, as fentanyl became more abundant in the illicit opioid supply.
- The CDC guidelines for opioid prescription were released in 2016 and led to a decline in opioid use. However, clarification was released in 2019, emphasizing individualized approaches and the avoidance of hard limits, abrupt tapering, and sudden discontinuation of opioids.
- 10.3 million Americans misused opioids in 2018, 9.9 million of which misused prescription pain medications. This was associated with over 48,000 opioid-related overdose deaths that year alone.
- Ultimately, pharmaceutical companies, drug distributors, pharmacies, physicians, nurses, and pharmacists share some responsibility for the opioid epidemic.
- Current and future efforts to combat the opioid crisis are necessary, but all efforts must maintain a balance between preventing the abuse of opioids and making them available for legitimate medical purposes.
- Pain physicians must understand the ongoing efforts to contend with the opioid epidemic and their roles in these efforts.

Evaluation for Opioid Management: Opioid Misuse Assessment Tools and Drug Testing in Pain Management

ROBERT N. JAMISON, SAMANTHA CURRAN

Background and Overview of Pain Issues

Chronic pain, defined typically as pain lasting longer than three months,[1] is a global problem that can negatively impact every facet of daily living.[2,3] It is estimated that in the United States, there are between 50 and 100 million adults with chronic pain, affecting more individuals than heart disease, diabetes, and cancer combined.[4] Chronic pain contributes to psychological distress, social isolation, sleep disturbances, and job loss and is the major reason people visit their primary care physicians.[5] Chronic pain is known to interfere with routine daily activities and negatively affect appetite, mood, energy level, and sexual activity. Persons with chronic pain often have recurrent worried thoughts about finances, family interactions, and future disability.[6] It is estimated that chronic pain costs up to $635 billion annually in healthcare expenses and lost productivity in the United States alone-more than any other chronic disease.[4] Treatment for chronic pain is three times more expensive than treatment for similar conditions without chronic pain.[7] The burden caused by chronic pain is escalating because of the increasing average age and associated medical comorbidities that come with living longer.[5] Chronic pain represents a significant public health challenge because of the lack of adequate assessment and treatment and noted disparities in the experience of pain among population subgroups.[4]

Opioids are known to be useful in the treatment of acute and cancer-related pain.[8] It is estimated that between 5 and 8 million Americans use opioids for the management of chronic non-cancer pain.[9] More recently, providers have become reluctant to prescribe opioids for the treatment of chronic non-cancer pain because of concerns regarding tolerance, dependence, and addiction, as well as uncertainty about their long term benefit in this setting.[10] There has been a dramatic increase in opioid-related deaths,[11] and significant media attention to concerns of addiction predominately from prescription opioid use,[12] resulting in what has been known as the "opioid crisis."[13,14] This crisis was attributed, in part, to the steady increase in the use of prescription opioids in the United States,[15,16] that was seen as the main contributing factor to the increased incidence of prescription opioid abuse,[17] and opioid-related overdoses and hospitalizations.[11,18] In the United States, prescription opioids are responsible for more deaths than cocaine and heroin combined and are known as the most abused drug class.[19,20] Although this percentage has been gradually decreasing, for a time the United States consumed an estimated 80% of all prescription opioids worldwide.[21] Persons who abused prescription opioids in the past believed that they were safer and more accessible than street drugs, often available as left-over medication from family and friends, and perceived to be pure because of increased regulations on the manufacturing of prescription drugs. Many providers who manage patients with chronic pain have limited training in the assessment and treatment of pain. They are unaware of risk assessment strategies and methods for close monitoring of persons receiving prescription opioids. Studies have shown that those at risk of misusing opioids tend to be the ones most likely to be prescribed opioids for pain.[22]

In this chapter, we present definitions of terms related to opioid misuse and abuse and share information on the prevalence of prescription opioid misuse. We will give an overview of risk factors and risk assessment strategies designed to improve opioid compliance. Last, we will briefly discuss behavioral interventions designed to improve and maximize compliance and explore future considerations for improving patient engagement.

Terminology

It is important to have a clear understanding of the terms used to describe the problem of prescription opioid abuse. Often abuse is used to describe non-medical use, misuse, and/or addiction. Therefore it is important to first define the terms used to describe this multidimensional problem. The definitions used in this chapter are presented in Table 51.1. For the purpose of this chapter, we define abuse as any repeated use of an illegal drug or the intentional self-administration of a medication for the express purpose of altering one's state of consciousness and achieving euphoria (such as getting high).[23,24] In contrast, misuse is the use of any drug in a manner other than indicated or prescribed, but not necessarily with unlawful intent. For example, a patient may split a pill to reduce the dose or double-up on the dose for added pain relief. In contrast, addiction is a primary,

TABLE 51.1 Definitions of Terms

Term	Definition
Aberrant drug-related behavior	Any behaviors that suggest the *potential* presence of substance abuse or addiction.
Abuse	Use of an illegal drug or the intentional self-administration of a medication for a non-medical purpose such as altering one's state of consciousness, e.g. getting high.
Addiction	A primary, chronic, neurobiologic syndrome characterized by behaviors that include one or more of the following: (1) impaired control over drug use, (2) compulsive use (that may interfere with function and performance of regular duties), (3) continued use despite harm, and (4) craving (e.g. preoccupation and obsession).
Diversion	The transfer of a controlled substance from a lawful to an unlawful channel of distribution or use.
Misuse	Use of any drug in a manner other than indicated or prescribed, but not necessarily with unlawful intent.
Physical dependence	A state of adaptation manifested by a drug class-specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of drug, and/or administration of an antagonist.
Pseudoaddiction	The presence of aberrant behaviors suggestive of abuse (e.g. "doctor shopping") that in reality signifies undertreated pain.
Tolerance	The need for increasing doses to obtain the same effect.

chronic, neurobiologic syndrome characterized by behaviors that include impaired control over drug use, compulsive use (that may interfere with function and performance of regular duties), craving, and continued use despite harm. Addiction refers to a behavioral pattern of substance abuse characterized by overwhelming involvement with the use of a drug. The compulsive use of the drug results in physical, psychological, and social harm to the user, and use continues despite this harm. Iatrogenic addiction is an addiction that results from exposure to opioids for acute pain.

Aberrant drug-related behaviors are any behaviors that suggest the potential presence of substance abuse or addiction (e.g. "doctor shopping").[10,25–27] Pseudoaddiction has been a term used to describe behavior that was thought to reflect addiction but which disappeared after suitable amounts of medication was given for the treatment of pain.[28] For example, it was thought that any patient with undertreated pain, due perhaps to the provider's fear of addiction or abuse, who sought care from another physician for the purpose of adequately relieving pain might have had signs of pseudoaddiction. It is uncertain whether this condition exists and was used in the past to support the increased use of opioids. However, this term has recently gone out of fashion.

Physical dependence is a condition of physiologic withdrawal after the dose of many medications, including an opioid, is rapidly reduced. Withdrawal symptoms are generally specific for the class of substance involved, e.g. opioids, and benzodiazepines. This is noted to occur among all mammals who have been administered opioids over time. After a rapid dose reduction, including decreased blood levels of an opioid and/or administration of an antagonist, signs of withdrawal may include diarrhea, rhinorrhea, piloerection, insomnia, irritability, and psychomotor agitation.[29,30] The effects of opioid withdrawal can be reduced by gradually tapering the dose downward over an extended period. Physical dependence is a common condition of anyone actively using opioid therapy on a chronic basis and is not considered an addiction. Tolerance is another phenomenon associated with the long term use of opioids, where there is a need for increasing doses to obtain the same effect.[23,24,31]

Diversion has been defined by the Drug Enforcement Administration as a redirection of a controlled substance for use in an unlawful manner.[32] Drugs can be diverted by being stolen or being sold on the street. Additionally, it includes obtaining the medication from a legitimate source for legitimate means but used for an illegal purpose such as selling the drug to get high. Among adults 50 years and older, the main source of receiving opioids is through a physician's prescription, with this age group making up 25% of the individuals who self-reported opioid misuse. For individuals under 50 years old, it is more commonly reported that opioids were obtained from an illegal source.[33]

Prevalence of Prescription Opioid Misuse and Addiction

Addiction is generally understood to be a chronic condition from which recovery is possible. However, the underlying neurobiologic dysfunction, once manifested, is believed to persist.[12,34] Therefore the prescription of opioid analgesics to a patient with a predisposition for or history of addiction could initiate an addictive disorder or relapse. Some of the disparity between the results of studies reporting an extremely low risk of addiction for hospitalized patients and the high proportion of substance abuse in the general population can be explained by the unreliable methodology of existing surveys of iatrogenic addiction (e.g. addiction as a result of exposure to opioids for acute pain) in hospitalized patients.

Although there has been a lack of high-quality evidence or consistent findings on the prevalence of substance abuse among persons with chronic pain, there is a trend to suggest that escalating doses of opioids among those with chronic non-cancer pain is associated with increased risks of substance use disorder and opioid-related adverse outcomes.[19] Rates of opioid misuse and addiction among persons with chronic pain have been varied and were thought to be much higher than initially published in the 1980s.[15,21,35] One reason given for the variable rates of addiction was because they were not obtained from representative chronic pain patients,[30] and vague definitions of addiction were used.[36] The studies in question examined the retrospective prevalence of cases rather than the incidence and onset of new cases of addiction.[37,38] Additionally, those

perceived to have mental health issues or substance abuse problems were often excluded. Patients with chronic pain often present with a mood disorder and a comorbid psychiatric condition, and they are likely to be prescribed opioids. Thus it has been assumed that early rates of prescription opioid abuse were low. Unfortunately, there are limited large-scale studies designed to determine reliable rates of addiction among individuals treated for chronic pain. A systematic review and meta-analysis of the incidence of iatrogenic opioid dependence and abuse revealed a pooled incidence of 4.7%.[36] The authors found that when diagnostic and statistical manual of mental disorders (DSM) criteria were used, the rates of addiction were higher (11.3%) than when using ICD-9 criteria (1.3%). Vowles et al.[39] found wide variability in prescription opioid addiction rates across studies (i.e. range: 8%–34.1%). The differences observed in opioid addiction rates are assumed to be due, in part, to differences in study populations, study designs, and settings in which opioids were prescribed. Unfortunately, when addiction is based on DSM-V criteria (opioid use disorder), the reported addiction rates tend to be much higher.

Prescription Opioid Misuse Risk Factors

Guidelines from the Centers for Disease Control (CDC) recommend that healthcare providers make every effort to identify abuse and possible diversion of prescription opioids.[18,32] The guidelines suggest that particular problematic behavior, such as seeking prescriptions from multiple providers, using illicit drugs, selling or diverting medications, snorting or injecting medications, and using drugs in a manner other than the way they were intended, should be carefully monitored. Despite the need to identify misuse of opioids and limit inappropriate prescribing, healthcare professionals need to provide appropriate pain relief for individuals who have evidence of genuine pain problems.[29]

Additional problems associated with chronic use of opioids include psychological dependence,[40,41] impaired cognition, problems with psychomotor function,[42] and possible development of opioid-induced hyperalgesia (OIH).[43,44] High-dose opioids, which some define as greater than 180 mg morphine equivalent a day, have been known to lead to sleep apnea, respiratory depression, and disordered breathing. Of most concern is the risk that greater dependence on opioids can lead to addiction.[12,21] This strongly supports the need for risk assessment at the point of opioid initiation and for continued careful monitoring,[15,45,46] maintaining lower doses of opioids when indicated,[18,20,47] tracking compliance,[10,24,48] and offering an interdisciplinary approach to pain management.[49,50]

There are identifiable characteristics of those individuals who are at lower risk of misusing opioids. In particular, those who are older, who present with stable mood, have a record of being reliable in keeping appointments and in following medical recommendations, who have no history of overusing medications, who have no cognitive deficits, and who are generally pleasant are at lower risk of opioid misuse.[20,50] Equally, there are characteristics of those who are at higher risk of medication misuse. These include those who are younger and have a history of risk-taking behavior, who have a history of legal problems, who are in frequent contact with others who misuse substances, who have a mood disorder, and who have a personal or family history of substance abuse.[50] Additional factors include previous drug or alcohol rehabilitation, history of early childhood abuse and trauma, multiple stressors, smoking cigarettes, or regularly using other substances that lead to dependence (Table 51.2).[51–53]

TABLE 51.2 Risk Factors for Opioid Misuse

- Family history of substance abuse
- Personal history of substance abuse
- Young age
- Mood disorder such as extreme anxiety, depression, and/or irritability
- History of criminal activity and/or legal problems, including driving under the influence
- History of childhood abuse and/or trauma
- Regular contact with others who misuse substances
- Problems with past employers, family members, and friends (personality disorder)
- Risk-taking or thrill-seeking behavior
- Heavy tobacco use or use of substances that lead to dependence
- Psychosocial stressors
- Prior drug and/or alcohol rehabilitation

An important reminder to anyone prescribed opioids for chronic pain is that they ultimately are the ones who must manage the opioids in a responsible manner, and they need to be vigilant about factors that may contribute to opioid abuse. It is important to remind anyone using prescription opioids for pain of factors that may increase their susceptibility of encountering problems. These factors may include impulsivity,[54,55] predispositions to self-medicate symptoms of anxiety or depression,[56,57] and experiencing drug liking or craving of the medications.[58,59]

Negative Affect and Opioid Misuse

We know that there is an overlap between chronic pain and mood disorders, including depression, anxiety, and irritability perceived by some to be a normal response to prolonged pain.[60,61] Psychiatric comorbidity is common among chronic pain patients.[62] It is estimated that 30% to 40% of pain patients in primary care centers have a significant psychiatric comorbidity and show signs of negative affect.[63,64] These percentages increase between 50% and 75% among patients treated at specialty pain centers.[65] Additionally, there is a high incidence of self-reported physical or sexual abuse and early childhood trauma among persons with chronic pain,[66] making psychiatric problems the most prevalent comorbidity in these patients.[67,68] There is a well-established relationship between increased self-reported emotional distress and increased pain sensitivity and pain-related disability.[68,69] An analysis of large insurance claims data performed by PharmMetrics of 36 million patients from 61 health plans comparing patients with anxiety and depression with matched controls found that those who had evidence of negative affect (high anxiety and depression) had more somatic complaints, more pain, and had greater utilization of medical services.[70]

Opioid Therapy and Mood Disorder

In an earlier survey study conducted by Arkinstall and colleagues, patients prescribed opioids were found to have a 50% prevalence of a mood disorder.[71] Grattan and others reported that it was more likely that patients would be prescribed opioids for their mood disorder and affective distress than their reported pain severity or physical pathology.[65]

Several studies have demonstrated that persons with chronic pain with significant psychopathology tend to demonstrate poorer outcomes than those with minimal psychopathology. These individuals

report greater pain intensity and more pain-related disability.[72,73] Elevated anxiety and depression are common among chronic pain patients, and having a mood disorder is correlated with poor rates of return-to-work.[74] In a blinded controlled trial examining the benefits of IV morphine compared with saline among chronic pain patients, those individuals who demonstrated higher levels of psychopathology reported the least reduction of pain when administered IV morphine.[72] Thus there is consistent evidence that individuals with chronic pain and significant negative affect benefit less from opioids and many other treatments designed to control their pain.[50,67]

Studies have found that individuals with chronic pain and high rates of emotional distress and negative affect are much more likely to misuse opioid medications.[65,75,76] There is some indication that certain patients use prescription opioids to help reduce their anxiety and depression.[74] Although many patients with emotional distress and a mood disorder also have a substance use disorder, a study among chronic pain patients without a history of substance abuse showed that having increased anxiety and depression increased the incidence of opioid misuse.[59,77] Taken together, there is evidence that attempts at reducing affective distress can cause reduced risk of substance abuse.[58]

Risk Assessment Tools

With recent attention to the "opioid crisis," healthcare providers have been challenged with the need to provide appropriate relief from pain while avoiding risks associated with the use of opioids. This has contributed to a greater need to employ risk assessment measures to identify those who are more predisposed to misuse of prescription opioids.[40,41] Guidelines from healthcare organizations and regulatory institutions have strongly encouraged the use of risk assessment screening tools.[78,79] Stressed within these guidelines is the importance of thoroughly evaluating all potential users of prescription opioids by conducting a complete social and medical history, with a medical examination and a review of medical records.

There are several validated and reliable self-report screenings that can help to assess the risk of opioid misuse. Unfortunately, many of the recommended ways to assess substance use disorders and alcohol dependence, particularly through the criteria outlined in the DSM, fifth edition (DSM-V), have not been validated with chronic pain patients.[80] These measures tend to use signs of opioid dependence and tolerance as indicators of abuse and addiction when no abuse exists.

Over the years, several screening measures have been developed that have been shown to be particularly useful in assessing the risk of prescription opioid abuse among persons with chronic pain. These include the Screener and Opioid Assessment for Patients with Pain—Revised (SOAPP-R),[81–83] that is a trait measure of abuse risk. Shorter versions of this measure[84–86] and a Spanish translation exist.[87] A sister questionnaire that assesses states of abuse risk (e.g. can change over time) is the Current Opioid Misuse Measure (COMM).[88,89] Both the SOAPP-R and COMM have been cross-validated and used extensively in clinics and research protocols.[90,91] A shortened version of the COMM also exists.[92] Other self-report questionnaires include the Opioid Risk Tool (ORT),[93,94] the Diagnosis, Intractability, Risk, and Efficacy (DIRE) scale,[95] the Drug Use Disorders Identification Test (DUDIT),[96] the Drug Abuse Screening Test (DAST),[97,98] the Screening Instrument for Substance Abuse Potential (SISAP),[99] the Pain Medication Questionnaire (PMQ),[100] and a single item of catastrophizing that is useful in predicting opioid misuse among chronic pain patients.[101] A systematic review by Lawrence and colleagues (2017) found the SOAPP-R, COMM, and PMQ to be most valid to assess the risk of problematic analgesic use among patients with chronic pain.[102] The ORT has been popular because of its brevity (five items), and a revised ORT that omitted the question about prior childhood sexual abuse now finds comparable opioid risk between men and women.[103] A brief checklist designed to reflect the content of a standard opioid agreement (opioid compliance checklist, OCC) has also been validated and used clinically.[10,25]

Although there are weaknesses with using any self-report measure of opioid risk, and it is always possible to under report problems, these validated self-report screening tools are one of several ways to gain some understanding of the chronic pain patient and help identify those with a predisposition for opioid misuse. It is important to state that while higher scores on these measures may not eliminate the option of prescribing opioids, they may draw attention to the need for more careful tracking and monitoring of certain individuals.[102] Brief descriptions of these assessments and other tools are provided in Table 51.3.

Strategies for Managing High Risk Patients

Practice Guidelines

Treatment approaches are needed that balance the proper treatment of chronic pain while minimizing the risks associated with opioid use. There has been a dramatic increase in the use of opioids for non-cancer pain over the past few decades, and guidelines from the CDC and elsewhere have been published about the steps needed to reduce abuse, diversion, and addiction as a result of prescription opioids.[104,105] These guidelines strongly recommend using validated screening instruments designed to identify individuals at higher risk of opioid misuse in clinical practice. The goal of these screening instruments is to reduce the risk of iatrogenic addiction. Risk assessment should be combined with a review of past medical records and a thorough history and physical examination—since each assessment process alone may not be accurate in identifying those individuals who are not suitable candidates for opioids or who might need very careful monitoring. Initial screening should also include the history of and current comorbidity of substance abuse. Urine toxicology screening is recommended, and the monitoring of prescribed opioids through a prescription drug monitoring program (PDMP). In addition, opioid therapy agreements and the practice of universal precautions are highly recommended.[106,107] Together, these combined strategies help to reliably stratify risk levels and help tailor treatments to match this risk. There has been a recent trend to prescribe lower daily doses of opioids over a shorter period,[108] although a recent systematic review suggests that prescribing higher doses of stronger opioids does not always predict increased incidence of opioid dependence and abuse.[36]

Urine Toxicology Screening

The use of urine toxicology screens to establish prescription opioid compliance is well documented.[109] Most hospital-based toxicology screens use immunoassay to determine the presence or absence of a class of drug in the urine sample. The use of gas chromatology/mass spectrometry (GCMS) allows the determination of the quantity of each drug present. GCMS offers a test of creatinine levels to determine possible tapering and establishing the absence

TABLE 51.3 Opioid and Medication Abuse Screening Assessments

Name of Questionnaire	References	Purpose of Questionnaire
Current Opioid Misuse Measure (COMM)	Butler et al. 2007; 2010; McCaffrey, 2019[88,89,92]	Seventeen item self-report assessment developed for identifying chronic pain patients who are currently misusing prescription opioids. The opioid risk cutoff score is nine. The reliability and predictive validity of the COMM were found to be highly significant. A shorter version has been developed and validated.
Diagnosis, Intractability, Risk, and Efficacy (DIRE)	Belgrade et al. 2006[95]	Predicts the feasibility of long term opioid treatment for non-cancer pain. Also used to pinpoint beneficial factors, if any, of an individual's opioid use. The opioid risk cutoff score is 14.
Drug Abuse Screening Test (DAST-2)	Tiet, 2017; Giguere, 2017[97,98]	Two item version of the longer DAST to assess evidence of substance use disorders. This test has not been validated for chronic pain patients.
Drug Use Disorders Identification Test (DUDIT)	Hildebrand, 2015[96]	Eleven item drug use disorders assessment tool that was developed for those exposed to opioid analgesic therapy. This was not initially developed for persons with chronic pain.
Opioid Compliance Checklist (OCC)	Jamison et al. 2014; 2016[10,25]	Twelve item questionnaire developed to assess compliance for chronic pain patients on long term prescription opioids. Five items were found to best predict subsequent aberrant behaviors based on multivariate logistic regression analyses.
Opioid Risk Tool (ORT)	Webster and Webster, 2005; Webster and Dove, 2007; Cheatle et al. 2019[93,94,103]	Five item checklist that allows the physician to determine if a patient will display aberrant drug-related behaviors. The opioid risk cutoff score is eight. An updated version without a history of childhood sexual abuse has been validated.
Pain Assessment and Documentation Tool (PADT)	Passik et al. 2004[137]	Forty-one item questionnaire that provides extensive documentation of the patient's progress and objectively monitors a patient's care. There is no numeric scoring method for this assessment.
Pain Catastrophizing Item	Lutz, 2017[101]	One item from the coping strategies questionnaire assessing catastrophizing that is shown to predict the risk of opioid misuse. It is highly correlated with the SOAPP-R.
Prescription Medication Questionnaire (PMQ)	Holmes, 2006[100]	A self-report questionnaire designed to assess risk for opioid medication misuse among chronic pain patients.
Prescription Drug Use Questionnaire (PDUQ)	Compton et al. 2008[116]	Forty-two item questionnaire used to identify subjects who are likely to be nonaddicted, substance abusing, or substance-dependent.
11. Screening Assessment for Substance Abuse Potential (SISAP)	Coambs et al. 1996[99]	Five item self-report screening questionnaire for substance abuse potential catered mostly toward alcohol abuse.
12. Screener and Opioid Assessment for Patients with Pain-Revised (SOAPP-R)	Butler et al. 2004; Butler et al. 2008; Butler et al. 2009; Butler et al. 2013; Finkelman et al. 2015, 2017; Black et al. 2018[81–87]	Twenty-four item self-administered screening tool designed to predict aberrant medication-related behaviors for chronic pain patients being considered for long term opioid therapy. The opioid risk cutoff score is 18. The reliability and predictive validity of the SOAPP-R were found to be highly significant. Shorter versions have been developed and validated.

of prescribed opioids or the presence of nonprescribed or illicit substances.[110] Providers rely on regular urine toxicology screenings as an objective way to assess compliance. Over time, despite their limitations, these tests have become more accurate with fewer false positives.[109,111] For those prescribed opioids for pain who are perceived to be at lower risk of opioid misuse, a toxicology screening at least once a year is recommended. More frequent screens are recommended for those who are identified as at higher risk of opioid misuse.[112]

In a study of 226 patients with chronic pain, 46.5% of these patients prescribed opioids for pain showed evidence of an abnormal urine toxicology screen, which underscores the importance of urine screens.[113] Many clinics use immunoassay urine screens as the first line of analysis, followed by the completion of GCMS testing when it is important to detect the specific level of drug metabolite in the urine. Because random urine toxicology screening has revealed a high incidence of abnormality, the use of self-report measures of risk alone may not be optimal, and a combination of urine toxicology screens, opioid checklists, and tracking the PDMP would be optimal.

Prescription Drug Monitoring Program

There has been an increased focus on government and regulatory action to help reduce opioid abuse and diversion. One instituted state-wide initiative has been PDMPs. This effort was designed to analyze and monitor electronic prescription data primarily from pharmacies. There has been a gradual increase in the use of PDMP

data among states.[3] The goal is to obtain reliable data collection of opioid use to help identify the use of prescription opioids.

Opioid Therapy Agreements

Specialty pain clinics have used opioid therapy agreements for many years to inform patients who are prescribed opioids for pain about the expectations and the proper use of opioids. These agreements are designed to inform the patients of potential risks with opioid use and to improve patient compliance with opioid medication.[106,114] These agreements serve to educate the patients in their need to be responsible with their use of prescription opioids and to document the risks associated with misuse. By agreeing to the expectations of use, the providers and patients can acknowledge in writing what would be expected of all the parties for adherence to opioid use. Although the evidence is weak that opioid therapy agreements improve adherence, they are universally recommended.

In most opioid therapy agreements, there are conditions required of the patient to remain on opioid therapy. Although not a legal document, the patients are made aware of potential risks and adverse effects associated with opioid use.[10,25] Typically, patients are informed that they should use the medication only as prescribed, that they should receive opioid medication only from one provider and one pharmacy, that they will not be given extra medication if they run out early over the designated time of the prescription, and additional medication will not be substituted if lost or stolen. They also agree to periodic urine toxicology screens and to be responsible for keeping their clinic appointments. If, as perceived by the prescribing physician, it is determined that the risk of opioid therapy outweigh the benefits, then a gradual tapering of the opioids would take place.[3,53]

It is important to review each component of the agreement with the patient and to have a signed copy saved in the electronic medical record. Clarification of all components of the agreement is important so that all parties are aware of what is expected. Signing the agreement and distributing copies to all involved helps to acknowledge the conditions and responsibilities set by the clinic. It is recommended that this agreement be read and signed each year that opioids are being prescribed for pain. This will serve to remind the persons with pain of their responsibilities for using prescription opioids and the need to be very careful with these substances. Additionally, patients should be reminded periodically that violation of the agreement could result in a gradual discontinuation of the opioids. The opioid compliance checklist is an eight item checklist that is administered monthly to those prescribed opioids for pain and was created based on a typical opioid agreement.[10,25] It serves to document adherence of the opioid users. The responsibility of maintaining compliance with opioids is up to the patients receiving this medication, but physicians should remain vigilant in tracking compliance and verifying adherence.[3] Unfortunately, the evidence in support of the effectiveness of opioid therapy agreements in reducing opioid misuse and abuse has been weak, but their use is very much encouraged in opioid therapy guidelines.[115]

Behavioral Strategies to Improve Opioid Treatment Adherence

Providers are often conflicted about ways to best manage chronic pain patients who have clear pathology to account for their pain but who also are at high risk for opioid misuse. Many choose to avoid the use of prescription opioids altogether. If the need arises to consider opioid therapy for individuals who have predisposing factors for opioid misuse (e.g. postoperative pain; see Table 51.2), certain strategies may be needed to help increase opioid compliance and avoid opioid abuse. In a randomized trial, high risk patients with primary lower back pain either received interventions to assist with improving opioid compliance or were assigned to a treatment as the usual control condition. A low risk patient group was also recruited. All subjects were followed for six months. Those in the high risk experimental group were asked to give a urine toxicology screen at each monthly appointment, complete an opioid compliance checklist, attend individual cognitive behavior motivational counseling, and participate in monthly group sessions designed to address ways to avoid opioid misuse.[53] Subjects who admitted to opioid misuse on the prescription drug use questionnaire (PDUQ),[116] who had abnormal urine, or who showed a positive score on the physician-rated addiction behavior checklist (ABC)[117] were classified as positive on the opioid misuse index (OMI). Results showed that those high risk subjects who were carefully monitored and who received motivational counseling showed significantly lower opioid misuse indexes than the high risk controls and, in fact, had as low an indication of opioid abuse as those designated as low risk subjects. These findings suggest that risk assessment and careful monitoring with cognitive behavior support can significantly improve opioid compliance and adherence.

It has now been recommended that anyone prescribed opioids for pain should be administered a comprehensive assessment. This would include a self-report questionnaire and a detailed history and physical. All patients should read and sign an opioid agreement and be monitored based on their level of risk. However, for those at greatest risk for opioid misuse, a lower dose of prescription opioids, regular urine screens, completion of an opioid compliance checklist, and motivational counseling would be recommended. Some providers encourage the use of pill counts.[3] The ultimate result is that with careful monitoring and risk assessment, the opportunities for opioid misuse will be mitigated.[46]

Future Considerations

Newer opioid analgesics have been recently developed with the goal of deterring abuse. These so-called abuse-deterrent opioids intend to prevent abusers from injecting, crushing, snorting, and otherwise altering long-active opioid formulas.[118,119] The goal is to create safe opioids to be used by patients while making them unattractive to those who want to use the opioids for purposes leading to euphoria. Different formulations have been developed that combine the opioid with an antagonist that is released when the drug is compromised.[120,121] There is evidence that abuse-deterrent opioids have decreased the incidence of prescription opioid abuse in long-acting opioids.[122,123]

Innovative technology has been used to track opioid compliance and to educate pharmacists and physicians, which will continue to be developed. Containers and patient-specific serialized blister-packaging of opioids can be electronically monitored along with the date and time a medication is taken. There has been a rapid growth of mobile phone applications (apps) in pain assessment and management.[124–126] The advent of mHealth (mobile health) technology using short messaging service and activity monitors has promoted ways for patients to communicate with healthcare providers and track activity between clinic visits.[124,127] Not only is this technology useful in collecting information in

clinical trials, but clinics can use this information to help document outcome and compliance. Currently, 95% of the world population has access to the internet, and remote tracking and monitoring are much more accessible to patients worldwide. There is a broadening of access to information and personal health data, which can improve coping and potentially reduce healthcare utilization. There is a call for better pain education among providers,[47] increased use of social media, incorporation of online peer education, and daily support to chronic pain patients on opioid therapy.[128–130] The future will likely include the use of artificial intelligence to identify those individual characteristics to help predict the optimal outcome from opioid therapy.[130,131]

Future identification of markers for opioid benefit and abuse within endogenous chemical reactive systems will shed light on our understanding of tolerance, OIH, craving, and potential opioid misuse.[132] Longitudinal studies investigating demographic variables or gender, ethnic origin, and personality characteristics will help in creating empirically based practice guidelines. Nanotechnology is used to deliver treatment to a specific targeted area, and the development of other delivery strategies like topical preparations will add to the treatment armamentarium. Increased understanding of how acute pain develops into a chronic pain condition will aid in identifying those at risk for developing chronic pain. Increasing the use of genome research and genetics testing to help identify markers for potential opioid abuse will make a positive impact on opioid risk assessment.[133,134] There has been a recent emphasis on the use of behavioral interventions such as mindfulness to reduce craving and improve coping.[135,136] The overall reduction of suffering related to chronic pain would be the long-range goal, and increased understanding of the mechanisms contributing to pain would be what is most hoped for in the future.

Summary and Conclusions

Chronic pain is a global health problem that exacts enormous costs both in terms of money spent treating pain and lost productivity because of pain. Chronic pain inflicts an enormous human toll of suffering and disability and is often associated with psychiatric comorbidities such as emotional distress, negative affect, depression, and anxiety. There is a corresponding relationship between mood disorder and opioid misuse, abuse, and/or diversion. There has been an opioid epidemic because of lax opioid prescribing practices in the past. The future of opioid prescribing calls for careful monitoring and risk assessment, opioid therapy agreements, urine toxicology screens, the use of PDMPs, and behavioral interventions designed to improve opioid compliance. There is a role for innovative technology to help healthcare providers manage chronic pain patients who are prescribed opioids for pain. Support is critically needed for future controlled trials to help in our understanding of the best ways to offer and manage chronic opioid therapy. Continued sponsorship of research to advance our empirical understanding of the use of opioids for pain is critically needed.

Key Points

- Chronic pain inflicts an enormous human toll of suffering and disability and is often associated with psychiatric comorbidities such as emotional distress, negative affect, depression, and anxiety.
- There is a corresponding relationship between mood disorder and opioid misuse, abuse, and/or diversion.
- Because of suboptimal opioid prescribing practices in the past, there has been an opioid epidemic, and the future of opioid prescribing calls for careful monitoring and risk assessment.
- There are several validated and reliable self-report screenings that can help to assess the risk of opioid misuse.
- Opioid therapy agreements, urine toxicology screens, the use of PDMPs, and behavioral interventions are designed to improve opioid compliance.

Pain and Addictive Disorders: Challenge and Opportunity

SHANNON NUGENT, MARK BEITEL, GRETCHEN HERMES, MARINA GAETA GAZZOLA, DECLAN BARRY

Introduction

The treatment of pain in patients with comorbid addiction or substance use disorders (SUDs) is complex.[1] Traditionally, chronic pain and SUDs have been treated by separate providers in different clinical settings. Until recently, pain researchers routinely excluded individuals with SUDs from clinical trials of treatments for chronic pain. Since chronic pain and SUDs frequently co-occur, pain management specialists must be able to recognize these interrelated chronic relapsing medical conditions in the patients they are evaluating and incorporate appropriate treatment strategies for these patients. This chapter aims to provide pain providers with an up-to-date overview of research related to pain management in patients with SUDs. We focus most on opioid use disorder (OUD) because this is the most commonly examined SUD in pain management literature. After reviewing the nomenclature, the SUD diagnostic criteria, and the neurobiology of addiction, we discuss the prevalence and causes of comorbid pain and SUDs and the challenges of treating pain in this population, including patient clinical complexity and changing perspectives on the role of prescription opioid analgesics and non-opioid treatments. We review the screening, monitoring, and management of SUDs in patients with chronic pain and approaches to treat chronic and acute pain in patients with SUD, with a particular focus on cannabis use disorder and OUD. Throughout, we discuss the importance of collaboration between pain specialists and addiction clinicians and the essential role that pain providers play in treating patients with SUDs.

Nomenclature

To promote a common taxonomy, the Board of Directors of the American Society of Addiction Medicine (ASAM) in December 2019, adopted the following definition: "Addiction is a treatable, chronic medical disease involving complex interactions among brain circuits, genetics, the environment, and an individual's life experiences. People with addiction use substances or engage in behaviors that become compulsive and often continue despite harmful consequences."[1] We draw the reader's attention to three often overlooked implications of this definition: (1) addiction is a chronic relapsing medical condition or disease similar to diabetes or hypertension[2]; consequently, providers should expect patients with addiction to be symptomatic periodically, and providers should not automatically discharge patients from treatment for being symptomatic, (2) addictions are treatable; effective treatments for SUDs (i.e. those which attenuate substance use and reduce risk of overdose, infectious disease, and all-cause mortality) vary by the nature of the substance used; in the cases of addiction to alcohol, nicotine, or opioids, effective treatment often consists of a combination of Food and Drug Administration (FDA)-approved medications and counseling to facilitate lifestyle changes,[3–6] and (3) the rates of success of addiction treatment are comparable to those for other chronic medical conditions.[2] For example, the median 12 month medication adherence in a meta-analysis of patients receiving medication for OUD was 57% globally.[7] In comparison, the mean medication adherence was 59% across studies in a meta-analysis of medication adherence in patients receiving antihypertensives, lipid-lowering agents, and oral anti-diabetics.[8]

The ASAM definition stands in stark contrast to common societal misconceptions that addiction is an acute condition because of a "moral defect" or character flaw.[9–11] Since providers and patients may be influenced by such inaccuracies, clinicians need to be aware of their own assumptions (and possible biases) concerning SUDs and the people who have them.[12] Language is one way that biases are manifested. Certain words or terms used by providers (and researchers) may promote stigma among patients. Consequently, in recent years, increased attention in addiction medicine scholarship and clinical practice has focused on using neutral and person-first terminology to avoid stigmatizing individuals (e.g. "person with a SUD" rather than "addict") and to reinforce that SUDs are medical conditions.[13–15] A recent paper suggests that medical students are still being exposed to pejorative terminology about SUDs in their materials when studying for the United States medical licensing examination.[16] It is notable that government agencies and the legal system have historically used derogative language when describing addictions or the people who have them. For example, the Controlled Substances Act defines an "addict" as a person who "habitually uses any narcotic drug to endanger the public morals, health, safety, or who is so far addicted to the use of narcotic drugs as to have lost the power of self-control regarding his addiction."[17]

[1]The terms substance use disorders and addiction are used interchangeably in this chapter.

Provider language may be particularly important because patients with chronic pain and/or SUDs experience stigma and discrimination within the healthcare system, which in turn reduces treatment-seeking and the likelihood of disclosing substance use.[12,18] Multiple studies have demonstrated that physicians underestimate pain among Black and Hispanic patients and that such patients are less likely than White patients to receive analgesia in acute pain settings.[19] Providers may screen Black pain patients for drug use more than White patients and are more likely to discontinue treatment for Black patients if their drug screens are positive.[20] However, Black patients are less likely than White patients to be referred for specialty pain management.[21] Research also shows that social determinants of health, including education and wealth, might play a role in pain prevalence and severity, with patients with less wealth and lower education experiencing more and higher severity pain.[22] Consequently, it is important for providers to solicit their patients' experiences of pain and SUDs and engage in patient-centered shared decision making regarding treatment plans. We recommend that providers standardize screening and monitoring practices for patients, regardless of patient demographics (see the section on screening instruments).[20,21]

While SUDs are associated with brain and other biologic changes (see the section on neurobiology), diagnoses are based on behavioral patterns and patient reports. In the United States, providers use the *Diagnostic and Statistical Manual, fifth edition (DSM-5)* to diagnose SUDs.[23] The DSM-5 criteria for "substance use disorder" require a maladaptive pattern of substance use leading to significant impairment or distress, as manifested by at least two of the following, occurring within a 12 month period (criteria have been abbreviated)[23]:

1. The substance is often taken in larger amounts or over a longer period than intended
2. There is a persistent desire or unsuccessful effort to cut down or control substance use
3. A great deal of time is spent on the activities necessary to obtain or use the substance or recover from its effects
4. Craving or a strong desire or urge to use the substance
5. Recurrent use of the substance results in failure to fulfill major role obligations
6. Use of the substance is continued despite causing or exacerbating persistent or recurrent social or interpersonal problems
7. Important social, occupational, or recreational activities are reduced because of substance use
8. Substance use occurs in situations in which it is physically hazardous
9. Continued substance use despite the knowledge that it has caused or exacerbated ongoing or recurrent physical or psychological problems
10. Tolerance[2]
11. Withdrawal[2]

The DSM-5 also includes one "non-substance-related disorder" under its classification of "addictive disorders": gambling disorder.[23] Anecdotally, we have heard that patients describe gambling or gaming as an activity that takes their focus off of pain, and the co-occurrence of gambling disorder and chronic pain is understudied.[24–25]

[2]As outlined in the next section, which includes a description of tolerance and withdrawal, neither of these criteria are considered to have been met for individuals taking opioids solely under appropriate medical supervision.

Terms Related to the Treatment of Opioid Use Disorder

The FDA has approved three medications for the treatment of OUD: methadone (full agonist), buprenorphine (partial agonist), and naltrexone (antagonist). Collectively, they were referred to as "medication-assisted treatment." The preferred nomenclature is currently "medications for OUD," in part to emphasize the central (and not secondary) role of the medications.[26] See the section titled "Medications for Opioid Use Disorder" for more information. Opioid agonist treatment refers to the treatment of OUD involving either methadone or buprenorphine.

Neurobiology of Addiction

Over the past several decades, basic and clinical research has uncovered neuroscientific explanations of SUDs. These explanations challenge stereotypes that invoke moral weakness as a reason for drug addiction and instead provide scientific reasons for addiction, offering guideposts to treatment-seeking patients and their doctors.

Addictive substances, including opioids, cocaine, amphetamine, ketamine, nicotine, and marijuana, exert powerful effects on dopaminergic neurons, which produce euphoric states exceeding what is typically produced by endogenous levels of dopamine. These sharp increases in feelings of reward can be associated with the environmental stimuli that surround drug use. With chronic drug exposure, wear and tear on dopaminergic neurons begin to suppress the experience of reward itself, which in turn drives craving, anticipation, and the need for more drugs to satisfy drug urges.[11,27] Notably, individuals with addiction are frequently confused by their ongoing use of drugs that no longer provide pleasure. Addiction can then be understood as a motivational push to avoid the discomfort associated with dysregulated reward circuity and the distress caused by feelings of being without sufficiently numbing, activating, or altering drugs.[11,27]

In the last decade, a useful heuristic has been developed that delineates the neuroanatomy, circuits, and signaling molecules involved in the cycle of addiction from stages of binge/intoxication to withdrawal/negative affect to preoccupation/anticipation. The delineation of these separable, tractable circuits and the signaling molecules involved establishes a framework for researchers to identify therapeutic targets, potential medications, validated animal models, and clinical trials to test new pharmacologic interventions based on rational therapeutic targets.[11,27] This heuristic has had critical epistemologic value for the field researchers, clinicians, and patients—and is worth reviewing here.

In the binge/intoxication phase of addiction, drug use is motivated primarily by positive, rewarding experiences subserved by the ventral and dorsal striatum, globus pallidus, and thalamus. Illicit drugs powerfully activate neurons in these brain regions with no connection to purposeful behavior. This overstimulation leads to progressive and insidious dysregulation of the brain's natural reward mechanisms. Over time, there is a downregulation of positive reward pathways, and increasing drug levels are needed to trigger the brain reward system. Animal and human studies have shown that long term exposure to drugs of abuse impairs dopamine neurons and dopamine signaling in the nucleus accumbens. This effect appears to be mediated by the actual physical shrinkage of dopamine neurons in response to chronic drug administration.[28] This underlying neuroanatomic change reduces the capacity for reward and leaves the addict "unrewarded," amotivational, and often depressed in the absence of a drug. Research has shown that

drugs of abuse decrease the size of dopamine neurons in the ventral tegmentum and nucleus accumbens by depriving the neurons of the crucial nerve growth factor, brain-derived neurotrophic factor.[28] What started off as euphoria in response to unanticipated reward turns over time into overwhelming behavior-modifying drug craving.

During the withdrawal-negative-affect stage, the dopamine systems are compromised, contributing to dysphoric mood states while simultaneously assigning greater salience to drugs and drug related stimuli in the context of these aversive states, and healthy rewards lose motivational power as they fail to satisfy. Drug consumption triggers much smaller increases in dopamine levels in the presence of addiction (in both animals and humans). Over time, the attenuated release of dopamine renders the brain's reward system much less sensitive to stimulation by both drug related and non drug related rewards. Individuals with addictions often seek a more potent release of dopamine in more explicitly risky settings. The human costs to relationships, community, and vocation increase as the drug produces less euphoria. Adaptations in the circuitry of the extended amygdala in the basal forebrain lead to the emergence of negative emotions.

During the *preoccupation-anticipation* stage, those with addiction desire and pursue drug use. This stage of the addiction cycle is characterized by chronic relapse frequently triggered by the long term effects of drugs of abuse on the basolateral amygdala, hippocampus, and prefrontal cortex.[11,27] Notably, the hippocampus is a target of opioid receptor agonists, such as morphine, methadone, heroin, and various short-acting opiates.[29] The opioid system within the hippocampus underlies context-associative learning, which is essential for linking drugs with a particular place and set of events.[30] In addition, chronic drug use impairs the prefrontal cortex and the capacity for self-regulation, decision making, and flexibility.[11] Together, these combined effects in the amygdala, hippocampus, and prefrontal cortex explain how earnest plans to cease substance use are upended by desire, environmental context, and impulsivity.

Finally, in addition to direct brain effects of drugs of abuse, considerable evidence from population-based studies supports a positive association between psychosocial adversity, chronic distress, and addiction.[31] The contribution of stressors to substance use appeared to occur in a dose-dependent manner. Repeated or chronic prolonged stress can induce lasting changes in stress responsivity and the magnitude and duration of stress hormone response to a stressor, which in turn increases the risk of stress-related disorders and addiction.[31] Similar to drugs of abuse, stress exposure increases dopamine release in the nucleus accumbens. Given that both drugs of abuse and stress activate mesolimbic pathways, each results in synaptic adaptations in the ventral tegmental area dopamine neurons and the prefrontal cortex. While persistent and poorly controlled responses to environmental challenges contribute to the persistence of and relapse to self-administration of drugs of abuse and addiction, it is clear that vulnerability to drug use and relapse may exist prior to the use of addictive drugs on a genetic or acquired basis-histories of childhood neglect and abuse, for example, may lead to the acquisition of addiction because of underlying baseline differences in stress responsivity.[29,31,32]

Misconceptions About Physical Dependence and Addiction

Many persons with SUDs report that compared with their first use, they increased the amount of the substance over time to obtain the same effect, or that the amount of the substance used to produce the effect no longer does (i.e. tolerance). They also may report that upon abrupt cessation of substance use, their bodies exhibit a characteristic pattern of symptoms (i.e. withdrawal). Withdrawal symptoms vary according to the category of substances involved (e.g. alcohol and opioids). According to the DSM-5, an individual who takes the substance (or a similar substance) to relieve or avoid withdrawal symptoms is also considered to have met the criterion for withdrawal. Depending on the severity of the addiction and the type of substance, withdrawal symptoms can range from relatively mild (e.g. headache because of caffeine withdrawal) to life-threatening (e.g. seizures because of alcohol withdrawal). However, the presence of tolerance or withdrawal, which are hallmarks of physical dependence, is not associated with the presence of a SUD. Tolerance and withdrawal are related to pharmacologic properties. Both tolerance and withdrawal can occur when patients take prescription medications as prescribed (e.g. anti-depressants and anxiolytics). Consequently, the DSM-5 specifies that for those prescribed opioid analgesics and who take them as prescribed (in the absence of other illicit opioid use), tolerance and withdrawal should not be counted toward the number of criteria needed to meet the diagnostic threshold for OUD.

Prevalence of Substance Use and SUDs Among Those With Chronic Pain

The estimated prevalence of SUDs among those with chronic pain ranges from 1%–40%. Reasons for this variability in estimates include study differences in time frames (e.g. current vs. lifetime), assessment methods (e.g. screening versus diagnostic assessment), and populations (e.g. in treatment vs. not in treatment).[33] Nevertheless, it is clear that a sizable proportion of patients with chronic pain, including those receiving long term opioid therapy (LTOT), have comorbid SUDs.[34] In 2019, an estimated 5.3% of the United States population aged 12 years or older had an alcohol use disorder, while an estimated 3.0% had an illicit SUD.[35]

Opioids

A systematic review estimated that 8%–12% of those on LTOT met the criteria for OUD and 21%–29% met criteria for "opioid misuse."[36] Conversely, the rate of chronic pain among patients with OUD entering opioid agonist treatment is high, with estimates varying between 37% and 61% who report chronic pain.[37–43]

Tobacco

Tobacco use is common among those with chronic pain, with prevalence estimates as high as 50% (twice that of the general population).[44–46] Relatedly, nearly 60% of individuals with tobacco use disorder also experience chronic pain. In a nationally representative sample of 9,282 United States adults, respondents with lifetime chronic neck or back pain were 1.3 times more likely to smoke cigarettes than the general population, 1.8 times more likely to be diagnosed with a lifetime nicotine use disorder, and 2.4 times more likely to meet the criteria for past year nicotine use disorder.[46] Previous research supports the theory that pain may contribute to the development of tobacco use problems,[44] and that tobacco use, in turn, may contribute to the development of painful conditions such as back pain[47] or rheumatoid arthritis.[48]

Cannabis

Approximately 36% of those on LTOT report cannabis use,[49] while as many as 15% of primary care patients report past 30 day cannabis use.[33] Because of the rapidly expanding legalization and availability

of cannabis, cannabis use disorder (CUD) is increasingly common in the general population,[50] although the prevalence of CUD among those with chronic non-cancer pain has been understudied. One study identified that the rate of CUD in patients hospitalized for chronic pain increased from 1.9% in 2011 to 3.0% in 2015.[51]

Alcohol and Sedatives

An estimated 25% of patients seeking treatment for pain report moderate to heavy alcohol use.[52] In the general population, those with chronic neck or back pain compared to those without are nearly twice as likely to meet the criteria for alcohol use disorder.[53] Alcohol has been linked to worse pain outcomes, such as increased pain disability and intensity. An estimated 9%–11% of those with chronic pain who are treated in a primary care setting meet the criteria for a sedative use disorder.[54,55]

Stimulants

Chronic pain may be associated with an increased risk of stimulant use. Among a national sample of adults, stimulant use was almost twice as prevalent among those with versus those without chronic low back pain (cocaine: 22% vs. 14%; methamphetamine: 9% vs. 5%).[56] A prior study of attendees at an outpatient pain management clinic estimated that the rates of cocaine and methamphetamine use were 5% and 2.5%.[57] Importantly, stimulants and opioids influence dopaminergic receptors in the central nervous system either by activating the dopamine receptors directly or by way of the opioid receptors.[58] For this reason, there is an enhanced risk of addiction and adverse events among those who concurrently use stimulants and opioids.

Chronic Pain Among Patients With SUDs

A recent study of participants in a large academic healthcare system found that most of those with SUD had chronic pain (opioid, 75%; cannabis, 64%; alcohol, 59%; tobacco, 60%).[59] Other studies have found that patients receiving opioid agonist treatment with co-occurring chronic pain frequently report using tobacco and alcohol as well as non-medical use of cannabis, opioids, and benzodiazepines to manage pain.[37,38] Given the extent of the co-prevalence of chronic pain and addiction, it behooves pain providers and addiction providers to be knowledgeable about both chronic medical conditions.

Complexity and Confounds

The presence of either chronic pain or SUD can obscure the diagnosis and treatment of the other.[60] In SUD treatment settings, chronic pain is not routinely assessed or addressed, while the reverse holds for pain management settings. For some individuals with chronic pain and SUDs, chronic pain precedes the onset of SUD. For others, SUD precedes or occurs at approximately the same time as the onset of chronic pain.[61,62] The order of onset may have implications for how patients self-identify (e.g. a woman whose pain occurred first and who reported developing an addiction to opioids that were prescribed for pain relief may view herself as a "pain patient" and downplay the presence of SUD). Although this field of research is nascent, one study found that among 170 patients seeking treatment for co-occurring chronic pain and OUD, those whose chronic pain preceded OUD were less likely to meet the criteria for a current non-opioid SUD compared to those whose OUD occurred first.[63]

Individuals with SUDs have high rates of medical problems, including trauma related to physical and sexual assault,[64] and painful illnesses such as cirrhosis, hepatitis C, and HIV.[65–67] Accidents (e.g. motor vehicles) are among the most frequently reported causes of chronic pain among patients receiving opioid agonist treatment.[68] Conversely, having pain increases the likelihood of exposure to controlled substances.[60] High rates of psychiatric disorders, including anxiety, mood, and personality disorders, are accompanied by chronic pain, especially among those with OUD.[69–71] We note that among patients on LTOT, psychiatric disorders are associated with higher opioid doses and a higher risk of accidental overdose.[72] Given the reliance on self-report in the assessment of pain, patients with SUDs seeking opioids for the management of chronic pain may be unintentionally motivated to de-emphasize the effects non-opioid therapies may have on their pain.[60] Conversely, increased focus in recent years on opioid-related harms may have dissuaded some patients on opioid agonist treatment to seek or take opioid analgesics in cases where it might be appropriate (e.g. prescribed by an emergency department provider to manage pain following a serious motor vehicle accident).

Comorbid addiction complicates the treatment of pain in numerous ways. Patients may rely on the use of substances for analgesic and mood-enhancing properties and are more susceptible to worse pain outcomes.[73] Those with comorbid addiction and pain are also at higher risk of adverse outcomes to opioid medications, including overdose and death.[72] Consequently, pain clinicians should screen for addiction risk before and during treatments, especially for treatments involving controlled substances, and they should be prepared to either provide treatment for SUDs or offer treatment referrals.

Universal Precautions

Screening tools for SUDs can be viewed as part of universal precautions in the treatment of pain, irrespective of the proposed pain intervention. Providers can check their state's electronic prescription drug monitoring program; these data can be compared to the information provided by the patient. Patients' relatives or significant others can also be important sources of collateral information.

Gourlay and Heit developed guidelines for universal precaution guidelines for pain management comparable to those used for infection control.[74] We suggest a modified version of these guidelines that concurs with the 2016 Centers for Disease Control and Prevention (CDC) guideline for prescribing opioids to patients with chronic non-cancer pain (Box 52.1).[75] The original Gourlay and Heit step six, which assumed that opioids were appropriate as a first line pain management intervention for many patients with non-cancer chronic pain, has been revised in our modified version: "Initiate pain management intervention." According to the CDC guidelines, for the modified step six, clinicians should consider non-opioid pharmacotherapies and evidence-based non-pharmacologic pain management interventions as first line treatment (see Chapters 34, 37 for treatment of neuropathic and chronic widespread pain; Chapters 53, 54, and 55 for non-opioid medications; and Chapters 58–61 for non-pharmacologic interventions) (Box 52.1).

Substance Use Disorder Screeners

Since the rates of SUDs are high in persons with chronic pain, pain management providers should consider assessing for SUDs, regardless of the provision of opioid analgesics. We review below some common SUD screeners. If patients screen positive, they should be further assessed for DSM-5 SUDs.[23]

• BOX 52.1 The Modified Ten Steps of Universal Precautions in Pain Medicine

1. Diagnosis with appropriate differential
2. Psychological assessment, including the risk of substance use disorders (SUDs)
3. Informed consent
4. Treatment agreement
5. Pre/post intervention assessment of pain level and function
6. Initiate pain management intervention
7. Reassessment of pain score and level of function
8. Regularly assess the "four a's" of pain medicine: analgesia, activity, adverse reactions, and aberrant behavior
9. Periodic review of diagnosis and comorbid conditions, including SUDs
10. Documentation

Note: Step 6 of the original guideline was updated in line with the most recent CDC guidelines.

Screening for Risk of Mon-medical Opioid Use or Opioid Use Disorder

While the 2016 CDC guideline for prescribing opioids for chronic non-cancer chronic pain does not recommend initiation of LTOT, some people with chronic pain will likely be prescribed LTOT. Additionally, a large number of patients are currently receiving LTOT or are being actively tapered off LTOT. Thus screening for non-medical opioid use and OUD is important.[76]

Opioid Specific Screeners

The Screener and Opioid Assessment Tool for Patients with Pain, Revised (SOAPP-R),[77] Opioid Risk Tool (ORT),[78] Current Opioid Misuse Measure (COMM),[79] and Pain Medication Questionnaire (PMQ)[80] screen for non-medical opioid use behaviors. The DIRE (Diagnosis, Intractability, Risk, Efficacy) assesses the risks and benefits of continued LTOT.[81] A comparison of these screens suggests that all have some value and are most useful when supplemented by a clinical interview.[82]

Non-opioid Screeners

Common screening instruments for non-opioid substances include the alcohol use disorder identification test (AUDIT),[83] and Cannabis Use Disorder Identification Test-Revised (CUDIT-R),[84] the Drug Abuse Screening Test (DAST-10),[85,86] and the World Health Organization Alcohol, Smoking, and Substance Involvement Screening Test (ASSIST).[87] Finally, the simple four-item CAGE (Cut down, Annoyed, Guilty, Eye-opener) inventory was modified to screen for SUDs[88] (Box 52.2).

• BOX 52.2 CAGE* Questions Adapted to Include Drugs (CAGE-AID)

1. Have you felt you ought to cut down on your drinking or drug use?
2. Have people annoyed you by criticizing your drinking or drug use?
3. Have you felt bad or guilty about your drinking or drug use?
4. Have you ever had a drink or used drugs first thing in the morning to steady your nerves or to get rid of a hangover (eye opener)?

**C*, Cut down; *A*, annoyed; *G*, guilty; *E*, eye opener.

The Opioid Crisis and Evolving Guidelines for the Use of Opioid Medications to Manage Pain

As prescriptions for opioid medication for non-cancer chronic pain escalated in the 1990s, there were substantial increases in the rates of OUD, admissions to addiction treatment facilities, and overdose deaths.[89] According to data from the Centers for Disease Control and Prevention (CDC), fatal poisonings involving opioids quadrupled between 2000 and 2014 from 1.5–5.9 deaths per 100,000.[90] Because of the opioid crisis, a major focus of opioid-related research in the last decade has centered on the prevention and treatment of non-medical opioid use and OUD. Non-medical opioid use includes behaviors such as taking a higher dose of an opioid medication than prescribed, using prescription opioid medications to manage symptoms other than pain, including depressed mood and using non-prescribed substances in addition to opioid analgesics (e.g. alcohol or cannabis). While patients with non-medical opioid use do not automatically meet the diagnostic criteria for OUD, repeated exposure to opioids places those on LTOT with non-medical opioid use at a higher risk of adverse events, including addiction and overdose. As noted previously, a systematic review estimated that among individuals with chronic pain who are prescribed opioids, rates of non-medical opioid use were estimated to be between 21% and 29%, and rates of OUD were between 8% and 12%.[36] Among those hospitalized for chronic pain between 2011 and 2015, the prevalence of OUD was approximately 7%, with an upward trend between 2011 and 2015.[91] In 1990, OUD was the 11th leading cause of disability-adjusted life years; by 2016, it became the seventh.[92] It is also important to note that the prevalence of non-medical opioid use is also relatively common among the general United States population. For example, in 2019, an estimated 10 million people aged 12 years and older had misused prescription opioids at least once in the past year.[35]

In response to the opioid crisis, in March 2016, the Centers for Disease Control and Prevention (CDC) released *the guideline for prescribing opioids for chronic pain*.[75] Although the CDC guidelines were met with some controversy,[93,94] subsequent studies continue to call into question the long term efficacy of LTOT and have found support for the risks associated with LTOT over time, especially at higher doses.[95–98] However, it is important to emphasize that for patients receiving LTOT for whom benefits outweigh harm, a continuation of LTOT along with close monitoring is reasonable. It is not evidence-based or concordant with CDC guidelines to taper involuntarily patients who are not experiencing harm from LTOT, and this practice may pose additional risks.[99] Bohnert et al. used a national data set of opioid prescriptions dispensed between 2012 and 2017 and identified decreases in rates of high dose and overall opioid prescribing following implementation of the CDC guidelines. In January 2012, the rate of high dose opioids (≥90 daily milligram morphine equivalents [MME]) was 683 per 100,000 persons, which decreased to 356 by December 2017. The overall opioid prescribing rate (per 100,000) decreased from 6577 opioid prescriptions dispenses (per 100,000 persons) in January 2012–4240 in December 2017.[98]

Medication for Opioid Use Disorder

Medication for opioid use disorder (MOUD), in combination with behavioral counseling, is the standard of care treatment for OUD.[3] MOUD reduces OUD related harm, including mortality and infectious disease transmission (e.g. HIV, hepatitis C, endocarditis).[4,100–102] MOUD consists of opioid agonist treatment

involving the long-acting full agonist methadone, partial agonist buprenorphine (most commonly prescribed in combination with the antagonist naloxone), or opioid antagonist naltrexone. Methadone is available from tightly regulated opioid treatment programs, which require six visits per week for supervised consumption for at least the first three months of treatment.[103,104] Buprenorphine may be prescribed by physicians and other practitioners depending on state regulations (e.g. advanced practice nurses and physicians associates) who have sought additional training (8 h for physicians, 24 h for advanced practice nurses and physicians associates) to obtain a waiver from the Drug Enforcement Administration (DEA) to treat OUD.[103] The government places patient limits on waivered providers: a 30 patient cap is in place the first year of waivered practice for most providers, with expansion to 100 patients in subsequent years. Providers with board certification in addiction medicine or psychiatry or who practice in certain settings can qualify for a 100 patient cap their first year, which expands to 275 the following year.[105] There are no specialty limits on who can seek additional training and a DEA (Drug Enforcement Administration) waiver. Thus obtaining a waiver might be useful for pain physicians interested in treating OUD in their own clinics.[105] Both methadone and buprenorphine are initiated at low, often sub-therapeutic doses, which are tapered over several weeks to find an individualized dose that reduces OUD symptoms without causing adverse effects (e.g. sedation).[103]

Iatrogenic Opioid Use Disorder

The indicators of iatrogenic OUD (i.e. OUD that occurs in the course of medically supervised opioid analgesic therapy) can be more subtle than those displayed for OUD related to recreational opioid use.[60] Loss of behavioral control, a key sign of addiction, may involve taking more opioids than prescribed, followed by visits to the emergency department or soliciting multiple prescribers for opioids; consequently, prescribers should check online state prescription drug monitoring programs to ascertain patients' use of controlled medications. Family members may also be useful in ascertaining possible indicators of iatrogenic OUD (e.g. patients lose the thread of conversation or fall asleep at inappropriate times).[60] Guidelines to date do not identify specific prescriber steps to take when concerns arise about medication-taking behaviors. However, a Delphi study of clinical experts suggests a patient-centered discussion of patients' behaviors, a recapitulation of the opioid treatment agreement, and providing a clear rationale for any decision to discontinue or taper opioid therapy.[106] However, it is important to note that some clinicians may encounter institutional or state policy pressure to discontinue opioids quickly.[106,107]

What to Do With Patients on Long-term Opioid Therapy With Suspected Opioid Use Disorder?

The development of OUD among patients prescribed opioids is a leading concern for both pain providers and patients.[108–110] Patient-centered tapering from LTOT may be appropriate in patients who feel their current opioid medication regimen is not effective or for whom risks outweigh the benefits.[111] For many patients who have been prescribed LTOT, switching to non-opioid therapy may not be feasible or in their best interest. One promising strategy in this scenario is to transition from LTOT to buprenorphine, which has a lower risk of adverse events, particularly for patients who have been on high opioid doses (>50 mg MME).[112–114] Although buprenorphine is classified as a partial mu agonist, it was initially developed to treat pain, and research has demonstrated that its risk profile may be safer than other opioids, and it may be effective for a wide range of pain types.[113–115] Additionally, there are options for patients who display signs or symptoms of OUD that still involve treating their pain. The standard of care treatment for OUD with MOUD is effective in reducing morbidity, mortality, and craving because of OUD.[4,102] For patients who are not currently enrolled in treatment for OUD, the following steps may help determine whether to continue LTOT or alter the treatment regimen[112]:

Step 1: Does the patient meet the criteria (see "Nomenclature") for a DSM-5 OUD? If so, go to Step 2. If not, go to step three.

Step 2: For patients meeting the criteria for OUD, urgent treatment using the standard of care, MOUD with methadone, buprenorphine, or naltrexone (see section "Medication for Opioid Use Disorder"). Opioid agonist therapy (methadone or buprenorphine) may be the preferred option among patients currently receiving LTOT because of the requirement of a seven to ten day washout period to prevent precipitated withdrawal with naltrexone.[103] Referral to an addiction specialist or opioid treatment program in this instance is warranted unless the pain management clinic has practitioners who have completed the DEA waiver process to prescribe buprenorphine.

Step 3: For patients not meeting the criteria for OUD, conduct a risk-benefit analysis for the continuation of LTOT. Factors that increase the risk of overdose or the development of OUD (i.e. medication interactions, age >65 years, reduced renal or hepatic function, and risk of respiratory depression).[116] The 2016 CDC guidelines consider improved pain and functioning as benefits that might lead to the continuation of LTOT.[75] For patients receiving doses below 50 mg MME of opioids and for whom the benefits of LTOT outweigh the harm, monitoring with routine reassessment may be appropriate. Switching to buprenorphine or approaching the topic of a patient-centered opioid taper is recommended for patients on daily doses greater than 50 mg MME or for those below 50 mg MME for whom benefits do not outweigh risks.[117]

Non-opioid Pharmacotherapy for Comorbid Pain and Substance Use Disorders

There is increasing evidence that the potential for harms of LTOT outweigh the benefit,[97,118] and non-opioid treatments are now the recommended first line treatment for anyone with chronic non-cancer pain.[75]

Non-opioid Pharmacotherapy

Depending on the type of pain being treated, medications to consider might include nonsteroidal anti-inflammatory drugs, anti-convulsant medications, and serotonin-norepinephrine reuptake inhibitors (SNRIs).[75] However, we note that newer data indicate that the anti-convulsant medications gabapentin and pregabalin have misuse potential, and they may increase the risk of respiratory depression and overdose among those currently using opioid medications.[119,120] Notably, some medications and non-pharmacologic therapies that treat pain have applications in the treatment of SUDs and vice versa.[112] Pain providers are sometimes surprised to learn that medications prescribed to treat chronic pain may also be indicated in the treatment of SUDs.[112] In the section below, we briefly describe pain and SUD use for common medications. We encourage pain clinicians to consult with their patients' addiction

providers to discuss dosing and applications of such medications, as the effective dose for SUD treatment might differ from the typical pain regimen. For patients with OUD, it is also worthwhile to consider altering a patient's pain regimen to incorporate medication that might treat their symptoms of both chronic pain and OUD, in collaboration with their addiction medicine provider. Notably, the use of adjunct medications that may cause sedation or increase the risk of respiratory depression (i.e. muscle relaxants, antiepileptics, benzodiazepines, and amitriptyline) is generally not recommended in patients currently receiving prescription opioids.[113]

Anti-convulsants

Pain physicians are likely to be familiar with the application of anti-convulsants, including gabapentin, pregabalin, and oxcarbazepine for neuropathic pain and fibromyalgia,[121,122] and topiramate for preventive migraine therapy. Topiramate has been investigated for neuropathic pain and fibromyalgia and found to have no benefit.[123,124] Research suggests that gabapentin may offer clinical benefits to patients with alcohol use disorders. Multiple studies have demonstrated reductions in cravings and alcohol use behavior among patients with AUD (alcohol use disorder) taking gabapentin compared to placebo, with some reporting improvements in mood and insomnia.[125–127] In December 2019, the FDA released a drug safety communication about the risk of respiratory depression with gabapentinoids combined with other central nervous system (CNS) depressants, particularly opioids, and how this impacts the future use of gabapentinoids in pain management is an evolving issue.[128] Topiramate has also shown clinical benefit in AUD, and some initial studies suggest that it could be applied in cocaine use disorder and tobacco use disorder, although much more research is needed.[129,130]

Muscle Relaxants

Baclofen has been used to treat spasticity and hypertonicity, particularly in conditions such as multiple sclerosis. Systematic reviews evaluating research into baclofen's utility in treating alcohol use disorder have not demonstrated a clear benefit, but this is an area of active investigation,[131,132] particularly among patients who are currently abstinent from alcohol.[133] Please see Chapter 55 for a more detailed description of the role of muscle relaxants in treating pain.

Benzodiazepines

Although the combination of benzodiazepines and opioids increases the risk of overdose, sedation, and OUD development, estimates for co-prescription are as high as 40% in outpatient settings.[134,135] Benzodiazepines are an important treatment for alcohol withdrawal syndrome that prevents seizures. However, outside of this indication, caution should be exercised when prescribing benzodiazepines in patients taking opioids.

α-2 Agonists

α-2 adrenergic receptor agonist drugs are commonly used for anesthesia.[136] For example, clonidine can provide prophylactic cardiovascular protection during intubation, while tizanidine can assist in the management of spasticity related to cerebral palsy. Although the α-2 agonist lofexidine is FDA-approved to manage symptoms during opioid withdrawal, clonidine is commonly used off-label for a similar indication. Studies have demonstrated the clear efficacy of these agents. However, they may have more side effects not seen with other agents such as methadone and buprenorphine and may not completely eliminate withdrawal syndrome-associated discomfort.[137]

Importance of Non-pharmacologic Pain Management Interventions

A recent systematic review focused on non-invasive non-pharmacologic treatment for chronic pain (without SUD) concluded that exercise, multi-disciplinary rehabilitation, acupuncture, cognitive behavior therapy (CBT), mindfulness practices, and mind-body practices most consistently exhibit modest improvements in pain intensity and function for specific pain conditions compared to usual care, sham treatments, or attention controls.[138] A narrative review that included 56 studies on psychosocial interventions for those with chronic pain and OUD underscored the promise that a similar group of psychosocial interventions including CBT, acceptance and commitment therapy, mindfulness-based cognitive therapy, mindfulness-based stress reduction, relapse prevention, and motivational enhancement therapy (MET).[139] Recognizing triggers (for pain and substance use), awareness of negative emotions, enhancing positive coping strategies, and pleasurable activity planning from both pain and SUD approaches are important elements of a hybrid psychosocial intervention that addresses both pain and SUDs.[140] A recent literature review focused specifically on treating those with pain and OUD described some evidence for stepped care approaches in primary care and emphasized the need for more integrated and multi-disciplinary services.[141]

Non-pharmacologic Interventions for Patients with Comorbid Pain and SUDs

A growing body of literature has examined the efficacy and effectiveness of behavioral interventions among patients with concomitant SUD and chronic pain. Some trials included those with a heterogeneous group of SUDs, while others focused on specific SUDs. Among those with more heterogeneous SUDs, the eight week improving pain during addiction treatment behavioral pain management intervention, which focused on relapse prevention and pain management skills, was associated with higher pain tolerance in men and lower pain intensity in women compared to those randomized to a supportive psychoeducational control. However, there were no differences in substance-related outcomes.[142] Other trials included those with specific SUDs. One recent study examined a mindfulness-oriented recovery enhancement intervention in patients with OUD and chronic pain and found that the eight week intervention improved opioid craving, pain unpleasantness, and increased positive affect compared to treatment as usual.[143] Pilot studies have demonstrated the feasibility and efficacy of CBT combined with MOUD for patients with comorbid pain and OUD with both methadone[144] and buprenorphine.[145] In a 12 week pilot study among 40 patients with OUD and low back pain receiving MMT (methadone maintenance treatment), patients reported higher satisfaction with CBT compared to methadone drug counseling as usual, and the CBT group contained a higher proportion of patients with negative urine drug screens for illicit opioids, with similar results for pain interference in both groups.[144] Another study demonstrated repeat attendance and high satisfaction in patients receiving MMT who attended CBT-informed counseling groups for pain.[146] Finally, a study of a brief smoking cessation intervention among those with chronic pain found that those randomized to the intervention had increased willingness to consider cessation.[145]

Managing Acute Pain in Patients With Chronic Pain and Opioid Use Disorder

Management of acute pain in patients receiving opioids, such as LTOT or MOUD, or with SUD histories, can be challenging. Patients who receive opioids may require increased doses of opioids to achieve pain relief because of increased tolerance to opioids and opioid-induced hyperalgesia.[147,150] Physicians may be wary of prescribing opioids to patients with a history of SUD, depriving these patients of pain relief following trauma, surgery, or other procedures resulting in acute pain. Patients with SUDs may also be hesitant to receive opioids out of fear they might relapse or develop OUD. Concern about inappropriate opioid prescribing and how to manage the large population of patients hospitalized for acute or chronic pain has led professional societies to develop guidelines for post-procedure analgesia in all patients. While these guidelines are not targeted specifically for populations with SUDs or chronic pain, they are useful for clinical practice or when helping a patient prepare for a procedure or intervention.[151–153] Strategies such as comprehensive pain plans for both individuals and institutions that include explicit guidance for emergency and hospital providers on how to manage an individual patient's acute pain flares may also be helpful for certain conditions. For example, the implementation of individualized protocols for acute pain in sickle cell disease has been shown to reduce admissions and readmissions, improve patients' pain, and provide patient satisfaction,[154] and is recommended by expert guidelines.[155]

More research is needed on the optimal management of acute pain in patients receiving MOUD, but there is evidence that continuing MOUD during surgery or treatment for acute pain is important.[149,156] The ASAM guidelines released in 2020 suggest that it may be appropriate to temporarily increase daily doses of opioid agonists or split doses to optimize pain management in patients receiving MMT and buprenorphine during acute pain episodes.[149] Guidelines from ASAM and the Pain and Addiction Interdisciplinary Network support the use of high dose opioid agonists for refractory pain in patients receiving buprenorphine for OUD,[157] and ASAM recommends this for patients receiving MMT as well. For patients receiving naltrexone, options during acute pain include local pain management (i.e. nerve blocks), use of sedatives including ketamine and benzodiazepines, non-opioid pharmacology, or overcoming the blockade of mu receptors with high potency opioids. In preparation for surgery, patients can discontinue naltrexone at a minimum of 72 h prior and require three to seven days without opioids before resuming naltrexone to avoid precipitated withdrawal.[149] For patients who make the decision with their care team to stop methadone or buprenorphine before surgery, ASAM now recommends discontinuation only the day prior to or day of surgery and that prescribers should determine how to resume.[149]

Cannabis Use for Pain and Cannabis Use Disorder

The availability and use of cannabis for chronic pain is increasing despite mixed evidence for its effectiveness and potential for harm,[158] including addiction (see also Chapter 56). Among regular users, cannabis use can lead to physiologic dependence with a withdrawal syndrome that may include dysphoric mood, disturbed sleep, gastrointestinal symptoms, and decreased appetite. Among adults, the overall prevalence of CUD is 2.5% over 12 months and 6.3% over a lifetime.[50,23] Furthermore, among those reporting past year cannabis use, 36% met the criteria for CUD over the previous year.[159] While CUD is more prevalent and of greater severity than many recognize, only 5% of those with CUD have sought treatment from a healthcare provider.[50]

Standard treatment of CUD includes psychotherapy, such as CBT, MET, or contingency management (CM).[160] However, these treatments may be inaccessible as well as time-and resource-intensive. Currently, no FDA-approved pharmacotherapies are available for CUD, although a number (e.g. cannabinoids, antidepressants, anxiolytics, and glutamatergic modulators) have been proposed for off-label use.[161] A recent systematic review on the treatment of CUD concluded that there is a dearth of evidence examining pharmacologic interventions for CUD, although there is evidence that several drug classes, including cannabinoids and selective SNRIs, are ineffective.[162]

Clinical considerations for those treating chronic pain among individuals with cannabis use include awareness of state, federal, and institutional policies regarding cannabis, the establishment of goals regarding cannabis use, screening for non-medical use and addiction, counseling patients on harms and risks, offering medical advice on routes of administration, continual monitoring of functional status, symptom severity, and use of other medications and substances; use of urine drug tests; monitoring for harms associated with cannabis (falls, cognitive issues, motor vehicle accidents), and providing advice on discontinuation or referral to SUD treatment.[49]

Importance of Coordinated Care

Many providers who treat chronic pain may be wary of the clinical complexity of accepting a new patient who is currently receiving treatment for OUD. We encourage pain providers to connect with the patient's MOUD program and prescriber. While research shows that providers treating chronic pain feel like they are less experienced in treating SUDs, addiction treatment providers reveal similar concerns about their experience and training surrounding pain treatment.[163,164] Pain providers have a lot to offer their colleagues in addiction medicine in terms of knowledge and experience of managing pain. Coordination between the two specialties can result in a better experience for the patient and the providers.

Conclusion

Chronic pain and SUDs are prevalent chronic medical conditions that often co-occur. Patients with both conditions are clinically complex and may have other comorbid psychiatric and medical conditions. While many patients have received long term opioid therapy for chronic pain over the last three decades, expert guidelines now recommend against LTOT for most patients, given the risk of opioid-related harm. There are high rates of chronic pain in patients with SUDs. Likewise, many patients with chronic pain have SUDs and may use substances to manage their pain. The clinical needs of patients can go untreated because of fragmented care for pain and SUDs. While there are effective treatments for SUDs, particularly MOUD for those with OUD, many patients with SUDs do not receive evidence-based treatment. There are also promising non-opioid interventions for chronic pain and SUDs, including non-opioid pharmacotherapy and non-pharmacologic pain management interventions. Pain treatment providers should screen for SUDs. If they are unwilling or unable to provide both SUD and pain management, they should consider coordinating care with addiction medicine providers. In the case of OUD, buprenorphine prescribing by licensed office-based clinicians provides an increased opportunity for pain providers to be part of the treatment for co-occurring chronic pain and OUD.

Key Points

- Addiction is a chronic relapsing medical condition or disease with effective treatments, similar to diabetes or hypertension.
- There are high rates of SUDs among patients with chronic pain and high rates of chronic pain among patients with SUDs.
- Pain clinicians should screen for addiction risk before and during treatments, especially for treatments involving controlled substances, and be prepared to either provide treatment for SUDs or offer treatment referrals.

Anti-depressants

ANTHONY H. DICKENSON, RYAN PATEL, CHARLES E. ARGOFF

Introduction

The second half of the 20th century saw the introduction of a range of therapeutic agents known to have an anti-depressant effect. These are currently classified partly based on their chemical structure and partly according to their primary *in vivo* effects (Box 53.1). Even before their introduction into clinical practice, the concept of an association between depression and pain was clear, and the possibility that this link was causal encouraged the use of anti-depressants for patients who exhibited features of both pain and depression. It is now recognized that the pain relief apparent with the use of anti-depressants can be independent of any alteration in mood caused by the drug,[1] and the analgesic effects can occur more rapidly,[2,3] at lower doses/serum levels than those required for anti-depressive effects.[4,5]

Our current understanding is that the primary mechanism of action of anti-depressant drugs in neuropathic pain is through blocking monoamine reuptake in descending modulatory pathways. In a normal state, activity within bulbospinal circuits are finely balanced to set the sensory gain at the spinal level, and these can rapidly adapt to amplify or suppress pain according to context. For example, neural circuits have been described that underly acute stress-induced analgesia and chronic stress-induced hyperalgesia,[6] and placebo responses are also in part because of recruitment of descending opioidergic inhibitions.[7]

Serotonin (5-HT) originating from the dorsal raphe nuclei exerts bi-directional control of sensory neuronal activity at the spinal level dependent on the particular receptor subtype targeted. At the cellular level, 5-HT receptors can be excitatory (subtypes 2, 3, 4, 6, and 7) or inhibitory (subtypes 1, 5). However, the complexity of their ability to amplify or suppress sensory transmission is determined by their expression patterns on excitatory and inhibitory interneurons.[8] The 5-HT_{2A} and 5-HT_{3} receptors are the predominant faciliatory receptors in the dorsal horn, and their excitatory effects on pre-synaptic primary afferent terminals outweigh their actions on inhibitory interneurons.[9,10] The 5-HT_{7} receptor conversely has a greater expression on inhibitory interneurons, and agonists suppress sensory transmission.[11] Running parallel to these serotonergic projections to the dorsal horn are pontine derived noradrenergic pathways, particularly from the A5 and A6 (locus coeruleus) groups; these terminate upon spinal α_1 and α_2 adrenoceptors. Activation of the α_2 adrenoceptor inhibits neuronal excitability, and these are largely expressed pre-synaptically on primary afferent terminals (α_{2A}) and excitatory interneurons (α_{2C}). Conversely, α_1 adrenoceptors are excitatory and are expressed by both inhibitory and excitatory interneurons. However, their net effect on sensory transmission is considered to be faciliatory.[8] There is compelling evidence that links a loss of noradrenergic inhibitory tone and enhanced serotonergic facilitation in the development and maintenance of chronic pain states.[12–15] Consequently, this imbalance in descending monoaminergic control in neuropathic rats can also present as a loss of diffuse noxious inhibitory controls (DNIC).[16] DNIC are a partly opioidergic and noradrenergic endogenous pain modulatory mechanism.[16,17] In the absence of nerve injury, DNIC are activated when two distant noxious stimuli are applied, recruiting a bulbospinal inhibitory pathway that overlaps with the canonical descending pain modulatory network.[18]

The human counterpart measure to DNIC is referred to as conditioned pain modulation (CPM; see Chapter 21). Typically, CPM is performed by determining pain scores (on a visual analog scale) or a pain threshold to a noxious test stimulus, followed by a repeat of the test in the presence of a distant heterotopically applied noxious conditioning stimulus, e.g. cold pressor. Functional CPM is then quantified as the decrease in pain scores or increase in pain threshold to the test stimulus. The use of CPM as a sensory testing tool has gained much traction in recent years to study the role of descending modulation in the cause of pain. Low CPM is associated with numerous chronic pain states of neuropathic and non-neuropathic origin,[19–23] and a higher risk of postoperative pain.[24,25] As an illustration of how patients can be separated according to putative pathophysiologic mechanisms, a large scale study attempting to stratify chronic pain patients according to mechanisms of spinal gain (enhanced temporal summation) or loss of descending control (low CPM) reported 37% of patients with low CPM and 21% with both low CPM and enhanced temporal summation.[26] Stratification will be key to future clinical trial design and treatment selection, given that nerve injury can induce numerous transcriptional changes and neuroplasticity throughout the sensory neuraxis. Any given drug with a defined mechanism of action would have to target the predominant pathophysiologic mechanism in a patient to provide relief. In this respect, it is perhaps unsurprising that many patients fail to achieve adequate pain relief.

The focus of this chapter is on the potential pain-reducing capability of drugs otherwise associated with the treatment of depression. In most cases, the clinical studies cited within are based on non-stratified patient cohorts and commonly use patient reported ongoing pain scores as primary endpoints of efficacy. However,

Tricyclic Anti-depressants

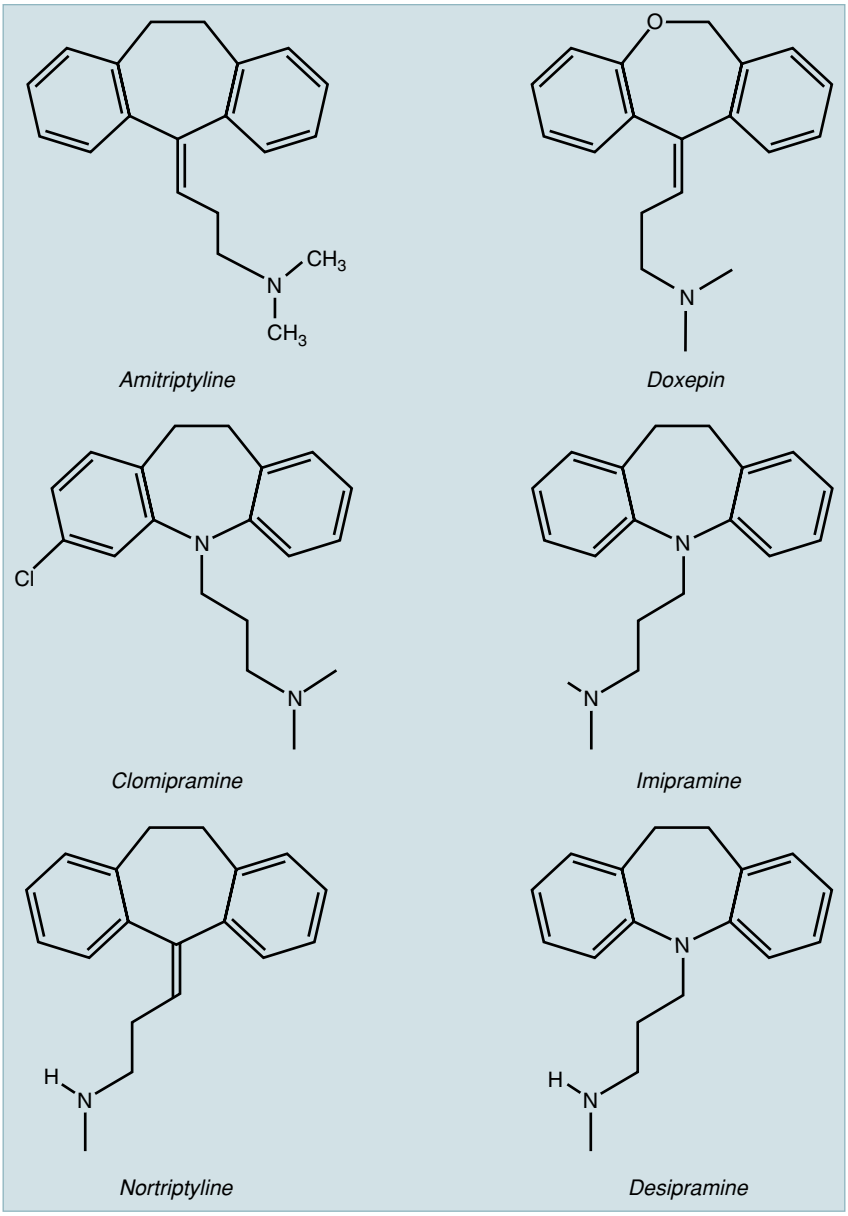
Mechanism of Action (Animal Models)

In addition to increasing synaptic monoamine concentrations, tricyclic anti-depressants (TCAs; Fig. 53.1) exert many pharmacologic actions. Table 53.1 compares the receptor affinity profiles for various TCAs. All TCAs have a low affinity for dopamine transporters but different binding profiles for serotonin and noradrenaline transporters. Amitriptyline has a comparable affinity for both transporters, whereas desipramine has higher selectivity for noradrenaline transporters (approximately 40-fold) and clomipramine has higher selectivity for serotonin transporters (approximately 230-fold). Despite having a low affinity for dopamine reuptake transporters, systemic amitriptyline promotes dopamine release at the spinal level in neuropathic rats, and antinociception is partially blocked by a D_2 receptor antagonist.[28] A possible explanation is an interaction between monoamine systems at the spinal level. Plasticity in the expression of serotonergic or noradrenergic receptors on dopaminergic terminals could promote the release of dopamine. Alternatively, this interaction may occur in higher centers leading to a top-down increase in descending dopaminergic drive. A potential confound is the role of dopamine in motor function and motivation that could alter behavioral responses to painful stimuli.

Dual blockers of serotonin and noradrenaline reuptake, such as most TCAs and serotonin-noradrenaline reuptake inhibitors (SNRIs), are known to be more effective for pain relief than the transporter selective drugs. As there is a considerable anatomic and functional interaction between the signaling systems, drug actions on one system will inevitably impact the other, which likely produces synergistic drug effects.[29] Modulation of coerulospinal activity is central to the anti-nociceptive effects mediated by TCAs and SNRIs. At the spinal level, amitriptyline increases spinal noradrenaline concentrations in neuropathic rats, coinciding with a reversal of evoked hypersensitivity and restoration of DNIC.[30] Increased release of noradrenaline within the locus coeruleus can exert excitatory or inhibitory effects on neuronal activity via α_1 and α_2 adrenoceptors, respectively. However, long-term desipramine and duloxetine dosing leads to the desensitization of α_2 autoreceptors and may restore descending inhibition.[31] Plasticity in channel function within the dorsal horn, such as increased receptor density and enhanced coupling to G-proteins, could also increase the magnitude of drug effects in pathophysiologic states.[32,33]

TCAs may mediate part of their analgesic effects via activation of opioidergic signaling.[34–36] The anti-nociceptive effects of chronic nortriptyline dosing were reversed by naloxone and selective antagonists of δ- and κ-Opioid receptors,[34] but not μ-Opioid receptors.[35] TCAs tend to have a low affinity for opioid receptors. Therefore these effects are considered secondary to other mechanisms such as changes in monoamines. Concerning other central targets, TCAs might also act to reverse central sensitization by targeting NMDA receptors, either directly[37] or through downregulation of NR2B subunits.[38] More recent investigations have revealed novel insight into potential peripheral mechanisms of analgesia. TCAs have been proposed indirectly to modulate neuroimmune responses such as downregulation of tumor necrosis factor (TNF) α and the nuclear factor κB (NFκB) signaling pathway, which reduces inflammatory sensitization of peripheral sensory neurons.[39–41] *In vitro* studies have shown that various TCAs are activation state- and use-dependent blockers of $Na_v1.3$, $Na_v1.7$, and $Na_v1.8$ with IC50s in the range of therapeutic plasma concentrations for the treatment of depression and neuropathic pain.[42,43] The latter channels $Na_v1.7$ and $Na_v1.8$ are almost exclusively expressed in nociceptors,[44,45] whereas $Na_v1.3$ is not normally expressed in adult neurons but is upregulated after nerve injury and promotes hyperexcitability.[46] There are some suggestions that amitriptyline can also reduce peripheral neuronal hyperexcitability by inhibiting adenosine reuptake.[47,48] However, there is no evidence that adenosine receptor agonists are effective against pain in clinical trials.[49] In all of these cases, it is impossible to ascertain that the non-monoamine actions contribute to pain control at clinical doses.



• **Figure 53.1** Tricyclic anti-depressants.

Clinical Management of Pain

Drug efficacy is often evaluated in terms of the number needed to treat (NNT). In terms of analgesics, this represents the number of patients who need to take the treatment to obtain a 50% or greater reduction in their pain. A meta-analysis of double-blind placebo-controlled trials of TCAs in neuropathic pain calculates the NNT at 3.6 (Fig. 53.2),[50] a higher efficacy than most other treatments. TCAs appear effective in peripheral and central origin neuropathies, including diabetic neuropathy,[1,51–53] postherpetic neuralgia,[54–56] peripheral nerve injury,[57] spinal cord injury,[58] central post-stroke pain,[59] and multiple sclerosis.[60] Limited effectiveness was observed in a trial involving HIV neuropathy patients,[61] and radiculopathy.[62] Amitriptyline is the most widely studied,[1,53,56–61] but the NNT for desipramine,[51,54,55] nortriptyline,[55] and imipramine[52] appear comparable albeit based on a smaller dataset. As TCAs can block serotonin and noradrenaline reuptake, it seems likely that inefficient CPM could predict analgesic efficacy as has been demonstrated for duloxetine.[23] Local or topical delivery of drugs has been explored as a method to reduce central side effects of analgesics, and the TCAs were considered a potential candidate because of numerous off-target effects at various ion channels known to be expressed in primary afferents. However, no randomized, double-blinded, placebo-controlled trials support the efficacy of topical amitriptyline.[63] In patients unresponsive to oral TCAs, a small decrease in ongoing pain scores was observed with topical doxepin, but paresthesia, allodynia, and shooting pains were unaffected.[64]

Fibromyalgia is not classified as a neuropathic condition but shares features of neuropathic pain, such as central sensitization and altered central modulation. Dysregulation of descending modulation is apparent in some patients with fibromyalgia,[65] and pain facilitation as well as a loss of pain inhibition during CPM has been reported.[66] A meta-analysis of TCA trials in fibromyalgia indicates an overall small to moderate improvement of pain, sleep

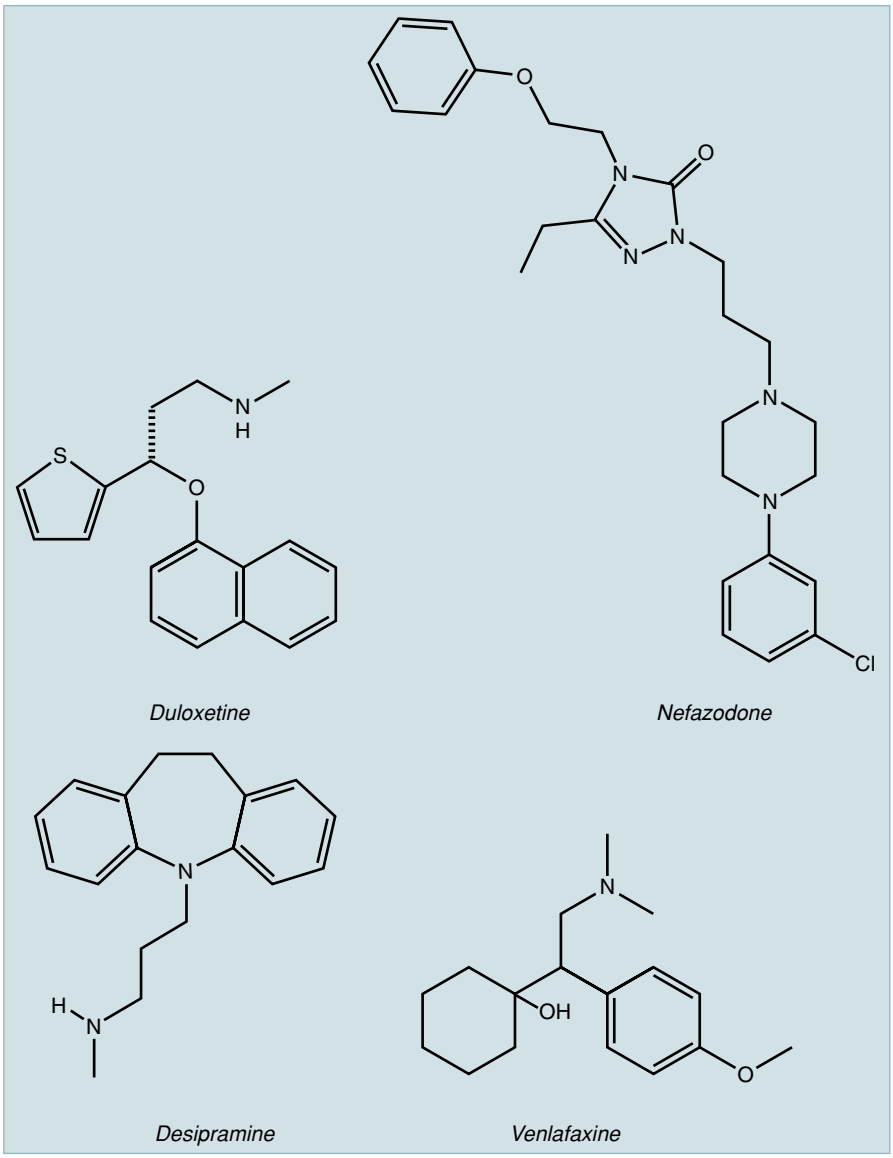
disturbances, and fatigue.[67] A small number of patients benefited greatly from treatment with anti-depressants. However, a large number are also known to drop out of trials because of intolerable adverse effects. It was suggested that TCAs appear more effective for patients with comorbid insomnia, whereas SNRIs may be preferable for patients with comorbid depression. Based on a lower meaningful effect size (reduction of pain by 30%), the NNT for TCAs in fibromyalgia is 4.9.

SNRIs

Mechanism of Action (Animal Models)

SNRIs (Fig. 53.3) selectively block the reuptake of serotonin and noradrenaline. Milnacipran has an equal affinity for serotonin and noradrenaline transporters, whereas duloxetine and venlafaxine have 10-fold and 30-fold selectivity for serotonin transporters,

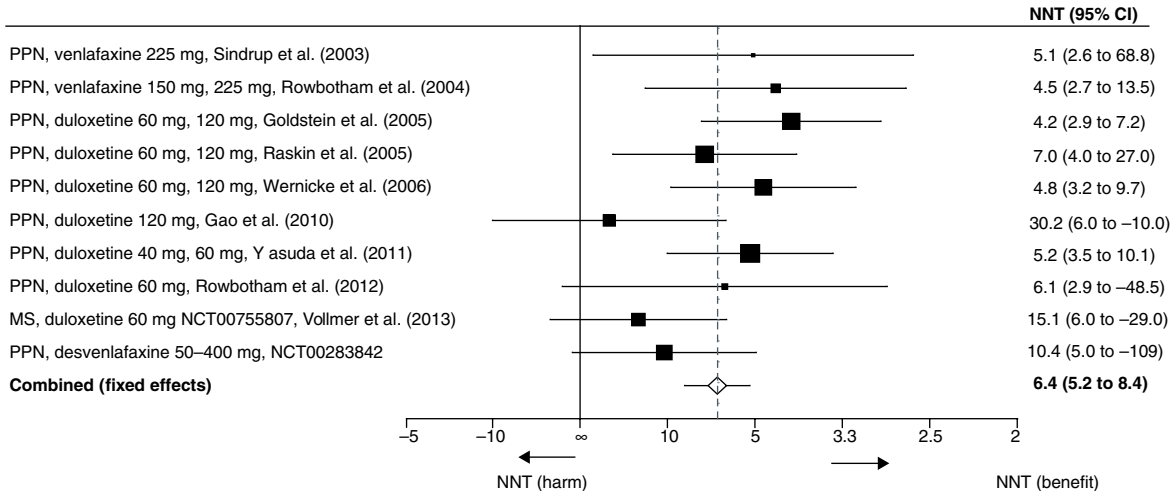


• **Figure 53.3** Serotonin-noradrenaline reuptake inhibitors.

respectively. A single systemic dose of duloxetine and milnacipran increases spinal concentrations of serotonin and noradrenaline though interestingly, the temporal kinetics of transmitter accumulation differ. Milnacipran increases both transmitter levels gradually with time. In contrast, duloxetine rapidly increases serotonin concentrations that decline with time, whereas noradrenaline concentrations increase progressively.[68] As discussed above, augmentation of noradrenergic signaling in the coerulo-spinal pathway is critical to the analgesic effects mediated by SNRIs. In neuropathic rats, duloxetine increases spinal noradrenaline content, and the anti-nociceptive effects are reversed by an intrathecal α_2 adrenoceptor antagonist.[69] In line with clinical observations,[23] DNIC are absent after nerve injury and are also restored by duloxetine.[69] There are conflicting data regarding the involvement of opioid signaling systems in the anti-nociceptive effects of SNRIs, and these effects differ according to the injury model and dosing protocols.[36,40,70,71] As this is a feature shared with TCAs, it seems likely that activation of endogenous opioid signaling occurs secondary to blocking the reuptake of noradrenaline and serotonin, which in turn could activate their respective receptors on inhibitory opioidergic interneurons in the dorsal horn. Peripheral actions of chronic duloxetine dosing have also been described, which rely on noradrenaline release from peripheral sympathetic terminals. This subsequently downregulates TNFα and NFκB pathways mediated via β_2 adrenoceptors on non-neuronal satellite cells in the dorsal root ganglia of neuropathic mice.[39,40]

Clinical Management of Pain

At present, duloxetine is the only licensed anti-depressant (in the United States) for the treatment of diabetic neuropathy, and approvals for fibromyalgia and chronic musculoskeletal pain have now been granted. A meta-analysis of double-blind placebo-controlled trials of SNRIs in neuropathic pain calculates the NNT at 6.4 (Fig. 53.4).[50] Against the primary endpoint of average pain scores, most trials in diabetic neuropathy patients reported decreased pain with duloxetine treatment (60-120 mg) compared to a placebo,[2,72–75] whereas one reported transient effects.[76]



• **Figure 53.4** NNT values (with 95% confidence intervals) are shown for each trial and for the overall estimate (fixed effects, Mantel-Haenszel) for serotonin-noradrenaline reuptake inhibitors (10 studies, 2541 participants). The size of the square represents the Mantel-Haenszel weight that the study exerts in the meta-analysis. *CI*, Confidence interval; *MS*, multiple sclerosis; *NNT*, number needed to treat; *PPN*, painful polyneuropathy. Data from Finnerup et al., Pharmacotherapy for neuropathic pain in adults: a systematic review and meta-analysis. *Lancet Neurol*. 2015;14(2):162–73.

In addition, duloxetine improved several secondary quality of life endpoints across these studies, including sleep,[72,75] mood,[2,72] and mobility.[72,75,76] In a study involving multiple sclerosis patients, duloxetine was more effective than placebo treatment, but notably, the NNT appears considerably higher than for diabetic neuropathy.[77] The NNT for venlafaxine, and its active metabolite desvenlafaxine, is comparable to duloxetine.[52,78,79] However, the dosage might require consideration as venlafaxine is proposed to act primarily as a selective serotonin reuptake inhibitors (SSRI) at a dose of 75 mg and as an SNRI at doses above 150 mg.[80] Quantitative sensory tests indicate that venlafaxine inhibits evoked pains, including brush allodynia, pinprick hyperalgesia, and temporal summation in addition to ongoing pain.[81]

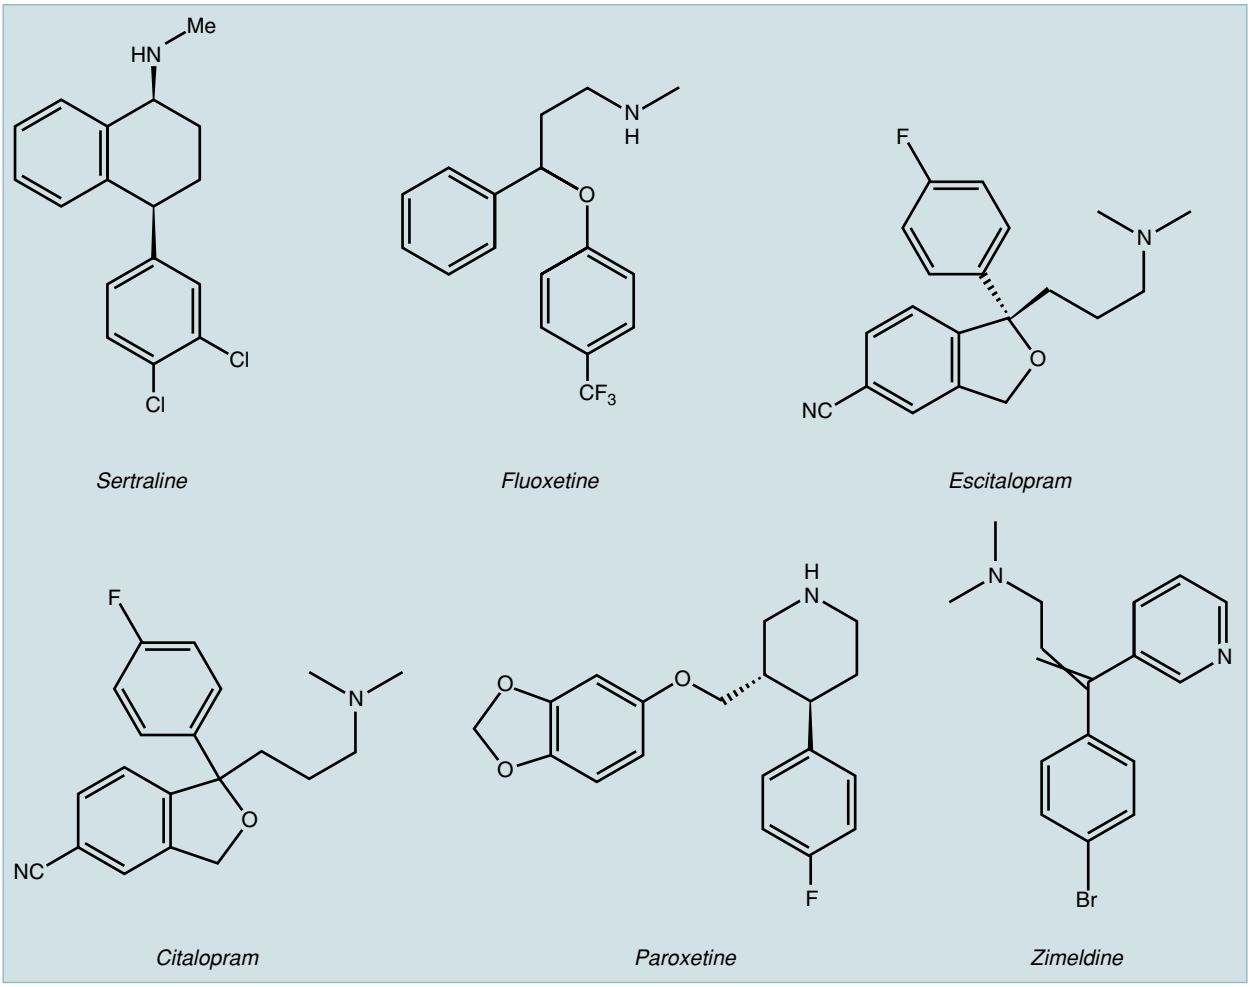
The high NNT values associated with anti-depressants, and other analgesics, have refocused trial design toward personalized approaches and predictive medicine. At present, there are no established sensory testing-led treatment algorithms, but in recent years there have been a few notable advances. Patients stratified according to hyperexcitable peripheral nociceptor function were more likely to benefit from the sodium channel blocker oxcarbazepine than those with a sensory loss phenotype.[82] *Post hoc* analysis of an overall negative pregabalin trial in HIV neuropathy revealed pain relief in patients with severe pinprick hyperalgesia.[83] Several have examined, with varying degrees of success, whether sensory phenotypes act as predictors of SNRI response.[84–86] One of the more elegant examples to date demonstrated that CPM efficiency in diabetic neuropathy patients correlated with analgesic outcomes.[23] The authors hypothesized that drugs should be prescribed according to the patient's pattern of pain modulation, and drugs that augment descending inhibition would benefit those that exhibited low endogenous pain modulation. Duloxetine (30-60 mg) efficacy was greater in patients with less efficient pretreatment CPM levels, whereas those with efficient CPM achieved little relief.[23] Similar outcomes have been observed with tapentadol (a dual μ-Opioid agonist/noradrenaline reuptake inhibitor [NRI]),[21] the common denominator with duloxetine being the NRI component. A caveat to interpreting CPM is that efficient CPM is considered the net inhibitory function extracted from the gross descending output. Hence an absence of CPM could result from enhanced facilitation, a loss of inhibition, or a combination of both. In a back-translational rodent study descending inhibition after nerve injury was vastly diminished and reversed by blocking spinal noradrenaline reuptake, but enhanced spinal 5-HT_3 mediated facilitations can mask residual inhibitory function, and DNIC was restored by a 5-HT_3 antagonist alone.[16] Thus an absence of effective CPM/DNIC could predict analgesia by agents capable of enhancing inhibitory signaling and/or reducing facilitatory activity.

SSRI

Mechanism of Action (Animal Models)

It was hoped that with the advent of anti-depressants with more specific modes of action, analgesia would still be associated with their use, and the potential to produce side effects would be reduced. However, studies in rodent models of neuropathy have produced mixed data on the efficacy of SSRIs (Fig. 53.5). Citalopram and fluoxetine do not appear to affect mechanical hypersensitivity after nerve injury.[34,87,88] However, citalopram partially reverses heat hypersensitivity.[87] At an effective dose, the SSRI fluoxetine attenuates nocifensive behaviors in short-term models of central sensitization, an effect that is diminished by depletion of endogenous serotonin.[89] However, at higher doses of SSRIs, analgesic effects could be attributed to non-selective actions at the noradrenaline transporter as paroxetine can increase spinal noradrenaline release.[90] In contrast, only spinal delivery of citalopram and fluoxetine restored deficient DNIC in neuropathic rats, whereas systemic doses were without effect suggestive of concomitant inhibitory/faciliatory actions at multiple sites. The effects of spinally delivered SSRIs were mediated via 5-HT_7 receptors allowing DNIC to be restored via α_2 adrenoceptors.[91]

Acute and chronic mechanisms of drug action in supraspinal structures can have complex actions on neuronal activity. Noradrenergic neurons in the locus coeruleus receive dense serotonergic projections, which exert tonic inhibitory influences on neuronal activity,[92] and this is augmented by SSRIs.[93] It is possible in a neuropathic state that the inhibitory spinal actions of SSRIs are countered



• **Figure 53.5** Selective serotonin reuptake inhibitors.

by further top-down suppression of descending noradrenergic inhibition. Within the dorsal raphe, spontaneous activity of putative serotonergic neurons is inhibited by SSRIs in a 5-HT_{1A} receptor dependent manner, but chronic dosing results in desensitization of 5-HT_{1A} auto-receptors leading to a recovery of activity.[94] In addition, cortico-limbic circuits are critical in assigning an emotional valence to sensory inputs, and these pathways are also subjected to serotonergic modulation. In a model of arthritis, inhibiting 5-HT_{2C} receptors within the basolateral amygdala potentiated the analgesic effect of fluvoxamine on supraspinal-organized behaviors (vocalizations and anxiety-like behaviors) but not spinal reflexes to painful stimuli.[95] The majority of rodent studies examine the acute effects of drugs. However, transcriptional changes can occur with chronic dosing, including altered expression of 5-HT_{2C} receptors at spinal and supraspinal sites,[96] and HDAC2 and mGlu2 receptors in the dorsal root ganglia, and dorsal horn, respectively.[97]

Clinical Management of Pain

Data from clinical trials provide weak evidence for the efficacy of SSRIs in the treatment of neuropathic pain. The lack of suitable comparable studies means that a reliable NNT has been difficult to calculate,[50] but is thought to be at least 6.7 for SSRIs, which is likely to be underestimated.[98] Three crossover studies in diabetic neuropathy patients compared the effects of citalopram, fluoxetine, and paroxetine (all 40 mg doses) to a placebo. Fluoxetine was found to be no better than placebo treatment,[4] whereas citalopram produced marginal improvement of pain.[99] Paroxetine reduced ongoing pain scores and paresthesia but provided no improvement in sleep disturbances and was considered less effective than imipramine.[100] Results from studies in fibromyalgia mirror the studies in neuropathic pain and are mixed at best. After a course of treatment with citalopram (20–40 mg), no improvements in pain scores, tender points, or depression scores were found,[101] and a separate study broadly reported similar findings with weak beneficial effects.[102] Trials of fluoxetine have reported similar outcomes with limited to no improvement of pain scores and tender points and inconsistent improvements in secondary measures such as sleep disturbances, wellbeing scores, and depression scores.[103–105]

Noradrenaline Reuptake Inhibitors

Mechanism of Action (Animal Models)

Reboxetine is a selective NRI with little or no affinity for serotonin and dopamine reuptake transporters. In a rodent nerve injury model, intrathecal reboxetine reverses the functional deficit in descending noradrenergic control by inhibiting evoked hypersensitivity and ongoing pain (conditioned place preference paradigm).[106] Similar actions are observed on evoked neuronal activity within the spinothalamic pathway in a pathophysiologic state dependent manner.[107] Furthermore, functional DNIC are blocked by an intrathecal α_2 adrenoceptor

antagonist, and intrathecal reboxetine restores absent DNIC in neuropathic rats.[16] This underlying noradrenergic mechanism explains the relationship between low CPM and the use of tapentadol (dual μ-Opioid agonist/NRI) and duloxetine (SNRI) for treating neuropathic pain.[21,23] Pontine derived noradrenaline projects throughout the neuraxis and has roles in regulating arousal, mood, learning, and memory. This functional dichotomy between the ascending and descending noradrenergic components may underly the negative side effects of systemic targeting of the noradrenergic system.[108]

Clinical Management of Pain

No comprehensive data has indicated that NRIs are suitable for treating neuropathic pain. Two Pfizer-led trials for postherpetic neuralgia and diabetic neuropathy were terminated because of a lack of efficacy (NCT00348894, NCT00354094). However, in fibromyalgia, Pfizer reported a small but sustained improvement in overall pain scores (primary outcome) and fatigue (secondary outcome) compared to a placebo.[109]

Dopamine Reuptake Inhibitors

Though classified as a dopamine reuptake inhibitor, bupropion also blocks noradrenaline reuptake transporters. Intrathecal dosing in neuropathic rats increases spinal concentrations of dopamine and noradrenaline, which produces anti-nociception in an α_2 adrenoceptor and D_2 receptor dependent manner.[110] Evidence for efficacy in patients is limited, although a single study reported that 73% of subjects with neuropathic pain studied in their placebo-controlled trial obtained some pain relief with bupropion treatment.[111]

Tetracyclic Anti-depressants

Limited evidence for an analgesic effect of tetracyclic anti-depressants exists. Like the TCAs, the pharmacology of tetracyclics is diverse, but in general, these drugs block noradrenaline reuptake and have little affinity for serotonin and dopamine reuptake transporters. In a crossover study in patients with postherpetic neuralgia, amitriptyline was deemed to be more effective than maprotiline.[112] A few rodent studies have demonstrated that maprotiline,[113] mianserin,[114] and mirtazapine,[115] reverse evoked hypersensitivity in neuropathic models.

Monoamine Oxidase Inhibitors

Renowned for their multiple side effects, drug interactions, and the necessity for a tyramine-free diet when used, monoamine oxidase inhibitors have no place in pain management. Little evidence exists for any analgesic effect.[116]

Safety and Side Effects

The safety of anti-depressants can be considered both from the perspective of normal use (Box 53.2) and in overdose. An analysis of United Kingdom prescriptions provided an interesting insight into the potential dangers of anti-depressants when taken in overdose calculated as the number of deaths per million prescriptions (Table 53.2). It is unclear why the fatality rate for desipramine is higher than other TCAs but suggests that overdose risks should be judged on the data for individual drugs rather than the therapeutic class.[117] In

• BOX 53.2 Anti-depressants: Safety and Side Effects

Weight - Weight gain is common with anti-depressants. When they are used for the treatment of depression, mood alteration may have an effect on appetite and wellbeing. TCAs are more likely than SSRIs to cause weight gain.[122]
Cholinergic-type side effects - including dry mouth, sedation, and urinary retention, may also complicate TCA use.
Risk for falls - A study of United States veterans showed that of 2212 patients with hip fractures, 70% had taken medication before the fracture, which may have contributed to their fall. Patients were twice as likely to have taken a TCA or SSRI as a matched control.[123]
Use in pregnancy - anti-depressant usage has been associated with increased risk of cardiac malformations, preterm births and neonatal respiratory distress.[124]
Automobile Driving - After acute dosing of sedating anti-depressants (e.g. amitriptyline, imipramine, doxepin, mianserin), a measure of driving ability gave results comparable to those of individuals whose blood alcohol concentration was 0.8 mg/mL.[125] It was also noted that concomitant use of a benzodiazepine with an anti-depressant makes driving impairment significant. When SSRIs are considered, no impairment in driving ability has been noted.[126] Consequently, when a TCA is given, the patient should be warned to avoid driving until stabilization with a fixed dose of the TCA has occurred.
SSRIs and NSAIDs - A study of 15,445 new users of anti-depressants with or without the use of nonsteroidal anti-inflammatory drugs (NSAIDs) reported that in the 691 individuals given TCAs who were not taking NSAIDs, the incidence of peptic ulcer drug request was 0.051%. In the SSRI-only group (1181 subjects), the incidence was 1.2%. When an SSRI was taken with an NSAID (86 subjects), the incidence of peptic ulcer drug request was 12.4% instead of 2.5% in the TCA-NSAID cohort. This would suggest that some caution needs to be taken when SSRIs are given to patients taking NSAIDs.[127]

TABLE 53.2 Numbers of Deaths per Million Prescriptions of Anti-depressants (in the United Kingdom)

	Drug	Deaths per million prescriptions (95% confidence interval)
TCAs	Desipramine	200.9 (92.0–381.6)
	Dothiepin	53.3 (50.5–56.1)

	Fluoxetine	0.9 (0.5–1.4)
	Paroxetine	0.7 (0.4–1.3)
NRIs	Reboxetine	0 (0–21.1)

NRIs, Noradrenaline reuptake inhibitor; *SNRIs*, serotonin-noradrenaline reuptake inhibitors; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic anti-depressants.

Data from Buckley and McManus. Fatal toxicity of serotoninergic and other antidepressant drugs: analysis of United Kingdom mortality data. *BMJ.* 2002;325(7376):1332–3.[117]

terms of overall comparative tolerability, it would be expected that the newer anti-depressants would be tolerated better than the TCAs. In a meta-analysis reviewing the tolerability of TCAs and SSRIs (when used for the treatment of depression), the number needed to harm (NNH)—in this case, the number of subjects receiving the treatment—for one subject to need to drop out because of side effects was calculated to be 4-30 for TCAs and 20-90 for SSRIs.[118] Similarly, in neuropathic pain, the NNH for TCAs was 13.4, and for SNRIs the NNH was 11.8.[50] For SNRIs, in trials for neuropathic pain, the dropout rates for milnacipran (28%) appear to be higher than for duloxetine (4%-19%) and venlafaxine (9%).[119] The most common adverse effects associated with duloxetine were nausea, dizziness, somnolence, and constipation, which were present in up to 30% of patients.

Conclusion

There is extensive evidence that anti-depressant drugs that block both reuptake of serotonin and noradrenaline can be highly effective for a subset of patients with neuropathic pain. An inherent drawback of the older trials is that drug effects on different types of pain were not evaluated but only showed whether patients with different types of pain achieved pain relief in general. The NNT values of the more recent duloxetine trials tend to be higher than the older TCA trials and reflect an increase in the placebo response over time.[120] Patients with neuropathic pain have been stratified according to their quantitative sensory testing profiles and broadly fall into three categories referred to as the mechanical phenotype, thermal phenotype, and sensory loss group.[27] These sub-groups have been hypothesized to represent surrogate sensory biomarkers of underlying pathophysiologic mechanisms. Concerning sensory profiles, *post hoc* analysis of clinical trials revealed that patients with sensory gain were more likely to benefit from imipramine treatment than those with sensory loss.[85] Other mechanism-based approaches to stratifying patients include exacerbated temporal summation (spinal amplification) or loss of CPM (diminished descending pain control).[121] Impaired CPM appears to be a much more reliable predictor of analgesic response to duloxetine,[23] and this approach could be applied to other anti-depressants with similar mechanisms of action. Although this chapter has focused primarily on neuropathic pain, similar sensory phenotypes have been described in osteoarthritis and fibromyalgia, and the same principles would apply.

Key Points

- Anti-depressants can be effective for treating neuropathic pain independently of their actions on comorbid depression.
- The analgesic effects tend to occur more rapidly and at lower doses than those used for treating depression.
- The primary mechanism of action is through a block of monoamine reuptake in descending modulatory pathways. However, many TCAs have an additional affinity for monoaminergic receptors, which can contribute to their analgesic effects. Side effects can also be attributed to a block of histaminergic and cholinergic receptors.
- Duloxetine and amitriptyline are considered first line therapies for neuropathic pain (NeuPSIG recommendation[50]), though duloxetine is often preferred because of a better side effect profile.
- Low CPM represents a surrogate measure of dysregulated descending modulation in neuropathic pain. CPM could be valuable for mechanism-led treatment selection as low CPM values correlate with the analgesic effects of duloxetine.
- There is little compelling evidence supporting the use of SSRI, noradrenaline reuptake inhibitors, dopamine reuptake inhibitors, tetracyclics, and monoamine oxidase inhibitors for the treatment of neuropathic pain.

Adjunct Medications for Pain Management

DANIEL B. LARACH, ANDREA L. CHADWICK, CHARLES E. ARGOFF, ROBERT W. HURLEY

Treatment of chronic pain involves understanding the delicate interplay of nociceptive, neuropathic, and nociplastic mechanisms involved in any given pain syndrome's pathophysiology. Research into the underlying pathways for chronic pain has provided the mechanistic basis to utilize numerous non-opioid medications to treat chronic pain disorders. Non-opioid medications, often referred to as adjuvant medications, can take the form of amine reuptake inhibitors, such as the serotonin-norepinephrine reuptake inhibitors (SNRIs) and tricyclic anti-depressants (TCAs); neuronal membrane stabilizers, such as the sodium and calcium channel–blocking anti-convulsants; nonsteroidal anti-inflammatory drugs (NSAIDs); topical analgesics; muscle relaxants; transient receptor potential vanilloid 1 (TRPV1) receptor agonists; N-methyl-D-aspartic acid (NMDA) receptor antagonists; opioid receptor antagonists; and botulinum toxin. The use of NSAIDs, topical analgesics, SNRIs, TCAs, and muscle relaxants in chronic pain disorders are described in other chapters in this text. For this chapter, we will discuss the use of neuronal membrane stabilizers, TRPV1 agonists (capsaicin), NMDA antagonists (ketamine), opioid receptor antagonists (low dose naltrexone), and botulinum toxin, along with data associated with their use for chronic pain management.

Membrane Stabilizers

Alterations in the functioning of sodium and calcium channels have been well-described in the literature regarding the pathophysiology of many chronic pain syndromes.[1,2] Clinically available agents that act on these ion channels include the membrane stabilizing agents typically used to treat epilepsy. Many of these agents have been tried with varying success in patients with pain. Multiple classes of medications that fall under the membrane stabilizer classification are beneficial in treating pain (Table 54.1). These agents include antiepileptic/anti-convulsants, local anesthetics, TCAs, and antiarrhythmic medications. As a group, they inhibit the development and propagation of ectopic neuronal discharges. The primary agents from this adjuvant drug class used to treat chronic pain include antiepileptic/anti-convulsants, local anesthetics, and the TCAs. TCAs are discussed in a separate chapter and not covered here. Gabapentin and pregabalin, also anti-convulsants, are discussed separately under calcium channel modulators because their mechanism of action differs from that of the other membrane stabilizing agents.

Calcium Channel Modulators

Calcium channel modulators are widely used non-opioid medications for chronic pain and are first line treatment agents for many neuropathic and nociplastic chronic pain conditions.[3] The intracellular free calcium ion concentration is only 1 in 10,000 that of the extracellular environment, and influx of calcium through calcium channels has important depolarizing effects on neurons. Voltage-gated calcium channels can be divided into high-voltage-activated (HVA) and low-voltage-activated (LVA) channels. Electrophysiologic characteristics allow division into HVA and LVA channels, depending on the threshold of activation. The HVA group is further divided into types L, P/Q, N, and R.[4] These groups require large membrane depolarization and are mainly responsible for the entry of calcium and release of neurotransmitters from presynaptic nerve terminals. Low-voltage channels, such as the T-type, regulate firing by participating in bursting and intrinsic oscillations. The spike and wave discharges from the thalamus with absence seizures are dependent on T-type calcium channels; these discharges are inhibited by valproic acid or ethosuximide. The N-type HVA calcium channels are thought to be primarily responsible for the release of neurotransmitters at synaptic junctions and become inactivated rather quickly. The P/Q-type calcium channel is so named because it was first described in the Purkinje cells of the cerebellum. The T-type channel, named after the transient current elicited, starts to open with weak depolarization, near resting potential. L-type channels are found in high concentration in skeletal muscle and in many other tissues, such as neuronal and smooth muscle, where it has been most studied. The voltage-gated calcium channel is composed of five polypeptide subunits and is the target of many drugs. Calcium channels consist of an α protein, along with several auxiliary subunits; the α protein forms the channel pore.

The calcium channel modulators that are used to treat chronic pain, such as gabapentin and pregabalin, bind to the $\alpha_2\delta$ subunit of L-type voltage-gated calcium channels, and such binding results in decreased release of glutamate, norepinephrine, and substance P.[5] Though structurally derived from the inhibitory neurotransmitter γ-aminobutyric acid (GABA), neither gabapentin nor pregabalin bind to or have activity at the GABA receptor. They also do not affect the uptake or metabolism of GABA.

TABLE 54.1 Membrane Stabilizers for Pain

Membrane Stabilizer	Mechanism	Side Effects
Carbamazepine	Na channel blockade	Sedation, dizziness, gait abnormalities, hematologic changes
Oxcarbazepine	Na channel blockade	Hyponatremia, somnolence, dizziness
Lamotrigine	Stabilizes slow Na channel; suppress the release of glutamate from presynaptic neurons	Rash, dizziness, somnolence
Gabapentin/pregabalin	Binds to $\alpha_2\delta$ subunit of voltage-gated Ca channel	Dizziness, sedation
Valproic acid	Na channel blockade; increases GABA	Somnolence, dizziness, gastrointestinal upset
Topiramate	Na channel blockade; potentiates GABA inhibition	Sedation, kidney stones, glaucoma
Mexiletine	Na channel blockade	Nausea, blurred vision
Lacosamide	Na channel blockade	Dizziness, nausea, double vision, headache

GABA, γ-aminobutyric acid.

Gabapentin (Neurontin, Gralise, Horizant)

Gabapentin is a non-opioid medication that has been ubiquitously used for chronic pain management. The standard initial dose of gabapentin is dependent on the particular gabapentin formulation used. For the first available preparation of gabapentin (Neurontin), it is 100 to 300 mg daily. Although the United States Food and Drug Administration (FDA)-approved therapeutic dose of this preparation for the treatment of postherpetic neuralgia (PHN) (the only chronic pain condition for which this preparation is FDA-indicated) is 1800 mg, many clinicians will start with a lower dose with a gradual increase to a maximum of 3600 mg/day administered in three divided doses as tolerated (Table 54.2). To minimize the consequence of certain adverse effects such as sedation and dizziness, the initial dose is often given at bedtime. After two to five days, the dose is increased to 300 mg twice daily and, after another two to five days, to 300 mg three times daily after that. Then the dose can be increased by 300 to 600 mg every few days as tolerated until an effective dosage is obtained, the maximum daily dose is reached, or side effects appear. A gastric-retentive formulation of gabapentin (Gralise) has also been approved by the FDA for PHN. It is intended to provide a simpler dosing paradigm than needed with the traditional generic gabapentin through the use of a polymer-based technology that allows gastric retention of the pill for extended delivery of the active medication. Another formulation of gabapentin, gabapentin enacarbil (Horizant), was developed and initially approved to treat restless legs syndrome. It is an actively transported prodrug form of gabapentin that allows twice-a-day dosing because of increased stability in bioavailability compared to the standard formulation of gabapentin. In a randomized controlled trial (RCT), this prodrug formulation was also found to be effective in the treatment of PHN when given twice per day.[6] This drug is approved by the FDA to treat PHN and restless leg syndrome.

The primary dose-limiting side effects of gabapentin are fatigue, somnolence, and dizziness, which are often attenuated by gradual dose titration. Although gabapentin has few drug interactions, a reduced dosage is necessary for patients with renal insufficiency. However, starting dosages of gabapentin often do not provide immediate pain relief, and the slow titration requirements may result in adequate pain relief taking up to two months to achieve when given as immediate-release gabapentin. When given as the extended-release formulation, therapeutic doses can be reached in approximately two weeks.

Gabapentin has uses in multiple chronic pain conditions. Studies have been performed on patients being treated for PHN, complex regional pain syndrome (CRPS), painful diabetic neuropathy (PDN), and other forms of neuropathic pain (NP) and pain of controversial etiology, including fibromyalgia and opioid-induced hyperalgesia.[7–9] A meta-analysis of 5914 participants in 37 studies found substantial benefits (at least 50% pain relief or "very much improved" on the patient global impression of change [PGIC] scale) for patients with PHN and PDN. Common side effects across the entire meta-analyzed population included dizziness (19%), gait disturbance (14%), somnolence (14%), and peripheral edema (7%). Among 2260 patients with PHN from eight studies, 32% of subjects had a substantial response to gabapentin ≥1200 mg daily compared with 17% of subjects receiving placebo (RR 1.8 [95% confidence interval [CI] 1.5 to 2.1]; number needed to treat (NNT) 6.7 [5.4 to 8.7]). When "moderate benefit" (at least 30% pain relief or PGIC of "much improved" or "very much improved") was examined, 46% of PHN participants met these criteria compared with 25% of those taking placebo (RR 1.8 [95% CI 1.6 to 2.0]; NNT 4.8 [4.1 to 6.0]). Evidence for both of these outcomes was graded as moderate quality. The same meta-analysis found that among 1277 PDN patients across six studies, 38% receiving gabapentin ≥1200 mg/day derived substantial benefit compared with 21% of subjects receiving placebo (RR 1.9 [95% CI 1.5 to 2.3]; NNT 5.9 [4.6 to 8.3]). Similarly, 52% of subjects receiving gabapentin had moderate benefit, while 37% of those receiving placebo did (1439 total participants across seven studies; RR 1.4 [95% CI 1.3 to 1.6]; NNT 6.6 [4.9 to 9.9]). Evidence was again graded as moderate quality. Of note, very limited data are available for gabapentin use in other neuropathic pain conditions such as nerve injury, spinal cord injury, and radicular leg pain despite this medication being commonly used for these indications.[10] Other meta-analyses have looked at gabapentin use in phantom limb pain, showing a mean Numerical Rating Scale (NRS) difference of –1.16 (95% CI –1.94 to –0.38) for gabapentin compared with placebo in a small total sample of 43 subjects,[11] and in chronic low back

TABLE 54.2 Dosing Recommendations for Neuropathic Pain

Membrane Stabilizer	Initial Dosage	Titration	Max Therapeutic Dosage
Carbamazepine	100–200 mg BID	Increase by 200 mg increments gradually	1200 mg QD
Oxcarbazepine	600 mg daily BID	Increase by 300 mg	1200–1800 mg TID
Lamotrigine	25–50 mg QHS	Increase by 50 mg every one to two weeks	300–500 mg QD
Gabapentin*	100–300 mg QHS	Increase by 100–300 mg or 100–300 mg TID every one to seven days as tolerated	3600 mg (1200 TID)
Gabapentin GR	300 mg QHS	Day one, 300 mg; day two, 600; days three to six, 900; days seven to ten, 1200; days 11–14, 1500, then 1800	1800 mg QHS
Pregabalin*	50 mg TID or 75 mg BID	Increase to 300 mg daily after three to seven days, then by 150 mg/day every three to seven days as tolerated	600 mg QD (200 mg TID or 300 mg BID)
Valproic acid	250 mg BID	Increase by 250 mg weekly	500 mg BID
Topiramate	50 mg QHS	Start at 50 mg BID after one week, then increase 100 mg BID after seven days	100 mg BID
Mexiletine	150 mg QD	Increase to 300 mg in three days and then 600 mg	Maximum: 10 mg/kg daily

*Reduce if impaired renal function.

BID, twice daily; *QHS*, at bedtime; *QD*, daily; *TID*, three times daily.

pain (cLBP), unsurprisingly showing no significant improvement in pain compared with placebo in 185 subjects (mean NRS difference –0.22 [95% CI –0.5 to 0.07]), with low quality evidence.[12] Overall, most guidelines for the treatment of NP include gabapentin as a first line agent.[13]

Recent attention has focused on the potential for misuse and use disorder related to gabapentin, as well as the risk of morbidity and mortality when this medication is co-prescribed with opioids. A systematic review of 59 studies examining gabapentinoid misuse and abuse found a 1.6% prevalence of abuse among the general population but prevalence ranging from 3%-68% among opioid abusers; overall risk factors for abuse included a history of substance misuse, particularly opioids, and psychiatric comorbidities. Prescribers should exercise caution with gabapentin in these populations.[14] A population-based nested case-control study of 1256 opioid users who died of opioid-related causes and 4619 opioid users found that opioid and gabapentin coadministration significantly increased the odds of opioid-related death compared with opioid use without gabapentin (adjusted odds ratio 1.49, 95% CI 1.18 to 1.88).[15] The FDA recently added a black box warning to gabapentin (as well as pregabalin, discussed below), cautioning that respiratory depression and sedation may occur in elderly patients or those with respiratory conditions receiving gabapentinoids concurrently with central nervous system (CNS) depressants such as opioids and benzodiazepines.[16]

Few studies have looked at the use of gabapentin on cLBP. One study by Atkinson et al. investigated gabapentin versus inert placebo for cLBP and found that within each treatment arm, there was statistically significant reductions in pain. However, when comparing gabapentin to placebo, there was no statistically significant difference in pain relief between the two groups.[17]

Gabapentin has been reported as useful in the treatment of fibromyalgia. However, only one rigorous RCT has been published investigating gabapentin versus placebo for this condition. In this study by Arnold et al. 150 patients were randomized to either placebo or gabapentin (titrated to doses of 1200–2400 mg/day) for 12 weeks.[18] Results showed that gabapentin-treated patients had significantly greater improvement in average pain scores of a modest effect.

Pregabalin (Lyrica)

Like gabapentin, pregabalin is used to treat chronic pain and acts by binding to the $\alpha_2\delta$ subunit of L-type voltage-gated calcium channels, which results in decreased neuronal excitation. Pregabalin is approved by the FDA for the treatment of PHN, PDN, fibromyalgia, and spinal cord injury-associated pain. Initial pregabalin dosing is 150 mg/day given in two or three divided doses or 25 to 50 mg given at bedtime in elderly patients. Upward dose titration can be completed after three to seven days to 300 mg/day and subsequently increased to a maximum dose of 600 mg/day within two weeks of initiation. Similar to gabapentin, dosing of pregabalin must be decreased in patients with reduced kidney function. Advantages of pregabalin over gabapentin include a more rapid onset of pain relief, linear pharmacokinetics with low inter-subject variability,[19] fewer dose-related side effects, thereby allowing faster upward dosage titrations, and twice daily versus three times a day dosing. Additionally, a maximum benefit often occurs after two weeks of treatment at target doses of 300 to 600 mg/day versus up to two months in gabapentin-treated patients. The advantage of pregabalin is its early response and favorable side effect profile.[20] The most common adverse effects include somnolence and dizziness, and they occur more frequently with higher doses. When discontinuing pregabalin, it should be tapered down gradually over at least one week to minimize symptoms, including insomnia, nausea, headache, and diarrhea.

As with gabapentin, pregabalin's efficacy has been established in patients with PHN and PDN. One meta-analysis included

11,906 patients from 45 studies.[21] Among subjects with PHN, subjects taking pregabalin 300 mg daily were more likely to experience ≥50% pain relief (32% vs. 13%; RR 2.5 [95% CI 1.9 to 3.4]; NNT 5.3 [3.9 to 8.1] among 713 subjects across four studies) and ≥30% pain relief (50% vs. 25%; RR 2.1 [95% CI 1.6 to 2.6]; NNT 3.9 [3.0 to 5.6] among 589 subjects across three studies) compared with those taking placebo. A dose-response relationship was observed among this population: Subjects administered pregabalin 600 mg daily compared with those given placebo were more likely to attain ≥50% pain relief (41% vs. 15%; RR 2.7 [95% CI 2.0 to 3.5]; NNT 3.9 [3.1 to 5.5] among four studies with 732 participants) and ≥30% pain relief (62% vs. 24%; RR 2.5 [95% CI 2.0 to 3.2]; NNT 2.7 [2.2 to 3.7]) in three studies with 537 participants. Evidence for all PHN analyses was graded as moderate quality.

For PDN, subjects administered pregabalin 300 mg daily compared with placebo were more slightly more likely to obtain ≥50% pain reduction (31% vs. 24%; RR 1.3 [95% CI 1.2 to 1.5]; NNT 22 [12 to 200] among 2931 participants in 11 studies) and ≥30% pain reduction (47% vs. 42%; RR 1.1 [95% CI 1.01 to 1.2]; NNTB 22 [12 to 200] among eight studies with 2320 participants), and substantially more likely to report "much" or "very much" improved PGIC (51% vs. 30%; RR 1.8 [95% CI 1.5 to 2.0]; NNT 4.9 [3.8 to 6.9] in five studies with 1050 participants). As with PHN, more improvement was observed with the 600 mg daily dose than with 300 mg, with ≥50% pain reduction noted in 41% of those taking this dose compared with 28% of patients taking placebo (RR 1.4 [95% CI 1.2 to 1.7]; NNT 7.8 [5.4 to 14] in five studies with 1015 participants) and ≥30% pain reduction seen in 63% versus 52% on placebo (RR 1.2 [95% CI 1.04 to 1.4]; NNT 9.6 [5.5 to 41]; 611 participants from two studies). In the PDN studies, evidence for the 300 mg daily dose was graded as moderate quality, while evidence for the 600 mg dose was graded as low quality.

Benefit was also seen for pregabalin 600 mg daily dose in mixed or unclassified posttraumatic neuropathic pain: Meta-analysis of 1367 subjects from four studies showed ≥50% pain reduction in 34% of patients taking pregabalin compared with 20% of those taking placebo (RR 1.5 [1.2 to 1.9]; NNT 7.2 [5.4 to 11]; moderate quality evidence) and ≥30% pain reduction in 48% vs. 36% (RR 1.2 [1.1 to 1.4]; NNT 8.2 [5.7 to 15]; low quality evidence).[21] Pregabalin was also more likely to be efficacious than placebo in central neuropathic pain. Among 562 participants in three studies, 26% (vs. 15%) obtained ≥50% pain relief (RR 1.7 [1.2 to 2.3]; NNT 9.8 [6.0 to 28]; low quality evidence) and 44% (vs. 28%) obtained ≥30% pain reduction (RR 1.6 [1.3 to 2.0]; NNT 5.9 [4.1 to 11]; also, low quality evidence). There was no evidence of benefit in HIV neuropathy when 674 subjects in two studies were meta-analyzed (moderate quality evidence) and limited data for other NP conditions, including cancer pain, polyneuropathy, back pain, and sciatica. Except for PHN, a daily pregabalin dose of 150 mg daily was found to be ineffective; clinicians should consider higher doses should therapy at lower doses prove unhelpful. Clinicians should also be cognizant of the potential for misuse, abuse, and respiratory depression with gabapentinoids, as discussed previously in this chapter.

Two studies have investigated pregabalin compared to active control groups, and pregabalin was not found to be superior to opioids[22] or celecoxib[23] for treatment of cLBP. However, celecoxib plus pregabalin was superior to monotherapy in the study by Romano et al.[23]

Many studies have been performed investigating the use of pregabalin for the treatment of fibromyalgia syndrome. Seven RCTs have investigated pregabalin monotherapy at varying doses ranging from 150 to 600 mg/day and were found to have superior pain relief compared to placebo. Arnold et al.[24] and Mease et al.[25] both found that daily total doses of 300/450/600 mg were all superior in pain efficacy to placebo. Crofford et al. found that only 450 mg/day dosing was superior to placebo for pain efficacy (not 150 or 300 mg/day).[26] At doses of 300 or 450 mg/day, Ohta et al. reported superior efficacy of pregabalin over placebo.[27] Arnold et al.[28] and Clair[29] et al. also reported superior efficacy of pregabalin in pooled groups of pregabalin doses (300-450 mg/day) over placebo. Pauer et al. published that only a modest statistically significant effect over placebo was noted at 450 mg/day (not at 300 or 600 mg/day).[30] In a study by Gilron et al. combination therapy of pregabalin plus duloxetine versus placebo or monotherapy was investigated, and the authors reported that combination therapy is superior to placebo and pregabalin monotherapy.[31]

Zonisamide (Zonegran)

Zonisamide is indicated as adjunctive therapy for partial seizures in adults and became available in the United States in 2000. It acts by blocking T-type calcium channels and sodium channels; its action also increases the release of GABA. The initial dose is 100 mg/day for two weeks with increases of 200 mg/week to a target of 600 mg/day. There have been case reports on its usefulness for post-stroke pain and headache. A randomized, double-blind, placebo-controlled pilot study of the efficacy of zonisamide for the treatment of PDN revealed that pain scores on the visual analog scale (VAS) and Likert (psychometric response) scales decreased more in the zonisamide group than in the placebo group. However, these differences did not reach statistical significance.[32] Side effects included ataxia, decreased appetite, rash, and renal calculi (resulting from the carbonic anhydrase inhibitor effect). Zonisamide is contraindicated in those with sulfonamide allergy because it is a sulfonamide derivative, and the drug is approximately 40% bound to plasma proteins. Children have an increased risk for oligohidrosis and susceptibility to hyperthermia. Convincing data for zonisamide's efficacy in other chronic pain syndromes has yet to appear.[33]

Ziconotide (Prialt)

Ziconotide is a ω-conopeptide (previously known as SNX-111) that is administered intrathecally because of its peptidic structure. It is derived from the venom of a marine snail (genus *Conus*). Ziconotide blocks calcium influx into N-type calcium channels in the dorsal horn laminae of the spinal cord, thus preventing afferent conduction of nerve signals. The administration is via an intrathecal infusion pump, and dosing should be started low, at a recommended dose of 2.4 μg/day (0.1 μg/h). Because of a lag time, it should be titrated up slowly at intervals of no more than two to three times per week to a recommended maximum of 19.2 μg/day.[34] Ziconotide does not cause tolerance, dependence, or respiratory depression, and adverse effects primarily involve the CNS and range from dizziness, ataxia, confusion, and headache to frank psychosis and suicidal ideation.

Ziconotide monotherapy's effect on chronic NP has been meta-analyzed from three RCTs with a total of 586 subjects. The pooled OR of ≥30% pain reduction with ziconotide vs. placebo was 2.77 (95% CI 1.37 to 5.59).[35] Serious adverse events were common in the included studies, but evidence shows that these

may be decreased by slow titration.[36] A prospective multicenter observational registry of ziconotide use (either as monotherapy or with other intrathecal medications) observed ≥30% pain reduction in 17.4% of patients at 12 weeks and 38.5% of patients at 18 months. Nearly all patients included in the registry experienced side effects, including 22.6% with confusion.[37]

The role of ziconotide in the management of chronic pain has yet to be fully elucidated. Currently, ziconotide is approved for the management of severe chronic pain in patients in whom intrathecal therapy is warranted and who are intolerant of or refractory to other treatments, including intrathecal opioids, local anesthetics, and α-adrenergic agonists. However, this medication should be used cautiously because of its poor side effect profile. Particular attention should be paid to patients with preexisting psychiatric disease.

Sodium Channel Blockers

Sodium channel blockers are used as primary therapy or adjunctive treatment of neuropathic pain syndromes such as trigeminal neuralgia (TN), CRPS, PDN, radicular extremity pain, chemotherapy-induced peripheral neuropathy, and PHN. When using these agents, as with all membrane stabilizers, it is crucial to be knowledgeable of the proper dosages, toxicities, and their effects when coadministered with other drugs. As a general rule, the dose should be titrated to patient comfort within safety standards.

When neurons are depolarized and approaching an action potential, the voltage-gated sodium channels quickly change conformation in response and permit the flow of sodium ions. Activation of sodium channels (and other voltage-gated ion channels) derives from the outward movement of charged residues because of an altered electrical field across the membrane. Sodium channels play an essential role in the action potentials of neurons and other electrically excitable cells. The flow of sodium ions is terminated by the inactivation of the channel in a few milliseconds (fast inactivation). Sodium channels can cycle open and close rapidly, which may result in seizures, neuropathic pain, or paresthesia. The structure of the channel is essentially a rectangular tube, with its four walls formed from four subunits, the four domains of a single polypeptide. A region near the N-terminus protrudes into the cytosol and forms an inactivating particle. It has been demonstrated that a short loop of amino acid residues, acting as a flap or hinge, blocks the inner mouth of the sodium channel and results in fast inactivation.[38] The highly conserved intracellular loop is the inactivating gate that binds to the intracellular pore and inactivates it within milliseconds. Site-directed antibody studies against this intracellular loop have prevented this fast inactivation.

The voltage-gated sodium channel can be divided into an α subunit and one or more auxiliary β subunits. At least nine α subunits have been functionally characterized—Nav1.1 through Nav1.9.[39] The sodium channels 1.2, 1.8, and 1.9 are preferentially expressed on peripheral sensory neurons, where they are important in nociception and may be a future target for channel-specific analgesics.[40] Seven of the nine sodium channel subtypes have been identified in sensory ganglia, such as the dorsal root ganglia and trigeminal ganglia. Nav1.7 is also present in large amounts in the peripheral nervous system. Nav1.2 is expressed in unmyelinated neurons, and Nav1.4 and Nav1.5 are muscle sodium channels. Sodium channel mutations that result in well-recognized syndromes have been described. A mutation in the gene encoding Nav1.4 is responsible for hyperkalemic periodic paralysis, and an inherited long QT syndrome can be caused by a mutation in the gene encoding Nav1.5. Mutations in *SCN9A*, which encodes Na 1.7, have been associated with several pain disorders: Primary erythromelalgia and paroxysmal extreme pain disorder are caused by gain-of-function variants. In contrast, congenital insensitivity to pain is caused by a loss-of-function variant.

Increased expression of sodium channels has been demonstrated in peripheral and central sensory neurons in patients with chronic pain; it is one mechanism for the observed hyperexcitability of pain pathways.[41] Anti-convulsants that modulate the gating of sodium channels include phenytoin, lamotrigine, carbamazepine, oxcarbazepine, and zonisamide, with some evidence for topiramate and valproic acid. It is important to note that at clinical concentrations, the sodium channel is only weakly blocked when hyperpolarized. When the neuronal membrane is depolarized, there is a much greater inhibition of the channel. The binding of the channel by anti-convulsants is slow in comparison to local anesthetics. The slow binding of anti-convulsants ensures that the kinetic properties of normal action potentials are not altered. Generally, anti-convulsants have no role in the treatment of acute pain, although they have demonstrated efficacy in chronic pain conditions. Interestingly, local application of phenytoin and carbamazepine has an antinociceptive effect that is more potent than lidocaine.[42] It has been demonstrated that phenytoin, carbamazepine, and lamotrigine bind to a common recognition site on sodium channels, probably as a result of their two phenol groups, which act as binding elements.[43] At normal resting potentials, these medications have little effect on action potentials. Besides the fast current of the open channel, there is also a persistent sodium current. This current, carried by persistent openings, is a small fraction of the fast current but may have an important role in regulating excitability. There is evidence that several anti-convulsants, such as phenytoin, valproate, and topiramate, also act by blocking the persistent sodium current.

Phenytoin (Dilantin)

Besides the widespread use of phenytoin for seizures, it was the first anti-convulsant to be used for NP, with a 1940s report on its use for TN. Phenytoin is known for its nonlinear metabolism, which is manifested as marked increases in plasma level with small increases in dose after saturation of metabolism. Around 95% of a phenytoin dose is excreted as metabolites from the cytochrome P-450 system. The initial dosage of phenytoin is 100 mg two to three times daily. It has primarily been used for the treatment of diabetic neuropathy. However, because of the mixed results of its efficacy and high side effects and medication interaction profile, it has fallen into disuse. Phenytoin provides pain relief by blocking sodium channels, thereby preventing the release of excitatory glutamate and inhibiting ectopic discharges.

Intravenous phenytoin has been studied in the chronic pain setting, but data are limited. A systematic review and meta-analysis did not identify any studies warranting inclusion.[44] Side effects of phenytoin include slowing of mentation and somnolence, with nystagmus and ataxia occurring in some patients. Among the epileptic drugs, phenytoin is unique in the development of facial alterations, including gum hyperplasia and coarsening of facial features. Fosphenytoin, an intravenously administered prodrug that converts to phenytoin, is used by some to avoid long dosing intervals or initial burning at the injection site.

Phenytoin activates the cytochrome P-450 enzyme system in the liver, and hence careful assessment of co-therapy is warranted. For example, phenytoin decreases the efficacy of methadone, fentanyl, tramadol, mexiletine, lamotrigine, and carbamazepine.

As a result, dosages of these medications should be adjusted accordingly. Coadministration with anti-depressants and valproic acid could lead to an increased blood concentration of phenytoin, thereby lowering the subsequent doses required for effect in patients. Most would not use phenytoin for the treatment of NP except perhaps in refractory situations.

Carbamazepine (Tegretol)

Carbamazepine has been used in the United States since the 1980s to treat partial and generalized tonic-clonic seizures. Interestingly, it was *first* approved by the FDA for the treatment of TN, not for epilepsy. Besides its anti-convulsant and TN indications, it is used frequently for bipolar disorder. It was one of the first anti-convulsants studied for the relief of NP. The analgesic properties of carbamazepine were first reported in 1962.[45] It is chemically related to the TCAs; reports have included studies of its use for PHN, PDN, post-stroke pain, and pain in Guillain-Barré syndrome. The initial dosage of carbamazepine is 100 to 200 mg twice daily, titrated to effect, with typical dose ranges of 300 to 1200 mg/day administered in two divided doses. Common maintenance doses are 600 to 800 mg.

Common side effects include drowsiness, dizziness, nausea, and vomiting, which can often be limited by slow titration. Carbamazepine is associated with very deleterious side effects, including pancytopenia, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

Carbamazepine is considered the pharmacologic treatment of choice for TN. Although the pathology of this severe neuropathic facial pain in one of the distributions of the trigeminal nerve has not been fully determined, the majority of cases are thought to be caused by compression of the trigeminal nerve at the pontine origin of the nerve by an aberrant loop of an artery or vein. Despite (and likely because of) its longstanding history of use for this condition, high quality evidence for the efficacy of carbamazepine in TN was found lacking in a recent meta-analysis. Only two small placebo-controlled studies of short duration from the 1960s were included, with an overall RR of 6.02 (95% CI 2.82 to 12.85).[46] However, societal guidelines emphasize the excellent treatment response seen in four such small studies, with 58% to 100% of patients obtaining meaningful pain relief compared with 0% to 40% in placebo groups and an NNT <2.[47] Regardless, TN is a disease process that in many patients is challenging to treat completely, with multiple agents often being required.

Carbamazepine has also been investigated for use in other chronic NP states, with a similar lack of high quality evidence. Combined meta-analysis of four studies including 188 patients with TN, PDN, and post-stroke pain calculated a RR of 6.5 (95% CI 3.4 to 12) with an NNT of 1.9 (95% CI 1.6 to 2.5) for ≥50% reduction in pain, with the caveat that studies were small and of short duration.[46] Importantly, patients maintained on carbamazepine therapy should have blood tests done every two to four months because of increased risk for the development of agranulocytosis and aplastic anemia with this agent. Studies have noted that the number needed to harm (NNH) for severe adverse effects was 24 and for minor adverse effects, such as sedation, was three.[47]

Oxcarbazepine (Trileptal)

Oxcarbazepine, the keto-analog of carbamazepine, was developed to preserve the membrane stabilizing effects of carbamazepine while minimizing minor adverse effects such as sedation and serious, life-threatening reactions. A major advantage of oxcarbazepine is that monitoring plasma drug levels and hematologic profiles is not generally necessary. Similar to carbamazepine, oxcarbazepine blocks sodium channels; it does not affect GABA receptors.

Significant hyponatremia (sodium <125 mmol/L) may develop during treatment with oxcarbazepine. This typically occurs during the first three months, with sodium levels normalizing within a few days of discontinuing the drug. Monitoring of sodium levels should be performed when instituting oxcarbazepine therapy. Frequently reported adverse effects of oxcarbazepine include dizziness, somnolence, nausea, and vomiting, which are generally well tolerated; dermatologic adverse effects such as Stevens-Johnson syndrome and toxic epidermal necrolysis have also been infrequently reported.

The superior side effect profile of oxcarbazepine over carbamazepine has led to its increased use. Published guidelines list it as "probably effective" for treating pain from TN based on two moderate quality RCTs showing equal efficacy of oxcarbazepine and carbamazepine in 130 patients, with 88% showing a reduction in pain attacks by 50%.[47] Oxcarbazepine has also been found effective in treating TN in patients who had no positive response to carbamazepine,[48] and physicians should consider substituting one for the other in patients with insufficient analgesic response.[49] Meta-analysis of oxcarbazepine data has identified no appropriate placebo-controlled trials related to TN, and little evidence to support its use in other forms of NP such as PDN, radicular pain, and mixed neuropathy,[50] although a single RCT of 146 patients with PDN did show a significantly greater number of subjects attaining ≥50% pain relief with oxcarbazepine compared with placebo (34.8% vs. 18.2%, RR 1.91 [95% CI 1.08 to 3.39], NNT 6 [95% CI 3 to 41]).[51]

Lamotrigine (Lamictal)

Lamotrigine received FDA approval in 1994; it is used as an adjunctive agent for partial seizures and as monotherapy for partial and generalized seizures. Like other agents discussed in this section, lamotrigine is an agent that blocks sodium channels in actively firing nerves. It has no effect on sensation in the native, normally functioning nervous system. Unique to lamotrigine is the fact that in addition to acting as a sodium channel blocker, the drug prevents the release of glutamate, an excitatory transmitter involved in pain propagation. Adverse events such as dizziness, somnolence, and cognitive impairment occur with lamotrigine.[52] There is little dose-dependent toxicity, so monitoring of laboratory values is not necessary. The most concerning side effect is rash, which occurs more often with rapid titration; it can manifest as Stevens-Johnson syndrome.[53] The risk for rash is similar to that with phenytoin or carbamazepine, 5% to 10%. Enzyme-inducing drugs reduce the serum level of lamotrigine. Lamotrigine has no effect on liver enzymes, is metabolized via glucuronidation, and is 55% protein bound with a half-life of 30 h. It needs slow titration, at least four to six weeks.

Lamotrigine is considered a second-line agent, along with baclofen and gabapentin, to treat TN. Although carbamazepine and oxcarbazepine are generally considered first line therapy for TN, they are not always effective in these patients. Lamotrigine has been investigated in this patient population for use as a coadministered drug and as a substitute for carbamazepine in several small studies with promising results.[54-56] The use of lamotrigine may therefore be considered for carbamazepine- or oxcarbazepine-resistant TN. Lamotrigine has been shown to be minimally effective in the reduction of pain intensity in PDN in two placebo-controlled

RCTs,[57,58] and no change in one.[58] Subjects had no improvement in sleep interference, quality of life, patient reported improvement in pain, or mood and the most common side effect was rash.[57,58] In the positive trials, the minimal effective dose ranged from 400 mg/daily, and pain reduction occurs within six weeks. A meta-analysis of 1511 participants from 11 studies found minimal evidence of efficacy in other NP states such as central post-stroke pain, chemotherapy-induced neuropathic pain, DPN, HIV-related neuropathy, post-spinal-cord-injury pain, and mixed neuropathic pain.[59]

Topiramate (Topamax)

Topiramate has multiple mechanisms of action and is broadly used for seizure disorders. Topiramate blocks voltage-sensitive sodium channels, limits sustained repetitive firing, and binds to GABAA receptors to enhance GABA activity through non-benzodiazepine- and non-barbiturate-related mechanisms. It increases the opening frequency of chloride ion channels in GABAA receptors and can block α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-kainate glutamate receptors by acting as a negative modulator of glutamate at this receptor. Topiramate also reduces the activity of L-type calcium channels and is a carbonic anhydrase inhibitor. Topiramate exhibits linear pharmacokinetics over its dose range and has a half-life of 19 to 25 h. Its oral bioavailability is about 85%, and it is not affected by food. Enzyme-inducing drugs may reduce the serum level of topiramate. Common side effects include paresthesia because of inhibition of carbonic anhydrase, drowsiness, fatigue, and cognitive symptoms. The incidence of nephrolithiasis was 1.5% in clinical trials, and mild weight loss is often noted. The propensity for weight reduction in some patients has led to an investigation of its potential as a weight-reducing agent.[60]

The initial dose is 50 mg at bedtime, with increases to an upper limit of 200 mg twice daily. Studies have demonstrated that pain relief begins to occur at doses of 200 mg/day. Two large trials on migraine prophylaxis with topiramate were published in 2004, and topiramate received FDA approval for this indication.[61,62] Topiramate has been shown to be borderline effective in the reduction of pain intensity, improvement in sleep interference, quality of life, and mood[63] in two RCTs for PDN,[63,64] but ineffective in all domains in two others.[64] In the positive trials, the pain reduction occurs within eight weeks.[63] The most consistent finding in all trials was weight loss. Significantly more subjects lost weight in the topiramate group than placebo control subjects.[63] However, a review of multiple double-blind studies examining the efficacy of topiramate for PDN failed to show significant analgesic benefit,[55] and a meta-analysis of 1684 patients with either PDN or lumbar radiculopathy found a similar lack of efficacy with doses of 200 to 400 mg daily compared with placebo.[65] Few studies have investigated topiramate for cLBP. However, in one placebo-controlled RCT, the effects of topiramate on cLBP compared to inert placebo showed that topiramate was superior to placebo in reducing pain scores.[66] As clear benefit for topiramate in neuropathic pain has not been shown, it may best be reserved as an adjunct for refractory pain management when failure to achieve successful analgesic relief has occurred with other membrane stabilizer agents.

Lacosamide (Vimpat)

Lacosamide is an effective and well tolerated antiepileptic drug that is used as adjuvant treatment of focal-onset seizures uncontrolled by other agents.[67] Although it has not been compared directly with other adjuvant treatment options, its different mechanism of action and favorable safety profile make this antiepileptic agent a valuable addition to the treatment options available. The primary action of lacosamide is an enhancement of slow inactivation of voltage-gated sodium channels without any apparent interaction with fast inactivation, a mechanism that differs from that of other sodium channel-blocking membrane stabilizers. In addition to treating epilepsy, lacosamide has been found to be beneficial in the treatment of PDN. A meta-analysis including 1863 patients with PDN from five studies found moderate quality evidence that a 400 mg daily dose is beneficial, with an NNT compared with placebo between 10 and 12.[68] Consequently, lacosamide may be considered as an adjunct in difficult-to-treat neuropathic pain.

GABAergic Medications

Valproic Acid (Depakote)

First synthesized in 1882, valproate became available in the 1960s as an antiepileptic agent and received FDA approval in 1978 as an immediate-release formulation.[69] The drug has a broad spectrum of use for seizure disorders, including absence seizures, and is now also used extensively by psychiatrists for mood disorders. The exact molecular mechanisms responsible for its clinical effects are unknown. Catabolism of GABA is inhibited, and the synaptic release of GABA is increased. There are conflicting reports in the literature regarding the efficacy of this agent for NP, although studies have demonstrated that it is effective as migraine therapy at dosages of 750 mg/day for three months.[70] A meta-analysis identified three small placebo-controlled RCTs of valproic acid for NP: two in PDN and one in PHN. Two of the three showed statistically significant (albeit mild) improvements in pain.[71] Side effects include gastrointestinal upset, somnolence, and dizziness. The exact role of valproic acid in the armamentarium of the pain practitioner is yet to be elucidated, but given the superior evidence available for other medications, it should not be considered for initial therapy of NP.[72]

Diazepam (Valium), Lorazepam (Ativan), Clonazepam (Klonopin)

Benzodiazepines, such as diazepam, lorazepam, and clonazepam, facilitate the actions of GABA in the CNS because of their binding to the GABAA receptor. The side effects of drowsiness and ataxia and the development of tolerance to the antiseizure effect limit the usefulness of benzodiazepines for chronic use. Clonazepam is sometimes used for chronic neuropathic pain but has limited evidence to support this.[73]

Although benzodiazepines are frequently prescribed for multiple pain syndromes, there is little, if any, evidence of their benefit as pain therapy, and they are more commonly associated with adverse events, particularly when co-prescribed with opioids.[74]Aside from recognized use for two rare pain conditions (burning mouth syndrome and stiff-person syndrome), benzodiazepines do not appear to have a risk-benefit ratio that warrants use as analgesics for chronic pain.[75]

Local Anesthetics

Local anesthetics are used in NP states to block the aberrant firing of abnormal nerves, although they also block normally conducting (non-nociceptive) nerves. As a group, they are effective in the treatment of PHN, TN, radiculopathies, and peripheral neuropathies.

Lidocaine

Intravenous lidocaine has been shown to have modulatory effects not only on sodium channels but also on potassium and calcium channels, muscarinic receptors and NMDA receptors, the glycinergic system, and G-protein-coupled receptors.[76] The anti-inflammatory properties of systemic lidocaine are also being recognized.[77] Intravenous lidocaine has been the focus of several studies for NP; meta-analysis has shown significant superiority to placebo, with a weighted mean difference in VAS of –11 mm (95% CI –17 to –5 mm) among 373 subjects.[78] However, while another recent meta-analysis observed a similar reduction in NP following individual lidocaine infusions (500 patients; weighted mean VAS difference –11.9, 95% CI –16.8 to –7), it did not show long-term efficacy for multiple lidocaine infusions over a four week period in decreasing NP (110 patients; weighted mean VAS difference –0.96; 05% CI –2.02 to 0.11).[79] Consequently, such infusions may be better suited to the acute rather than chronic settings. The typical intravenous infusion dose of lidocaine is 0.5 to 2 mg/kg/h. Side effects include dizziness, blurred vision, and seizures, which typically occur at a plasma level of 10 mg/mL.[80] Given that lidocaine is an antiarrhythmic, bradycardia and cardiac depression (present at a 20- to 25 mg/mL plasma concentration) are potential risks with this agent. Therefore electrocardiographic studies are indicated for long-term or high-dosage use of lidocaine, as is close monitoring.

A patch formulation of 5% lidocaine (Lidoderm) is available in a topical preparation, as is a 1.8% lidocaine topical system (ZTLIDO). Approved by the FDA for PHN, it has also proved to be of benefit in patients with various other types of neuropathic pain, including PDN, post-thoracotomy pain, intercostal neuralgia, and meralgia paresthetica.[81] Few studies have been performed investigating the use of lidocaine patches for musculoskeletal pain conditions. In a study investigating the use of lidocaine patch in cLBP, 30 patients were randomized to either a 5% lidocaine patch or placebo patch.[82] After two weeks of use, both lidocaine and placebo patch groups reported a greater than 50% decrease in pain, suggesting that there may be no independent efficacy of 5% lidocaine patch for cLBP. In myofascial pain syndrome (MPS), one RCT compared the effects of a topical lidocaine patch (total daily dose 350 mg), placebo patch, and injection of 0.5% bupivacaine over one painful trigger point for a total of four days.[83] This study found that lidocaine patches and local anesthetic infiltration were effective for pain and superior to placebo in the short-term for patients with MPS. In another RCT, it was reported that a 5% lidocaine patch used for 14 days in cervical MPS might be superior to placebo, but the significant difference between the two groups may have been skewed by an unexpected increase in pain in the placebo patch group.[84] While the evidence for lidocaine use in NP is strong, as evidenced by the FDA approval for lidocaine patch for many neuropathic pain syndromes, the evidence is not as strong for musculoskeletal pain conditions. Thus although a 5% lidocaine patch is low-risk and potentially beneficial, it may be prudent to use other agents known to benefit these conditions and only utilize a 5% lidocaine patch in refractory cases.

The eutectic mixture of local anesthetics (EMLA)—composed of prilocaine and lidocaine—has also been advocated for use as a topical local anesthetic. This agent is sometimes used as an adjunct for venipuncture in the pediatric population, but care must be taken with the amount of EMLA cream given to patients to avoid toxicity. Prilocaine is readily metabolized to *O*-toluidine, which can lead to methemoglobinemia. However, if dosages of prilocaine are kept below 600 mg, clinical methemoglobinemia is less likely to develop.

Mexiletine

Mexiletine is an antiarrhythmic and, for pain relief, can be considered an oral analog of lidocaine. Pain physicians may provide intravenous lidocaine for pain management, with monitoring of dose and effect. After receiving a dose of intravenously administered drug, treatment may readily be converted to oral mexiletine. The standard starting dose is 75 to 150 mg/day with a target of 300 to 450 mg/day.

Mexiletine can be used for PDN, thalamic stroke pain, spasticity, allodynia, and myotonia.[85] Meta-analysis of 377 subjects from nine placebo-controlled RCTs showed results for NP similar to lidocaine (weighted mean VAS difference –11 mm; 95% CI –16 to –6 mm).[78] Mexiletine has also been used successfully in patients with the rare Nav1.7 mutation causing erythromelalgia.[86] Common side effects, including somnolence, irritability, blurred vision, and nausea, and vomiting, limit the utility of this medication. Patients are also at risk for the development of blood dyscrasias, and blood tests should be obtained regularly.

Miscellaneous

Magnesium

Research has been performed to evaluate antagonists of the NMDA receptor, including the membrane stabilizing effect of magnesium. A systematic review identified nine RCTs with a total of 418 chronic pain patients, but the marked heterogeneity of these studies (three on NP, three on migraine, two on CRPS type one, and one on cLBP with a neuropathic component) precluded formal meta-analysis. Data were generally mixed or negative, although some individual studies showed significant positive results.[87] Larger-sized and higher-quality RCTs are needed to help determine the role of magnesium in the treatment of chronic NP.

Ketamine

Ketamine, another NMDA receptor antagonist, has been extensively studied for the treatment of NP. Recent studies have suggested that while this medication's analgesic effects are chiefly because of NMDA modulation, other receptors like AMPA may also be involved, as may the metabolite norketamine. Furthermore, ketamine-induced decreases in the sensory-discriminative component of chronic pain tend to not persist beyond the infusion period, suggesting that the ability of ketamine to cause long-term pain relief in some patients may be because of effects on the affective-motivational component of chronic pain.[88] Recently published societal guidelines for intravenous ketamine suggest starting dosing with a single outpatient infusion of at least 80 mg for at least 2 h and assessing patients for response prior to further administrations.[89] There is considerable variability in reported regimens, with some publications describing multiday infusions in intubated patients at doses as high as 7 mg/kg/h.[89] Psychomimetic and cardiovascular side effects are most common, leading some centers to require psychology and cardiology clearances prior to

starting infusions. However, hepatotoxicity (possibly cholestatic in nature) and cystitis have also been reported; the latter is more common with illicit ketamine use. Ketamine should be avoided in patients with active substance use disorders, severe hepatic dysfunction, poorly controlled psychotic disorders, and poorly controlled cardiovascular disease.[89]

Most data for the use of ketamine in chronic pain is related to intravenous administration. A recent meta-analysis aggregated 191 patients from seven studies examining both NP and non-NP pain, finding a significant decrease in pain by NRS compared with placebo up to two weeks post-infusion (mean difference –1.83; 95% CI –2.35 to –1.31; for studies reporting responder rates, the RR for a positive response to ketamine vs. placebo was 2.43, 95% CI 1.10 to 5.40). Subgroup analysis of 79 patients with either NP or mixed neuropathic-nociceptive pain also showed a significant decrease in pain scores following ketamine infusion vs. placebo (mean difference –1.75, 95% CI –2.08 to –1.43).[90] Continued large RCTs are needed to determine ideal intravenous dosing and treatment chronicity. Data are less available and less consistent for oral ketamine, which has only 10%-20% bioavailability.[91,92] The previously mentioned guidelines found low quality evidence for the consideration of oral ketamine (recommended dose 150 mg daily, or 0.5 mg/kg every 6 h) after IV infusions; the risk of abuse with prescribed oral ketamine warrants careful patient selection.[89]

Levetiracetam (Keppra)

Levetiracetam is a newer anti-convulsant that was approved in 1999 as adjunctive therapy for partial seizures in adults. It appears that inhibition of voltage-gated sodium channels or T-type calcium channels is not involved in the anti-convulsant effects of levetiracetam, which does not appear to have direct GABAA receptor effects. The mechanism of action of levetiracetam thus does not involve modulation of the four main systems. The starting dose of levetiracetam is 500 mg twice daily, and it may be increased to a recommended 3000 mg/day in divided doses. Dosages of up to 5000 mg/day have been assessed for the treatment of NP.[93] Its linear pharmacokinetics results in predictable effects as the dosage is increased. Levetiracetam is not metabolized by the cytochrome P-450 system and thus does not have significant drug interactions.[94] Adverse effects include asthenia, dizziness, somnolence, and headache. The drug has several favorable characteristics and has been investigated for adjuvant use in areas such as pain. Unfortunately, in several well conducted RCTs, it was found to be ineffective in the treatment of NP secondary to spinal cord injury,[95] polyneuropathy,[96] and post-mastectomy pain.[97]Meta-analysis of 240 participants with NP in four studies found very low quality evidence and no statistical difference in response to levetiracetam compared with placebo.[98]

Botulinum toxin

Botulinum toxin type A (BOTOX, Dysport, Xeomin) is a neurotoxin that causes muscle relaxation by blocking acetylcholine release at the neuromuscular junction. It is FDA approved to treat urinary incontinence associated with detrusor overactivity associated with a neurologic condition, chronic migraine, upper limb spasticity, cervical dystonia, axillary hyperhidrosis, blepharospasm, and strabismus. It can also be used in the treatment of chronic pain, including neuropathic pain and musculoskeletal pain. The analgesic mechanism of botulinum toxin type A (BTX-A) for neuropathic pain may be related to the inhibition of nociceptive neurotransmitters such as glutamate, CGRP, and substance P, as well as reduction of transient potential vanilloid 1 (TRPV1) channel activity.[99] Side effects can include injection site irritation and pain, muscle weakness, and rash. The FDA has also placed a black box warning because of the potential for delayed distant spread of this neurotoxin beyond the administration site leading to a botulism-like syndrome: swallowing and breathing difficulties, severe muscle weakness, and speech dysfunction.

Data for botulinum toxin in neuropathic pain conditions are primarily available for TN and PHN. A recent meta-analysis including 391 subjects from ten RCTs for TN and peripheral neuropathic pain identified a pooled effect of BTX-A three months after treatment superior to placebo: standardized mean difference –0.55 NRS points, 95% CI –0.87 to –0.22. Subsequent subgroup analysis found that the greatest decrease in pain intensity was seen in TN and PHN patients.[100] Another meta-analysis of 495 patients with undifferentiated neuropathic pain from 12 RCTs also found a significant pain reduction with BTX-A at 24 weeks (mean difference –1.61 NRS points, 95% CI –2.81 to –0.40).[101] A small meta-analysis of BTX-A for PDN has also been published (two studies; 58 patients), showing a pain reduction of 1.96 NRS points (95% CI –3.09 to –0.84) following treatment.[102] Further large high quality RCTs are necessary to determine the role of this medication in the treatment of NP. It may be reasonable to consider BTX-A use for NP patients who are unresponsive to standard therapy.

BTX-A has been studied in chronic musculoskeletal pain conditions, including cLBP and MPS. In a study on cLBP, 15 patients with cLBP received 200 units BTX-A in the lumbar spine paraspinal muscles, and 16 received a normal saline injection.[103] Those who received BTX-A injections had superior pain relief compared to saline injections at three and eight weeks after treatment. Numerous RCTs have been performed investigating BTX-A for chronic MPS. Most investigated patients with cervical and shoulder girdle MPS, and the majority utilized a placebo or control procedure. The sole study looking at lumbar MPS was performed by De Andres et al. and found that BTX-A was not superior in efficacy to placebo but was efficacious in a within-group analysis.[104] Seven studies showed superior efficacy of BTX-A injections for cervical MPS either compared to saline,[105–109] local anesthetic and dry needling,[110] or steroid.[111] Eight published studies had negative findings where BTX-A was not found to have superior efficacy to control procedure, either saline,[112–118] or local anesthetic.[119] The discrepancies between positive and negative studies have been postulated to exist because of heterogenous research design methodology and the use of control procedures that are thought to produce analgesic benefits of their own.[120]

Capsaicin

Capsaicin, the active compound in chili peppers, binds to the TRPV1 nociceptor in the skin, causing depolarization and action potential formation classically felt as a burning or pricking sensation. Its analgesic properties are thought to be because of repeated application (or a single application of highly concentrated capsaicin), causing long-lasting "defunctionalization" marked by reversible degeneration of nerve terminals. The principal adverse effects of capsaicin, unsurprisingly, are stinging, burning, and redness at the application site (these also make placebo-controlled study design challenging). There are also reports of respiratory irritation from inhalation of dried cream. Capsaicin is available in both low (<0.2%) and high dose (8%) formulations. Most studies of the low dose version have not shown results superior to placebo.[121]

The 8% formulation (Qutenza), which requires supervised administration and subsequent monitoring, has been studied in

two recent meta-analyses. For its principal indication, PHN, significantly more subjects receiving capsaicin in four studies with 1272 participants reported a ≥30% reduction in pain at two to eight weeks compared with active placebo (typically 0.04% capsaicin). RR was 1.3 (95% CI 1.1 to 1.5) and NNT 11 (95% CI 6.8 to 26). Data on ≥50% improvement in pain over the same period was available from three studies with 870 participants and similarly showed an RR of 1.4 (95% CI 1.1 to 1.9) and NNT 12 (95% CI 7.2 to 41). Evidence was graded as moderate quality. Very low quality evidence was found for 8% capsaicin use in HIV neuropathy and PDN. For the former, a meta-analysis of two studies with 801 participants showed an RR of 1.4 (95% CI 1.1 to 1.7) and NNT 11 (95% CI 6.2 to 47) in favor of capsaicin. For the latter, a single study of 369 subjects found that PGIC of "much improved" or "very much improved" occurred more frequently at eight weeks after capsaicin administration (RR 1.3 [95% CI 1.0 to 1.8] and NNT 10 [95% CI 5.2 to 520]).[122] A network meta-analysis for PDN that compared 8% capsaicin with several oral neuropathic agents included 25 RCTs and found that ≥30% reduction in pain was significantly more common with capsaicin than placebo (OR 2.28 [95% CI 1.19 to 4.03]). Statistically significant superiority was not seen compared with pregabalin, gabapentin, or duloxetine, although data suggested similar efficacy.[123] Overall, it is reasonable to consider high dose capsaicin therapy for refractory neuropathic pain, particularly PHN and PDN (its two FDA approved indications), keeping in mind the practical considerations necessary for administration.

Low Dose Naltrexone

Naltrexone, 17-(cyclopropylmethyl)-4,5-epoxy-3,14-dihydroxymorphinan-6-one, is a long-acting opioid receptor antagonist that was initially approved by the FDA in 1984 for the treatment of opioid dependence and is currently also FDA approved for the treatment of alcohol dependence.[124] Naltrexone and its active metabolite, 6-beta-naltrexone, are reversible competitive antagonists at μ-opioid and κ-opioid receptors, with the highest affinity for μ-opioid receptors.[124,125] The standard dose of naltrexone for the FDA approved indications at 50 to 150 mg also prevents inhibition of γ-aminobutyric acid receptor and inhibition of dopamine release. The premise behind using low dose naltrexone (LDN) stems from the fact that its kinetics do not follow a linear dose-effect curve. Rather, it follows multiple dose-dependent pharmacologic pathways with different end results. LDN has been identified to have multiple mechanisms of action that underlie its emerging utility in chronic pain syndromes, including transient opioid receptor blockade, which upregulates opioid signaling, glial modulation with a neuroprotective effect via inhibition of microglial activation in the CNS through Toll-like receptor four antagonism, and blockade of the opioid growth factor (OGF) receptor resulting in biofeedback response that increases production of endogenous OGF, also known as [Met5]-enkephalin, with a concomitant increase in μ-opioid, δ-opioid, and OGF receptor expression, thereby facilitating interactions between OGF and opioid growth factor receptor (OGFr).[124,126,127]

With a therapeutic dosing range of 0.5 to 9 mg taken once daily (most commonly 3-5 mg), LDN has been shown in multiple published case reports and studies to be efficacious in improving chronic pain severity in patients with fibromyalgia,[126,128–130] CRPS,[131] cLBP,[132] and PDN.[133] Naltrexone is an inexpensive medication with a low side effect profile, with some reported incidences of vivid dreams, nightmares, headaches, and anecdotal reports of anxiety and tachycardia. Current evidence supports its safety and tolerability, and most available evidence shows improvement in subjective pain measures such as quality of life and self-reported pain, but objective data are limited.[134] There are currently no guidelines for the clinical use of LDN and no FDA approved use for naltrexone at any dosage to treat chronic pain. In addition, LDN is not commercially available and must be produced in a compounding pharmacy.

To conclude, naltrexone remains an off-label option for the treatment of chronic pain. Further clinical research with RCTs is warranted, and the use of this medication is recommended for those chronic pain patients who fail gold-standard or other conventional therapy.

Conclusion

There exists a wide variety of non-opioid adjuvant medications for the treatment of chronic pain syndromes. The majority of RCTs to determine the effectiveness of these agents have involved select conditions, with extrapolation of these results to other chronic pain conditions based on the known underlying pathophysiology. As the science of pain medicine has advanced, studies have begun to examine less common chronic pain conditions and the efficacy of these adjuvant agents to treat them. Emerging therapies including NMDA antagonists, capsaicin, and LDN show promising results, but large-scale confirmation via well-designed RCTs is lacking.

Key Points

- Multimodal medical management of cancer- and non-cancer-related pain can involve the use of non-opioid medications, as well as opioid medications.
- Calcium channel modulators used to treat chronic pain, such as gabapentin and pregabalin, bind to the $\alpha_2\delta$ subunit of L-type voltage-gated calcium channels and result in decreased release of glutamate, norepinephrine, and substance P.
- Evidence is strongest for gabapentin and pregabalin as the membrane stabilizers that are most efficacious for neuropathic pain and a variety of other chronic pain syndromes.
- Topiramate has not been convincingly shown to be efficacious for the treatment of chronic pain.
- With rare exceptions, benzodiazepines should not be used to treat chronic pain because of their considerable risks and limited evidence of benefit.
- Intravenous lidocaine has shown promising short-term effects for treating chronic pain, but data are lacking for longer-term benefit.
- Intravenous ketamine is quite propitious for chronic pain, but further research is required to determine the optimal dose and treatment chronicity.
- Botulinum toxin type A, high dose topical capsaicin, and LDN may be considered in refractory chronic pain.

Acknowledgments

The authors gratefully recognize the contributions of Dr. Brian E. McGeeney, co-author of the prior edition of this chapter.

Skeletal Muscle Relaxants

RAVNEET BHULLAR, EVANGELINE P. KOUTALIANOS, CHARLES E. ARGOFF, ANDREW DUBIN

The term *skeletal muscle relaxant* can be confusing for patients and clinicians alike as there are different classes of skeletal muscle relaxants. Specifically, antispasticity, antispasmodic classes of skeletal muscle relaxants exist, and some medications overlap in both of these categories. (Table 55.1).[1–4] The use of such agents with or without nonsteroidal anti-inflammatory drugs (NSAIDs) can be considered for acute low back pain.[5] Medications commonly referred to as skeletal muscle relaxants include carisoprodol, chlorzoxazone, cyclobenzaprine, metaxalone, methocarbamol, and orphenadrine.[6] These agents are labeled by the United States Food and Drug Administration (FDA) with an indication for the relief of discomfort associated with an acute, painful, musculoskeletal condition. Baclofen and tizanidine have FDA indications for the treatment of spasticity caused by upper motor neuron syndromes, including multiple sclerosis and spinal cord disease or injury. Benzodiazepines, principally diazepam, are also used and indicated for adjunctive relief of skeletal muscle spasms and are often considered in discussions regarding skeletal muscle relaxants.

In discussing this broad class of skeletal muscle relaxants medications, it becomes difficult to cull out the actual intended therapeutic outcomes. These agents are typically prescribed during the initial presentation of acute low back pain. The injury normally occurs to the muscles, ligaments, or tendons, structures around the lumbar spine. The presentations may include local pain and tenderness, muscle spasms, and limited range of motion. Muscle spasm is often the most difficult to define and is the subject of controversy among some clinicians.[7] Muscle spasm can be described as a vicious pain-spasm-pain cycle that protects compromised tissues and structures. Secondary to these pain impulses, an involuntary reflex muscle contraction at the site of injury can occur, which in turn can lead to local ischemic injury. This can further facilitate the pain-spasm-pain paradigm. Muscle spasm phenomena may be considered a variation of a myofascial pain presentation.[8]

Mechanism of Action

In considering this discussion of muscle spasm pathophysiology, the problem with defining the activity of the skeletal muscle relaxants becomes manifest. The exact mechanism of action for these various agents has not been fully elucidated. However, it is generally accepted that skeletal muscle relaxants can depress polysynaptic reflexes within the dorsal horn via various mechanisms (Box 55.1), which may relax the skeletal muscle tissue in an indirect manner.[1–3] In animal studies, these agents exert their muscle-relaxing effects by inhibiting interneuronal activity and blocking polysynaptic neurons in the spinal cord and descending reticular formation in the brain. Interesting to note is that sedating agents also depress polysynaptic reflexes, making it difficult to determine whether skeletal muscle relaxants produce their clinical activity via sedation or a change in the pain-spasm-pain cycle.

• BOX 55.1 Classification of Agents by Proposed Mechanism of Action

Drug	Mechanism of action	Site of action
Baclofen	Similar to GABA acts on the presynaptic $GABA_a$ site, decreasing synaptic transmission to the spinal cord	Centrally acting-spinal cord
Dantrolene	Prevents the release of calcium from the sarcoplasmic reticulum in skeletal muscle cells	Peripherally acting
Carisoprodol	Causes altered neuronal output at the reticular formation and spinal cord	Centrally acting - spinal cord and brain
Chlorzoxazone	Acts on the spinal cord and subcortical regions to inhibit reflex arcs involved in causing and maintaining muscle spasm	Centrally acting-spinal cord and brain
Cyclobenzaprine	α_2 agonists at descending noradrenergic neurons on the supraspinal area of the brain stem, seratonergic antagonism at $5HT_2$ receptor	Centrally acting - brainstem
Metalaxone	CNS depressant	Centrally acting
Methocarbamol	CNS depressant	Centrally acting
Orphenadrine	Central atropine like structure alleviates muscle spasm	Centrally acting
Diazepam	Benzodiazepine increases GABA mediated presynaptic inhibition at spinal and supraspinal sites	Centrally acting - spinal cord and brain
Tizanidine	α_2 adrenergic agonist, presynaptic inhibition of motor neurons	Centrally acting
Botulinum Toxin	Neurotoxin- blocks the release of acetylcholine at the neuromuscular junction, causing muscle paralysis	Centrally and peripherally acting

Indications for Use

Despite the common use of skeletal muscle relaxants, relatively little data exist to elucidate their role in the treatment of chronic low back pain.[9,10] None of the agents discussed in this chapter have an indication for use in the setting of chronic back pain. In one survey of skeletal muscle relaxant use in the United States, muscle relaxants, although indicated for short term treatment, are most often prescribed on a long term basis.[11] In general, skeletal muscle relaxants, excluding baclofen and tizanidine, maintain FDA labeling as adjuncts for treatment of short term acute low back pain (LBP) and are commonly used to treat muscle spasms and associated pain for periods of one to three weeks as most patients with acute or subacute low back pain improve with time.[5] In this context, it may be difficult to discern the role of these agents, other than the palliative analgesic quality that they may provide for patients. Therefore skeletal muscle relaxant selection depends on an evaluation of adverse effects, contraindications, patient tolerability, and clinical experience. This discussion will also include a brief review of the clinical use of botulinum toxin as a treatment for musculoskeletal pain.

Specific Drugs By Class

Antispasmodic Agents

Carisoprodol (Soma)

Carisoprodol is a Schedule IV substance and is available as a 250 mg or 350 mg tablet and in combination with aspirin (soma compound) and with aspirin and codeine (soma compound with codeine). Carisoprodol dosing should not exceed four doses in a 24 h period (Table 55.1). In addition, it should not be prescribed for longer than three weeks.[12,13] Similar to other muscle relaxants, carisoprodol has additive sedative effects when taken with alcohol or other central nervous system (CNS) depressants. Its most common side effects are drowsiness, dizziness, and headache.[12–14]

Carisoprodol is converted in the liver to meprobamate, a substance with a long half-life of 10 h.[12,13] Meprobamate is well known to produce phenomena that result in physical and psychological dependence.[13–15] After oral ingestion, carisoprodol has a quick onset of action with time to maximum plasma concentration being 1.5 to 1.7 h.[12] Within the United States since 2012, carisoprodol has been listed as a Schedule IV controlled substance by the Controlled Substance Act. Because of the risk of physical and psychological dependence potential, carisoprodol use should be avoided. It should also be cautiously tapered as opposed to immediately discontinued following long-term use.

Chlorzoxazone (Paraflex, Parafon Forte DSC)

Chlorzoxazone is available as 250 and 500 mg tablets, taken up to four times daily. It is a centrally acting muscle relaxant acting primarily at the level of the subcortical regions of the brain and spinal cord.[16,17] It has been suggested that chlorzoxazone may be less effective than the other skeletal muscle relaxants.[9] It does not have any significant drug-drug interactions, but it does have a significant adverse effect profile that includes a rare idiosyncratic hepatocellular reaction. The role of this agent is unclear, considering the potential lack of efficacy and significant toxicity profile.[16,17]

Cyclobenzaprine (Amrix, Flexeril)

Cyclobenzaprine is available as 5 and 10 mg tablets, with recommended dosing of up to three times daily for up to three weeks as longer therapy is not well supported. It is also available in an extended-release form. Cyclobenzaprine is structurally and pharmacologically related to tricyclic anti-depressants. It is a centrally acting serotonin receptor antagonist as well as an α two agonist at descending noradrenergic neurons rather than a CNS depressant skeletal muscle relaxant.[18–20] As with other skeletal muscle relaxants, cyclobenzaprine does not have activity directly on muscle tissue, with animal data suggesting that this agent acts primarily in the brainstem. The net result of this action is a reduction in tonic somatic motor activity.[21] Although no human evidence exists to support this mechanism, the 5 mg dose has yielded similar clinical efficacy with less sedation than the more sedating 10 mg dose.[22] In the future, this may prove to be an important distinction with other CNS depressant agents. In an open-label study of patients with acute neck or LBP associated with muscle spasm who were randomized to be treated for seven days with cyclobenzaprine 5 mg PO three times daily alone or cyclobenzaprine 5 mg PO three times daily in combination with ibuprofen, at doses of 400 mg PO three times daily or 800 mg three times daily, no significant treatment differences were found among these groups.[23]

Cyclobenzaprine shares a similar side effect profile, including prominent anticholinergic effects, as it is structurally related to tricyclic anti-depressants. The most common anticholinergic side effects include drowsiness, dizziness, and dry mouth. Other side effects also include urinary retention, hypotension, and constipation.[23] Use of cyclobenzaprine is contraindicated in the setting of arrhythmias, congestive heart failure, hyperthyroidism, acute glaucoma, narrow angle glaucoma, or during the acute recovery phase of a myocardial infarction. One report suggested that coadministration with pro-serotonergic agents such as selective serotonin reuptake inhibitors may predispose patients to serotonin syndrome.[24]

Cyclobenzaprine can increase the risk of serotonin syndrome in patients taking tramadol, increasing the risk of seizures. Attendant use of cyclobenzaprine with monoamine oxidase inhibitors or use within 14 days after their discontinuation is contraindicated. It can also enhance the effects of agents with CNS depressant activity. Older adults appear to have a higher risk for CNS-related adverse reactions, such as hallucinations and confusion when using cyclobenzaprine. Withdrawal symptoms have been noted with the discontinuation of chronic cyclobenzaprine use. Use of a medication taper may be warranted for chronic-use patients.

Metaxalone (Skelaxin)

Metaxalone is available as a 400 and 800 mg tablet and has a recommended maximal dose of 800 mg three or four times daily. Its exact mechanism of action is not well understood, but it does cause general depression of the CNS.[25] Metaxalone does not have any significant drug-drug interactions and appears to have a minimal risk side effect profile. However, fatalities attributed to the use of metaxalone have been reported.[25,26] Hemolytic anemia, leukopenia, and impaired liver function have been seen with the use of metaxalone, but they are uncommon. Metaxalone is contraindicated in patients who have severe renal or hepatic impairment. It is known to cause an elevation in the cephalin flocculation test, necessitating serial liver function assessments. Metaxalone can also produce a false-positive result for Benedict's test. In this scenario, alternatives to urine glucose testing may be necessary.[27,28]

Methocarbamol (Robaxin, Robaxisal)

Methocarbamol is available in oral and parenteral forms. However, many complications have arisen with the injectable form, including pain, sloughing of the skin, and thrombophlebitis. The exact mechanism of action is unknown. However, it causes general

TABLE 55.1 Skeletal Muscle Relaxant Profiles

Drug	Onset of Action	Duration (h)	Dosing (can be taken as needed or standing)	Side Effects	Important Drug Interactions
Dantrolene Antispacticity agent	>7 days (PO)	Variable (PO) peak plasma concentration in 6 h	25–100 mg PO four times daily	Muscle weakness, phlebitis, respiratory failure, gastrointestinal failure	Chronic therapy can cause hepatic dysfunction. Ace-Inhibitors, paralytics, i.e. Vecuronium
Baclofen Antispasticity agent	Three to four days (PO) 4–6 h (IT) 30 min (IT)	Variable (PO)	5–10 mg PO three times daily	Drowsiness, slurred speech, hypotension, constipation, urinary retention	Anti-depressants (short-term memory loss); additive effects with imipramine
Carisoprodol Antispasmodic	30 min	4–6	250–350 mg PO three times daily	Drowsiness, dizziness, headache	CYP2C19 inhibitors and inducers
Chlorzoxazone Antispasmodic agent	~1 h	3–4	250–750 mg PO four times daily	N/V, headache, drowsiness, dizziness	Additive effects when taken with alcohol or other CNS depressants
Cyclobenzaprine Antispasmodic agent	~1 h	12–24	5–10 mg PO three times daily	Drowsiness, dizziness, dry mouth	Additive effects with barbiturates, alcohol, other CNS depressants; seizures with tramadol and MAOIs; additive effects with TCAs
Metaxalone Antispasmodic agent	1 h	4–6	800 mg PO four times daily	Dizziness, headache, drowsiness, N/V, rash	Additive effects when taken with alcohol or other CNS depressants
Methocarbamol Antispasmodic	30 min (PO)	4–6	750–1500 mg PO four times daily	Dizziness, blurred vision, with drowsiness	Additive effects when taken with alcohol or other CNS depressants
Orphenadrine Antispasmodic	1 h (PO)	4–6	100 mg PO twice daily	Tachycardia, lightheadedness, anxiety	Propoxyphene (confusion, N/V, dry mouth, tremors)
Diazepam Antispasmodic and antispasticity agent	30 min (PO)	Variable, depending on elimination	2–10 mg PO four times daily	Sedation, fatigue, hypotension ataxia, respiratory depression	Potentiation of effects when taken with phenothiazines, opioids, barbiturates, MAOIs
Tizanidine Antispasmodic and antispasticity agent	Two weeks	Variable	2–8 mg PO four times daily	Drowsiness, dry mouth, dizziness, hypotension, increased spasm, or muscle tone	Additive effects with alcohol and other CNS depressants; reduced clearance with oral contraceptives

CNS, Central nervous system; *IT*, intrathecal; *MAOIs*, monoamine oxidase inhibitors; *N/V*, nausea and vomiting; *TCA*, tricyclic anti-depressant.

CNS depression. If combined with benzodiazepines, barbiturates, codeine, or its derivatives, methocarbamol can cause respiratory depression.[29] The injectable form should be used cautiously in patients with known latex hypersensitivity. The oral dosage form of the medication is marketed as a 500 and 750 mg tablet, with a recommended daily dosage range of 4000 to 4500 mg as three or four divided doses daily. For difficult situations, the dose for the first 24 to 48 h can be up to 6 to 8 g/day. Methocarbamol is also combined with aspirin and marketed as Robaxisal. In a randomized, double blinded placebo-controlled trial of naproxen with or without orphenadrine or methocarbamol for acute LBP in the emergency department population, no functional improvement was demonstrated in either group compared to placebo with naproxen.[30]

Orphenadrine Citrate (Norflex, Norgesic, Norgesic Forte)

Orphenadrine is structurally related to diphenhydramine and thus exhibits antihistaminic and anticholinergic properties. Orphenadrine appears to block muscarinic acetylcholine receptors and

N-methyl-D-aspartate receptors in the CNS.[31] Like methocarbamol, orphenadrine is available in a parenteral dosage formulation. However, there have been reports of severe adverse reactions with parenteral use (e.g. anaphylactoid reaction), making this formulation difficult to use. Orphenadrine is available as a 100 mg tablet (Norflex) and in combination with aspirin (Norgesic) and caffeine (Norgesic Forte).

Orphenadrine's anticholinergic actions have been noted to produce significant adverse effects at high dosages such as tachycardia, palpitations, urinary retention, and blurred vision.[32] Given its significant anticholinergic profile, orphenadrine use is contraindicated in patients with underlying neuromuscular junction defects such as myasthenia gravis and Lambert Eaton syndrome.

Antispasticity and Antispasmodic Agents

Diazepam (Valium)

Diazepam is approved for the management of anxiety, acute alcohol withdrawal, skeletal muscle spasm, and convulsive disorders.[33] With respect to muscle relaxation, γ-aminobutyric acid (GABA)-mediated presynaptic inhibition at the spinal level is thought to be the main mechanism of action for diazepam.[34] This medication is a Schedule IV controlled substance with serious adverse effects such as sedation and abuse potential and should not be considered as a first-line muscle relaxant agent.[35] It is important to taper this agent slowly after long-term use to avoid any withdrawal symptoms. Withdrawal symptoms can range from mild headaches and pain to psychosis, hallucinations, seizures, mania, and death from convulsions if high dose chronic treatment is stopped abruptly.[36] Diazepam is available in a wide range of dosages, and each patient should be treated on an individual basis. For example, the recommended dosage range for musculoskeletal pain is 2 to 10 mg orally, administered two to four times daily.[34] There are serious medication interactions in patients taking both benzodiazepines and opioids, increasing the risk of respiratory depression and mortality from respiratory failure.

Tizanidine (Zanaflex)

Tizanidine is a centrally acting α-2 noradrenergic receptor agonist and inhibits excitatory neurotransmitters at the spinal and supraspinal levels. Through its inhibition of neurotransmitter release and the spinal pathways that enhance muscle movement, tizanidine has been found to be effective in reducing muscle spasticity in patients with spinal cord injury.[37] The main adverse effects are sedation, dizziness, hypotension, hepatotoxicity, and dry mouth.[38] Liver function tests should be monitored periodically while on this medication. Currently, tizanidine is FDA approved for the management of spasticity, which may be caused by multiple sclerosis, acquired brain injury, or a spinal cord injury. A meta-analysis that compared tizanidine, baclofen, and diazepam found that they were equally effective in decreasing excessive muscle tone in patients with multiple sclerosis or cerebrovascular lesions, and muscular strength improved in all three treatment groups, but the improvement was greatest with tizanidine.[39] There are published studies on tizanidine's effectiveness in cervical and lumbar spine myofascial pain.[40] A double-blind, multicenter study evaluated 105 patients with acute LBP given tizanidine 4 mg PO three times daily with ibuprofen 400 mg PO three times daily, or ibuprofen 400 mg PO three times daily with placebo. The study results suggested that the tizanidine-ibuprofen combination is more effective for treating moderate or severe acute lower back pain than placebo and ibuprofen alone.[41] Dosing for tizanidine begins at 2 to 4 mg tablets daily, usually given at bedtime, and may gradually be increased to a maximum of 36 mg per day, divided three to four times daily, depending on patient tolerance.[42]

Tizanidine should be used with caution in the setting of renal impairment. Tizanidine clearance decreases by 50% in patients with creatinine clearance lower than 25 mL/min. Therefore it is recommended to start patients with renal insufficiency at 2 mg/day rather than at 4 mg/day for this reason.[43] Liver function tests should be monitored regularly while on this medication, as this medication has been found to cause hepatotoxicity. In addition, coadministration with alcohol increases the maximum concentration by approximately 15%, and concomitant use of oral contraceptives decreases the clearance of tizanidine, which can enhance its sedating effects.

Antispasticity Agents

Baclofen (Lioresal)

Baclofen functions as a $GABA_B$ receptor agonist and produces its effects by inhibiting monosynaptic and polysynaptic transmission along the spinal cord. This drug is FDA approved for the management of reversible spasticity, particularly for the relief of flexor spasms, clonus, and associated pain, which commonly occurs in patients with spinal cord lesions and multiple sclerosis.[44] Studies have shown baclofen to have superior efficacy and tolerance when compared with tizanidine.[45] Baclofen can be administered intrathecally in cases of severe spasticity and for patients who do not tolerate or have failed oral therapy. Intrathecal baclofen therapy allows a patient to receive a high concentration of the medication directly to the spinal cord while reducing the CNS side effects, such as sedation, that develop with high oral doses of baclofen.[46] Oral administration of baclofen is initially 5 mg three times per day with a dose increase every three days until optimal response is achieved. However, the dose should not exceed 80 mg daily. The usual therapeutic range of baclofen is 40 to 80 mg daily.[44] Common adverse effects of baclofen are muscle weakness, somnolence, paresthesia, vertigo, and nausea.[47] A gradual dose reduction is recommended to prevent withdrawal symptoms. Abrupt discontinuation of oral baclofen can cause seizures and hallucinations, while discontinuation of intrathecal baclofen may result in hyperpyrexia, impaired mental status, muscle rigidity, and severe rebound spasticity. As baclofen use can lead to adverse effects in several organ systems, it should be used with caution in older patients and patients with renal impairment.[48]

Dantrolene

Dantrolene is a direct acting skeletal muscle relaxant that interferes with the release of calcium ions from the sarcoplasmic reticulum in skeletal muscle cells. It binds to the ryanodine receptor 1 and decreases intracellular calcium. This, in turn, slows the contraction cycles of muscle cells. It is FDA approved to treat malignant hyperthermia in both adults and children, neuroleptic malignant syndrome, as well as upper motor neuron disorders involving the brain and spinal cord. It is not recommended to be used as an agent for acute musculoskeletal pain.

It is available in both oral and intravenous forms. Common adverse effects include skeletal muscle weakness, hepatotoxicity. Therefore it is contraindicated in patients who have preexisting underlying liver disease.[31,49]

Botulinum Toxins (Botox-onabotulinumtoxin A, Dysport-abobotulinumtoxin A, Xeomin-incobotulinumtoxin A, and Myobloc-rimabotulinumtoxin B)

Botulinum toxin is a potent neurotoxin protein produced by the gram-positive anaerobic bacterium *Clostridium botulinum*.[50] Botulinum toxin types A and B have been developed for routine commercial use. The toxin's primary mechanism of action has been linked to its ability to inhibit the release of acetylcholine from cholinergic nerve terminals. However, it also inhibits the release of glutamate, substance P, and calcitonin gene-related peptide, as well as inhibiting the expression of the transient receptor potential vanilloid type 1 (TRPV1) and Purinergic ($P2X_3$ receptor) in the dorsal root ganglion (DRG) ganglion.[51] These effects likely contribute to the analgesic properties of botulinum toxin. Botulinum toxin has been studied in several chronic pain conditions associated with painful muscle spasms, including head and neck myofascial pain, temporomandibular joint disorders, cervical dystonia syndromes, and chronic LBP.

The potential benefit of botulinum toxin for the treatment of chronic myofascial pain in the head and neck has been noted. A 2016 meta-analysis reviewed 13 randomized controlled trials evaluating the efficacy of botulinum toxin type A injections for head and neck myofascial pain compared to placebo.[52] This review included a total of 656 total participants, with 366 receiving botulinum toxin type A injections to myofascial trigger points and 290 participants in the control group receiving saline injections. This review concluded no significant improvement in pain intensity at four to six weeks posttreatment with botulinum toxin injections. However, there was a significant improvement in pain intensity with botulinum toxin injections at two to six months compared to placebo ($p=0.008$).[52] A 2017 retrospective review evaluated the efficacy of botulinum toxin (onabotulinumtoxin A, Botox) for patients with chronic temporomandibular disorders with injections into the temporalis and masseter muscles. Fifty-five of the 71 subjects (77%) reported beneficial effects with Botox. In addition, patients reported a greater pain improvement after Botox injections at five to ten weeks post-injection compared to less than five weeks ($p=0.009$).[53] This is consistent with the above meta-analysis, showing pain improvement several weeks after botulinum toxin injections. More recently, a randomized clinical trial evaluated onabotulinum toxin A injections for the treatment of masseter and anterior temporalis myofascial pain.[54] This study concluded that botulinum toxin injections reduced pain intensity ($p<0.0001$) and increased pressure pain threshold ($p<0.0001$) for up to 24 weeks compared to placebo. However, dose-related adverse effects were seen, such as a transient decline in masticatory performance ($p<0.05$), muscle contraction ($p<0.0001$), and decrease in muscle thickness ($p<0.05$) and coronoid and condylar process bone volume ($p<0.05$).[54] As a result of these findings, low doses of botulinum toxin are recommended for persistent myofascial pain that does not improve with conservative treatments.

Botulinum toxins are considered first line therapy for the treatment of cervical dystonia, and a systematic review and meta-analysis were published in 2014 evaluating the efficacy of onabotulinumtoxin A in these patients.[55] A total of 18 studies were reviewed in the meta-analysis showing a mean duration of 93.2 days after injections with onabotulinum toxin A and doses greater than 180 units were associated with longer durations of effect (107–109 days) compared to less than 180 units (86–88 days, $p<0.01$).[55] Based on the published literature and duration of effect, patients with cervical dystonia treated with onabotulinumtoxin A should require approximately four treatments annually.

Botulinum toxin injections have also been studied in the treatment of chronic LBP. In one study, 31 patients with chronic LBP were randomized, 15 patients received 200 units of botulinum toxin A (onabotulinumtoxinA) injected into five sites (40 units injected per site at five lumbar paravertebral levels), and 16 patients received placebo injections.[56] Pain and disability were measured at three and eight weeks after injection using both the visual analog scale (VAS) and the Oswestry LBP and disability questionnaire. At three weeks, 73.3% of the patients receiving botulinum toxin A had >50% pain relief vs. 25% of patients receiving placebo ($p=0.012$). At eight weeks, 60% of patients receiving botulinum toxin A and 12.5% of patients receiving placebo injections experienced pain relief ($p=0.009$).[56] None of these patients experienced adverse effects. This study concluded that botulinum toxin A injections within the paravertebral muscles could improve chronic LBP and physical functioning at three and eight weeks posttreatment. An open-label pilot study also evaluated the efficacy of botulinum neurotoxin A on patients with chronic LBP.[57] The effect of botulinum toxin A on chronic LBP was prospectively studied in 75 patients with repeated treatments over the course of 14 months. Injections were placed into the paraspinal muscles at four to five levels between L1 and S1, with dosing ranging between 40 and 50 units per site. Pain intensity using the VAS pain frequency, functional status using the Oswestry scale were assessed at baseline, three weeks, and at two, four, six, eight, ten, 12, and 14 months. At three weeks, 40 patients (53%) and at two months, 39 patients (52%) reported significant pain relief. The change in VAS, Oswestry score, and the number of pain days were significant compared with baseline at two months after each injection period ($p<0.005$) and continued to remain significant over subsequent treatments. The majority, 91%, responded well to the injections throughout the length of the study, with 4% of the patients experiencing transient mild flu-like symptoms.[57]

Conclusion

Clinical data has shown that skeletal muscle relaxants are more effective than placebo in relieving acute LBP.[58] It is important to recognize the different classes of muscle relaxants and the intended effect when selecting an agent for a patient. Most clinical guidelines list skeletal muscle relaxants as optional agents for use individually or in combination with an NSAID. An open-label, prospective, multicenter study evaluated patients with acute LBP and provided either a fixed dose combination of chlorzoxazone 500 mg and ibuprofen 400 mg or ibuprofen 400 mg alone for three times daily for a total of seven days.[59] This study revealed that the fixed dose combination of chlorzoxazone and ibuprofen demonstrated a superior efficacy than ibuprofen monotherapy in acute LBP patients. Most clinicians and researchers agree that skeletal muscle relaxants may be beneficial to patients with acute LBP by reducing the duration of discomfort and accelerating functional recovery. It is recommended to consider the use of skeletal muscle relaxants as an adjunct or alternative to NSAIDs, especially in cases in which NSAID toxicity is a concern or when NSAID monotherapy proves suboptimal.

Skeletal muscle relaxants have CNS depressant effects and should be used with caution, particularly for the elderly and in patients with concomitant use of alcohol, anxiolytics, opioid analgesics, and/or other sedating medications. Skeletal muscle relaxants are associated with higher risks for total adverse effects, especially those involving the CNS. The most common and

consistent adverse effects noted with the CNS were drowsiness and dizziness.[60] The benzodiazepines-muscle relaxants such as diazepam and sedative-muscle relaxants such as carisoprodol are highly addictive and should never be used as first line agents.[61]

Considering many medications are found to be ineffective or not tolerable by some patients (e.g. adverse effects of NSAIDs), it is important to consider the use of skeletal muscle relaxants in patients with persistent and intractable myofascial pain.

Key Points

- There are three broad classes of muscle relaxants: antispasmodic, antispasticity, and combination agents.
- Muscle relaxants may treat muscle spasticity in two manners. First, they can modify the stretch reflex arc, either by reducing the excitatory signals or by augmenting the inhibitory interneurons. This decreases activation of the alpha motor neuron. Second, they can disrupt the excitation-contraction coupling that produces muscle contraction.
- Cyclobenzaprine is a centrally acting skeletal muscle relaxant that is structurally related to tricyclic anti-depressants; it acts primarily at the level of the brainstem.
- As a $GABA_B$ agonist, baclofen causes hyperpolarization and thus decreases the release of excitatory neurotransmitters in the brain and spinal cord. It causes less sedation than benzodiazepines and may reduce pain by decreasing substance P release.
- Skeletal muscle relaxants have been shown to be more effective than placebo for patients with acute LBP with respect to outcomes, such as short term pain relief, global efficacy, and improvement of physical outcomes.
- Botulinum toxin not only inhibits the release of acetylcholine from cholinergic nerve terminals but has also been found to inhibit the release of glutamate, substance P, and calcitonin gene-related peptide, as well as inhibiting the expression of the transient receptor potential vanilloid type 1 (TRPV1) and $P2X_3$ receptors in the DRG ganglion. These effects contribute to its analgesic properties.
- Botulinum toxin type A (onabotulinumtoxinA) injections are found to be effective for head and neck myofascial pain, temporomandibular joint disorders, cervical dystonia, and chronic LBP.
- Carisoprodol is converted in the liver to meprobamate, an intravenous controlled substance. Meprobamate is well known to produce phenomena that result in physical and psychological dependence.

Cannabinoids for Pain Management

NING NAN WANG, ANUJ BHATIA

Introduction

Cannabis is a plant genus in the family of Cannabacae, and its medical use dates to ancient China (around 2,700 BC).[1] Its use for medical purposes was first recorded in the worlds' oldest pharmacopeia, the Pen-Ts'ao Ching. Cannabis was indicated for diseases such as rheumatic pain, intestinal constipation, and others.[1] Though awareness about its medicinal properties spread soon to India, Middle East, Africa, Europe, and the Americas, it was not until the 18th century when Willian B. O'Shaughnessy, an Irish physician, first introduced cannabis and its use for rheumatism, convulsions, and muscular spasms in the Western medicine.[2] Cannabinoids have the potential to treat several medical conditions, including refractory epilepsy, cancer chemotherapy induced nausea and vomiting (CINV), and loss of appetite and weight loss in people with HIV/AIDS. In addition, there is a growing body of evidence for the analgesic effect of cannabinoids for acute and chronic pain.[3–5] Cannabinoids also are a potential option to reduce the dose of opioids prescribed for chronic pain.[6] Today, cannabis and its related products have gained a broader acceptance in the popular culture with widespread recreational and medicinal use.

Definitions/Terminology

The cannabis genus encompasses many species, but the most well-known are *cannabis sativa, cannabis indica,* and *cannabis ruderalis*. The cannabis plant contains about 540 chemical substances, and the word "cannabis" refers to all products derived from the plant *cannabis sativa*. The word "marijuana" refers to parts of or products from the plant *cannabis sativa* that contain substantial amounts of Δ9-tetrahydrocannabinol (THC), the substance primarily responsible for cannabis's physiologic effects through its actions on cannabinoid receptors (CBR).[7] The term "medical marijuana" refers to using the whole, unprocessed marijuana plant or its basic extracts to treat medical conditions.[8]

Cannabinoids are a group of over 100 different chemicals found in the cannabis plant that are used for recreational or medicinal purposes. In addition to THC, cannabidiol (CBD) and cannabinol (CBN) are other cannabinoids found in cannabis that stimulate CBR. The cannabis plants also contain over 120 volatile compounds that are called terpenes and sesquiterpenes that are responsible for their characteristic aroma. Synthetic cannabinoids are products manufactured to stimulate CBR.[9]

Endocannabinoid System

The endocannabinoid system is a complex biologic system composed of endogenous CBR and their respective agonists. It is involved in the regulation of multiple physiologic and cognitive processes in the human body to maintain homeostasis.

Cannabinoid Receptor

CBR are cell membrane G protein-coupled receptors (GPCR) with seven transmembrane spanning domains.[10] These receptors are of two types, cannabinoid receptor 1 (CB1R) and cannabinoid receptor 2 (CB2R), and these were identified and cloned in 1990[11] and 1993.[11,12] CBR exist in various locations in the body such as the brain, spinal cord, pituitary gland, thyroid gland, adrenal gland, and digestive system,[13–16] but their distribution, signaling pathways, and functions are still being elucidated.[17–19] Please see Table 56.1 for details.

The GPCR 18, 55, and 119 (GPR18, GPR55, GPR119)[20] are novel CBR that can be activated by several ligands, including THC, arachidonoylethanolamine (anandamide or AEA), and 2-Arachidonoylglycerol (2-AG) and many other non-cannabinoid compounds such as lysophosphatidylinositol (LPI).[21] GPR18 is involved in microglia migration.[22]

Molecular and Cellular Consequences of Cannabinoid Receptor Activation

A variety of cellular functions, including synaptic transmission, gene transcription, and cell motility, are modulated by CB1R and CB2R.[23] CB1R mediates the function of both excitatory and inhibitory neurotransmitters (acetylcholine, noradrenaline, dopamine, serotonin, GABA, glutamate, D-aspartate) and cholecystokinin.[23] Both CB1R and CB2R inhibit the activity of cAMP, decrease cAMP production, and increase the activity of mitogen-activated protein kinases.[10] Activation of CB1R stimulates inwardly rectifying potassium channels and inhibits L-, N- and P/Q-type voltage-activated calcium channels, thus decreasing neurotransmitter release.[24] CB2R shares a similar signaling pathway as that for CB1R but with different affinities and minimal effect on ion channels.[10] A subpopulation of CBR is also detected intracellularly in the lysosome, endosome, and mitochondria. They have distinct pharmacologic properties, including inhibition of

TABLE 56.1 Cannabinoid Receptors and Their Roles

	CB1R	CB2R
Location	Predominantly in the central nervous system (CNS: brain - hippocampus, basal ganglia, cerebellum, olfactory bulb, amygdala, hypothalamus, and cerebral cortex,[14] spinal cord, dorsal root ganglion); some in the peripheral nervous system (PNS), liver, reproductive system, cardiovascular system, and gastrointestinal system	Predominantly in the peripheral tissues, immune cells, hematopoietic cells, bone, liver, keratinocytes, PNS, and some in the CNS[15]
Chromosome location of cannabinoid receptor gene	Chromosome 6	Chromosome 1
Physiologic actions	Psychoactivity, pain & memory processing, and motor control[16]	Regulation of analgesia in response to inflammation, peripheral analgesia, intestinal inflammatory response, and neuroimmune interactions[17]
Involvement in disease processes	Anxiety, depression, addiction, schizophrenia, stroke, multiple sclerosis, neurodegeneration, and epilepsy[18]	Alzheimer's, multiple sclerosis, autoimmune diseases, hepatitis, endometritis, pancreatitis, and inflammatory bowel disease[19]

mitochondrial cellular respiration and cAMP production, hence regulating cellular energy metabolism.[10,25]

Endocannabinoids

Endocannabinoids are endogenous fatty acid neurotransmitters that are responsible for intercellular signaling. Seven endocannabinoids have been identified to date, but the most studied are AEA and 2-AG.[26] AEA is a high-affinity, partial agonist for CB1R, with very-low efficacy at CB2R, whereas 2-AG is a full agonist at both CB1R and CB2R with moderate-to-low affinity.[27] Endocannabinoids' concomitantly interact with other receptors involved in pain, such as transient receptor potential cation channel vanilloid 1 (TRPV1) and peroxisome proliferator-activated receptors. These interactions may contribute to their regulatory role in synaptic transmission and analgesic effects.[28] Endocannabinoids are produced as part of a specific physiologic response against tissue injury in neuronal and non-neuronal cells. They participate in pain inhibition, sensitization, and modulation of the inflammatory response through CB1R and CB2R signaling described above.[28] Both anandamide and 2-AG are autocrine and paracrine messengers. They act through retrograde signaling for synaptic transmission. Endocannabinoids are produced on-demand from post-synaptic vesicles in response to increased intracellular calcium concentration from membrane lipid precursors, and unlike traditional neurotransmitters, they are not produced and accumulated intracellularly.[29] AEA and 2-AG have a short duration of action. They are degraded efficiently by enzymatic degradation, hydrolysis, or oxidation, respectively, by fatty acid amide hydrolase (FAAH) on AEA and monoacylglycerol lipase on 2-AG.[29,30]

Cannabinoid

Phytocannabinoids

Phytocannabinoids are natural substances capable of either directly interacting with CBR or sharing chemical similarities with endocannabinoids or both. More than 100 active phytocannabinoids have been identified within the *cannabis Sativa* plant alone.[31] Cannabinoids, including cannabis terpenoids, have also been identified in other plant species.[32] Besides phytocannabinoids, cannabis sativa, contains additional pharmacologically active molecules, such as terpenoid and β-caryophyllene, that are members of other chemical families. These also interact and mediate potential therapeutic actions through CBR.[7]

The two most studied phytocannabinoids, CBD and THC, were discovered in 1940 and 1964, respectively. THC acts as a partial agonist at CB1R and CB2R,[33] and it is the primary psychoactive component of cannabis. In animal studies, activation of CB1R by THC suppresses locomotor activity and is associated with hypothermia and antinociception in the tail-flick or hot-plate test.[34] THC also has other effects, including stimulating appetite, antiemesis, antispasticity, and analgesia. CBD is a non-psychoactive phytocannabinoid, and it accounts for 40% of the *cannabis Sativa* extract.[35] It acts as a partial antagonist of CB1R (i.e. it attaches to the active site but does not completely block out CB1R's effects) and as a weak inverse agonist of CB2R (i.e. it indices a pharmacologic response opposite to that of an agonist).[36,37] CBD also interacts with other non-cannabinoid targets, including the 5-HT1A receptor, TRPV1, and adenosine A2A receptors that regulate the perception of pain.[38] CBD can act as a non-competitive negative allosteric modulator of CB1R and,[39] in the presence of THC, CBD has complex physiologic effects. CBD works synergistically with THC for its analgesic effect while decreasing THC's psychoactive and cognitive side-effects such as sedation and memory impairment.[40]

In addition, various extracts of cannabis are offered to consumers and marketed under miscellaneous categories such as dietary supplements, hemp oil, CBD-enriched products.[7] Popular ingredients added or contained in CBD and hemp oil products include a diverse span of phytocannabinoids ranging from *C. Sativa, b-Caryophyllene, limonene, and cannabichromene*.[7] Given the large assortment of products, Van Dolah et al. have proposed a checklist of four questions to choose high quality products.[7]

1. Does it meet the following quality standards? a. Current Good Manufacturing Practices certification from the United States Food and Drug Administration; b. European Union, Australian,

or Canadian Food Inspection Agency organic certification; c. National Science Foundation International certification
2. Does the company have an independent adverse event reporting program?
3. Is the product certified organic or eco farmed?
4. Have their products been laboratory tested by batch to confirm THC levels <0.3% and no pesticides or heavy metals?

Synthetic Cannabinoids

Synthetic cannabinoids are chemical molecules that have been designed to possess active pharmacologic properties through activation of CBR. Only two synthetic THC have established clinical applications: nabilone and dronabinol. Nabilone is approved for treating CINV, and dronabinol is indicated for the treatment of AIDS-induced anorexia and CINV. The classification of synthetic cannabinoids is according to their chemical families.[9] There is also a separate category of cannabinoid receptor antagonists or inverse agonists that is under research and development.

Classification of Synthetic Cannabinoids

1. Classical cannabinoids: These are the first chemical family developed based on a similar chemical structure as THC and tricyclic dibenzopyran ring.[41]
2. Non-classical cannabinoids: These are the first chemical compounds consisting of cyclohexyl phenol derivatives that were used recreationally as a drug of abuse.[34]
3. Hybrid cannabinoids: These compounds have a chemical structure combining classical and non-classical cannabinoids.[9]
4. Aminoalkylinodoles: This is a large class of chemical compounds structurally dissimilar to THC or endocannabinoid with cannabinomimetic properties.[9]
5. Endocannabinoid analogs or eicosanoid: This is a new group of synthetic cannabinoid discovered in 2012 based on indole-3-carboxylates.[42]
6. Miscellaneous: These are all other compounds not belonging to any of the above families.[9]

Nabilone (Cesamet®)[43]

Nabilone is an oral synthetic THC analog that is available on prescription.[43] It is approved and licensed for the treatment of CINV and AIDS-induced anorexia in many countries. It exerts a complex pharmacologic effect through interaction with CB1R, CB2R, and the endocannabinoid system. Its application in chronic pain has been studied in several small randomized controlled trials (RCTs) on patients with neuropathic pain, fibromyalgia, cancer pain, and chronic non-cancer pain. A recent systematic review by Tsang et al. analyzed current evidence for its role, including eight RCTs, two prospective cohort studies, and one retrospective chart review[44] with the conclusion that nabilone has a role as an adjunct to conventional analgesic pharmacotherapy. In another systematic review and meta-analysis, a subgroup analysis of three RCTs on nabilone, the authors were unable to find support for analgesic efficacy with nabilone in chronic pain.[3] In a more recent systematic review, a subgroup analysis of four RCTs on nabilone demonstrated a small and clinically insignificant VAS reduction of 10%, but the benefit persisted at six months.[5]

Dronabinol (Marinol® and Namisol®)[45,46]

Dronabinol is a synthetic oral THC analog. Similar to Nabilone, it is approved and licensed for the treatment of CINV and AIDS-induced anorexia.[45] There is limited evidence concerning the role of dronabinol and its analgesic efficacy in patients with chronic pain. In a systematic review and meta-analysis that included a subgroup analysis of studies on dronabinol in patients with functional chest pain, multiple sclerosis (with spasticity and central neuropathic pain), amyotrophic lateral sclerosis, idiopathic cervical dystonia, and spinal cord injury, a lack of analgesic benefit with dronabinol was reported following two weeks to six months of use.[5] Namisol® is a novel formulation of natural THC as a tablet.[46] However, there is a lack of data on its efficacy in patients with chronic pain. In a Phase II placebo-controlled study, Namisol failed to demonstrate analgesic efficacy in patients with chronic abdominal pain.[47]

Nabiximol (Sativex®)[48]

Nabiximol is a cannabinoid oromucosal spray containing extract of THC and CBD in a 50:50 ratio, with each spray containing 2.7 mg THC and 2.5 mg of CBD.[48] It is approved for the treatment of spasticity related to multiple sclerosis in many countries. In a subgroup analysis of six RCTs on nabiximol in a systematic review and meta-analysis on cannabinoids for neuropathic pain, the analgesic benefit was found to be uncertain.[3] The difference in the mean pain scores between nabiximol and comparator groups was statistically significant but clinically small in patients with neuropathic pain (mean difference -0.50 points on a 0-10 scale; 95% CI, -0.89 to -0.12 points).[3]

A summary of the pharmacokinetics and applied pharmacology of synthetic cannabinoids is provided in Tables 56.2 and 56.3.

Mechanisms of Analgesia of Cannabinoids

Several analgesic mechanisms have been proposed for cannabinoids' analgesic effect on acute, chronic inflammatory, and neuropathic pain. Similar to opioids, cannabinoids act on both the CNS and the PNS. CBR are involved in the transduction, transmission, modulation, and perception of pain in both the ascending and descending nociception pathways.[49] A summary of these antinociception mechanisms is detailed below.

Acute pain models: Animal studies have demonstrated that intracerebroventricular administration of cannabinoids increased rats' tail-flick latency, thereby suggesting an analgesic effect.[44] In other acute pain models, micro-injection studies of exogenous cannabinoid receptor agonists into the periaqueductal gray (PAG) and the rostroventral medulla (RVM) (both areas responsible for modulation of descending inhibitory pathways), the amygdala and dorsal raphe nucleus resulted in antinociception.[50] Furthermore, activation of the endocannabinoid system inhibits presynaptic neurotransmitter release from GABAergic and glutamatergic neurons through retrograde signaling in the RVM and PAG,[51] and cannabinoids also modulate post-synaptic neuron excitability. Research in the spinal mechanisms of analgesia of cannabinoids demonstrates that intrathecal administration of exogenous cannabinoid agonists attenuates formalin-induced pain behavior in the mouse model.[52] Exogenous cannabinoids also reverse established mechanical hyperalgesia in the partial sciatic nerve ligation model of neuropathic pain via CB1R signaling, and they may be more effective than opioids.[53] In addition, CB1R is abundantly expressed in the PNS, in specific regions such as the primary afferent neurons of the dermis, dorsal root ganglion, and trigeminal ganglion, where it regulates nociception.[54,55] Evidence of peripheral analgesia mechanisms of endogenous CB1R agonists (AEA) and CB2R selective activation in nerve endings in the PNS further supports the role of peripheral

TABLE 56.2 Pharmacokinetics of Synthetic Prescribed Cannabinoids

	Nabilone/ Cesamet®[43]	Dronabinol/ Marinol®[45,123]	Nabiximol/Sativex®[48]	Cannabidiol/Epidiolex®[124]
Indication	CINV	CINV, AIDS-induced anorexia	Multiple sclerosis induced spasticity	Seizures (Lennox-Gastaut syndrome and Dravet syndrome)
Minimum recommended age	18 years	18 years	18 years	Two years
Dosage formulations	0.25, 0.5 and 1 mg	2.5 mg, 5 mg, 10 mg	10 mL vial - 90 sprays/ vial, vial concentration: THC 27 mg/mL / CBD 25 mg/mL	Oral solution: 100 mg/mL
Dose range	1 or 2 mg BID	2.5 mg orally twice daily	Starting dosage one spray BID, therapeutic: 4-8 sprays daily	Starting dose: 2.5 mg/kg BID, maintenance dose: 5 mg/kg BID, maximum: 10 mg/kg BID
Maximum recommended dosage per day	6 mg	50 mg	12 sprays	20 mg/kg
Adverse effects and other important facts	Nabilone is not detected in drug urine tests	Hypersensitivity reactions to dronabinol or sesame oil	Glossodynia, mouth ulceration, oral discomfort secondary to a reaction to ethanol pain, application site irritation	Possible dose-related elevation of liver transaminases, hypersensitivity to cannabis, require dosage adjustment in hepatic impairment

AIDS, Acquired immunodeficiency syndrome; *CINV*, chemotherapy induced nausea and vomiting.

mechanisms of action for cannabinoids.[54,56] Non-cannabinoids such as meptazinol (a non-opioid analgesic) also display agonism at CBR as one of their analgesic mechanisms,[57] and injection of a CB1R antagonist into supraspinal sites such as the PAG or RVM reverses meptazinol-induced analgesia.[57]

Inflammatory pain models: There is growing evidence for the role of cannabinoids in relieving inflammatory pain. Microinjection studies of exogenous CB1R agonists into supraspinal location inhibits formalin-evoked nociceptive and aversive, panic-like behavior in rats.[58] At the level of the spinal cord, CB2R has been suggested to be involved in rat models of inflammation. CB2R mRNA is upregulated in rats with chronic inflammatory conditions,[59] and CB2R activation influences the CNS response to inflammation through microglial migration.[60] Peripherally, CB2R activation mediates suppression of thermal and mechanical hypersensitivity in inflammatory pain models.[61] Activation of CB2R results in similar anti-allodynic effects in capsaicin models of inflammatory pain.[62]

Neuropathic pain models: Cannabinoid and endocannabinoid interactions provide potential targets for attenuation of neuronal hyperexcitability in the treatment of neuropathic pain. In the neuropathic disease rat model, upregulation of CB1R mRNA in the thalamus, an area of the brain involved in processing pain, has been reported.[63] Multiple experimental animal models based on sciatic nerve injury or ligation (SNI or SNL), spinal nerve ligation, and spared-nerve injury (SPNI) have been used to explore the cannabinoid system's role in neuropathic pain. Studies reported the blockade of TRPV1 and FAAH resulting in decreased symptoms and sequelae in the medial prefrontal cortex of neuropathic pain in the SNI rats model.[64] At the spinal cord level, there is some evidence for synthetic cannabinoids in mitigating mechanical and thermal hyperalgesia or cold allodynia in neuropathic models.[63,65] In summary, *in vitro* and *in vivo* animal studies demonstrate the analgesic potential of cannabinoids. However, more work is necessary for the translation from basic science studies to clinical practice.

Review of Evidence for Cannabinoids' Use in Relieving Chronic Pain

Several studies have evaluated the analgesic efficacy of cannabinoids. A recent systematic review and meta-analysis of 36 RCTs with 4,006 participants by Johal and colleagues examined the evidence for smoked cannabis (four RCTs), oromucosal cannabis sprays (14 RCTs), and oral cannabinoids (18 RCTs).[5] There was a significant but small analgesic effect favoring the use of cannabinoids over placebo (VAS (range 0–10) -0.63, 95% confidence interval [CI]: -0.85 to -0.42), and the evidence was deemed to be of a low quality. Oral cannabis demonstrated a greater reduction in pain than oromucosal and inhaled formulations. Across all routes and formulations, cannabinoids had a greater analgesic effect at two weeks (VAS -0.54, 95% CI: -0.76 to -0.31; moderate quality evidence) as compared to six months (VAS -0.43, 95% CI: -0.75 to -0.10; low quality evidence).[5]

Another systematic review and meta-analysis in 2018 reviewed 104 studies (n = 9,958 participants) with 47 RCTs and 57 observational studies on cannabinoids and analgesia from 1980–2017.[4] Forty-eight studies were on patients with neuropathic pain; seven studies were on fibromyalgia, one was on rheumatoid arthritis, and 48 other were on chronic non-cancer pain. Across RCTs, the pooled event rates (PERs) for 30% reduction in pain scores was significant for cannabinoids (29.0% cannabinoids vs. 25.9% placebo; CI: 15-61%).[4] The review also suggested positive secondary pain-related outcomes with cannabinoids, including low quality evidence for improved sleep and patients' global impression of change.[4] Another systematic review and meta-analysis published in 2017 evaluated cannabinoid analgesic efficacy specifically in neuropathic pain patients, including 11 RCTs (1,219 patients).[3] It reported a statistically significant but clinically uncertain reduction in mean numeric rating scale pain scores (zero to ten scale) compared with comparator groups (-0.65 points; 95% CI: -1.06 to -0.23 points). It also reported secondary benefits with cannabinoids on improvement in quality of life (five out of eight studies) and sleep (six out of seven studies).[3]

Routes of Administration

A large diversity of cannabis-derived products exist in the market for recreational and medicinal uses. The iconic embodiment of consuming cannabis has been linked to inhalation. Inhalation or smoking via a joint, spliff, pipe, blunt, water-pipe/bong is the most commonly used form of consumption.[66,67] Other routes of administrations (ROA) include vaporizing (inhalation), dabbing, e-cigarettes, oral sprays, edibles, drinkables, tinctures (alcohol-based liquid cannabis extracts), other oromucosal/sublingual (e.g. strips and lozenges), transdermal topicals (cannabis-infused lotions, balms, oils), intravenous (syringe), and rectal (suppositories).[68–70]

Both THC and CBD are metabolized extensively in the liver. THC is metabolized via by microsomal hydroxylation and oxidation by cytochrome P450 enzymes CYP 2C9, 2C19, and 3A4,[38] and it is eliminated in the urine and feces. CBD undergoes extensive phase 1 metabolism,[71] and it is metabolized by primary oxidation and side-chain oxidation.[72]

Smoking cannabis results in rapid and efficient absorption with a peak effect, shorter duration of action, and higher blood concentration of THC as compared to other routes (Table 56.4).[73,74,75] Absorption and bioavailability of smoked cannabis depend on the depth of inhalation, type of smoking device, duration of puffs and breath holding, and the composition of cigarettes.[76] Little clinical data exists in the literature for the pharmacology of smoked CBD. It is estimated to be similar to those of THC, including a bioavailability of 31% (range 11%–45%).[77] On average, each joint of cannabis contains 500 mg to 1 g of the cannabis plant, 7.5–225 mg of THC (1%–30%), and 0–180 mg of CBD (0%–24%).[78] Vaporization offers a potentially lower-risk tool with a similar pharmacologic profile as smoked cannabis[79] because it reduces the formation of harmful substances such as carbon monoxide, polycyclic aromatic hydrocarbons, and tar.[79] Variability in the effects of vaporized

TABLE 56.4 Applied Pharmacology of Cannabis-Based Products According to the Route of Administration

	Inhalation[66,67,73–75]	Oral[80,81]	Topical[85]	Liquid Extract[71]	Rectal[84]	Ophthalmic[125]
Absorption	Rapid (seconds)	1–2 h	Variable (enhanced by water and oleic acid in ethanol)	10–45 min	Variable (depends on its base formulation)	1 h
Peak plasma availability	3–10 min	4–6 h	Variable (~1.4 h)	Variable	2–8 h	Several hours
Bioavailability	10%–35%	Variable (6%–10%)	Variable	Variable	Variable (up to 13.5%)	6%–40%
Duration of action	1–6 h	4–12 h	48 h (steady-state)	2–8 h	Variable	Variable

cannabis depends on the type of cannabis, amount of cannabis placed in vaporizer, temperature, and duration of vaporization, and type of vaporizer used. As an example, one single oro-mucosal administration of Nabiximols with four sprays (total of 10.8 mg THC and 10 mg CBD) results in peak plasma concentrations of both THC and CBD within 2–4 h.[48]

In comparison to inhaled routes, oral absorption of cannabinoids is slow, variable, and highly dependable on the associated food ingested with cannabinoids.[80,81] Based on the bioavailability alone, the conversion factor for inhaled to orally ingested cannabinoids has been estimated to be 2.5.[82] Given that cannabinoids are lipophilic, there is weak evidence that fatty meals or a lipophilic formulation (cookie or oil-based) enhance cannabinoid absorption and bioavailability.[83] Any cannabinoid ingested orally undergoes extensive first-pass metabolism in the liver (e.g. dronabinol has a bioavailability of 10%–20% of the administered dose after ingestion).[45,74] However, both rectal and transdermal application of cannabinoids avoid the first-pass metabolism. In rectal suppositories, THC-hemisuccinate formulation can offer a bioavailability of up to 13.5%,[84] and for transdermal cannabis-based products, absorption is enhanced by using water and oleic acid in propylene glycol and ethanol.[85]

Direct data comparing analgesic efficacy and safety profile associated with different ROA of cannabis products is scarce.[68] Large-scale studies have documented the many harmful effects of smoking cannabis.[86] Smoking, as the specific ROA, has been associated with many pulmonary complications listed in the "Acute and Chronic Adverse Reactions" section below. Table 56.4 summarizes important pharmacologic facts related to the ROA of cannabinoids.

Adverse Effects of Cannabinoids With Acute and Chronic Use

Short-term Use

Short-term use of cannabis results in cardiovascular AE manifesting shortly after its use and include tachycardia, supine hypertension, peripheral vasodilation, and orthostatic hypotension.[87–89] A retrospective study reported that the first hour after smoking marijuana is associated with a 4.8 (95% CI: 2.4–9.5) times increase in the risk of myocardial infarction.[88] In the respiratory system, cannabinoids cause bronchodilation and a decrease in airway resistance, but an increase in airway reactivity can also occur.[90] In the CNS, cannabinoid consumption can generate both increased or decreased anxiety and paranoia.[90] Other significant cognitive effects include euphoria, hallucinations, memory impairment, headaches, and dizziness.[87] Inhalation of marijuana is also associated with documented strokes and transient ischemic events.[91,92,93] Though cannabinoids have an appetite-simulating and anti-nausea effects, a cannabinoid hyperemesis syndrome with recurrent episodes of severe nausea, vomiting, and abdominal pain has also been described.[94]

Chronic Use

In chronic cannabinoid users, there is an increase in the annual risk of MI, myocardial infarction from 1.5%–3% per year.[95] In a cohort study in cannabinoid users who sustained a MI, a 4.2 fold increased risk (95% CI, 1.2–14.3) of mortality was also noted.[96] In the respiratory system, the route of ingestion determines the degree of potential harm. For example, chronic smoking of marijuana is associated with chronic cough, bronchitis, and emphysema, similar to cigarette smoking.[87] Chronic users of cannabinoids are also at risk for developing tolerance, addiction, and cannabis use disorder.[90] Three recent systematic reviews and meta-analyses on cannabinoids have reported a large number of AEs with cannabinoids. Non-serious treatment-related AEs include dizziness (most common, seen in 1 in 3 patients), throat discomfort, asthenia, fatigue, drowsiness, dry mouth, increased appetite, hallucinations, nausea, and refractory spasticity.[3–5] Serious AE, requiring either medical intervention or withdrawal from the study have an incidence of 5.9%.[5] Another systematic review for chronic non-cancer pain by Stockings et al. found that PERs for all-cause AEs were 81.2% (cannabinoids) vs. 66.2% (placebo).[4] The number needed to harm (NNH) for nervous and psychiatric-related AEs were three and six, respectively.[4] Given the high prevalence of non-serious AEs and considering the relatively low NNT for cannabinoids, the therapeutic index for these substances seems to be narrow.

Contraindications to the Use of Cannabinoids

Cannabinoids are an emerging pharmacotherapy, and the contraindications to their use are evolving as research continues in this field. The use of cannabinoids is not recommended in patients with a known or suspected hypersensitivity to these compounds.[97] Other absolute contraindications include a personal history of schizophrenia and other forms of psychotic disorders.[98] Cannabinoids are also contraindicated during pregnancy and breastfeeding. In animal models, cannabinoids cause a delay in fetal growth and development and sexual maturation, neurobehavioral changes, and adverse effects on male reproductive organ development and fertility.[99] In the human fetus, cannabinoids may cause severe neurologic impairment in the embryo.[100] Synthetic cannabinoid medications (e.g. Nabilone) are classified in the pregnancy category C evidence of AE on the fetus in animal reproduction studies with no adequate and well-controlled studies in humans. However, potential benefits may warrant the use of the drug in pregnant women despite potential risks.[101] Their use is discouraged during breastfeeding. Evidence of the transfer of cannabinoids through breastfeeding is inconsistent and scarce in the literature. Obstetric and gynecology societies have advised against the use of cannabis-based products during breastfeeding for fear of adverse reactions in infants.[102]

Adult populations with severe cardiovascular, respiratory, liver, or renal diseases require specific medical attention to evaluate the risk-benefit ratio with the use of cannabinoids.[103] In patients on opioids and benzodiazepine, caution should be exercised if cannabinoids are used because of the potential increased risk of sedation and cognitive impairment.[97]

Cannabis-based products are contraindicated in children and adolescents for the treatment of chronic pain with some exceptional medical circumstances.[97] Longitudinal studies about heavy recreational use in young adolescents have reported correlations of cannabinoid use with poor cognitive, psychiatric, and neurodevelopmental parameters.[104] There is a consensus around avoiding the use of cannabinoids in individuals under 25 years old because of ongoing neurologic development.[105] A systematic review in 2017 demonstrated insufficient evidence for medical cannabinoids for neuropathic pain in children and adolescents.[106] Caution should also be exercised in patients with a personal or family history of addiction and mental health disorders. Problematic cannabis use can be associated with a cannabis use disorder based on criteria

in the *Diagnostic and Statistical Manual of Mental Disorders* (fifth edition).[107] Clinical tools have been developed to screen rapidly for the severity of psychological and physical dependence, such as the Severity of Dependence Scale and the Cannabis Use Disorder Identification Test-Revised (CUDIT-R).[108] Use of the CAGE tool for screening for alcohol and substance abuse is also recommended because appropriateness for using cannabis is also dependent on patterns of use relating to other current or past substances of abuse.

Limitations of the Current Research on Cannabinoids

Evidence on indications, benefits, and risks of using cannabinoids continues to evolve. The majority of the clinical studies on phyto- and synthetic cannabinoids had small sample sizes and a relatively short duration of follow-up. A recent systematic review reported that only 21 of the 104 included studies had at least 100 participants per treatment arm, and the median length of these studies was eight weeks.[4,5] There is also a lack of standardization concerning the composition of the cannabinoid administered and the doses used in the studies. Differences in dosing and routes of administration create unique challenges in the interpretation of clinical outcomes. In addition, most studies focus on THC, while CBD and CBN have not been adequately investigated in the clinical context and phytocannabinoid studies in the United States often use dried cannabis supplied by the National Institutes of Health (NIH) with CBD levels of less than 1%.[4] However, there is an increasing interest in CBD and CBN, given their lack of psychoactive properties. Additionally, the variable combinations of THC and CBD from different strains of cannabis and its extracts exert varying physiologic effects. Furthermore, many earlier studies were animal studies, and their results have been extrapolated to humans. This may not be appropriate because there is a significant interspecies variation in the physiologic effects of cannabinoids. As an example, cannabinoids cause tachycardia and postural hypotension in humans but bradycardia in dogs.[109]

Other concerns about the published studies include poor records of the precise dose and duration of cannabinoids consumed by participants. This is an important limitation because participants were often allowed to self-titrate the dose of cannabinoids in these studies. Also, given the high prevalence of polypharmacy in the chronic pain population, the focus for most studies was on the role of cannabinoids as adjuvant analgesics and not as the main analgesic therapy. Finally, there is a paucity of long-term data on the efficacy and safety of cannabinoids for the treatment of chronic pain syndromes.

Legal and Regulatory Considerations

In addition to the evolving science around cannabinoids, legislation and regulatory considerations for the growing, selling, and use of cannabis are also rapidly evolving. At the time of the submission of this chapter, 33 states in the United States, District of Columbia, Guam, Puerto Rico, and United States Virgin Islands have approved comprehensive, publicly available medical marijuana/cannabis programs. Fourteen states allow the limited use of "low-THC/high-CBD" products for medical reasons.[110] Despite the numerous cannabis access state legislations, the U.S. Drug Enforcement Administration (DEA) considers CBD and hemp oils to be a Schedule 1 substance.[111] As per DEA regulations, Schedule 1 drugs have no medical value and a high potential for abuse (e.g. heroin, LSD, ecstasy), and any use outside approved research is considered illegal. The paradox is highlighted by the labeling of cocaine and methamphetamine as Schedule 2 drugs—in other words, these are considered to be less dangerous and to have a greater medical value than cannabinoids. However, in April 2020, the DEA announced that Epidiolex (a cannabinoid used to treat refractory epilepsy) had been descheduled from Schedule V of the Controlled Substances Act.[112] In Canada, Marijuana Medical Access Regulations (MMAR) had provided access to cannabinoids for medical purposes since 2001, and the Cannabis Act legalized the recreational use of marijuana in 2018.[113,114]

Summary of Current Guidelines and Practical Recommendations for the Use of Medical Cannabis

The recommendations around the dosing of cannabis-related products continue to evolve. There is no established dosing schedule for dried cannabis, smoked/vaporized marijuana, and CBD oil. The common guiding principle of titrating cannabinoids is to "start low and go slow," aiming for the maximum potential therapeutic effect while minimizing AE. It is also important to consider regional legislative/regulatory differences in the availability and approval of cannabis-based products and medications.

There are several guidelines and recommendations for the use of cannabinoids for chronic non-cancer pain. The Neuropathic Pain Special Interest Group of the International Association for the Study of Pain found weak evidence against cannabinoids for treating neuropathic pain.[115] However, the European Pain Federation (EFIC) and the Canadian Pain Society recommend cannabinoids as third-line agents for the treatment of neuropathic pain based on low level evidence in the literature.[97,116] EFIC recommends the use of nabiximol oromucosal spray for cancer pain as an individual or additive analgesic if opioid or other analgesic agents fail.[97] For chronic non-neuropathic, non-cancer pain, EFIC recommends cannabinoids only in exceptional cases as an individual therapeutic trial. [97] The European Federation of Neurological Societies recommends cannabinoids as third-line therapy in the treatment of central neuropathic pain and spasticity caused by multiple sclerosis (Grade A evidence).[117] The Australian National Drug and Alcohol Council published palliative care guidelines for the use of medical cannabis in 2017.[118] It recommends a trial of 4–12 weeks and subsequent use of medical cannabis if all other standard treatments have failed.[118]

In the recommendations for the use of medical cannabis, the College of Family Physicians of Canada recommends cannabinoids as a third-line agent in the treatment of refractory neuropathic pain and refractory palliative cancer pain based on weak evidence.[119] It strongly recommends against the use of cannabinoids for any other type of pain. It also recommends starting with a prescription medication such as Nabilone or Nabiximols instead of medical marijuana as agents of choice.[119]

Perioperative Use of Cannabis

A recent systematic review and meta-analysis by Abdallah and colleagues studied the analgesic efficacy of cannabinoids on acute pain management postoperatively.[120] The primary outcomes consisted of the cumulative oral morphine equivalent consumption at 24 h and the rest pain scores at 24 h postoperatively. A total of

eight RCTs (924 patients) and four observational studies (4259 patients) were included, offering insufficient data to pool for quantification of differences in cumulative.[120] However, there is evidence of increased pain in patients receiving cannabinoids at 12 h postoperatively and an increased odds of hypotension in the postoperative period.[120]

In a series of discussion articles with contrasting perspectives about the above study, Meeker et al. highlight the lack of evidence for supporting the use of cannabinoids in the acute postoperative pain.[121] It also emphasizes the partially elucidated analgesic mechanism for cannabinoids and its interaction with the endocannabinoid system for acute pain.[121] Clarke et al. argue that Abdallah and colleagues' systematic review and meta-analysis have limited clinical relevance.[122] In fact, some of the drugs and chemical compounds included are not accessible to the public. For details of the limitation of the current literature, please consult *Section 10.Limitations of the Current Research on Cannabinoids.* Clarke et al. suggests for clinicians to consider 1) the potential for cannabis withdrawal; 2) remove the stigma associated with considering all cannabis products as "weed"; 3) education about the eCB system and cannabis products being consumed by patients; 4) consider the potential interactions on anesthetic care associated with the use of plant-based cannabis products.[122]

Conclusions

Cannabinoids have the potential to be a therapeutic option for neuropathic pain and in select and exceptional cases of palliative/oncologic care, but their efficacy has not been established in other chronic pain conditions. Their complex mechanism of action, partially elucidated interactions with the endocannabinoid system, diversified pharmacology, and a choice of multiple routes of administration require ongoing animal and clinical research to allow recommendations to be based on hard data. An understanding of the rapidly evolving science, evidence-based guidelines, and legislations regarding cannabinoids is important for establishing efficacious and safe protocols for their use.

Key Points

- The endocannabinoid system is a complex biologic system composed of endogenous CBR and their respective agonists. It is involved in the regulation of multiple physiologic and cognitive processes in the human body to maintain homeostasis.
- Endocannabinoids are endogenous fatty acid neurotransmitters that are responsible for intercellular signaling. Seven endocannabinoids have been identified to date, but the most studied are AEA and 2-AG.
- CBR are cell membrane GPCR. The most well-known CBR are cannabinoid receptor 1 (CB1R) and cannabinoid receptor 2 (CB2R).
- CBR exist in various locations in the body such as the brain, spinal cord, pituitary gland, thyroid gland, adrenal gland, and digestive system,[13] but their distribution, signaling pathways, and functions are still being elucidated. Please see Table 56.1 for details.
- Phytocannabinoids are natural substances capable of either directly interacting with CBR or sharing chemical similarities with endocannabinoids or both. More than 100 active phytocannabinoids have been identified within the cannabis sativa plant alone.[31]
- Synthetic cannabinoids are chemical molecules that have been designed to possess active pharmacologic properties through activation of CBR. Only two synthetic THC have established clinical applications: nabilone and dronabinol. Nabilone is approved for treating CINV, and dronabinol is indicated for the treatment of AIDS-induced anorexia and CINV.
- Several analgesic mechanisms have been proposed for cannabinoids' analgesic effect on acute, chronic inflammatory, and neuropathic pain. Similar to opioids, cannabinoids act on both the CNS and the PNS. CBR are involved in the transduction, transmission, modulation, and perception of pain in both the ascending and descending nociception pathways.
- A large diversity of cannabis-derived products exist in the market for recreational and medicinal uses. Common ROA include inhalation or smoking via a joint, spliff, pipe, blunt, water-pipe/bong, vaporizing (inhalation), dabbing, e-cigarettes, oral sprays, edibles, drinkables, tinctures (alcohol-based liquid cannabis extracts), other oromucosal/sublingual (e.g. strips and lozenges), transdermal topicals (cannabis-infused lotions, balms, oils), intravenous (syringe), and rectal (suppositories).
- Short-term and long-term use of cannabis may result in significant adverse events affecting the cardiovascular system, the respiratory system, the neurologic system, and the gastroenterology system.
- At the time of the submission of this chapter, 33 states in the United States, District of Columbia, Guam, Puerto Rico, and U.S. Virgin Islands have approved comprehensive, publicly available medical marijuana/cannabis programs.
- The recommendations around the dosing of cannabis-related products continue to evolve. There is no established dosing schedule for dried cannabis, smoked/vaporized marijuana, and CBD oil. The common guiding principle of titrating cannabinoids is to "start low and go slow," aiming for the maximum potential therapeutic effect while minimizing AE.

57 Topical Analgesics

MAGDALENA ANITESCU, CHARLES E. ARGOFF

In contrast to the use of a systemic analgesic, the use of a topical analgesic may result in pain relief without the requirement for notable systemic absorption.

In certain situations, and with specific agents (i.e. nitroglycerine, fentanyl, clonidine), *transdermal* application results in systemic uptake. In these cases, absorption through the skin while achieving a certain therapeutic blood concentration is responsible for the effects of the drug.

In contrast, a *topical* analgesic requires neither systemic absorption nor a significant systemic concentration to be clinically effective. Its effect occurs when applied locally and directly to the painful areas, with the primary site of action being local to the application site.

Topical analgesics are used for acute pain, as well as for various types of chronic neuropathic and non-neuropathic pain. Different topical analgesics are associated with different mechanisms of action. Using functional neuroimaging, some changes related to topical analgesics can also be seen in the central nervous system (CNS), in addition to effects occurring locally, at the site of application and within the peripheral nervous system (PNS).

Background

A topical analgesic may interrupt specific mechanisms of pain transmission and, by doing so, lead to a reduction in central pain mechanisms and, consequently, perception of pain. As such, skin application of a topical analgesic may reduce activation of the PNS, thus minimizing pain signal transmission and central processing by the CNS. This chapter reviews the use of topical analgesics to treat various painful conditions and provides an update of previously published similar reviews.[1–3]

As topical analgesics are locally applied, without significant systemic absorption, the risk for and severity of significant adverse effects and drug-drug interactions are often less than those for the same analgesic administered systemically.[4] As such, using topical nonsteroidal anti-inflammatory drugs (NSAIDs) versus oral formulations in knee osteoarthritis (OA) may prove effective in limiting the side effects. Rash and unpleasant skin sensations may occur with the use of a topical analgesic, but neither is typically experienced.[5] Among the topical analgesics currently approved by the Food and Drug Administration (FDA) (see Table 57.1) is the 5% lidocaine patch (Lidoderm). Several studies have confirmed the safety and tolerability of topical lidocaine. When using 12 h/day, 5% lidocaine patches demonstrated no significant systemic side effects with plasma lidocaine levels significantly below those known to be associated with cardiac abnormalities.[6] No significant dermal reaction was observed in patients treated long-term with 24 h lidocaine patches.[5–7]

While dermal sensitivity is a potential side effect of all topical analgesics, specific topical analgesics such as capsaicin can be associated with other local adverse effects. After its application, topical capsaicin is commonly associated with severe localized burning. Skin application of capsaicin, at currently available low-dose formulations, does not result in significant systemic accumulation or any life-threatening outcomes; the incidence of burning may decrease with repeated use. However, the occurrence of this side effect may negatively affect treatment adherence and, consequently, the patient's ability to benefit from its use.[8] In contrast to the over-the-counter capsaicin formulations that need to be applied multiple times, the 8% capsaicin patch (Qutenza) can be applied once for 1 h for analgesic effects lasting up to 12 weeks. Qutenza was generally well tolerated in clinical trials even though burning occurred, and the FDA approved it for the treatment of postherpetic neuralgia (PHN) and painful diabetic peripheral neuropathy in July 2020.

In patients suffering from chronic pain in addition to other afflictions and comorbid conditions, such as hyperlipidemia, hypertension, coronary artery disease, and diabetes, a trial of topical analgesics may be beneficial in limiting drug-drug interactions, especially if patients have been administered significant amounts of systemic medications for their underlying conditions.[9,10] Since the topical analgesics available typically do not involve dose titration and many systemic agents do, this may provide an additional potential benefit for a patient.

Commercially available FDA approved topical analgesics must have demonstrated to the FDA consistent manufacturing standards and quality control, in contrast to those manufactured and sold by

TABLE 57.1 Food and Drug Administration Approved Topical Medications

Drug	Painful Condition
Lidocaine	Postherpetic neuralgia, intercostal neuralgia, painful diabetic neuropathy
Lidocaine/prilocaine	Postherpetic neuralgia
Diclofenac	Soft tissue injuries, osteoarthritis, musculoskeletal pain
Doxepin	Chemotherapy-induced neuropathy, atopic dermatitis, lichen simplex chronicus
Capsaicin	Painful diabetic neuropathy, human immunodeficiency virus neuropathy, postherpetic neuralgia, postmastectomy pain

a specialized compounding pharmacy. Topical analgesics made by a compounding pharmacy may consist of a combination of substances, such as a local anesthetic, NSAIDs, and anti-depressants combined in a chemical base that is not commercially available and FDA approved topical products. There is no current general requirement for compounding pharmacies to demonstrate manufacturing consistency. However, those compounds are commonly prescribed as almost 1/3 of pain physicians members of the American Society of Regional Anesthesia and Pain Medicine have reported that they prescribe topical analgesics.[11] Topical preparations containing opioids, local anesthetics, anti-depressants, glutamate receptor antagonists, α-adrenergic receptor agonists, adenosine, cannabinoids, cholinergic receptor agonists, gabapentinoids, prostanoids, bradykinin, adenosine triphosphate, biogenic amines, and nerve growth factor are each at various stages of clinical development.[12]

The mechanism of action of a specific topical analgesic depends on the chemical entity or entities in the specific agent. In the case of the topical agent capsaicin, the mechanism appears to be through agonist activity at the transient receptor potential vanilloid 1 (TRPV1) on Aδ and C-fibers.[13,14] Substance P and calcitonin gene-related peptide are released as a result of this activity. Subsequent depletion of substance P in the C-fibers induces reduced peripheral and central excitability, resulting in less pain through reduced afferent input in response to capsaicin application.[8,13,15] The results of both human nerve biopsy and animal studies demonstrate nerve fiber degeneration in the skin underneath the site of capsaicin application. Such nerve fiber degeneration associated with the application of capsaicin has been suggested to be one of the mechanisms through which its use results in pain relief.[16]

The mechanism of action of a topical NSAID is probably associated with the inhibition of prostaglandin synthesis and the resulting anti-inflammatory effect. However, the extent of the anti-inflammatory effect is not consistently proportional to the pain relief experienced; therefore other mechanisms of action might be considered.[17]

It may be worthwhile to consider the potential benefits of mixed agents with potentially more and synergistic mechanisms of action. For example, the antinociceptive effects of topical morphine may be enhanced by a topical cannabinoid, as demonstrated in studies in rats.[18]

Local anesthetic agents are known to suppress the activity of peripheral sodium channels within sensory afferents and subsequent pain transmission. It has been noted that decreased expression of mRNA for specific sodium channel subtypes may occur following local anesthetic use.[1,5] Several local anesthetic topical analgesics are currently available commercially, including the 5% lidocaine patch, EMLA cream (eutectic mixture of local anesthetics, 2.5% lidocaine/2.5% prilocaine), and the Synera patch (lidocaine, 70 mg/tetracaine, 70 mg). Of these three agents, only the 5% lidocaine patch is associated with an *analgesic* effect without creating *anesthetic* skin, whereas the use of EMLA cream or the FDA approved Synera patch may create both analgesia and anesthesia. This difference among the preparations is useful for application in specific clinical settings, such as venipuncture, lumbar puncture, intramuscular injections, and circumcision, for which creating both anesthesia and analgesia would be helpful.[5]

A novel area of topical analgesic development involves the use of tricyclic anti-depressants as topical analgesics. Certain tricyclic anti-depressants such as amitriptyline and doxepin have been demonstrated to block sodium channels, and the potential clinical benefit of this mechanism when such an agent is topically applied seems to be especially effective in chemotherapy-induced peripheral neuropathy.[19,20] One commercially available topical anti-depressant, doxepin hydrochloride (Zonalon) cream, is currently approved by the FDA for the short-term treatment of adult patients with pruritus associated with atopic dermatitis or lichen simplex chronicus.[21]

Use of Topical Analgesics for Specific Clinical Conditions (see Box 57.1)

Neuropathic Pain

The use of specific topical analgesics for the management of neuropathic pain has been established by several clinical trials that highlight their efficacy.[22–24]

Local Anesthetics

The first medication to receive FDA approval for the treatment of PHN was a 5% lidocaine patch. Initial studies showed that, when compared with patients treated with placebo, patients treated with 5% lidocaine patches experienced statistically significantly more pain reduction in a safe and well tolerated manner.[25,26] Multiple studies have been conducted regarding the clinical efficacy of the 5% lidocaine patch. In an open-label study comparing 5% lidocaine patch with pregabalin (Lyrica) for PHN, the topical local anesthetic was as effective as pregabalin for pain relief in PHN patients. Additionally, the study showed that for patients who did not respond to either the 5% lidocaine patch or pregabalin alone, using these agents in combination resulted in greater benefit and was well tolerated by these patients.[27]

A review that analyzed results from randomized, controlled, and open-labeled studies suggested that the use of 5% lidocaine medicated plaster is effective in the treatment of localized neuropathic pain (LNP), both as part of multimodal analgesic regimen and as a single agent.[28] In a European randomized, double-blinded, placebo-controlled study, 5% lidocaine patch was reported to be effective in mononeuropathies such as intercostal and ilioinguinal neuralgias.[29] The results of this study demonstrated that adding the 5% lidocaine patch to other pharmacotherapeutic regimens could reduce ongoing pain and allodynia within the first 8 h following application over seven days.[29] Use of 5% lidocaine has been included in the international treatment guidelines for treating LNP either as monotherapy or in a multimodal analgesic regimen.[30] Several noncontrolled studies using a 5% lidocaine patch for painful diabetic neuropathy showed pain reduction and good tolerability of this medication.[31–34] Similarly, an open-label study using the 5% lidocaine patch in patients with painful idiopathic sensory polyneuropathy noted significant improvements in both pain and quality-of-life measures.[35]

Topical patches with lidocaine 5% applied to the skin of 150 patients suffering from PHN (up to three patches, 12 h each day) showed reduced pain qualities as described by the neuropathic pain

• Box 57.1 Pain Conditions Treated With Topical Analgesics

Neuropathic pain (various syndromes)
Musculoskeletal pain (acute and chronic)
Soft tissue pain (acute and chronic)
Other pain (dressing changes, cancer treatment related)

scale in a multicenter, randomized, vehicle-controlled study.[36] Of interest was that certain types of neuropathic pain (deep, sharp, and burning) that were reduced had previously been assumed to not be related to PNS but to CNS mechanisms. In the discussion of their results, the authors proposed that given the localized primary PNS mechanism of action of the 5% lidocaine patch, peripheral mechanisms of neuropathic pain might also be important in the development of these neuropathic pain qualities.[36] The results of a functional brain magnetic resonance imaging study of patients with PHN treated with the 5% lidocaine patch for various lengths of time demonstrated that the brain activity occurring with the spontaneous pain of PHN appeared to be modulated in a manner related to the length of application of this medication, thus suggesting again that a peripherally acting agent may have an impact on CNS pain mechanisms.[37]

Another commercially available local anesthetic preparation is the EMLA cream. Its FDA approved indication is for use on normal intact skin for analgesia, but it is not FDA approved for any specific neuropathic pain disorder. Several studies of EMLA cream for the treatment of PHN have reported mixed results. While EMLA cream alone did not show a significant difference in treatment compared to placebo in PHN, it provides excellent analgesia as a pretreatment to 8% capsaicin patch (Qutenza).[38] The results of two uncontrolled studies were more favorable and suggested that the use of EMLA cream could relieve the pain associated with PHN.[39,40]

Capsaicin

Even though there has been interest in using capsaicin for several neuropathic pain disorders such as diabetic neuropathy, painful human immunodeficiency virus (HIV)-related neuropathy, PHN, and postmastectomy pain, many of the older studies had yielded disappointing results, perhaps partly as a result of the weakness of previously available strengths of capsaicin (0.025% and 0.075%), as well as poor tolerance to the treatment and poor treatment adherence, with resulting insufficient pain relief.[41] In contrast, the results of a higher-strength capsaicin preparation demonstrated better analgesia. In one reported study of patients with painful HIV neuropathy treated with 7.5% topical capsaicin cream, the patients experienced notable pain relief but could not tolerate this medication; concurrent treatment with epidural anesthesia was required.[42] High concentration topical capsaicin showed significant relief in patients with HIV-associated distal symmetric polyneuropathy and PHN. The duration of pain relief lasted as long as 48 weeks (PHN), but most commonly 12 weeks.[15,43] A review of the published randomized trials on the use of topical capsaicin for the treatment of either neuropathic or musculoskeletal pain syndromes concluded that it might be useful as an adjunct or sole therapy for a small number of patients who are unresponsive to or intolerant of other treatments.[44] In studies leading to approval by the FDA, the 8% capsaicin patch (Qutenza) was shown to be more effective in reducing pain intensity when compared with an active, lower concentration capsaicin product that served as a placebo. It was also generally well tolerated. In July 2020, the FDA approved the preparation for the treatment of painful diabetic neuropathy. Favorable outcomes have been reported in other neuropathic pain states, such as HIV neuropathy.[45–49]

Other Agents

Topical tricyclic anti-depressants for the treatment of neuropathic pain have emerged as a possible favorable agent. However, evidence has shown mixed results.

A double-blind, randomized, placebo-controlled study involving 92 patients with diabetic neuropathy, PHN, or post-surgical or posttraumatic neuropathic pain, showed no difference in analgesic benefit among any of the four treatment groups (placebo, 2% amitriptyline alone, 1% ketamine alone, or a combination of 2% amitriptyline and 1% ketamine).[50] However, the results of an open-label study completed by the same investigators involving 28 patients with neuropathic pain for six to 12 months treated with the combination topical analgesic 2% amitriptyline and 1% ketamine demonstrated that the average reduction in pain was 34%.[51] In another open-label study using the same type of preparation, the same investigators also demonstrated some encouraging results.[52] More recent evidence established the effectiveness of these preparations for the treatment of PHN.[53]

Noncontrolled trials evaluating the use of topical ketamine in PHN concluded that topical ketamine might be an effective topical analgesic. However, serum ketamine levels were not measured; therefore, it is unclear how "topical" the ketamine preparations were.[54] One report suggested that topical application of geranium oil may provide temporary relief of PHN.[55]

Soft Tissue Injuries and Osteoarthritis

Common musculoskeletal pain conditions include soft tissue injury and osteoarthritis (OA). Since 2007, the FDA has approved three topical NSAIDs for the treatment of these conditions: 1% diclofenac sodium gel (1% Voltaren gel), 1.3% diclofenac epolamine topical patch (Flector patch), and 1.5% diclofenac topical solution (Pennsaid). Each of these FDA approved topical NSAIDs has different indications. Diclofenac sodium 1% gel (1% Voltaren gel) is FDA approved for treating pain associated with OA in joints that can be managed with topical treatment, such as the knees and hands. It has been approved for use as an over-the-counter formulation as of 2020. The diclofenac epolamine topical patch (Flector patch) is FDA approved for the topical treatment of acute pain from minor strains, sprains, and contusions. The diclofenac sodium topical solution (Pennsaid) is FDA approved for the treatment of the signs and symptoms of OA of the knee.[56]

The use of other topical NSAIDs has been studied, most notably outside the United States. A topical ketoprofen patch (100 mg) was found to be superior to a placebo in reducing pain intensity after seven days of treatment in a two-week randomized, placebo-controlled study of 163 patients with pain from an ankle sprain.[57] In a separate study, a comparable topical ketoprofen preparation was evaluated in patients with tendinitis in a randomized, double-blind, placebo-controlled study and found that subjects treated with the active medication fared better than the placebo-treated group with minor skin irritation being only side effect infrequently.[58] Ketoprofen gel has also been shown to be helpful in knee osteoarthritis and was found superior to oral celecoxib.[59] A randomized, open-labeled parallel design trial examined the efficacy of diclofenac patch compared to oral diclofenac for chronic musculoskeletal conditions and found both formulations equally effective.[60] Diclofenac patch has proven efficacious in acute sports injury-related pain in a randomized, double-blind, placebo-controlled study.[61] These results were confirmed in a recent systematic review that included 23 studies and more than 11,000 participants where topical diclofenac proved effective in acute pain such as sprains with minimal side effects.[62] Proved efficacious in many pain conditions, with an excellent safety profile, in April 2020, the FDA approved over-the-counter use of the diclofenac gel to treat acute pain of minor musculoskeletal injuries.

Compared with oral diclofenac, topical flurbiprofen was associated with greater pain reduction and fewer adverse effects in a noncontrolled study of patients described as experiencing "soft tissue pain."[63] Similar findings were reported in a controlled study; the use of topical ibuprofen cream for the management of acute ankle sprains was found to be superior to placebo in reducing pain.[64] In a single-center, randomized, single-blinded, parallel-group study, 5% ibuprofen gel containing 3% levomenthol proved equally effective to 1.16 % diclofenac gel and superior to ibuprofen gel alone for patients acute soft tissue injuries.[65] Placebo and 5% ibuprofen gel administered for a maximum of seven applications showed a significant reduction ($P < 0.001$) in pain intensity plus improvement in physical activities in the study group.[66] Comparing topical with oral NSAIDs, several studies, including a Cochrane database review, showed that topical NSAIDs could provide good levels of pain relief without the systemic adverse effects of oral NSAIDs in the treatment of acute musculoskeletal pain.[67,68]

Topical analgesics proved effective in the treatment of OA.[69–72] A diclofenac patch preparation, studied in a randomized, double-blind, controlled study in patients with chronic pain secondary to knee OA, demonstrated that this patch might be safe and effective for this common condition.[73] A randomized controlled study comparing the use of a topical diclofenac solution and oral diclofenac for the treatment of OA of the knee concluded that use of the topical diclofenac produced relief of symptoms that was equivalent to that of oral diclofenac and resulted in a significantly reduced incidence of diclofenac-related gastrointestinal complaints.[74] A long-term study with the same topical diclofenac solution confirmed its safety during the study period.[75] Individuals with pain in the temporomandibular joint benefit from topical diclofenac solution. The treatment proved effective when applied topically several times daily and was as effective as oral diclofenac. Patients also reported significantly fewer gastrointestinal side effects with the diclofenac topical solution.[76] Placebo-controlled and randomized controlled trials demonstrated the efficacy of 1.16% topical diclofenac gel in patients with painful OA of the knee.[77,78] One meta-analysis examining the use of topical NSAIDs for the treatment of OA found evidence suggesting that topical NSAIDs are more effective than placebo during the initial two weeks of treatment only.[79] The authors concluded that the evidence available indicates that topical NSAIDs are inferior to oral NSAIDs during the first week of treatment.[79] A separate meta-analysis reviewed the evidence for the use of topical NSAIDs for chronic musculoskeletal pain and concluded that topical NSAIDs are effective and safe in treating chronic musculoskeletal conditions for two weeks.[80] Another meta-analysis on the use of topical NSAIDs for OA suggested that of the four studies that compared a topical NSAID with placebo or vehicle in patients with OA of the knee, pain relief did occur for a longer period with the topical NSAID than with placebo but that the results were not uniform for the preparations reviewed.[81]

Patients using over-the-counter preparations often use topical salicylates. Those agents may be associated with significant side effects such as skin irritation. When used excessively, salicylates progress to poisoning that starts with hyperventilation and respiratory alkalosis from direct stimulation of the medulla and progresses to uncoupling of oxidative phosphorylation and resultant lactic acidosis.[82] A randomized controlled study completed in Europe with the topical eltenac examined its effect compared to placebo in 237 patients with knee OA and concluded that the use of topical eltenac for the treatment of OA of the knee is safe and effective.[83] In an additional clinical trial, topical eltenac gel was compared with oral diclofenac and placebo in patients with knee OA. Each active treatment resulted in analgesia superior to that achieved with placebo, and the incidence of gastrointestinal side effects was notably lower in the group treated with topical eltenac gel than in those treated with oral diclofenac.[84] Early discovery studies have demonstrated that topical diclofenac may be effective in reducing the pain associated with various types of degenerative joint disease.[85–87]

Other topical agents have been studied for musculoskeletal pain conditions. However, studies have shown mixed results. In a randomized, double-blind study of 30 patients with temporomandibular joint pain, capsaicin 0.025% cream was determined to be no better than the vehicle (not active) cream.[88] A randomized controlled study of a topical cream containing glucosamine sulfate, chondroitin sulfate, and camphor for OA of the knee showed a significant reduction in pain in the treatment group after eight weeks compared with the placebo group.[89]

Although morphine has been reported as a potential topical analgesic in the management of chronic OA-related pain, the presence of morphine metabolites in urine was identified in treated patients, calling into question how truly "topical" this preparation was, given its systemic effects.[90]

Low Back and Myofascial Pain

Few studies have been published on the use of topical analgesics for low back pain or myofascial pain, two very common conditions. A randomized, double-blind, placebo-controlled study comparing the use of topical capsaicin with placebo in 154 patients with chronic low back pain resulted in 60.8% of capsaicin-treated patients versus 42.1% of placebo patients experiencing 30% pain relief after three weeks of treatment ($P < 0.02$).[91] A multicenter, open-label study involving 120 patients with acute (< six weeks), subacute (< three months), short-term chronic (three to 12 months), or long-term chronic (>12 months) low back pain with four 5% lidocaine patches applied to the most painful areas in the low back region demonstrated that, during the six-week study period, the majority of patients experienced moderate degree of pain relief.[71] A double-blind, placebo-controlled study compared over-the-counter lidocaine 3.6% and Menthol 1.25% patch with 5% lidocaine patch and placebo and showed non-inferiority of the over-the-counter formulation.[91] Additional studies[92] have been published in abstract form, probably because they involve the use of a local anesthetic for conditions not typically thought of as being responsive to this form of treatment.

Other Conditions

Topical analgesics have been used in other painful conditions. However, the number of studies was relatively small. Some topical analgesics, including opiates, may help reduce the pain associated with pressure ulcers or dressing changes.[93–99] Controlled studies have demonstrated the benefit of EMLA cream in reducing the pain associated with circumcision and venipuncture as well as reducing the pain associated with breast cancer surgery.[5,100] At least two studies have suggested that either topical ketamine or topical morphine can be used for mucositis-associated pain following chemotherapy or radiation therapy in patients with head and neck carcinoma.[101,102] Topical opiates have been reported to reduce pain in two children with epidermolysis bullosa.[103] In one report, the observed analgesic effect of menthol, an ingredient common

in many over-the-counter analgesic preparations, is hypothesized to result from activation of κ-opioid receptors.[104] Burn pain has been reported to be treated effectively with a topical loperamide preparation.[105] Two randomized controlled studies showed good efficacy in postoperative pain (diclofenac patch) and wound pain treatment (capsicum plaster topically applied at acupuncture sites).[106,107] Central neuropathic itch was treated successfully with the 5% lidocaine patch in a single case report.[108] The results of an enriched enrollment study in which an open-label initial study led to the randomization of responders in a placebo-controlled study of the use of either 4% amitriptyline/2% ketamine cream, 2% amitriptyline/1% ketamine cream, or placebo in patients with PHN. The study demonstrated that after three weeks of treatment, the average daily pain intensity was lower in patients receiving the higher-concentration combination cream than in those receiving the lower concentration combination or placebo ($P = 0.026$ for the high concentration cream vs. placebo).[109] An open-label study of the use of a 0.25% topical capsaicin agent in a lidocaine-containing vehicle in 25 patients with painful diabetic polyneuropathy and seven patients with PHN demonstrated pain relief in the majority of patients who were studied.[110] In a noncontrolled study of 23 patients with acute migraine headache, 0.1% capsaicin gel applied topically helped reduce mild or moderate pain.[111] In a randomized, double-blind study assessing 154 patients with chronic pain from lateral epicondylitis, topical glyceryl trinitrate (0.72 mg/day) was found to provide statistically significantly greater pain relief after eight weeks compared with placebo.[112] In a study of 52 patients with chronic pain secondary to chronic Achilles tendinopathy, patients who had been treated with topical glyceryl trinitrate for six months were more likely to have less pain and more function than those who had been treated with placebo, three years after treatment ended.[113] Published reports on the use of topical phenytoin for the treatment of pain from superficial burns or chronic leg ulcers are noted as well.[114,115]

Conclusion

Clinicians should consider the use of topical analgesics for a variety of painful conditions. Notably, the number of FDA approved topical agents has increased. Off-label use of the available therapies must include careful consideration of the potential risks and benefits. Repeated observations have shown that topical analgesic use is generally associated with a more desirable side effect profile than oral, transdermal, parenteral, or intrathecally administered analgesics; this factor should be considered when developing a pain management treatment regimen for individual patients, especially when pharmacotherapy is involved. Indeed, additional large, well-designed studies that include comparative trials with non-topical analgesics would be helpful to better understand the role of topical analgesics in the management of acute and chronic pain.

Key Points

- Topical analgesic effects occur when applied locally and directly to the painful areas, with the primary site of action being local to the site of application.
- Topical NSAIDs currently approved by the FDA for soft tissue pain and painful osteoarthritis are 1% diclofenac sodium gel, 1.3% diclofenac epolamine topical patch, and 1.5% diclofenac topical solution.
- Topical lidocaine and capsaicin are FDA approved for neuropathic pain in PHN, with 8% capsaicin approved for painful diabetic neuropathy.
- In contrast to the use of a systemic analgesic, the use of a topical analgesic is less likely to be associated with systemic side effects because the systemic concentration of a topical analgesic is likely to be lower than that with systemic administration.
- Despite the localized, peripheral mechanism of action of a topical analgesic, there may be CNS effects related to topical analgesics.

Psychological Approaches in Pain Management

DENNIS C. TURK, AKIKO OKIFUJI

Psychological interventions for managing individuals experiencing chronic pain include a wide range of approaches and therapeutic targets. They are based on several theoretical perspectives. This chapter will first provide an overview of the basic principles and backgrounds on which psychological approaches to chronic pain are predicated and then provide reviews of the evidence-based approaches that have demonstrated the greatest empirical support.

From a psychosocial perspective in general, we should differentiate between the concepts of "patient" and "person with chronic pain." "Patient" implies a recipient of treatment in a healthcare setting, whereas a "person with chronic pain" resides beyond the confines of the healthcare system, extending the context into their entire life experience. For the most part, chronic pain is not curable and can persist over extended periods, for years and even decades. Individuals experiencing chronic pain must learn how to adapt and self-manage their lives and any impairments despite the presence of pain.

To illustrate, consider that the primary entry criterion in most clinical trials for pain treatments is moderate pain (usually defined as a pain intensity rating of four or greater on a zero to ten numerical rating scale where zero equal no pain and ten equals the "worst pain possible" or the "worst pain imaginable"). At the termination of these trials, even with "statistically significant" pain reduction by the experimental treatment, the end-point pain intensity is greater than four for most patients. This suggests that people with chronic pain likely continue experiencing at least a moderate level of pain even with helpful treatment. Consequently, it is the individual's intentional efforts that will be required for adaptation and resilience, and those efforts occur largely outside of the purview of health care. For healthcare providers to assist patients in transforming their lifestyle to maximize their ability to manage pain and minimize life disruptions, a good grasp of the chronic pain experience is necessary.

Plight of Individuals With Chronic Pain

People with chronic pain and recurrent, episodic acute pain (e.g. migraine, trigeminal neuralgia) often feel rejected by the very elements of the society that exist to serve them. They typically begin their healthcare journey expecting that there is some physical cause of their pain, that the pathology causing their pain will be identified by a healthcare provider, and that their pain will be eliminated by treatments prescribed by their providers and in a reasonable time interval. In this scenario, the "patient" with chronic pain remains a passive recipient awaiting a "cure" provided by healthcare providers. However, for many of these individuals, the journey becomes an arduous one as they shuttle from one healthcare provider to another, to increasingly invasive laboratory testing, to imaging procedures, to other specialists, and yet more diagnostic tests, all in the quest for an eventual cure. Usual life roles are altered, family and social interactions are impaired, gainful employment may become increasingly difficult, conflicts with third-party payers escalate, and medical expenses for unsuccessful treatments accumulate. They are often informed at various times that no specific pathology can be identified to account for the pain they report and, eventually, that all treatment options are exhausted ("there is nothing else I can do for you"). The perpetual experience of being in the "medical limbo" taxes their patience and perseverance. A frustrated person with chronic pain may lose their faith in health care and feel helpless; psychological distress compounds the difficulty of having to live with chronic pain and disability.

A vicious cycle is initiated when an equally frustrated physician, with no ways to explain the persistence of pain reported and no new treatment options are in sight, may implicitly or explicitly suggest that the pain is caused by "psychological issues." Once optimistic, family members also experience pervasive frustration that adversely affects the family dynamics. Over time, the legitimacy of the pain may be questioned by significant others, employers, and third-party payers, as diagnostic and therapeutic efforts fail despite the sophisticated biomedical technologies. Many individuals with chronic pain feel disbelieved, dismissed, and stigmatized by their situation, which further exacerbates their distress.[1] It is hardly surprising to see the increasing emotional distress that accompanies these people's quest to finding relief.

To place the situation for an individual experiencing chronic pain in context, consider that chronic pain affects over 20% of the adult United States population (50 million), with over 8% reporting high impact chronic pain (limited life or work activities on most days or every day during the past six months).[2] If we extend our view to the impact of chronic pain on families and friends, many more people in our society are affected directly or indirectly by chronic pain. Pain has societal consequences beyond those of the individuals affected. Pain is expensive; health care and indirect costs associated with disability, lost tax revenues, retraining, unemployment or under employment, and legal fees exceed $550 billion annually.[2] These astronomical figures do not incorporate

the incalculable human suffering attended to chronic pain. To put it bluntly, pain hurts the individual with the symptoms, people around the person, and society as a whole. The Institute of Medicine aptly labeled the current situation of chronic pain as a "crisis."[2]

Despite an increased understanding of the pathophysiology of pain, technologic advancements, and pharmacotherapeutic innovations, a *cure* for chronic pain has eluded the best efforts and intentions of researchers and healthcare providers. Regardless of the treatment modality, the pain reduction averages only about 35%, and fewer than half of persons treated obtain this outcome. The extent of improvement in emotional, physical, and social functioning is often below this level.[3]

People with chronic pain continually confront noxious symptoms and experiences that affect every aspect of their lives. Thus those with chronic pain face a dire need to manage their symptoms. Recall Bonica's comment in the preface of the first edition of his seminal work The Management of Pain over 60 years ago:[4]

> *"The crucial role of psychological and environmental factors in causing pain in a significant number of patients only recently received attention. As a consequence, there has emerged a sketch plan of pain apparatus with its receptors, conducting fibers, and its standard function, which is to be applicable to all circumstances. But . . . in so doing, medicine has overlooked the fact that the activity of this apparatus is subject to a constantly changing influence of the mind." (p. 11)*

It should be evident that psychological, social, and contextual factors play significant and contributory roles in the experience, maintenance, and exacerbation of pain. The neurophysiology does not exist apart from psychology and the context in which pain occurs. Instead, what we do, how we think, and how we feel constantly send feedback to the brain to modulate the neurophysiologic system. Psychological processes such as emotional states, thoughts about pain, and attitudes in response to pain may impact on, and be affected by, how an individual interprets, perceives, and manages his or her pain.[5]

With the advent of innovative research, we have become aware that psychological factors are interconnected with brain regions implicated in the perception, attention, and modulation of pain.[6,7] In this sense, research has shown that it is not the pain itself but rather the interpretation of the pain that predicts how an individual behaves in response to it. How others respond to people with pain can affect the experience of pain, adaptation, and disability. These observations are the basis for the emergence of interest in using psychological approaches to assist individuals in managing their pain and lives despite pain.

Psychological Formations of Chronic Pain

To many healthcare providers, "psychological treatment" is a generic term. However, various psychological interventions form the basis for a diversity of psychological treatments based on their tenets. Although all psychological treatments have a fundamental commonality, emphasizing the whole person affected and self-management rather than cure, they do have essential differences. A brief review of the history of the area is warranted to provide a better understanding of the current practices of psychological interventions with individuals experiencing chronic pain. This is important for non-mental health professionals for their treatment planning and making referral requests about which psychological treatment to select from among those available. Since there are different emphases among the various treatments, providers need to identify and select a treatment approach that best fits each of their specific patient's current state, most pressing problems, and personal characteristics. However, depending on resources, there may be limitations and constraints on the options available.

Psychogenic View

As is often the case in medicine, when physical explanations seem inadequate and no treatments seem to provide consistent outcomes, individuals' reports of pain are often attributed to a psychological origin (i.e. psychogenic). This unfortunate trend in medicine has a long history but was first systematically articulated in the 1960s when people with persistent pain were viewed as having compulsive and masochistic traits, inhibited aggressive needs, and feelings of unresolved guilt—"pain-prone personalities."[8] It was commonly believed that people reporting persistent pain had histories of troubled childhoods, including emotional abuse, family dysfunction, loss of parents, and pressure to attain unreasonably high goals for themselves.[9] Some have insinuated the psychogenesis of pain from the psychological "wounds" by linking childhood trauma to adulthood chronic pain, although the findings to support this contention are not consistent and remain controversial.[10,11]

The psychogenic model has focused clinicians' efforts toward identifying the etiologic and historical psychopathologic processes involved. Addressing the maladaptive psychological needs that allegedly caused pain was common in the early days of pain medicine.[12,13]

Although the incidence of depression and anxiety are common in people with chronic pain, and how could they not be given the description of the plight of the person with chronic pain outlined, attempts to establish the causal link have been inconsistent.[14] To address the gap, the American Psychiatric Association formulated a psychiatric diagnosis, "Somatoform Pain Disorder," in their 4th edition of the *Diagnostic and Statistical Manual of Mental Disorders*.[15] The diagnosis of Somatoform Pain Disorder was made by default when persistent pain could not be explained biomedically, and the pain was associated with excessive thoughts, feelings, or behaviors about the symptoms. This diagnostic category was highly criticized for the questionable meaning of "medically unexplained" pain and appropriateness of the assumption that poorly defined "excessive distress" has an etiologic role in pain.[16] The classification was deleted from the latest version of the diagnostic manual and replaced by a new designation, Somatic Symptom Disorder. Notably, in this new iteration, pain is no longer required to be "medically unexplained."[17] Nevertheless, it remains unclear how the diagnosis leads to appropriate treatment plans, and it continues to risk misdiagnosing a medical condition as a psychiatric illness.[16] For the most part, the psychogenic model has thus come under appropriate scrutiny and has fallen out of favor.

Behavioral Formulations

Learning principles play an important role in dysfunctions associated with chronic pain. Three behavioral principles can influence people with chronic pain individually and interactively. Through experiential learning based upon the classical (Pavlovian) conditioning model, a painful experience can lead to an emotional association between contextual factors and activity with fear of pain. For example, for a person who tries to vacuum rugs and then experiences a pain flare, the co-occurrence of vacuuming the floor and the resulting pain becomes conditioned to pain-related

fear. Avoidance is a natural response to feared activity. Pain-related fear-based conditioning is ubiquitous in chronic pain, leading to further deconditioning and loss of function. The Fear-Avoidance Model has incorporated the conditioned fear and avoidance into a vicious circle of pain, avoidance of activity, and subsequent deconditioning and the resulting disability.[18] Several studies have shown the significant association between pain-related fear-avoidance and disability.[19–21]

Another contribution of the learning principles to pain comes from the operant conditioning model, pioneered by Fordyce at the University of Washington in the 1970s.[22] The operant conditioning model posits that the likelihood of particular behavior recurring depends upon the immediate consequence of the behavior. For example, imagine that a man grimaces and complains of his back pain while arguing with his wife. The wife immediately stops arguing, brings him a cold beer, tells him to take it easy, and rubs his back. Here, the likelihood of grimacing and complaining reoccurring will increase because of immediate consequences of (1) negative reinforcement (removal of the aversive situation) and (2) positive reinforcement (attaining something positive: beer, sympathy), and a back rub. Fordyce posited that over time, various pain-related behaviors (e.g. sighing, moaning, bracing, limping, guarding, medication taking) could be reinforced through operant conditioning and, consequently, shaping and maintaining the person's chronic pain experience.

From the operant perspective, the central features of pain behaviors are that behavior is (1) a source of communication and (2) observable. People express their pain in different ways. Their significant others respond to those expressive behaviors in different ways. However, the principles of operant conditioning apply to all behavioral communications. Maladaptive behavioral patterns that are reinforced could lead to significant disability and increased healthcare utilization.[23] Consequently, identifying maladaptive patterns of reinforcement and replacing them with adaptive patterns to reinforce "well behaviors" (e.g. activity, reduced time reclining) is a critical focal point of behavioral treatment of individuals with chronic pain.

Fordyce's operant conditioning model does not concern itself with the initial cause of pain. It also does not directly address pain per se, which is a subjective and perceptive experience. Instead, it focuses on observable behaviors presumably related to the communication of pain and subsequent reinforcement. Observable behaviors help people with chronic pain communicate with the world around them, but they can lead to greater dysfunctionality if maladaptive behaviors are continually reinforced and maintained.

However, it is important not to mistakenly view pain behavior as synonymous with "malingering." Malingering is a psychiatric and legal construct that involves consciously and purposefully faking symptoms for personal gain. Operantly conditioned behaviors are neither intentional nor faked, and people do not explicitly use operantly conditioned behaviors—pain behaviors—to obtain something they value and desire.

The third learning principle is encapsulated in the social learning model. The principle of social learning emphasizes that behaviors can be learned not only by actual experiential conditioning but also by observation of what others do, how they are responded to, and how they respond themselves. For example, a middle-aged man might learn how to act when a pain flare occurs by observing how other middle-aged men in similar circumstances act. This type of learning is ubiquitous in our lives, from a baby learning how to react to stress by observing her parents to popular figures and social media shaping cultural norms. Consider the case of the television series, "House." The central figure, Dr. Gregory House, demonstrates how he responds to his chronic pain—he exclusively and excessively takes analgesic drugs. Thus we can acquire responses that were not previously in our behavioral repertories by observing others. We learn not only observable behaviors but also briefs and attitudes from others. Our response to pain is no exception. Expectations and behavioral responses to nociceptive stimulation are based, at least partially, on one's social learning history,[24] and expectations play an important role in shaping the pain experience.[25]

Understanding social learning history is clinically important in pain medicine. Children develop attitudes and expectations about health and health care from their parents and other close adults. This lets them learn how to appraise somatic signals and respond to pain. Research has shown that children of parents with chronic pain show greater pain-related behaviors during stressful times than children of healthy parents.[26,27] It has also been demonstrated that people can acquire physiologic responses to pain by observation.[28]

Gate Control Theory

Though not a psychological formulation itself, the Gate Control Theory (GCT)[29] popularized the importance of central psychological factors in pain perception. The GCT has revolutionized thinking about nociceptive processes and the perception of pain. Melzack and Casey differentiated three systems related to nociceptive processing: sensory-discriminative, motivational-affective, and cognitive-evaluative—all contributing to the eventual experience of pain perception.[30] The GCT contradicts the dualistic notion that pain is either somatic or psychogenic. Instead, it postulates the physiologic basis of the psychological factors modulating the pain experience.

The GCT was the first integrated model of pain. Before this, psychological processes were largely dismissed as a reaction to pain. The GCT specifically points to the psychological factors as significant moderators of pain. Although the physiologic details of the GCT have been challenged,[31] its impact on pain research has been substantial. It also became a source of inspiration for technologic and clinical applications, such as neuromodulation, pharmacotherapy, and multimodal approaches to treating pain.

Cognitive-Behavioral Perspectives

The cognitive-behavioral (CB) perspective is a broad psychological model integrating many of the aforementioned behavioral, emotional, social, and cognitive factors.[32–34] The model focuses on the cognitive factors as a driver of one's emotional, context, and behavioral experience, forming a dynamic personal psychosocial environment that interacts with chronic pain experience.[35] It suggests that negative cognitive constructs such as fear appraisals, catastrophizing, beliefs about helplessness, and protective factors such as resilience and self-efficacy can affect the experience of pain. The model posits that cognitive processing is more influential than sensory activity in how individuals perceive, interpret, and manage their pain.[35,36] Treatments based on the CB perspective are directed not toward a cure but rather toward addressing the negative appraisals and interpretations, encouraging positive beliefs about self-efficacy, fostering resilience, and encouraging adaptive behaviors despite the persistence of pain. A set of techniques, described below, are used to achieve these ends.

To illustrate the potential of cognitive factors, consider the case of a person waking up with abdominal pain. She would make use of her prior experiences and cognitive ability to try making sense of this new sensory experience. If she attributes the pain to her rigorous work out at the gym yesterday versus if she thinks of a family history of colon cancer, her emotional response and the actions she takes would be very different. The thought process often serves as filters that determine the meaning of the experience and the appropriate responses. Thus threatening thought processes will likely lead to negative emotions, a sense of being overwhelmed and distressed, whereas a more benign interpretation might have relatively little impact.

Biopsychosocial Model

The biopsychosocial model integrates and expands both the GCT and CB perspectives of pain, viewing chronic pain as an outcome of dynamic interactions among and within the biologic, psychological, and sociocultural variables.[37,38] It accepts the idiosyncratic nature of such dynamicity yet provides a conceptual framework to work with a range of people with chronic pain. Initial pain onset may have driven all the systems at first, but then, each system influences other systems reciprocally—maladaptive momentums of how the dynamic interaction lead to further disability and distress. From the biopsychosocial perspective, physiologic, psychological, and social factors each make important contributions throughout the trajectory of pain. However, the relative contributions of each may vary over time, with biologic factors making a larger contribution during the acute phase, the roles of psychological and social factors increase as the presence of pain persists. The biopsychosocial model has become a basis of multimodal approaches in pain medicine, as the model indicates that pain is a multifactorial phenomenon and addressing just one area will likely yield unsatisfactory outcomes.

Referral for Psychological Intervention

Ideally, attention to psychosocial factors is considered for all patients with persistent pain. A comprehensive psychosocial assessment may be beyond the purview of primary care providers, even when they acknowledge the importance of psychological and social contributors. Thus the healthcare provider should sometimes consider a referral of psychological assessment and treatments as part of a comprehensive treatment plan. The healthcare provider should be alert for red flags that may serve as an impetus for referral for a more thorough evaluation by a mental health professional who specializes in the treatment of pain.

Box 58.1 lists a general set of questions worth considering by primary care providers for patients who report persistent or recurring pain that may help guide decisions regarding more comprehensive psychosocial evaluation. Positive responses to these questions should not be considered sufficient to make a referral for more extensive evaluation, but when more than six or seven are positive, referral should be considered. These questions should not be viewed as a replacement for a more comprehensive psychosocial evaluation but rather as screening questions that should be routinely included when interacting with chronic pain patients during a discussion of their history. They may help identify those patients who might be considered candidates for referral for a psychosocial evaluation. Chapter 15 provides a discussion of what is typically included in a comprehensive psychosocial evaluation when it is determined that such an evaluation is warranted.

• BOX 58.1 Screening Questions[a]

Has the patient's pain persisted for three months or longer despite appropriate interventions and in the absence of progressive disease? [Yes]

Does the patient repeatedly and excessively use the healthcare system, persist in seeking invasive investigations or treatments after being informed that these are inappropriate, or use opioid or sedative-hypnotic medications or alcohol in a pattern of concern to the patient's physician (e.g. escalating use)? [Yes]

Does the patient come in requesting specific opioid medication (e.g. hydromorphone [Dilaudid], oxycodone [OxyContin])? [Yes]

Does the patient have unrealistic expectations of the healthcare provider or the treatment offered ("total elimination of pain and related symptoms")? [Yes]

Does the patient have a history of substance abuse, or is he or she currently abusing mind-altering substances? [Yes]

Patients can be asked, "Have you ever found yourself taking more medication than was prescribed, or have you used alcohol because your pain was so bad?" or "Is anyone in your family concerned about the amount of medication you take?" [Yes]

Does the patient display a large number of types of pain behavior that appear to be exaggerated (e.g. grimacing, rigid or guarded posture)? [Yes]

Does the patient have litigation pending? [Yes]

Is the patient seeking or receiving disability compensation? [Yes]

Does the patient have any other family members who have had or suffer from chronic pain conditions? [Yes]

Does the patient demonstrate excessive depression or anxiety? [Yes]
Straightforward questions such as "Have you been feeling down?" or "What effect does your pain have on your mood?" can clarify whether this area needs more detailed evaluation.

Can the patient identify one significant or several stressful life events before symptom onset or exacerbation? [Yes]

If married or living with a partner, does the patient indicate a high degree of interpersonal conflict? [Yes]

Has the patient given up many activities (e.g. recreational, social, familial, in addition to occupational and work activities) because of pain? [Yes]

Does the patient have any plans for renewed or increased activities if the pain is reduced? [No]

Was the patient employed before the onset of pain? [No] If yes, does he or she wish to return to that job or any job? [No]

Does the patient believe that he or she can ever resume normal life and normal functioning? [No]

[a]If there is a combination of more than six "yes" answers to questions one to 13 and "no" answers to questions 14 to 16 or if there are general concerns in any one area, consider referral for psychological assessment.

Psychological Interventions

As we noted, psychological treatment is a generic phrase that encompasses a range of interventions based on conceptual models that are not identical and with different emphases. The approach taken by any mental health professional will be based on his or her adherence to the specific theoretical model described above.

Insight-Oriented Therapies

Insight-oriented therapies rely on psychogenic and psychodynamic concepts of human development and focus on the early relationship experiences of the individual. Within the context of the therapeutic relationship, maladaptive experiences are reconstructed with an intent to help patients to redo the experiences in a "correct" way.[9] Patients attain insight into their own emotional needs and motivation through interpreting their therapeutic relationship. It is unclear as to how common this approach is used for chronic pain.

Empirical evidence supporting the psychogenic view is lacking. This is not to say that insight-oriented therapies have no role in treating people with chronic pain, and there may be some who might benefit.[12] However, insight-oriented psychotherapy has not been shown to be particularly effective in reducing symptoms in most patients with chronic pain. Furthermore, studies have suggested that the emotional distress observed in people with chronic pain typically occurs in response to pain[39,40] and may resolve once the pain is treated adequately. Furthermore, prior maladaptive experiences may not play a significant role in the maintenance of chronic pain.[41]

Behavioral Approaches

Extinction/Exposure Intervention (EI)

Based on the conditioning model described, EI is predicated on a paradigm designed to disconnect the association between pain and fear and the subsequent avoidance of functional activities. Treatment begins with a thorough identification of avoided behaviors that are associated with subjective emotional distress. Clinician and patient work together to develop a hierarchical list of avoided activities based upon the level of emotional distress associated with each activity. Clinicians provide education on the behavioral principle of conditioning and how EI will lead to better physical and emotional functioning. Exposure to feared activities will then follow, in a graded fashion, from the bottom of the list of avoided behaviors (those causing the least degree of emotional distress) and workup toward the tasks with greater emotional distress. As the patient moves up the list of feared activities, he or she will be encouraged to relax to reduce the accompanying emotional arousal and reducing the fear associated with the specific activity that has been avoided. The key to the EI is direct experience and repetition. A person will engage in avoided behavior until the emotional distress that was initially attached to the task diminish in a clinical setting at first, but it may be extended to the individual's natural environment through home practice.

EI is experiential by nature, and it leads to behavioral modification by providing a powerful disconfirmation of assumed risks associated with the avoided tasks. An important behavioral concept is a generalization where responses to an initial stimulus, such as a specific activity, will be extended to stimuli (e.g. activity) that are perceived as similar. So, in the case of avoidance of a specific activity may be extended to related activities and thereby lead to increased functional limitations and physical deconditioning, further escalating functional disability.

Although EI is considered a "behavioral" approach, its effects extend to cognitive and emotional domains. A recent randomized control trial for people with back pain with a session by session analysis has revealed that EI and CBT, described below, share the same psychological processes.[42]

Studies evaluating the EI have shown a significant decrease in pain and functional limitation in a range of pain conditions in adults, including back pain,[42–44] complex regional pain syndrome (CRPS),[45] posttraumatic neck pain,[46] and upper-extremity pain.[47]

However, as with all psychological interventions, EI is not for everyone. The contraindications include the use of benzodiazepine. The successful extinction of the pain-fear-avoidance link depends upon the full experience of conditioned fear, which can be attenuated by medication, leading to incomplete extinction trials. Some people may feel comfortable working through fear in this way. Some thoughts should be given to careful patient selection.

Operant Approach

The aims of the operant approach are two-fold: to diminish the positive consequence for pain behaviors and reinforce "well behaviors" (e.g. physical activity, positive social interactions, open communication). The operant approach does not address pain intensity directly; instead, it focuses on guiding people away from maladaptive pain behaviors and moves them toward behavioral patterns of wellness. A careful behavioral analysis to delineate how people communicate their pain and how such communications are responded to (i.e. reinforced) sets up a treatment target.

For example, consider a case where every time a woman complains of pain, her children tell her to go rest, and they take over specific household chores. The behavioral analysis reveals that the verbal complaint of pain is rewarded by her children, giving her attention and encouraging her to rest (positive reinforcement) and by her avoiding responsibility for household chores (negative reinforcement). A clinician could work with the patient and her children to help them understand this contingency and modify the women's response. The children do not have to be unsympathetic, but they no longer should encourage her to rest and take over her chores. The clinician and the family can work to come up with responses acceptable for both. Another example is the use of medication on an as-needed basis (as illustrated by the television character referenced above, Dr. House). To reduce the pharmacologically mediated reinforcement (e.g. reduced distress and pain), time-contingent use of medication (i.e. scheduled regardless of current pain intensity) is encouraged in the operant-based program. Similarly, the operant program discourages pain-contingent activities (e.g. ceasing activity because of increased fatigue rather than planned rest intervals). The pain levels typically fluctuate, but the operant approach discourages changing the activity level based solely on pain. Instead, the program sets specific goals in a graded fashion for people to increase their physical function, regardless of pain levels.

It is helpful to remind patients treated with operant conditioning that changing the reinforcement contingency can temporarily increase the maladaptive behaviors they are trying to eliminate. It is called behavioral "potentiation," a phenomenon of increased target behaviors when reinforcement is withdrawn. Many people become discouraged by the escalated behaviors they are trying to work on. It is important to help them understand that this is expected and will dissipate as long as they adhere to the operant regimen and their physical conditioning improves.

The efficacy of operant treatment has been demonstrated in several studies for persons with low back pain[48] and fibromyalgia.[49] Behavioral principles are often incorporated as a part of multimodal approaches (e.g. physical therapy, interdisciplinary rehabilitation programs). However, as noted with ET, not all patients respond well to operant treatment, and research is needed to identify the characteristics of those who are likely to derive the greatest benefit.[50]

Cognitive-Behavioral Therapy (CBT)

CBT is the most accepted, mainstream psychological intervention for people with chronic pain. However, it is extremely important that CBT not be confused with a specific set of cognitive and behavioral *techniques*. The CB perspective focuses on the objectives of self-management and resilience. A variety of cognitive and behavioral techniques are often used to accomplish the objectives.

One of the primary assumptions of the CBT is that pain-related functional disability in chronic pain is linked to those

• BOX 58.2 Assumptions of the Cognitive-Behavior Perspective

- People are active processors of information and not passive reactors.
- Thoughts (e.g. appraisals, expectations, beliefs) can elicit and influence mood, affect physiologic processes, have social consequences, and serve as an impetus for behavior; conversely, mood, physiology, environmental factors, and behavior can influence the nature and content of thought processes.
- Behavior is reciprocally determined by individual *and* environmental factors.
- People can learn more adaptive ways of thinking, feeling, and behaving.
- People should be active collaborative agents in changing their thoughts, feelings, behavior, and physiology.

experiencing chronic pain's sense of helplessness in managing their pain. Thus treatment goals focus on helping these individuals realize that they can acquire adaptive coping skills and apply them to manage pain and enhance resilience despite physical symptoms and impairments. Although there is no specific CBT protocol that all therapists follow, all CBT approaches share the goal of increasing a sense of self-efficacy for actively managing their pain. Typically, CBT includes modifying the maladaptive cognitive process, acquiring behavioral skills, and incorporating a CBT lifestyle. The assumptions underlying CBT are listed in Box 58.2.

Cognition is a powerful mediator of our behaviors and emotions. Therapists can use simple examples to demonstrate the mediating effect by using a contrasting example. Consider the two types of thoughts following a pain flare: what would be the consequence of (1) if a woman believes this means she will never, ever, get better versus (2) if a woman thinks that although this is a challenge, she can still do many things today and see that with effort she may be able to do more desired activities if she tries to self-manage her pain, its impact, and her life. During CBT, a fair amount of time is spent helping patients understand the effects of maladaptive, negative, and often extreme thought processes, such as catastrophizing and dichotomous (black/white) thinking. Patients will then be directed to note how they respond to stress and pain to identify their own maladaptive thoughts. They are then taught to challenge the thoughts ("Am I sure I know that my pain is never going away? On what am I basing that assumption"?) and to come up with alternative thoughts ("what I am sure is, although I am uncomfortable now, I just do not know if the pain will continue forever. Maybe I can practice some stretching and see if this helps").

People with persistent pain often have low expectations about their own ability to manage pain and see themselves as helpless. Such negative appraisals lead to demoralization, inactivity, procrastination, and over-reaction to pain and stressors. Challenging such negativity and finding alternative appraisals can empower patients to transfer from a passive recipient of care to an active participant in pain management.

Along with the modification, the acquisition of behavioral skills is critical in helping patients cope better with pain and stress. There are several skills-training protocols for communication skills, coping skills, problem solving, autonomic skills (relaxation), behavioral rehearsal, time management, pacing, distraction, imagery, and meditation. Note that with CBT, as operant and EI interventions, the goal is not to eliminate stress and pain. Be realistic and help patients become self-efficient in re-regulating their physiologic and emotional responses through cognitive and behavioral skills. Individuals vary greatly in their aptitude and preference for various skills. There is no one skill training that works for everyone. Clinicians may need to try out a few options and ultimately customize the skill training for the specific needs of individuals to optimize the therapeutic benefit.

CBT will not be beneficial if it does not become a part of individuals' lifestyles. The integration of skills in life is critical for the successful implementation of CBT. Thus a key element of CBT is home practice. Intensive monitoring of symptoms, thoughts, behaviors, and emotions at home is needed at the beginning to delineate the areas of therapeutic targets. As patients advance through the therapy, they are expected to apply the skills to daily life situations. Subsequent treatment sessions (in-person, technologically delivered, individual or group) gradually become the time to review, troubleshoot, and refine the skills. This process of generalizing the skills outside of the clinic becomes the vehicle of sustainable, long-term benefit.

We have described CBT in some detail as it is perhaps the most frequently evaluated psychological approach in pain medicine with a great deal of replicated support demonstrating the efficacy for treating various chronic pain conditions in adults and children.[51–53] Imaging studies have shown that CBT significantly alters cortical density/volume in people with various pain conditions.[54,55] The effects of CBT are more pronounced when CBT is tested against treatment as usual or wait-control than when compared to active control (e.g. psychoeducation). However, the interpretation of these reviews is somewhat confusing as they include the trials with CBT alone and CBT and other modalities.[56] Generally, when CBT is provided alone without other daily, effect sizes on maladaptive thoughts and emotional distress are low to moderate, but effects are limited for pain reduction.[57] Most often, CBT is integrated within more comprehensive rehabilitation programs. CB principles have been adapted and used by nurses and physical therapists as well as being directly provided by mental health professionals.[58]

CBT and Interdisciplinary Rehabilitation

Studies evaluating interdisciplinary pain care programs typically include medication management, physical therapy, and CBT. Interventional procedures may be included. The fundamental premise of this integrated multimodal approach is of the biopsychosocial, CB perspective in which clinicians try to assist patients to become proficient in managing their pain via improving physical functioning and coping skills. Comprehensive and concurrent treatment plans may include drug tapering or adjusting, exercise and other physical therapy modalities, and behavioral medicine components to improve cognitive and behavioral skills.

The interdisciplinary pain treatment is the most evidence-based approach in pain medicine. A large volume of empirical outcomes exist that support the effectiveness of the interdisciplinary approach to pain for improving pain, physical functioning, mood, work functioning, and healthcare utilization[59–62] with evidence for long term sustainability of the benefit.[63,64] [For a more extended discussion of rehabilitation see Chapter 60.]

Acceptance and Commitment Therapy (ACT)

ACT is a variation of CBT that integrates mindfulness (described below), diffusion of inflexible cognition, acceptance of pain, and value-based behavioral activation.[65] A central premise of ACT is not to focus on controlling pain. ACT involves acceptance of pain through mindfulness training and identification of life activities

important to them. ACT education attempts to help people experiencing pain to understand experiential avoidance: a tendency to avoid a certain activity because it brings aversive feelings (e.g. anxiety, fear) even though the activity can lead the person to achieve the goal they would like in life. For example, a child who avoids going to school because she does not know how to deal with peers and worries about what others think of her, even though going back to school is a critical activity to achieve her goal of going to college. Experiential avoidance is common in chronic pain. It is often misunderstood as a lack of motivation or being lazy on patients' part when the lack of progress toward a goal is encountered in treatment. It is helpful for clinicians to evaluate the possibility of experiential avoidance; ACT is one treatment modality that directly addresses it.

Chronic pain experience often limits both the physical and social domains of a person's life. Rehabilitation and recovery do not necessarily mean they return back to life as it was prior to the pain onset. Establishing a "new normal" requires a readjustment of expectations from self and others and navigating through how patients portray themselves to the world. ACT therapists work on the psychological process called "psychological flexibility,"[66] defined as the ability to adapt to situational demands by modifying behavioral or psychological repertories to achieve a goal that the person values. ACT addresses maladaptive cognition to aid this process, as in CBT; however, whereas CBT disputes negative cognitions, ACT accepts it and attempts to "defuses" them.

ACT has been shown to outperform the United States Food and drug administration—approved pharmacotherapy in treating fibromyalgia.[67] As in the case with CBT, ACT seems to achieve clinically meaningful benefit in multiple outcome domains when integrated as a part of a multimodal, interdisciplinary treatment program.[68–70] A recent systematic review has demonstrated that interdisciplinary programs with ACT would yield a significantly greater effect size for physical functioning, psychosocial impact, and mood than ACT alone.[71]

Despite some reported positive results, meta-analytic research has concluded that ACT and mindfulness-based approaches do not show clear superiority to more traditional CBT across studies but remain viable and comparably effective interventions for chronic pain.[72,73] The relative lack of distinction between the benefits of ACT and other approaches may also be because of non-specific therapeutic factors resulting in a blurring of these treatment mechanisms; a recent study reported significant increases in pain acceptance after completion of a predominantly CBT-focused multi-disciplinary care program.[74]

Mindfulness-Based Stress Reduction (MBSR)

MBSR is a collection of meditative techniques designed to minimize stress response through mindfulness exercises often used within ACT. As a part of the training, people are taught to accept bodily experiences, regardless of averseness, as naturally occurring experiences. When applied to chronic pain, this approach emphasizes the importance of accepting pain as something natural. It aims to reduce the threat value of pain and thereby modifies the emotional reaction to pain.

The central objective of mindfulness meditation is to enhance one's awareness of the entire perceptual field. It incorporates focused attention and whole-filed awareness in the present moment. Individuals are encouraged to experience pain by simply observing it without judgment, thoughts, and emotions, as it comes moment by moment.[75] The belief is that physical pain will be transformed from something feared into an object to be investigated, experienced, and explored through mindfulness meditation.[76] There is no universally accepted definition of mindfulness and the underlying factors that constitute this concept. Thus comparisons between different studies exploring mindfulness may be inappropriate because of mindfulness being measured, taught, and practiced in different ways across these studies.[77]

Thus the evaluation of MBSR outcomes is difficult because there are so many variations of approaches and techniques. Another problem is the general weakness in the methodologic rigor in research evaluating MBSR. Several systematic reviews concluded that the effectiveness of MBSR could not be conclusively stated because of the poor quality of the studies.[73,78–81]

Not all outcomes are discouraging. A recent parallel randomized trial showed MBSR to CBT to have a comparable benefit that was superior to outcomes of the treatment as usual group.[82] It will take some more accumulations of evidence from rigorous studies, however, before we can confidently evaluate the effectiveness of MBSR for treating chronic pain.

Other Psychological Techniques

Several psychological techniques and skill training procedures can be used to treat people with chronic pain. These tools are often included as a part of a comprehensive CBT or ACT approach described. Here, we briefly describe some of the commonly used techniques.

Controlled Breathing and Relaxation

Inability to properly regulate stress response and is common in chronic pain patients.[83] It is frequently observed that people with chronic pain complain that "I can never relax." There are many types of relaxation exercises, and no evidence to substantiate any of them is more effective than any other. Relaxation training helps people to achieve a psychophysiologic state of relaxation and manage hyperarousal. Relaxation training has an entirely different connotation from the general term "relax." Many people equate relaxation to doing nothing. Relaxation training, however, is an active practice where people learn to pay attention to their bodily state to modify tension levels actively. Breathing techniques, particularly diaphragmatic breathing, stimulate the parasympathetic nervous system via activation of the vagus nerve.[84] There are several relaxation and breathing techniques. For those who are interested in the technical aspects of those training, see these handbooks.[85,86]

The relative rarity of using relaxation skill training as a sole treatment modality to treat chronic pain makes it difficult to gauge its clinical benefit as a unimodal approach because they are often included within interdisciplinary treatment programs and are incorporated in the ET and CBT. Generally, the outcomes for relaxation are positive, albeit modest.[87,88] However, the effect seems to be time-limited.[89] Furthermore, there are several methodologic challenges in designing rigorous trials to test breathing, making it challenging to establish conclusive benefit.[90]

Biofeedback

Developed in the 1960s, biofeedback is a self-regulation technique that has been used to successfully treat several chronic pain states, such as headache, back pain, chronic myofascial pain, and irritable bowel syndrome.[91,92] The objective of biofeedback is to teach people to exert control over their physiologic processes, which are

believed to be involved in symptoms such as headaches, back pain, and pain associated with temporomandibular disorders.

Biofeedback uses electrical sensors on the skin over muscles to detect this rising tension. The electrical sensors are linked to the biofeedback machine, which provides audible or visual signals to the patient. These signals enable people to understand their physiologic activities and control them consciously and, over time, more automatically. With experience, people can determine what mental or physical adjustments produce the greatest reduction in tension. They may then use these exercises with no biofeedback machine.

As noted, during biofeedback, the patient is connected by electrodes to equipment linked to a computer that records physiologic responses. These processes may include skin conductance, respiration, heart rate, heart rate variability, skin temperature, brain wave activity, and muscle tension. The recording equipment amplifies and converts the readings into visual or auditory signals on a monitor that the patient can observe. In this way, the information recorded is "fed back" to the person, which potentially helps the individual learn to change physiologic responses by manipulating the auditory or visual signals.

One form of biofeedback therapy particularly relevant to musculoskeletal pain and tension-type headaches is electromyographic (EMG) biofeedback. Patients are provided with information fed back to them from the physiologic recordings and taught to manipulate the tension in specific muscles related to their symptoms. Patients with migraines are provided with thermal feedback. They are instructed to warm the temperature of their hands by using visual or auditory cues.[37] Alternatively, patients may be given biofeedback to regulate the autonomic nervous functions via heart rate variability, which has been shown to impact pain perception.[93,94]

An innovative approach to biofeedback uses real-time fMRI ("neurofeedback") to help train people to control activation in the rostral anterior cingulate cortex (rACC) and has shown promising results. This brain region is reputedly involved in pain perception and regulation. When the participants deliberately induced changes in the rACC, there was a corresponding change in their perception of the pain.[95] However, a recent systematic review on the effect of "neurofeedback" on chronic pain points out that the promising outcomes are largely from low-quality studies and suggests that the conclusions need to wait for high-quality research on the topic.[96]

The actual mechanisms involved in the success of biofeedback are still unknown. However, with biofeedback treatment, it is assumed that the level of pain is maintained or exacerbated by dysregulation of the autonomic nervous system, which is believed to be associated with the production of nociceptive stimulation (e.g. muscle tension localized in the erector spinae in a person with low back pain). Besides the physiologic changes accompanying biofeedback, patients are provided with a sense of control over their bodies. Given the high levels of helplessness observed in those with chronic pain problems, the perception of control may be as important as the actual physiologic changes observed. A general sense of relaxation is also an important feature of biofeedback. Again, it is not clear whether the alterations in specific physiologic parameters putatively associated with pain are the most important component of biofeedback or whether it is the broader relaxation and self-control created.

Guided Imagery

Guided imagery can be useful as an adjunct to help people with pain relax, achieve a sense of control, and distract themselves away from noxious sensations, emotional distress, and demoralizing thoughts by directing their attentional focus on more positive images and sensations. A coping strategy that they can use and thereby combat feelings of helplessness.

This modality involves the generation of mental images by oneself or through the guidance of a clinician. Training usually starts with neutral imagery, such as visualizing a room in their house in their mind and progressing to more engaging and positive ones. The most successful imagery involves all the senses (i.e. vision, sound, touch, smell, and taste) as if the person is "present" within the imaged scene.

Once the person feels comfortable using the experiential imagery, a clinician and the person collaboratively work to define specific imagery or storyline that can be therapeutic for the person. When the person with chronic pain is feeling pain or is experiencing an exacerbation of pain, he or she can use imagery to help redirect attention away from the pain and achieve a psychophysiologic state of relaxation with chronic pain.

The ability to elicit experiential imagery varies across individuals, and not all people are successful in using this technique. If a person has difficulty generating a particularly vivid visual image, it may help to listen to a taped description or look at a poster or picture in a magazine on which they can focus their attention as a way of assisting their imagination.

Although some have advocated using guided imagery as a stand-alone intervention to reduce presurgical anxiety and postsurgical pain and accelerate healing,[97] it is a single modality that is most often used with other treatment interventions, such as CBT, meditation, or relaxation.[35,38]

Hypnosis

Hypnosis has been used as a treatment intervention for pain control since at least the 1850s. Hypnotic suggestions have been used to instill positive attitudes in people, facilitate compliance with treatment, foster distraction from negative thoughts or stimuli, alleviate anxiety related to medical procedures, reduce reliance on medication, and promote relaxation and rehearsal of adaptive behavior.[98]

Hypnosis has been defined as a "natural state of aroused attentive focal concentration coupled with a relative suspension of peripheral awareness." There are three central components of a hypnotic trance: (1) absorption, or intense involvement in the central object of concentration; (2) dissociation, in which experiences that would commonly be felt consciously occur outside of conscious awareness (i.e. the converse of meditation); and (3) suggestibility, in which persons are more likely to accept outside input without cognitive censorship or criticism.[99]

Hypnosis has been shown to be somewhat beneficial in relieving pain in selective people with headaches, burn injury, arthritis, cancer, and chronic back pain.[98,100,101] A meta-analysis has suggested an overall benefit of the addition of hypnosis to nonhypnotic pain management strategies, although this may be affected by the level of hypnotic suggestibility of any individual patient.[98] There are discrepancies in the literature regarding the methods used to induce hypnosis, making it difficult to accurately evaluate the efficacy of this intervention.[102] Finally, based on systematic reviews, Patterson and Jensen suggested that hypnosis has more usefulness for the treatment of acute pain than chronic pain.[100,101] Thus the degree to which hypnosis is helpful beyond the effectiveness of other interventions and for which populations it is useful and for whom remains to be elucidated.

Conclusions

A person experiencing chronic pain is continually in quest of relief that may remain elusive, which leads to feelings of helplessness, hopelessness, demoralization, and outright depression. Emotional distress may be attributed to various factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse or medications, disability, financial difficulties, litigation, disruption of usual activities, inadequate social support, and sleep disturbance. Thus chronic pain represents a demoralizing situation; the individual with pain not only faces the stress created by pain but experiences a cascade of ongoing stressors that compromise all aspects of life. Living with chronic pain requires considerable emotional resilience, tends to deplete emotional reserve, and taxes not only the person experiencing pain but also the capability of family members and significant others to provide support. Given the complexity of chronic pain experience, it should be abundantly clear that the treatment of people with chronic pain must reach beyond neurophysiology. As discussed in this chapter, a large body of evidence has demonstrated that psychological factors are critical determinants of how people with chronic pain fare. Psychological interventions are becoming standard practice in pain medicine, most commonly in conjunction with other treatment modalities. The main goals of psychological treatments are to modify the pain modulation by addressing cognitive, behavioral, and emotional factors relevant to pain and improving adaptation to the chronic state of pain and functional limitation.

Typically, psychological interventions have been provided to patients in the clinicians' office in a face-to-face situation. However, a growing body of literature demonstrates the potential of technology-delivered psychological treatments for various chronic pain conditions.[103] These approaches have the advantage of convenience to patients, availability, and potentially lower cost. Although appealing, the preliminary reports have mainly been small scale demonstration projects, not conducted in randomized clinical trials and often with no control groups, high drop-outs, and limited follow up. Although these efforts look promising, they remain in need of well-designed research to demonstrate effectiveness compared to alternatives and sustained benefits.

It is important to emphasize once again that none of the treatments described in this chapter are successful in eliminating pain completely, nor, as we noted, are they designed for this purpose. Instead, the goals are functional improvement and improved health-related quality of life. The limited success of psychological treatments on pain reduction per se is true for all modalities in pain medicine, including pharmacologic, medical, and interventional treatments. The results for all are modest.[3] Therefore most people with chronic pain have to eventually adapt to the presence of pain, learn to self-manage the symptoms, and find ways to function and stay productive despite some symptoms. Treatment modalities rooted in biopsychosocial perspectives, such as described in this chapter in conjunction with traditional, physically-based interventions, appear to be optimal treatment plans for patients with chronic pain.

It is also important to acknowledge that none of the psychological treatments described have proven effective for all individuals.[49] Currently, few data are available that consistently identify the characteristics of those who would most likely benefit from the pain treatment methods described in this chapter. It may be that psychological treatments are most effective when matched to specific patient characteristics. Research is needed to determine which treatments and how they should be delivered are most effective for patients with certain characteristics and result in the fewest iatrogenic complications and adverse events.[35,49] Positive results will permit more clinically effective and cost-effective ways to treat the difficult population of patients with chronic pain. Research is needed to test this hypothesis and identify the characteristics most likely to benefit from specific psychological approaches and treatment modalities.[104] Given the evidence reviewed, it is highly recommended that clinicians consider using psychological interventions in conjunction with medical or procedural practice in pain medicine as a comprehensive treatment program.

Key Points

- Pain is a complex, subjective experience with psychosocial, behavioral, and biologic contributors.
- The biologic treatments currently available may not be adequate, and significant levels of pain persist despite the most advanced pharmaceutical, anesthetic, and surgical treatments.
- Persistent pain affects all aspects of individuals' lives.
- People with chronic pain are demoralized because their bodies and the healthcare system have let them down.
- Chronic pain affects not only patients but also their significant others, healthcare providers, employers, and third-party payers.
- There is vast individual variation in the experience of chronic pain, styles of coping and adaptation, and response to treatment.
- Environmental factors (e.g. attention by significant others, including healthcare providers) can reinforce behavioral responses by patients.
- Patients' beliefs, attitudes, and expectations influence the experience of pain, disability, and treatment response.
- A comprehensive approach to the assessment of patients with chronic pain that addresses the medical, psychological, and environmental contributors is necessary to develop an optimal treatment plan.
- Most commonly practiced psychological approaches combine multiple techniques and skill training, as in CBT, ACT, and MBSR techniques.
- Since there is no cure for chronic pain, patients need to learn to accept their role in self-management of their pain and their lives.
- Several behavioral (e.g. relaxation, biofeedback) and cognitive (e.g. problem solving, meditation) modalities that may be helpful to patients can be taught and learned as complements to traditional medical treatments.
- Interdisciplinary pain rehabilitation programs that integrate psychological and physical treatments have been demonstrated to benefit patients with recalcitrant chronic pain.
- Research is needed to identify the best treatment combination for patients with different physical and psychosocial characteristics.

Evidence-Based Rehabilitation Approaches to Acute and Chronic Pain Management

DANA DAILEY, KATHLEEN A. SLUKA, CAROL G.T. VANCE

A rehabilitation approach utilizes a combination of person-centered, non-pharmacologic, and pharmacologic strategies for pain management. A number of different healthcare practitioners participate and can provide rehabilitation to the patient, including physicians who specialize in physical medicine and rehabilitation, pain medicine, sports medicine, and clinicians in physical therapy, occupational therapy, and integrative health. Rehabilitation for a person with pain is used to provide treatment during the acute, sub-acute, or chronic phases and aims to reduce functional improvement and pain reduction. Rehabilitation is best approached using a multi-disciplinary team approach. While both pharmacologic and non-pharmacologic strategies are used in rehabilitation, the focus of this chapter will be on the use of non-pharmacologic strategies.

Rehabilitation Approach

A rehabilitation approach is a multi-faceted, multimodal approach to pain management with the goal of client independence in self-management.[1] The approach is based on a biopsychosocial model for pain prevention, assessment, and intervention to address the multidimensional aspects of pain and provide a personalized approach to pain management (see Figure 59.1A). The goal of the self-management program is to enhance the ability of a person to self-manage their pain through the use of physical activity, pacing, and non-drug therapies. Successful self-management requires the client to develop a mastery of transferable skills and strategies into a comprehensive self-management plan. The plan may include many aspects of pain management, such as education, movement, physical activity, and adjunctive non-pharmacologic strategies.

Multiple guidelines have been published to assist healthcare providers in developing person-centered self-management plans for the treatment of pain for a variety of painful conditions.[2–5] These guidelines routinely include exercise recommendations with strong evidence.[6–11] A recent review of guidelines for non-specific low back pain reviewing 15 different guidelines for care suggests a consistent agreement in the approaches with few discrepancies in practice guidelines.[2–4,8,12–18] Bed rest is avoided for all stages of injury, and education, psychosocial interventions, and exercise are particularly recommended for chronic pain.[16]

The release of the Institute of Medicine (IOM) Report in 2011, Relieving Pain in America, recommended the use of a comprehensive, interdisciplinary approach as the most effective way to treat pain.[19] In addition, the Department of Health and Human Services National Pain Strategy in 2016 emphasized self-management approaches for the management of chronic pain as well as prevention strategies for acute and chronic pain.[20] The National Pain Strategy also recommended the use of self-management programs.[20]

The National Pain Strategy (United States) recommends that "people experiencing pain would have timely access to patient-centered care that meets their biopsychosocial needs and takes into account individual preferences, risks, and social contexts."[20] The use of a biopsychosocial approach by the clinician entails a comprehensive assessment of individuals with chronic pain to develop an integrated, patient-centered plan of care using evidence based practices. While most individuals are managed through primary care providers, referral to an interdisciplinary team should be used when needed. Therefore treatment is often multi-disciplinary and aims to alleviate pain and improve the client's physical function and psychological health.

Ideally, rehabilitation team approaches involve multiple practitioners and can be multi-disciplinary or interdisciplinary. The approach used will likely depend on the current status of the individual with pain, geographic location, access to care, and client resources.[21] Multi-disciplinary treatment, defined as a multimodal treatment provided by practitioners from different disciplines,[21] is the most common and generally involves each profession working separately with discipline-specific therapeutic goals. On the other hand, interdisciplinary treatment, defined as multimodal treatment provided by a multi-disciplinary team collaborating in assessment and intervention using a shared biopsychosocial model and shared goals,[22] is often used when unimodal treatment is insufficient.

An interdisciplinary team will vary in size and depend on the needs of the individual. Interdisciplinary team members begin with an individual or a person with pain. Physicians, physical therapists, psychologists, or psychiatrists make up the remainder of the team.[23] Additional team members may comprise professionals from occupational therapy, pharmacy, dietetics, and complementary and integrative health fields. A key aspect of an interdisciplinary team is regular communication and meetings

between team members and between the patient and team. A physician provides comprehensive examination and assessment of pain and clinical presentation, coordinates care for the individual, and provides both pharmacologic and non-pharmacologic strategies for pain relief. Physical therapy pain management focuses on improving function and movement through education, exercise, and electrophysical agents.[24–26] Occupational therapists assist individuals' participation in daily activities through the adaptation of activities, self-management, education, and exercise. Psychologists provide skills for individuals with pain to cope with emotions, feelings, and behavior related to pain, using various approaches to assist in self-management related to pain beliefs.[27,28] Pharmacists provide services through education and management of medications, including dosage, monitoring adverse responses to medication, costs, and decision making, to both individuals with pain and with prescribing providers.[29,30] Other professionals who may be part of the rehabilitation team may include care in diet, chiropractic, acupuncture, massage therapy, music therapy, recreational therapy, and vocational therapy, to name a few. Each interdisciplinary team will be unique to the individual and focus on the inclusion of professions and strategies to best meet the needs of the individual (Table 59.1).

Approach to Treatment

In a rehabilitation approach to pain, a hierarchy of care is used to treat pain. Acute pain treatment is designed to determine and treat the underlying cause, maintain or improve function, and reduce pain. Chronic pain treatment is designed to promote self-management and improve function and quality of life. Adequate treatment of pain and risk factors during an acute episode of pain is essential to decrease the potential for transition to chronic pain.[31–33]

Based on pain presentation, patient preference, clinical experience, and clinical evidence, various approaches can be used in rehabilitation. The primary interventions in rehabilitation are education and exercise. Secondary interventions can include the use of electrophysical agents,[34] manual therapy,[5,35] and pharmacology.

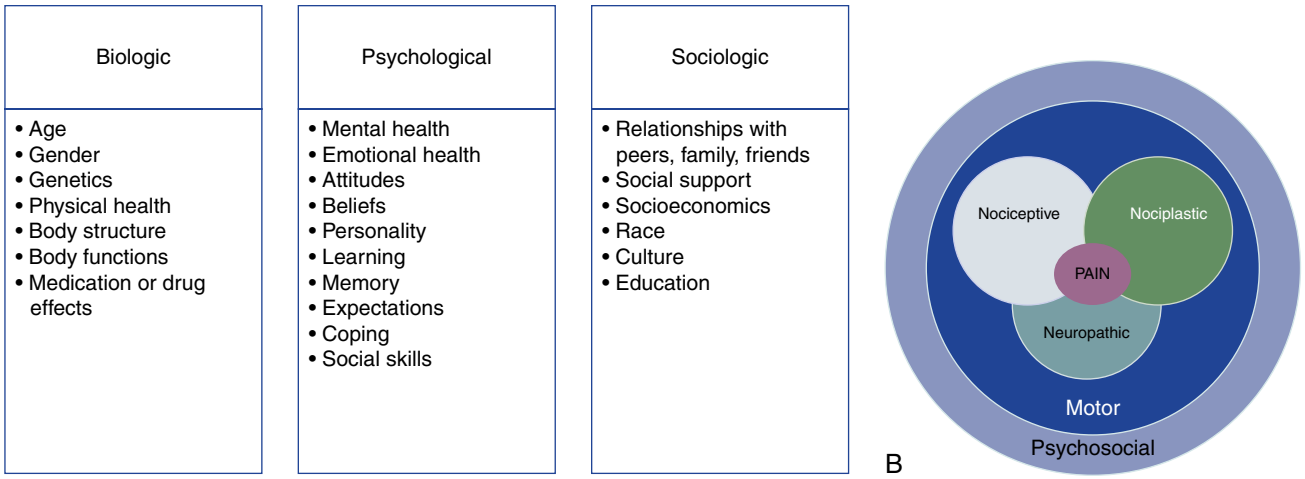
Pain Management Considerations

Evaluation

Key aspects of the evaluation for rehabilitation focus on function, biomechanical presentation, and activities of daily living at home and work. Movement can be impacted by pain, and

TABLE 59.1 Roles of Professionals in Rehabilitation Approach to Pain Management

Profession	Role
Physician	A medical provider or physician provides comprehensive examination and assessment of pain and clinical presentation with a specialty in musculoskeletal conditions. A physician may utilize pharmacologic and non-pharmacologic strategies for pain relief for acute to chronic pain. A medical provider assists in coordinating care through the interdisciplinary team, and a pain management specialist may provide interventional pain management procedures.[1]
Nursing	Nursing pain management includes both pharmacologic and non-pharmacologic strategies. Nursing pharmacologic strategies include monitoring analgesic therapy, medication reconciliation, medication education, and safety. Non-pharmacologic strategies in nursing include client education regarding pain and pain management, relaxation, distraction, and assisting in the referral process for the interdisciplinary team.[2]
Physical Therapy	Physical therapy pain management focuses on improving function and movement through education, exercise, electrical stimulation, heat and cold modalities, motor imagery, sensory re-education, and virtual reality.[3,4]
Occupational Therapy	Occupational therapists assist individuals with pain to participate in daily activities through adaptation of activities, self-management, education, and exercise. The occupational therapist will also include interventions for relaxation, stress management, pacing, problem solving, and communication skills training.[5]
Psychology	Psychologists help individuals and caregivers cope with emotions, feelings, and behavior related to pain, most often chronic pain. They have a wide variety of approaches to assist in self-management related to pain beliefs (self-efficacy, catastrophizing, coping fear and avoidance, life control acceptance and psychological flexibility, sleep, negative affect, cognition, quality of life, relaxation, biofeedback, cognitive behavior approaches to pain self-management).[6,7]
Pharmacy	Pharmacists have an integral role in the pain self-management process. They provide services through and between the stages of pain–acute, subacute, and chronic. They provide education to individuals with pain regarding medication information, use, dosage, monitoring, and possible adverse responses to medication, costs, and decision making to both individuals with pain and with prescribing providers (ref- us pharmacist resource). As part of the interdisciplinary pain management team, pharmacists collaborate for medication reconciliation, the timing of medication if needed for interventions, and possible adverse responses to medication.[8]
Dietitian	Dietitians play an important part of the interdisciplinary team for the individual with pain. Nutrition plays a large part in how the body responds to increased inflammation and pain. A dietitian assesses an individual's diet and nutritional status, caloric intake, hydration, and medical and nutritional needs. They provide education for food planning that may include anti-inflammatory foods, whole foods, and nutrients to assist in the self-management of pain. Studies looking at the influence of diet on inflammatory markers show that consumption of foods high in fiber, healthful oils, fruits, vegetables, and those low in sugars, starchy carbohydrates, and unhealthful fats can reduce inflammation and disease. The dietitian includes the biopsychosocial aspects of diet and nutrition in a person-centered approach.[9]
Other	Other professionals of the interdisciplinary team may include caregivers in chiropractic, acupuncture, massage therapy, music therapy, recreational therapy, and vocational therapy, to name a few. Each interdisciplinary team will be unique to the individual and focus on the inclusion of professions and strategies to meet the needs of the individual best.[9]



• **Figure 59.1 A,** Biopsychosocial factors to consider in pain management. **B,** Biopsychosocial Model: Adapted from Chimenti RL, et al. (2018).[1]

altered movement patterns can impact pain (see Figure 59.1).[36,37] Rehabilitation specialists focus on the International Classification of Functioning (ICF) from the World Health Organization to determine functional limitations and activity participation.[38] Performance-based functional tests, such as a walk test or sit-to-stand test, evaluate the ability of a person to perform a standardized task. Biomechanical assessments include posture, strength, and range of motion of the affected body structures. Further impact of pain on function and ability to perform activities of daily living at home and work are used to guide treatment.[39,40]

Assessment of psychosocial variables is critical in the evaluation process to determine the impact of psychosocial variables on function and pain. Each individual has a range of factors with dynamic interactions between biologic, sociologic, and psychological factors that modulate the pain experience and are unique to each person.[41,42] Psychological factors can enhance pain and impact recovery from pain.[41] Both positive and negative psychosocial factors influence the response to pain. Negative factors can include increased pain catastrophizing, fear avoidance, fear of pain, fear of movement, negative affect, and decreased mood. Positive factors include enhanced resiliency, self-efficacy for managing pain, pain-related coping, and self-management skills.[41,43,44]

The three mechanisms of pain are useful for guiding treatment. Nociceptive pain arises from actual or threatened damage to non-neural tissue and is caused by the activation of nociceptors in a normally functioning somatosensory system.[45] Nociplastic pain arises from altered nociception despite no clear evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence for disease or lesion of the somatosensory system causing pain.[45] Neuropathic pain is caused by a lesion or disease of the somatosensory nervous system.[45] These mechanisms can overlap in individuals with acute or chronic pain. Identifying the mechanism of pain can help guide evidence based evaluation and interventions that are person-centered (Figure 59.1).[36,37]

Development of a Plan of Care

Based on the evaluation results, along with patient and clinician preferences, a variety of approaches can be used to manage pain from a rehabilitation perspective. The primary goal for pain management using a rehabilitation approach is to enable individuals to develop independence in the self-management of pain. It is important to regularly assess the strategies that are working and those that are not, develop new strategies that may be more successful or add additional tools to go in the individual's self-management "toolbox." This independent self-management plan allows the person with pain to play an active role in setting goals for pain relief, reduction, function, activities, and participation at home or in the community. This skill development should be individualized and focus on problem solving, patient-centered goals, and communication within and between disciplines. Tools for self-management include education, functional training, self-care, home and/or work management, therapeutic exercise, manual therapy, and electrophysical agents.[46–48] A combination of interventions is important to focus on person-centered care and provide multiple strategies to manage pain. While each of these interventions alone may have success, a combination of these interventions is more effective than one intervention alone.[35,49]

One common denominator in all these interventions is education and the utilization of an evidence based approach to active engagement and participation of the client. Education is critical for the independence of self-management. Determining a patient's learning style, preferences, previous experience, and expectations is the first step to promoting independence and future adherence to the tools needed for self-management of pain.

Specific Rehabilitation Interventions

Self-Management Strategies

Self-management strategies are the standard of care for individuals with either acute or chronic pain.[50,51] For those with chronic disease, self-management programs encourage active participation and support ongoing medical care.[46–48] Healthcare practitioners should adopt approaches that allow patients to be active during the recovery process. All interventions (exercise, manual therapy, biophysical and electrical agents, and behavioral modification) should be delivered with an education component stressing self-management and client adherence.

For patients with acute pain, the importance of activity modification (positions of comfort and avoidance, appropriate movement) and education on the expected course of pain are the primary interventions.[52–54] Secondary management strategies of electrophysical agents can be employed for home management of pain or supplement pharmacologic interventions.[16,55–57] Postoperative patients may benefit from guided imagery, relaxation therapy, or music/video distraction pain management.[58] As the acute phase progresses, the focus is directed to the addition of appropriate

exercise, activity, and functional activities to maintain and improve function.[59] Education is progressed to understanding "hurt" versus "harm" and the addition of exercise/movement designed to stress tissues for optimal healing.[60,61] Electrophysical agents may be employed to assist in participation in exercise interventions.[36,56,62,63]

Self-management has become increasingly important and has become the main goal for people to manage their chronic pain effectively.[1,64] Common components of self-management for chronic pain include 1) education on pain and disease, 2) education on increased activity and pacing, 3) development of pain management skills using non-pharmacologic approaches, and 4) development of coping skills.[65–67] Self-management programs can be delivered in many formats, including individualized, group classes, or internet-based, and are often provided by multiple practitioners on the rehabilitation team.[67–70] Self-management for this population can be difficult. Therefore methods for developing adherence to the intervention become the most critical.

The main goal of self-management is to provide resources and skills to the client to manage their chronic pain effectively.[61,67] Self-management is part of a more comprehensive plan that includes physical therapy, medical management, and psychological interventions, as appropriate.[22,71] The aim is to make the client an active participant in managing their condition; thus the primary outcome expected is a change in behavior.[72] The development of an individualized skill set, or toolbox, is a key component of all self-management programs. This toolbox may include pacing, relaxation and stress management, physical activity and exercise, and safe and effective pain-relieving modalities (transcutaneous electrical nerve stimulation [TENS], heat, cold).[56,73–77]

Clinical data practice guidelines and the National Pain Strategy (United States) recommend the use of self-management skills for the management of a variety of chronic pain conditions.[12,71,78,79] Systematic reviews on the effectiveness of self-management programs are mixed and show small effect sizes when given alone.[68,80–84] The key components of self-management programs are still being developed. More recent studies using a biopsychosocial and individualized approach as an adjunct to the standard of care have shown that self-management programs improve adherence to exercise and physical therapy.[85–88]

Physical Activity and Exercise

Exercise is a key component of the rehabilitation approach. Clinical practice guidelines strongly recommend exercise for various painful conditions,[12,16,89–94] and exercise is supported by systematic reviews of the literature suggesting exercise is a first line treatment for individuals with chronic pain.[95] Mechanistically, exercise is a multimodal treatment with peripheral effects at the injury site to promote healing and pain relief, reduce central excitability, increase central inhibition, modulate the immune system, and modulate mood.[96,97] Several neurotransmitters and receptors are activated by exercise, including endogenous opioids, serotonin, and cannabinoid receptors.[96,97] Additionally, exercise can improve motor control, strength, aerobic capacity, and function.

Movement therapies, including traditional structured exercise (aerobic, strengthening), functional training, complimentary exercise techniques (yoga, tai-chi), and behavioral exercise approaches (graded exercise), can be used to reduce pain and disability, improve function, prevent the development of chronic pain, and reduce the recurrence of chronic pain (for review see reference 95). While clinical evidence suggests that exercise training is effective for most pain conditions, the type of exercise may be less important than the act of doing exercise. Several studies have compared different types of exercise for different types of pain and showed no difference between active exercise interventions.[98–101] For example, a comparison of proprioceptive training to craniocervical flexion in individuals with neck pain exercises showed no differences between groups.[99] Similarly, a comparison of graded exercise and graded exposure for those with chronic low back pain showed similar effects.[102] We suggest that this lack of specificity of exercise may be related to the multiple and widespread mechanisms by which exercise reduces pain and improves function. Thus the most important component of exercise selection is choosing a mode that the person will adhere to and enjoy.

Adherence is critical to the success of an exercise program.[103] High levels of self-efficacy, self-motivation, intention to engage, social support, and health locus of control have been associated with improved adherence to interventions, including exercise.[72,85,104–106] Assessing these variables and using strategies aimed at increasing motivation and some level of supervision by the clinician may also significantly improve adherence.[107] Shared decision making is a component of improving adherence. Frameworks designed to include patients in the decision making process and that are tailored to the individual and their diagnosis may improve adherence.[3,85,104] As noted above, self-management programs can improve adherence to exercise,[72,85–87,107,108] and these should be employed together to achieve the best outcomes. With the importance of adherence emerging, developing measures that capture this outcome in pain populations is warranted.[104,109]

Manual Therapy

For the purpose of this chapter, manual therapy techniques are defined as the skilled hand movements of clinicians intended to improve tissue extensibility, modulate pain, promote relaxation, and mobilize soft tissue and joints.[59] There are numerous methods whereby clinicians use their hands, such as classical massage, soft tissue mobilization, and joint manipulation. The use of massage therapies has been documented across the ages, and nearly every society and culture has a form of manual therapy in its history. Massage may have therapeutic effects indirectly through reductions in inflammation, promotion of healing, and restoration of normal movement patterns.[110–112] While clinical evidence for massage therapy exists, the evidence is generally weak and based on lower quality clinical trials. Furthermore, massage is rarely used as a standalone treatment, potentially creating bias in reports attempting to evaluate the overall effectiveness of massage when evaluated in isolation. This concept is illustrated by a systematic review including 23 studies addressing neck pain, where the main finding was that pain reduction with the combination of manual therapy and exercise was better than manual therapy or exercise alone.[113] Systematic reviews examining the effectiveness of massage have reported significant reduction in pain and improvements in function compared to sham in patients with low back pain, fibromyalgia, and neck pain.[114–117] However, massage produces similar improvements in pain and function compared to other therapies, and only short term use is suggested.[118] The reviews note the lack of consistency in reporting specific techniques and low quality methodology, making clinical recommendations unclear. Interestingly, two clinical trials examined the duration of massage, and both showed that durations of 60 min over several weeks were more effective than 30 min duration in individuals with either knee osteoarthritis or neck pain.[119,120] Furthermore, in individuals with non-specific low back pain, similar results were found using either traditional massage

techniques or targeted soft tissue techniques.[121] Thus systematic reviews and clinical trials support the effectiveness of massage when administered repetitively for short term pain relief.

Manipulation includes both high velocity, short duration joint movements as well as low velocity, longer duration joint movements (also referred to as joint mobilization). Traditionally, joint manipulation has been used to improve the movement of the restricted joints. However, evidence suggests that joint manipulation modulates nociceptive transmission both peripherally and centrally. Peripheral nociception can alter motor neuron excitability and muscle spindle activity and reduce electromyography (EMG) activity of paraspinal muscle.[122–125] Joint mobilization can also increase pain thresholds, reduce central excitability measured by temporal summation, and produce analgesia through the release of noradrenaline and serotonin in the spinal cord.[122,125,126] Other neurotransmitters may also be involved in analgesia, including μ-opioid receptors peripherally, adenosine receptors both peripherally and centrally, and cannabinoid receptors both peripherally and centrally.[127,128] Thus these data suggest that joint manipulation modulates the motor activity and activates endogenous inhibition peripherally and centrally to reduce pain.

Systematic reviews of joint manipulation routinely show statistically significant effects on pain reduction in patients with neck or low back pain.[92,94,129–132] It should be noted that these effects are short term and may not be clinically significant, with an effect less than 10 on a 100-point pain scale. Spinal manipulation is more effective than sham but shows similar analgesic effects to other adjunctive therapies, including physical therapy or exercise.[132] Furthermore, for those with acute low back pain, spinal manipulation is not more effective than control conditions.[131] Joint manipulations and mobilizations can also be applied to peripheral joints to improve the range of motion and function and reduce pain. Few studies have examined the peripheral joint manipulation. In people with osteoarthritis, lateral epicondylalgia, or acute or chronic ankle sprains, joint mobilization reduces pain and improves function compared to placebo.[126,133–135] Thus joint mobilization can provide short-term pain relief and improve function.

Biophysical and Electrotherapy Agents

Biophysical and electrotherapeutic agents are commonly used as adjunct treatments to self-management and exercise programs to reduce pain and promote healing.[56] These treatments include the use of heat, cold, and electrotherapy. These modalities are safe, inexpensive, and can be performed in home environments. A review of the evidence of these adjunctive interventions (Table 59.2) suggests that attention to proper dosing is critical to their effectiveness.[56] For example, electrotherapy treatments delivered at a sensory threshold[34] or ultrasound treatments passing over a large area with a short treatment duration are ineffective in reducing pain.[136] Thus when applied at adequate doses, biophysical and electrotherapeutic agents can be included as part of a pain management program.

Electrotherapy. For the purpose of this review, the term electrotherapy represents any form of electrical current applied to the body to reduce pain. The most frequently utilized clinical approaches include TENS and interferential current (IFC). TENS is the application of a low voltage pulsed alternating current via electrodes applied to the skin. Importance parameters include the application of high, low, or mixed frequency current; a sufficient amplitude to evoke a strong but comfortable sensation; and a duration of at least 30 min. IFC is the application of two high frequency currents applied to the skin via four electrodes to produce an amplitude-modulated beat frequency in the tissues.

TABLE 59.2 Summary of Effectiveness of Non-pharmacologic Approaches to Pain Management

Condition	Self-management	Exercise	TENS/IFC	Heat	Cold	Ultrasound	Massage	Joint Manipulation	Photobiomodulation

Inconclusive/equivocal evidence from systematic reviews or clinical practice guidelines

- Lacking evidence

TENS and IFC stimulate the afferent fibers in the skin and, more importantly, the deeper tissues.[137] TENS analgesia is produced by the activation of neural pathways in the central nervous system by reducing central excitability and increasing central inhibition (for an extensive review of the mechanisms, see reference 37). Briefly, high frequency stimulation (50–125 Hz) activates δ-opioid receptors, and low frequency TENS (1–10 Hz) activates μ-opioid receptors throughout the central nervous system pathways involved in analgesia.[34,138] TENS reduces central excitability by reducing central sensitization of dorsal horn neurons and the release of the excitatory neurotransmitter glutamate in the dorsal horn. TENS also produces analgesia through the activation of serotonin, γ-aminobutyric acid (GABA), and muscarinic receptors spinally.[34,37,139,140] Thus TENS uses multiple mechanisms to produce analgesia.

Clinically, TENS is used for both acute and chronic pain. Several systematic reviews have reported negative or inconclusive findings regarding the use of TENS for a variety of pain conditions, including osteoarthritis, postoperative pain, and fibromyalgia.[141–146] On the contrary, reduction in pain has been reported for diabetic peripheral neuropathy, postoperative knee arthroplasty, fibromyalgia, post-thoracic surgery, and rheumatoid arthritis.[147–152] Furthermore, a systematic review and meta-analysis on chronic pain similarly reported a significant reduction in pain when compared to a placebo.[153]

Two recent analyses of the TENS literature suggest several issues in the quality and design of existing TENS trials that lead to equivocal results.[154,155] One key aspect of TENS effectiveness is the provision of an adequate dose of stimulation with a minimal intensity that is strong but comfortable.[154,156] This is supported by systematic reviews that show that when applied at adequate doses, TENS is effective for postoperative pain, knee osteoarthritis, and acute pain.[157–159] Another issue related to existing clinical trials is the timing of the outcome measurement, as TENS works best while the TENS unit is turned on.[77,159] This is not surprising given the neuropharmacologic mechanisms of TENS (reviewed above). Furthermore, in both human and animal studies, repetitive TENS administered at the same frequency can lead to analgesic tolerance, and low frequency TENS is less effective in opioid-tolerant individuals.[160–163] Tolerance effects are because of tolerance at spinal opioid receptors[160] and can be alleviated by alternating between low and high frequency in a single session.[164] A recent clinical study testing the efficacy of TENS in fibromyalgia addressed the weaknesses of prior studies using an alternating frequency of stimulation, strong but comfortable intensity, and measured the effects of TENS with the unit on.[63] This study showed a clinically significant reduction in movement-evoked pain and fatigue, as well as resting pain and fatigue when compared to placebo or the no-TENS condition. The number needed to treat was relatively low (three to four), while the number needed to harm for minimal adverse events was high (20–100),[63,165] indicating that TENS is effective and safe. A responder analysis showed that the response to a single treatment predicted the response to treatment one month later, with those showing a 10% response to the first treatment likely to respond with greater than 30% reduction after a month of home use.[165] Thus TENS, when applied at adequate doses, is effective for reducing movement-evoked pain in individuals with fibromyalgia, with similar efficacy to pharmaceutical treatments. TENS is low cost and safe and is a recommended choice for individuals with both acute and chronic pain.

IFC is widely used to treat musculoskeletal pain, and systematic reviews show effectiveness for various pain conditions, including osteoarthritis, fibromyalgia, and postoperative pain.[141,166–168] In contrast, a meta-analysis by Fuentes et al. showed that IFC given alone was not more effective than placebo, manual therapy, or massage and was unclear when applied as an adjunct intervention to existing treatment.[169] Importantly, TENS and IFC produce similar effects in the treatment of acute and chronic pain.[168] The systematic reviews caution about the quality and heterogeneity of the studies.

Thermal modalities (heat and cold agents) have been used throughout history, and the concept of heat or cold-induced analgesia is generally well accepted. The process is characterized by energy transfer between the agent and tissues of the body. Moist or dry heat packs are examples of common heating agents, and cryotherapy can be accomplished with ice massage, ice bags, or commercial cold packs. Hydrotherapy can be used in clinical settings. These have the advantages of circumferential exposure, the ability to maintain a constant temperature, and the ability of the client to exercise while receiving the thermal intervention. The type of agent is selected by the clinician depending on the diagnosis, the body part in question, the stage of injury, and the ease of application if the modality is intended for client self-management of symptoms or use in a clinical setting.

The effects of thermal therapy on pain are because of both direct and indirect effects. Direct effects include changes in nociceptor firing in the peripheral tissues where the agent is applied and alterations in nerve conduction velocity.[170] Indirect effects include changes in blood flow, tissue metabolism, and removal of chemical irritants in the treatment area.[170] In the case of heat therapies, tissue extensibility and joint stiffness may be reduced, resulting in decreased input of nociception to the central nervous system. Other neural mechanisms for heat therapy propose a reduction in muscle spasm because heat reduces type II spindle afferents firing.[171]

Despite widespread use and general acceptance of pain-reducing qualities of thermal therapy, sparse clinical evidence exists to support its use. Few high quality studies have investigated the effectiveness of thermal modalities, resulting in mixed data on the effectiveness of thermal modalities for pain relief.[130,172–177] For example, Wong et al.[130] concluded that heat, cold, and ultrasound therapy are ineffective for reducing neck pain, while the American College of Physicians guidelines and a systematic review showed that heat therapy reduces low back pain.[16,176] For postoperative pain, it is not recommended or discouraged,[3] while for rheumatoid arthritis, it is recommended.[178] For osteoarthritis, cold therapy improves the range of motion, function, and knee strength but does not affect pain.[173,179] While the evidence is mixed, the use of thermal agents is low cost, easy to apply, and low risk. Heat and cold therapy can be applied at home by the subject and should be included in a self-management program as a non-pharmacologic option.

Therapeutic ultrasound is the use of acoustic sound waves applied to tissues and has been widely used for over 60 years. Treatment effects are dependent on parameter settings and include both thermal and non-thermal effects. The effect of ultrasound on pain can be attributed to the targeting of deeper tissue by improving blood flow to the area, increasing tissue metabolism, and increasing tissue extensibility.[136,170] Thus the vascular changes of improved delivery of oxygen and nutrients and removal of metabolic irritants can account for the reduction in pain with the use of ultrasound.

Parameters for treatment included treatment frequency (1 or 3 MHz), intensity (0.01–2.00 Watts/cm^2), and treatment duration. Ultrasound applied at intensities greater than 1.0 Watt/cm^2 is reported to increase tissue extensibility and decrease inflammation, and pain reduction is typically not the primary goal of clinicians using ultrasound. The clinical use of ultrasound is widely

used and remains popular despite conflicting reports and relatively low quality evidence support for this modality.

Despite its widespread use, research supporting its use for pain reduction is limited and inconclusive. Systematic reviews have shown that ultrasound does not affect pain in patients with low back pain, neck pain, carpal tunnel syndrome, rotator cuff tendinopathy, or acute ankle sprains.[130,180–184] Although several RCTs support the use of ultrasound in the treatment of myofascial pain, one systematic review of 10 studies suggests that the evidence is unclear because of the high risk of bias and low quality evidence.[185] In contrast, systematic reviews have demonstrated the efficacy of ultrasound for pain reduction and functional improvement in people with knee osteoarthritis.[186–188] Ultrasound is recommended for rheumatoid arthritis and calcific tendonitis of the shoulder.[189,190] Thus the evidence for the use of ultrasound is equivocal, except for a few very specific conditions, and the clinical utility of this modality is unclear.

Photobiomodulation. Over the last 30 years, photobiomodulation also referred to as low level laser therapy, has been used to treat painful musculoskeletal conditions. This non-pharmacologic intervention uses low energy irradiation of tissue to alter cellular processes and provide an anti-inflammatory effect.[56] Similar to other non-pharmacologic interventions, studies of photobiomodulation showed a pattern of wide variability in the results obtained. Studies that use the World Association for Laser Therapy parameters to deliver what is considered an effective dose window (wavelengths in the range of 632–1064 nm) are associated with increased effectiveness for a variety of musculoskeletal conditions.[191–193] Similarly, recent systematic reviews indicate that when properly dosed, photobiomodulation is effective for reducing pain in the management of musculoskeletal conditions, shoulder tendinopathy, knee osteoarthritis, plantar fasciitis, and fibromyalgia.[151,185,193–197] As with other non-pharmacologic interventions, reviewers suggest participant heterogeneity and trial design in the studies included warrant caution in the interpretation of results.[191] However, photobiomodulation is emerging as an effective tool for pain reduction in various painful conditions.

Emerging non-pharmacologic interventions. Three other non-pharmacologic adjunct interventions for pain management in recent years include extracorporeal shock wave therapy (ESWT), dry needling, and static magnet therapy. ESWT is a pulse of acoustic energy believed to cause localized microtrauma that stimulates angiogenesis. Recent interest in ESWT has resulted in numerous randomized controlled trials for Achilles and knee tendinopathy, lateral epicondylitis, low back pain, and other musculoskeletal pathologies. One systematic review concerning the treatment of lateral epicondylitis showed a significant reduction in pain up to six months after treatment compared to traditional ultrasound.[198] Pain reduction for plantar fasciitis showed favorable results of ESWT when compared to placebo, but the results suggest that neurostimulation, traditional ultrasound, and photobiomodulation may potentially be better alternatives.[199] A systematic review comparing ESWT to corticosteroid injection for plantar fasciitis showed that both methods decreased pain.[200] This finding is worth considering for those desirous of a noninvasive intervention. Given the large number of individual studies of ESWT and these preliminary findings, additional high quality randomized controlled trials of this modality are warranted.

Dry needling involves the insertion of a solid filiform needle into the trigger areas of the muscle. Evidence for the use of dry needling is controversial. For orofacial pain and general musculoskeletal conditions, systematic reviews have shown inconclusive results because of the heterogeneity and quality of the studies.[201–203] In contrast, for myofascial pain, a recent systematic review concluded that dry needling reduced pain when compared with placebo or no treatment, but had similar results compared to other therapeutic approaches.[204–206] The effects of dry needling are immediate and can last up to four weeks.[206] However, because of the small number of high quality randomized controlled trials, additional studies should be performed to support the use of dry needling for myofascial pain.

Static magnetic therapy involves the use of pulsed magnetic fields. Magnets have been used for therapeutic purposes for more than 2000 years.[207] Over the last 20 years, magnets have been incorporated into garments and therapy wraps. They are relatively inexpensive and worn without direct supervision, have low risk, and therefore can be included as part of a self-management strategy. However, we found no convincing evidence indicating their effectiveness in pain management.

Summary

The use of a rehabilitation approach to pain management is a patient-centered process, with the primary goal of an individual's independence in the self-management of pain. It is based on a biopsychosocial model that incorporates biologic, psychological, and sociologic factors. In this model, it is important to consider the stage of pain and inflammation, source of pain, positive and negative psychosocial factors, environment, participation, activities, and function for the individual with pain. With the goal of independence in the self-management of pain, it is important to utilize a team-based rehabilitation approach that includes the requisite disciplines, evaluation, and specific evidence based interventions to address the goals and needs of the individual in pain. Individuals in pain should be active participants in the process, which is better when delivered in a multimodal, dynamic fashion. Education is a key factor that is woven into this approach across disciplines, interventions, and strategies. All interventions (exercise, manual therapy, biophysical and electrical agents, behavioral modification) should be delivered with evidence based dosing parameters and an education component emphasizing self-management and client adherence.

Key Points

- The goal of a rehabilitation approach to pain management is self-management independence. The main goal of self-management is to provide resources and skills to clients to effectively manage their pain.
- A rehabilitation approach to pain management is patient-centered, based on a biopsychosocial model, and utilizes a multidisciplinary team as appropriate for the individual in pain.
- Evidence based guidelines and interventions should be utilized in a rehabilitation approach to pain management.
- A combination of interventions is important to focus on person-centered care and provide multiple strategies to manage pain. A combination of interventions was more effective than one intervention alone.

- Non-pharmacologic interventions of education and exercise/movement should be considered as first line treatments in all stages of pain.
- The aim of a rehabilitation approach is to make the client an active participant in managing their condition; thus the primary outcome expected is a change in behavior with a long-term goal of adherence to self-management of pain.

Physical Rehabilitation for Patients With Chronic Pain

HARRIET WITTINK, JEANINE A. VERBUNT

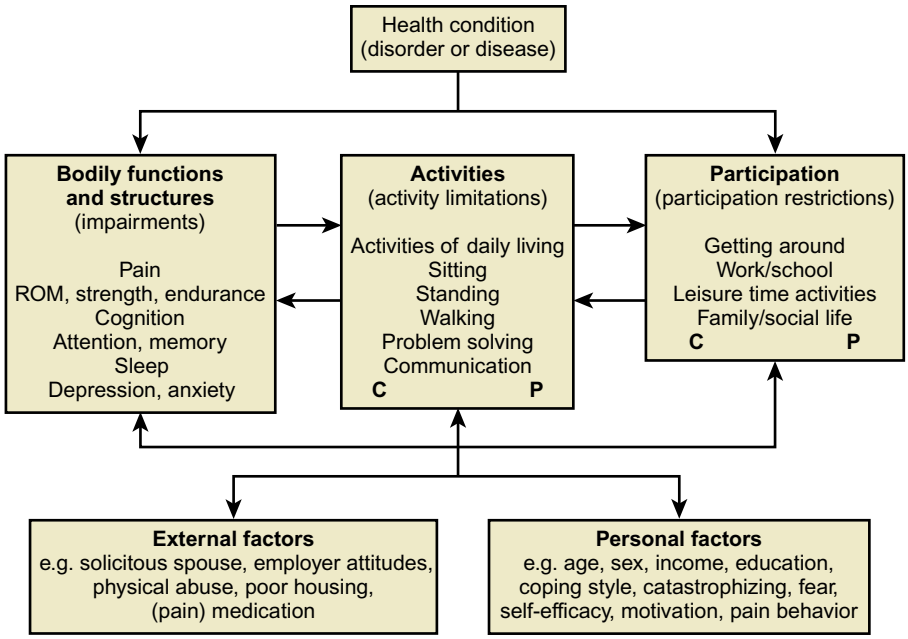
Ideally, patients with pain related disability resulting from chronic pain are treated by an interdisciplinary team of health professionals, commonly consisting of physicians, psychologists, physical and occupational therapists, social workers, and nurses, to address the biopsychosocial nature of pain. Interdisciplinary treatment is defined as multimodal treatment provided by a multi-disciplinary team collaborating in assessment and treatment using a shared biopsychosocial model and goals. For example, the prescription of an anti-depressant by a physician alongside exercise treatment from a physiotherapist, and cognitive behavior treatment by a psychologist, all working closely together with regular team meetings (face to face or online), agreement on the diagnosis, therapeutic aims, and plans for treatment and review.[1] Rehabilitation specialists working in pain management settings appreciate the complexities of chronic (vs. acute) pain, i.e. unclear relationships between pain, impairments, and disability, and the need to address the behavioral, emotional, and cognitive aspects of chronic pain. Chronic pain is understood as a disease, a pathology of the nervous system that produces abnormal changes in the brain and spinal cord and not as a symptom or warning of tissue damage.

Patients come to our pain management programs with certain expectations for evaluation and treatment. Although several studies investigated the expectations of patients with chronic pain of their physicians in a pain management program, there is a paucity of patients' expectations of their rehabilitation specialists. Most patients expected an explanation or an improved understanding of their pain problem (pain education), pain relief, and a definitive diagnosis from physicians.[2,3] Many patients with chronic pain resist referral to physical rehabilitation. Part of the difficulty lies in the history of treatment failures with which patients often present. Several factors may be responsible for past treatment failures, including persistent failure of health professionals (physicians, physical and occupational therapists) to recognize and treat the differences between acute and chronic pain states, past treatment that did not address the emotional and cognitive aspects of chronic pain, and an inability of the patient to recognize anything less than total pain relief as success.[4] Therefore it is crucial to identify patient expectations at the initial visit to prevent disappointment with referrals to physical rehabilitation for pain management.

Patient Evaluation

In evidence based practice, clinical decisions must include consideration of, first, the patient's clinical and physical circumstances to establish what is "wrong" and what treatment options are available to address this problem. Second, the latter needs to be tempered by research evidence concerning the treatment options' efficacy, effectiveness, and efficiency. Third, given the likely consequences associated with each option, the clinician must consider the patient's preferences and likely actions (in terms of what interventions she or he is ready and able to accept). Clinical expertise is needed to bring these considerations together and recommend a treatment that the patient agrees to accept.[5] The purposes of a rehabilitation specialist evaluation are to establish a baseline from which to plan and begin interventions, help to select appropriate interventions, and evaluate the efficacy of interventions.

As described in the biopsychosocial model of pain introduced by Fordyce, contributing factors to disability can be biologic, psychological, as well as social.[6] Essential in this model is the idea that factors maintaining the pain problem are not necessarily the same as those initiating pain. Therefore to establish a baseline, a thorough inventory of all factors contributing to a patient's perceived level of disability is important. The International Classification of Functioning, Disability and Health (ICF) provides a biopsychosocial model that identifies three concepts described from the perspective of body systems, the individual, and society. Within the context of health, the ICF defined *bodily functions and structures* as physiologic functions of body systems or anatomic elements, such as organs, limbs, and their components. Second, *activity* is defined as the execution of specific tasks or actions by an individual, whereas *participation* is envisioned as encompassing involvement in a life situation. In the ICF, *functioning* refers to all body functions, activities, and participation. *Disability* is the ICF umbrella term for impairment, activity limitation, and participation restrictions. Contextual factors are provided within the ICF framework (Fig. 60.1), consisting of external environmental factors (such as significant others, employers, medications, and healthcare providers) and personal factors (such as age, education, income, worry that activity will exacerbate pain or injury resulting in avoidance of activity to prevent anticipated negative consequences).



• **Figure 60.1** Example of International Classification of Functioning, Disability, and Health (ICF) framework. *C*, Capacity; *P*, performance; *ROM*, range of motion. (Adapted from Ustun TB, Chatterji S, Bickenbach J, et al. The international classification of functioning, disability and health: a new tool for understanding disability and health. *Disabil Rehabil.* 2003;25:565–71.)

Qualifiers for the activities and participation classification make it possible to clearly separate the patient's inherent capacity to perform actions within a domain and performance in his or her actual environmental context.[7] *Capacity* refers to the environmentally adjusted inherent ability of the individual or, in other words, the highest probable functioning of a person in a given domain at a given point in time, in a standardized environment. Capacity can be measured by physical tests or by questionnaires that ask, "Can you?" Performance describes what a person actually does in her or his current environment and thus describes the person's functioning as observed or reported in the person's real-life environment with the existing facilitators and barriers.[8] Performance can be measured by direct observation. However, as visual observation is often highly impractical, self-report measures can be substituted that ask, "Do you?" Increasingly accelerometers are being used to get some objective sense of a person's activity and sedentary level.

The rehabilitation problem solving (RPS) form is based on the ICF[9] and is a practical tool to use to visualize the patient's state of functioning and disability. The form is used to specify precise and relevant target problems, discern factors that cause or contribute to these problems, and plan the most appropriate intervention. In addition, the form was designed as a tool to facilitate both intra- and interprofessional communications and improve the communication between healthcare professionals and their patients.[9] The form is divided into three parts: (1) the header provides basic information, (2) the upper part is used to describe the patient's perspective, and (3) the lower part is used for the analysis of the healthcare professionals.

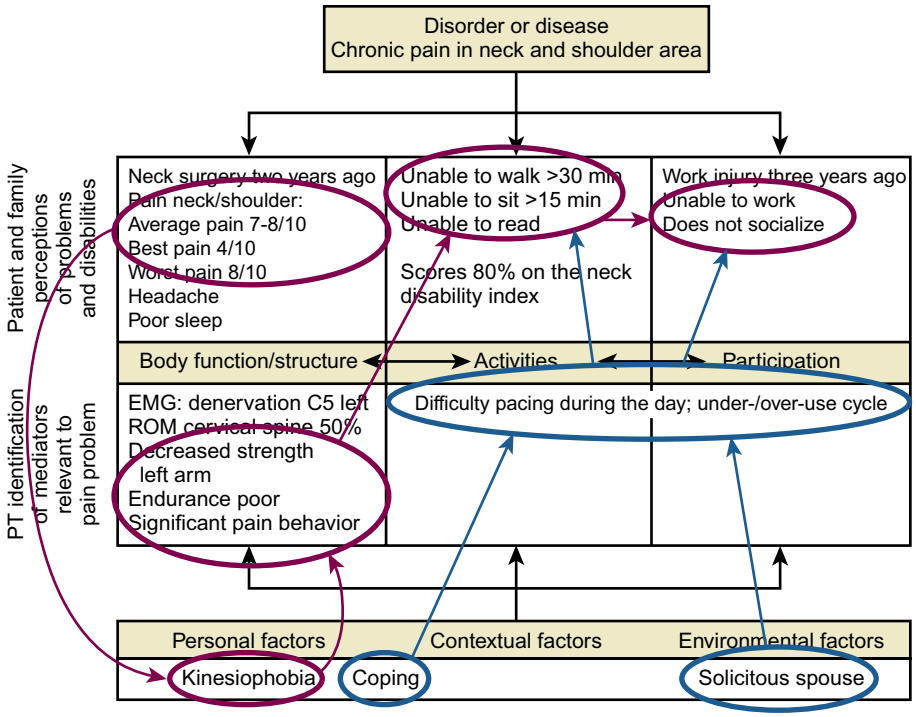
The form can visualize the current understanding of the patient's state of activities and participation, his or her target problems, and how the healthcare team relates them to hypothetical mediators and contextual factors (Fig. 60.2).

From the information obtained through carefully selected questionnaires, an interview, the physical examination, and physical tests, most of the information needed to develop an appropriate treatment plan should be obtained.

Patient Interview

The Joint Commission on Accreditation of Healthcare Organizations requires that all patients have the right to an adequate pain assessment, including documentation of pain location, intensity, quality, onset/duration/variations/rhythms, manner of expressing pain, pain relief, what makes it worse, effects of pain, and a pain plan. Besides questions about the location, intensity, frequency, and duration of pain, questions such as "What do you think causes your pain?" and "What is the worst thing you think might happen to you because of your pain?" will give insight into the patient's belief system—especially important if the patient comes from a different culture—and the presence of catastrophizing. In addition, rehabilitation specialists focus on determining how much the pain interferes with activities and participation: activities of daily living such as housework, grocery shopping, and getting around in the community; recreational and social activities; and the ability to do work and sleep. For example, the number of hours lying down and changes in activity level because of pain during a day is noted. Patients are further asked about significant others, partners, parents, and children; do they help out, ignore the patient, or prevent them from doing things as they fear the patient might "harm" him- or herself.

Unfortunately, there are no perfect measures of physical activity or activity limitations. Comparison measures include both "subjective" measures (based on self-report) and "objective" measures (based on direct measurement). Self-report measures can be self-administered or interviewer administered, both in person and on the telephone. However, self-report of physical activity can reflect a difference between how active patients really are and how active they perceive they are, resulting in a



• **Figure 60.2** Rehabilitation Problem Solving (RPS) form used for a patient with chronic neck and shoulder pain. *EMG*, Electromyelogram; *PT*, physical therapist; *ROM*, range of motion. difference between self-reported physical activity level and the actually observed active behavior.[10] Studies, including self-report and objective measures on activity and activity-related disability, indicated a gap between self-report and objective measurement.[11] In rehabilitation practice, there is a tendency to use objective and self-report measures to assess physical activity. Objective measures include functional capacity tasks, markers of movement (accelerometers, registration of activity by smartphone, or activity monitors), and observed or videotaped activity (direct observation).[12] Self-reported status often involves outcomes of most relevance and importance to patients and their loved ones because they capture patient experience and perspective.[13] Rehabilitation professionals should know these differences during their assessment. Besides assessing a patient's level of activity, labeling a patient's activity-related behavior style seems of additional value when choosing the most appropriate ingredients for treatment: Will this patient avoid activities because of pain (avoider), or will he or she persist in the performance of activities regardless of pain (persister)?[14]

Psychosocial factors have been found to have a significant impact on perceived disability, particularly among persons with chronic pain. The rehabilitation professional's observations of a patient's behavior during the interview or functional testing as a part of a screening procedure can deliver valuable information and should be communicated clearly to the rest of the team, which can then direct appropriate psychological and psychiatric treatment. Psychological screening by rehabilitation professionals with history taking has been shown to have low sensitivity and predictive value for identifying distressed patients. Thus formal screening of some sort, such as with a questionnaire, is recommended.[15] Psychosocial factors contributing to a patient's disability level that can be assessed by a questionnaire are, for instance, fear of movement[16] (Tampa Scale of Kinesiophobia),[17] catastrophizing (pain catastrophizing scale[18]), and depression (the Beck depression inventory).[19] High pain catastrophizing has also been found to be a predictor for patient dropout during treatment.[20] As previously mentioned, particularly important are questions about what the patient expects from treatment. Patients' beliefs and expectations play a large role in treatment participation and eventual treatment outcome. Studies have shown that high patient expectations may positively influence clinical outcomes independent of the treatment itself.[21] Treatment of chronic pain is often complex and may be further complicated when patients and healthcare providers have differing goals and attitudes concerning treatment. Difficulties in engaging in collaborative treatment decision making may result. A negative expectation on treatment outcome can influence treatment compliance. For instance, a patient who is looking for pain relief only and insists on medication management as the sole treatment for the pain is not likely going to comply with a rehabilitation program. Efforts to enhance patient-provider communication as well as to systematically examine non-specific treatment factors are likely to promote effective management of chronic pain. This includes adapting health information to the level of patients' health literacy by not using medical jargon, not delivering too much information at a time, and confirming patients' understanding of what was discussed by using teach back techniques.[22] Unfortunately, despite the widespread recommendations to medical practitioners to check patients' understanding directly, it does not yet appear to be routine practice.[23]

Physical Examination

The traditional rehabilitation-oriented physical examination assesses impairments in joint range of motion (ROM), strength, neurologic integrity, and gait. Diagnostic procedures should

focus on identifying potentially serious "red flag" conditions that require prompt medical evaluation. The main objective is to determine whether there is a relationship between pain reports and objective physical findings or whether the patient presents with chronic primary pain or chronic secondary pain.[24] In the former, rehabilitation might focus on improving physical functioning in general and have a more significant behavioral approach. In contrast, in the latter case, rehabilitation might focus more specifically on impairments related to pain that interfere with the ability to function.

Patient anxiety may complicate the physical examination. Catastrophic cognitions, behavioral displays of pain, and somatic sensations measured during examination have been shown to uniquely predict anxiety experienced during examination.[25] Muscle guarding and pain behaviors are often displayed during physical examination and include moaning, sighing, rubbing, reluctance to perform any active movement (ROM), and the presence of giveaway weakness and non-physiologic signs. Waddell's non-physiologic or behavioral signs in patients with back pain can be assessed through palpation and simulation tests,[26] including axial loading (pressure applied to the top of the patient's head), simulated rotation (moving shoulders and hips together so that no rotation occurs in the trunk), inconsistency between the straight leg raise in a sitting versus supine position, giveaway weakness with resisted muscle testing, and regional sensory change. Several studies examined the cross-sectional construct validity of the Waddell score and found evidence that it measures a combination of pain intensity, illness behavior, physical dysfunction, and psychological functioning,[27] somatic over-reporting,[28] increased perceived disability, and pervasive pain interference.[29] Recognizing that studies in patients with chronic pain have identified discrepancies between self-report of physical activity and actual level of physical activity, capacity testing is performed in addition to traditional impairment examination. This involves direct observation of patient performance on specific tasks and assessment of whether the patient is willing to move or fears performing specific tasks. Baseline functional ability assessment can provide objectively verifiable information about a patient's quality of life and ability to participate in normal life activities.

Functional tests can be used to focus on performance in basic daily life activities, such as walking, stair climbing, and lifting. Various specific tasks or sets of tests that intend to represent daily functioning are available for this purpose. Simple tasks such as 5 min walking, 50 foot walking, sit-to-stand, 1 min stair climbing, loaded forward reach, or various lifting tasks are available to test a patient's capacity during one specific activity. However, the ability of the tests to reflect the level of functioning in patients with pain has to be taken with caution. The test-retest reliability[30] and responsiveness appeared to be only moderate for most of the tests.[31] In addition to single tests, test batteries have been introduced to represent functioning in patients with pain. For example, the Back performance scale is a condition-specific performance measure of activity limitation in patients with back pain and includes five tests of daily activities requiring mobility of the trunk: sock test, pickup test, rollup test, fingertip-to-floor test, and lift test. The psychometric properties of this test battery have been demonstrated.[32,33] A second example is a generic test battery that includes nine physical performance tests: the time taken to complete various tasks (e.g. picking up coins, tying a belt, reaching up, putting on a sock, standing from sitting, a 50 foot fast walk, a 50 foot walk at preferred speed), the distance walked in 6 min, and the distance reached forward while standing. The reliability and discriminant ability of this battery has been confirmed.[34]

In the assessment of work related performance, a functional capacity evaluation (FCE) is often used.[35,36] An FCE is an evaluation of the capacity of activities that are used to make recommendations for participation in work while considering the person's body functions and structures, environmental factors, personal factors, and health status.[37] The purpose of an FCE is to test a person's physical abilities to the maximum to produce objective documentation regarding work and activities of daily life. The FCE has become part of the accepted practice in work injury prevention and rehabilitation.[38,39] During an FCE, the patient has to complete a standard protocol of physical tasks while a trained observer records the capacity and limitations. Assessment includes the ability to lift weights from the floor to waist and from waist to overhead, carry, crawl, squat, sit, stand, walk, climb stairs, and push and pull weights. Aerobic capacity may be determined from a maximal bicycle or treadmill test. Additional specific tests may be performed, such as those used to evaluate fine motor skills for the hands and handgrip strength. Practical data on the use of FCEs to determine an individual's physical capacities have been available since the early 2000s, and normative data have now been established.[36] Biopsychosocial factors may influence functional test and FCE test results, although it is unclear to what extent and which factors are important. A systematic review concluded that there is conflicting evidence for the influence of psychological factors and absence of evidence for the influence of social and biologic/physiologic factors in patients with non-specific chronic low back pain (CLBP) that influence capacity test results.[40] Therefore interpretation of FCE test results is not entirely objective because the observer has to decide if a patient performed maximally or submaximally during the test. In addition, pain and pain related constructs have been shown to negatively influence FCE performance levels. FCE should thus not be considered a purely "objective" indicator of functional impairment independent of subject or evaluator perceptions.[41]

Several studies have shown that self-report and performance and capacity tests, although related, appear to tap into different aspects of the physical functioning domain.[11] For instance, patients with CLBP showed considerable differences in limitations when comparing self-report, clinical examination, and functional testing for assessing work related limitations. Professional healthcare workers should be aware of these differences when using them in daily practice.[42,43]

Therapy for Chronic Pain

An important difference between patients with acute pain and those with chronic pain is the variation in relationships between pain, activity limitations, and participation restrictions. For patients with acute pain, nociception, perceived pain, activity limitations, and participation restrictions often have a close relationship. Therefore treatment in the acute phase focuses on eliminating the causal factor of the pain, resulting in a reduction of activity limitations and the prevention of disability. However, for patients with chronic pain, this treatment strategy is often insufficient. Patients with chronic pain may never return to work even when the only impairment identified is pain. Treatments that address chronic pain as a warning of tissue damage, like in acute pain, do not alter the illness and disability behavior of patients with chronic pain, nor will they improve their health-related quality of life. The focus of therapy should be to help these patients regain control

over their lives by active participation in their pain management program and learning to cope with pain. To achieve this goal, an active partnership is needed between the patient and the rehabilitation professional. Like other patients, patients with chronic pain want a confidence-based association that includes understanding, listening, respect, and being included in decision making.[44] The input from the interview and patient assessment form the basis of shared decision making, which involves at least two participants who engage in a process of both mutual information and interactive discussion. Patient participation should result in a greater sense of personal control, more satisfaction with treatment, better compliance, and transfer into the daily routine of disease management and, consequently, better outcomes.[45]

Patients with chronic pain are not a homogeneous group, and there is no magic bullet that fits all. Because each patient has a unique set of circumstances, psychosocial issues, and physical findings, treatment is individualized and based on the comprehensive assessment of the patient and the patient's individual goals.

Chronic pain management should include:[46]

- collaboration between the rehabilitation professional and the patient
- a personalized rehabilitation plan
- tailored education of the patient on the nature of the problem
- resolution of treatable barriers related to functional goal attainment
- tailored instruction in independent management of pain
- instruction in methods to prevent future problems
- monitoring of outcome (achievement of patient goals)
- monitoring of adherence to treatment
- planned follow up

Collaboration Between the Rehabilitation Professional and Patient

Implementing patient centered approaches in caring for individuals with chronic pain and using principles drawn from the chronic disease management model to improve care systems may improve patient and provider satisfaction with chronic pain care.[47] For instance, significant positive associations were found between a positive therapeutic alliance and the patient's global perceived effect of treatment, change in pain, physical function, patient satisfaction with treatment, depression, and general health status in patients with chronic musculoskeletal pain in physical rehabilitation.[48] Contributing to a positive therapeutic alliance are (1) therapist-patient agreement on goals of treatment, (2) therapist-patient agreement on intervention, and (3) the affective bond between patient and therapist.[48] Several studies indicate that a patient's perception of a provider's engagement and concern impacts their perceived satisfaction more than improved health.[49]

Coming to a mutual agreement on goals and intervention can be a challenge. To decrease the negative impact of chronic pain on functioning and health-related quality of life, patients must adopt self-management skills. In order to do so, in case of persistent non-reducible pain, patients have to be ready to stop focusing on further medical diagnostics to find a definite medical solution for pain and change to an active orientation regarding self-management. Not all patients are ready for this. For a good collaboration between the physical therapist and the patient, the patient must at least be planning to take an active orientation toward self-management, and the therapist should support and encourage this goal. Exercise improves pain and function in people with persistent musculoskeletal pain (PMSK), but adherence is often poor. Evidence suggests that exercise behaviors are modifiable, and behavior initiation and maintenance may be enhanced with behavior change interventions.[50,51] In a systematic review on behavior change techniques (BCTs) associated with adherence to prescribed exercise in patients with persistent musculoskeletal pain, a moderate level of evidence to support adherence for five BCTs was found, including (1) Social support (unspecified), (2) Goal setting (behavior), (3) Instruction of behavior, (4) Demonstration of behavior, and (5) Behavior practice/rehearsal. Treatment groups including seven or fewer BCTs, which were unique to any BCTs used in the control group, were most effective at enhancing exercise.[52]

Not only do patients bring expectations about treatment, but the provider does as well. Treatment decisions are often heavily influenced by the personal beliefs of the provider. Several studies have indicated that the personal attitudes and beliefs regarding pain of rehabilitation professionals and other healthcare providers are associated with their advice to patients regarding regaining activities and return to work. Practitioners with a more biomedical orientation are more likely to use a pain-contingent treatment approach and focus on "curing" impairments, whereas practitioners with a more biopsychosocial orientation will more likely use a time-contingent treatment approach and focus on increasing activities. Linton and associates investigated the level of fear avoidance beliefs in practicing general practitioners and physical therapists.[53] Compared to providers with low fear avoidance, providers with high levels of fear avoidance belief had an increased risk for believing sick leave to be a good treatment, not providing good information about activities, and being uncertain about identifying patients at risk for developing persistent pain problems. The combination of a high fear avoidant provider with a high fear avoidant patient seems a recipe for disaster in chronic pain management and should at all costs be avoided.

Different assessment tools are currently available to measure practitioners' beliefs toward pain, such as the Attitudes to Back Pain scale for musculoskeletal practitioners (ABS.mp), the Healthcare Providers' Pain and Impairment Relationship Scale (HC-PAIRS), and the Pain Attitudes and Beliefs Scale for Physiotherapists (PABS.PT).[54]

It can be concluded that for optimal interaction with his or her patient, a rehabilitation professional should have (1) a dynamic, multidimensional knowledge base that is patient centered, (2) a clinical reasoning process that is embedded in a collaborative, problem solving venture with the patient, (3) a central focus on movement assessment linked to patient function, and (4) consistent virtues seen in caring and commitment to patients.[55]

Personalized Rehabilitation Plan

To win the collaboration of patients and their families, rehabilitation professionals need to negotiate and agree on a definition of the problem they are working on with each patient. They must then agree on the targets and goals for management and develop an individualized, collaborative self-management plan.[46] The patient and rehabilitation professional need to agree on the goals of treatment to prevent confusion and disappointment on both sides and to establish a collaborative relationship. Adopting a shared decision making approach to goal and treatment setting may be useful. Training and support for both health professionals and patients may facilitate a shared decision making approach.[56] Establishing specific but attainable goals can facilitate task

performance. Unrealistic goals can lead to decreased motivation and a sense of failure. Self-efficacy facilitates goal setting. People with high self-efficacy choose to perform more challenging tasks.[57] They set themselves higher goals and stick to them. Self-efficacy can be understood as the confidence one has in one's ability to deal with certain life stressors. High self-efficacy is related to better treatment outcomes, such as higher levels of physical functioning and the use of pain coping strategies related to better adjustment to chronic pain.

Linking goals to patient values (value-based goals) should help in achieving those goals, as values (the things that are important to us) are one of the predominant determinants of how we choose our goals. Goals can be thought of as stepping stones that move patients toward their values. Goals must be measurable so that treatment can be time limited and have an observable end point. Return to a pain-free state is a good example of an unrealistic goal. Common (realistic) goals are associated with a reduction of the impact of pain on the patient's life (i.e. increased level of activities and participation), independent pain management, and the attainment of functional goals. Examples of functional goals are being able to walk for an hour, sitting through a meal or a movie, being able to carry and lift a certain amount of weight, playing with the kids, going out with the family, and being able to perform essential job components. Return to work or vocational rehabilitation should be part of the treatment plan when appropriate. Goals must be realistic and attainable within a reasonable time. A gauge such as the Canadian Occupational Performance Measure can be helpful during the process of goal setting and goal attainment during treatment.[58] It is helpful to determine the number of treatments per week and the number of weeks of treatment before initiating treatment (i.e. treatment will occur three times per week for six weeks). Having a definite end point increases patient adherence and provides a framework to the patient and the treatment team in which to achieve goals. A treatment contract that includes goals, the intensity and frequency of treatment, and expected compliance with treatment can be helpful.

During treatment, the use of goal setting charts is recommended. Patients set a target for activities each week, record their achievements on the chart, note the nature of any difficulties and how these will be tackled next time, and make other comments. Patients may comment on their performance or on the appropriateness of the goals they had set. In this manner, they can monitor their progress and improve their accuracy in goal setting.

Education on the Nature of the Problem

Several studies have shown that most patients expect an explanation or an improved understanding of their pain problem, a clear diagnosis of the cause of their pain, information, and instructions. They expect confirmation from the healthcare provider that their pain is real.[2,44] For patients attending pain clinics, the explanation of their pain problem is rated as important as the cure or relief of their pain.[2] Evidence from systematic reviews shows that reconceptualizing pain improves patients' knowledge of pain biology, reduces catastrophizing thoughts, and improves pain and function.[59–63] Education on the neurophysiology of pain seems important and may be considered a precondition for pain management success.[61,63,64] The sensitization model can be used to explain pain as a physical cause related to changes in the nervous system and to explain how chronic pain exists without tissue damage. This explanation may improve the patient's motivation to discuss the importance of psychosocial factors that contribute to the maintenance of chronic pain. However, not all patients benefit. For some patients, the message about danger signals and the brain is too abstract. These patients may benefit from "learning by doing" or from cognitive behavior therapy and educational programs that are simplified for reading ability, which have been shown to result in improved pain and physical functioning in children with chronic pain and adults with chronic pain and limited health literacy.[65,66]

The main goals of education are reassurance and empowerment for further treatment. Do not utilize patient education and counseling strategies that either directly or indirectly increase the perceived threat or fear associated with low back pain, such as in-depth, pathoanatomic explanations for the specific cause of the patient's (low back) pain.[67] When treating patients in a group, education comes from other patients as well. They may share solutions to functional problems, ways to better pace their activities, or independent pain management techniques they have found helpful.

Resolution of Treatable Barriers Related to Functional Goal Attainment

Barriers related to the attainment of functional goals in patients with chronic pain are usually because of a combination of physical factors and patient beliefs and cognitions. Physical conditioning programs that include a cognitive behavior approach plus intensive physical training (specific to the job or not) that includes aerobic capacity, muscle strength, endurance, and coordination; are in some way work related, and are given and supervised by a rehabilitation professional, or a multi-disciplinary team seem to reduce the number of sick days for some workers with chronic back pain when compared to usual care.[68,69] Ideally, exercise therapy is combined with a cognitive behavior approach in a chronic pain rehabilitation program.

Exercise Therapy

The "deconditioning syndrome"[70,71] was postulated in the mid-1980s as a factor contributing to the intolerance to physical activities and subsequent (further) loss of function and disability in patients with chronic pain. Physical disuse has been presented as one factor that perpetuates chronic pain in theoretical pain research models. Although current evidence does not support the disabling influence of a deconditioning syndrome in chronic pain syndromes,[72] reconditioning is still used as a foundation for various pain rehabilitation programs. Enhancing physical activity and fitness can indeed have a beneficial effect on patients with chronic pain. For example, meta-analyses have demonstrated strong evidence for the efficacy of muscle conditioning and aerobic exercise to lessen symptoms in persons with arthritis, other rheumatic diseases,[73] and shoulder pain.[74] There is evidence (although the studies have been classified as low quality) for the effectiveness of exercise therapy compared to usual care in patients with back pain.[75]

Exercise therapy encompasses a heterogeneous group of interventions, and several studies have found beneficial effects of exercise on pain and function. However, there continues to be uncertainty about the most effective exercise approach. Most studies had insufficient data to provide useful guidelines on optimal exercise type or dosage, although some evidence exists that "sicker" patients may benefit from more intensive treatment. Haldorsen and associates,[76] for instance, showed that

patients with a poor return to work prognosis returned to work at significantly higher rates when they completed a more intense multi-disciplinary treatment program. In contrast, patients with a good return to work prognosis benefited equally from ordinary treatment and multi-disciplinary treatment. Patients thus do not all benefit from the same exercise program. Therefore exercise programs need to be designed and tailored to the individual needs of the patient. In addition, the mechanisms by which physical treatment supports improvement in patients with chronic pain may not only be based on changes in muscle strength or fitness. In a study of Smeets and coworkers, it appeared that pain catastrophizing mediated results in both cognitive behavior treatment and physical treatment.[77] Changes in the level of catastrophizing, instead of changes in physical fitness, were associated with changes in disability during treatment.

Little evidence supports the use of passive modalities in the treatment of patients with chronic pain. High-quality evidence suggests that there is no clinically relevant difference between spinal manipulative therapy and other interventions for reducing pain and improving function in patients with CLBP.[78] There is currently insufficient evidence to draw a firm conclusion on the clinical effect of low-level laser therapy, massage, traction, superficial heat/cold, and lumbar supports for patients with CLBP.[75] Systematic reviews and meta-analyses on transcutaneous electrical nerve stimulation (TENS) are contradictory, reporting TENS does not improve symptoms of lower back pain, but may offer short term improvement of functional disability,[79] offer significant pain reduction in CLBP,[80] and inconclusive evidence of TENS benefits in patients with LBP because of the low quality of the studies.[81]

Passive modalities (TENS, ultrasound, massage, corsets, traction, acupuncture) should be limited and used only combined with an active exercise program.

Cognitive Behavior Approach

Cognitive behavior therapy (CBT) is a combination of cognitive and behavioral therapy. Behavioral therapy addresses the connections between situations and patients' habitual reactions to them (i.e. walking with a limp because it gets positive attention from the spouse). Cognitive therapy addresses patients' thoughts or beliefs that cause them to feel and act the way they do ("If I use my back, I will become paraplegic, so the safest thing to do for me is to lie on the couch and do nothing"). Therefore if patients exhibit unwanted behaviors, it is important to identify the beliefs that cause the behaviors and to teach patients how to replace or modify the beliefs so that more desirable behavior might ensue.

Cognitive-behavior modification can be accomplished in several ways: by talking about beliefs, by gaining exposure to avoided activities, by increasing the number and duration of usual activities, by participating in a "reward system" in which healthy behavior is rewarded and encouraged, and non-healthy behavior is ignored, and by listening to feedback from other patients on their behavior.

Pain related fear has been consistently associated with the initiation and maintenance of chronic pain disability.[82] For patients with high levels of pain and activity-related fear who avoid activities, behavioral methods such as graded activity and graded exposure treatment have both been shown to be effective in reducing disability.[83] Repeated exposure to avoided activities decreases anxiety and fear about them. In graded exposure, patients are challenged to perform the specific physical activities that they believe will harm them. Most of the time, exposure treatment is performed in combined therapy with a physical therapist and a behavioral therapist.

Although multi-disciplinary programs have shown effectiveness in patients with chronic pain,[84] it is still unclear which component is most effective. In a study in which the effectiveness of three rehabilitation interventions (an active physical, cognitive behavior, and combined treatment) for patients with CLBP was compared with that for a waiting list control group, it appeared that all three active treatments were effective in comparison to no treatment. However, no clinically relevant differences between the combined and the single-component treatments were found.[85] A new approach in CBT, or the third-wave CBT, has been introduced in pain treatment. An example of a third-wave CBT approach is acceptance commitment therapy (ACT). ACT differs from traditional CBT in that instead of trying to teach people to better control their thoughts, feelings, and sensations. ACT teaches them to "just notice," accept, and embrace personal life events. ACT aims to help individuals clarify their personal values and take action on them to bring more meaning to their lives.[86] ACT may be a helpful alternative to traditional CBT because of its shift of emphasis from trying to reduce or control the experience of pain to a focus on valued action in the presence of pain. Acceptance of chronic pain requires that an individual maintain functioning and participate in enjoyable and reinforcing activities in daily life even while continuing to experience sensations of pain. Random effects meta-analyses found small to large effects on the range of outcomes favoring ACT over control conditions at posttreatment.[87]

Self-Management Techniques

Self-management is as yet a difficult to measure complex concept.[88] To maintain sufficient quality of life, successful self-management—the ability to manage symptoms, treatment, physical, psychological and social consequences, and lifestyle changes related to one's chronic condition—is essential. Self-management skills include problem solving, decision making, resource utilization, forming a partnership with a healthcare provider and taking action.[89] To date, generic self-management interventions have been shown to have limited effectiveness for patients with chronic musculoskeletal pain.[90] However, there is emerging evidence that for participants with non-headache conditions, psychological therapies delivered via the Internet reduce pain, disability, depression, and anxiety post-treatment. The positive effects on disability were maintained at follow up. These effects are promising, but considerable uncertainty remains around the estimates of effect.[91]

Instruction in Methods to Prevent Future Problems

It is almost inevitable that a patient with chronic pain will experience an exacerbation of the pain problem. Relapse may be because of an individual physical event, or it may result from cumulative physical and psychological stresses that challenge patients' coping resources. The rehabilitation professional can help to identify situations that are challenging and develop strategies to cope with them. Strategies may include setting criteria to visit health professionals, using pain medication, or briefly resting and relaxing. Plans for resuming activity following an exacerbation are critical.[92]

Technologic applications, such as apps, virtual reality, or telephone-based interventions, may help patients maintain the skills they learned in their pain management programs and prevent relapse.

If returning a patient to work is an important goal, a job description with as much detail as possible provides important ergonomic information. Patients can then practice components of the job description with the physical therapist and at home.

The goal of ergonomics is to ensure that the workplace is designed to prevent work-induced injuries. Non-neutral postures, forceful exertions, constrained or static postures, repetitive work, use of pinch grip, work over shoulder height, prolonged periods with the trunk inclined forward, heavy lifting, twisting while lifting, and whole body and vibration are all risk factors for work related musculoskeletal disorders. A common type of ergonomic instruction is educating the patient on manual handling and lifting, optimal seated postures and activities, and the relationship of the seat to the workbench or desk. The patient is taught to take "stretch breaks" during work or to alternate job components.

At the end of treatment, a vocational assessment is advised, which preferably includes an FCE assessment. Then the FCE is matched with the job description. Recommendations for return to work are based on this evaluation. Changes in the job that would enable the patient to return to work may be suggested. If possible, a worksite analysis also should be performed to help identify risks to the patient and to suggest changes to the work environment to accommodate the patient.

A "light duty" job or a gradual increase in the hours worked per day is usually recommended for a return to work. Some therapists offer a "work hardening" program in which a pain patient gradually "works" up to a simulated 8 h workday. In workers with chronic back pain, pooled results of five physical conditioning studies showed a small effect on sickness absence at long-term follow up. The addition of cognitive behavior therapy to physical conditioning programs was not more effective than physical conditioning alone. Workplace involvement might improve the outcome.[69] After discharge from these programs, a full-time return to work is appropriate.

Monitoring of Outcome (Achievement of Patient Goals)

Generic and disease-specific measurement tools have been developed. Recommendations based on the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) can be helpful for designing sets for routine assessments to monitor treatment progress.[93] Important domains to consider for assessment as advised by IMMPACT are pain, fatigue, disturbed sleep, physical functioning, emotional functioning, patient global ratings of satisfaction, and health-related quality of life. In addition, patients' treatment goals can serve as outcome measures to determine treatment efficacy. A simple visual analog scale can visualize progress, for instance:

In the past week, were you able to walk a mile?

Completely unable_____Completely able

Monitoring of Adherence to Treatment

As early as 1990, Turk and colleagues reported that nonadherence with therapeutic recommendations during treatment and subsequent to treatment termination are neglected topics in the treatment of patients with chronic pain.[92] The topic remains under-researched.

Besides outcome domains mentioned earlier, IMMPACT focuses on participant disposition (e.g. adherence to the treatment regimen and reasons for premature withdrawal from the trial). Adherence to pain management treatment recommendations and the number of "no shows" should be monitored in clinical practice. Rehabilitation professionals need to offer an appropriate behavioral framework by maintaining a clear structure, consistent rules, and rewards for a positive patient response during treatment. When a patient is persistently nonadherent, the problem should be addressed, and the reasons for nonadherence explored. Reasons for nonadherence can include poor satisfaction with treatment results or a patient-provider relationship that does not work well.

Planned Follow Up

There is a paucity of literature on planned follow-up after multidisciplinary treatment. Planned follow up can be done individually or in group settings and serves to prevent crisis management. It can also serve as an external motivator (they are going to know I did not do my exercise/self-management techniques). However, there is no evidence as to the optimal frequency or duration of follow up visits to date.

Conclusion

Generally, the evaluation and treatment of chronic pain patients are difficult tasks that are best performed in an interdisciplinary team setting because both biomedical and psychosocial aspects related to the pain problem have to be addressed. Therefore the role of the rehabilitation professional is to form a close partnership with patients, help patients set and attain individual goals at activities and participation levels, and teach patients self-management skills. Ultimately, patients should become experts in managing their own chronic pain in order for them to enjoy the best health-related quality of life possible.

Key Points

- Interdisciplinary care of patients with chronic pain has proven to be of significant value.
- A collaborative relationship between patients and rehabilitation professionals is essential to enhance successful outcomes.
- The pain management treatment plan must be tailored to the individual patient.
- Establishing treatment goals, patient education, therapeutic exercise, and behavioral techniques are at the core of rehabilitation management.
- Active involvement of patients and treatment adherence are necessary.

The Integrative Approach to Pain Management

DELIA CHIARAMONTE, BRIAN MORRISON, CHRIS D'ADAMO

Integrative Medicine: Overview

Integrative Medicine is a philosophy of care that integrates conventional allopathic medical therapies with modalities not typically included in conventional care and addresses the physical, emotional, and spiritual needs of the patient. This field of medicine is sometimes referred to as complementary medicine or complementary and alternative medicine. However, these terms refer more precisely to modalities, such as acupuncture, meditation, nutritional supplements, and massage, all of which may be included in the integrative medicine "toolbox." Some organizations are now using the term "integrative medicine and health" to highlight the field's emphasis on personal and community health promotion. The Academic Consortium for Integrative Medicine and Health defines integrative medicine and health as follows: "Integrative medicine and health reaffirms the importance of the relationship between practitioner and patient, focuses on the whole person, is informed by evidence, and makes use of all appropriate therapeutic and lifestyle approaches, healthcare professionals and disciplines to achieve optimal health and healing."[1]

In the past several decades, there has been an increased interest in use of and body of research evaluating the integrative approach to care, and many medical schools now include integrative medicine topics in their curricula. An increasing body of evidence suggests that integrative medicine can be helpful in the management, and even prevention, of many chronic illnesses that negatively impact individual wellness, societal wellness, and financial burden on the United States healthcare system. In 2011 the Bravewell Collaborative initiated a survey to clarify how integrative medicine was being practiced in the United States.[2] Twenty-nine integrative medicine programs participated.

The most commonly employed practitioners were physicians, massage therapists, meditation instructors, and acupuncturists. The most common interventions prescribed were, in descending order, as follows:

- Nutritional interventions
- Dietary supplements
- Yoga
- Meditation
- Traditional Chinese Medicine/acupuncture
- Massage
- Pharmaceuticals

The survey identified five conditions that the respondents felt were the most effectively treated at their integrative medicine centers: chronic pain, gastrointestinal conditions, depression, stress, and cancer. There was significant consistency across centers in the use of specific interventions for particular clinical conditions, which suggests that a common knowledge base has emerged to guide integrative clinical care. In addition, 72% of the programs provided self-care/wellness experiences for their practitioners and staff. Integrative medicine incorporates conventional and complementary treatments and attends to the mind, body, spirit, and community of the patient, family, and practitioner.

Physicians may recommend complementary approaches to their patients, or patients may seek them out on their own. In one recent study,[3] massage therapy was the modality most frequently suggested by clinicians to their patients, followed by chiropractic/osteopathic manipulation, herbs/non-vitamin supplements, yoga, and acupuncture. Over 50% of physicians recommended at least one complementary approach to their patients in the previous year. Comparison of complementary modality usage over time (2002–2012) revealed that dietary supplements (particularly fish oil and glucosamine/chondroitin) remained the most popular modality across periods, with deep breathing exercises being the second most commonly used approach.[4] The use of yoga, tai chi, and Qigong increased linearly over the measured time period, and chiropractic/osteopathic manipulation and meditation were also commonly used. Ayurveda, biofeedback, guided imagery/hypnosis, and energy healing were low and had no significant change over time.

Pain syndromes, such as chronic back pain, are associated with significant healthcare costs.[5] Unresolved pain has a wide-reaching impact, affecting physical, emotional, and spiritual wellness and negatively impacting social and occupational functioning. Integrative medicine, which adopts a mind-body approach to the treatment of pain and employs multiple effective complementary modalities, is well-suited to address chronic pain syndromes and may result in decreased healthcare costs.[6] Chronic pain is one of the most common reasons that people use complementary and integrative medicine modalities,[7] and acupuncture, mind-body modalities, dietary interventions, and herbs/supplements are common choices. Complementary and integrative pain management strategies are also used for cancer pain[8] and in community-dwelling older adults.[9]

Multidimensional Perception of Pain

The perception of pain is multifactorial and involves a complex interplay between the peripheral and central nervous systems. As pain signals reach the brain from the periphery, the brain can

modify these signals by activating the inhibitory pathways and releasing substances such as endorphins and neurotransmitters. Alternately, the brain can magnify nociceptive signals if they are perceived to be threatening, thus increasing the perception of pain. Pain has both nociceptive and affective components; thus emotion and pain are deeply intertwined.[10] The connections between the cerebral cortex and the limbic system allow the brain to give meaning to the pain experience. It is this connection between emotions and pain perception that forms the basis of the mind-body approach to pain. Psychological factors such as the tendency to catastrophize have been associated with chronic pain,[11] and pain catastrophizing is associated with reduced health-related quality of life.[12] Overall, multiple psychosocial variables impact the likelihood of developing chronic pain, the ability to cope successfully despite pain, and the effectiveness of pain treatments.[13] These variables include childhood trauma, negative affect, level of social support, pain catastrophizing, self-efficacy, and more.

Life stress in childhood[14] or adulthood[15] can be associated with adult pain syndromes, and anxiety and chronic pain often coexist.[16] Depression and pain are related, with each negatively impacting the other. The serotonergic and norepinephrine systems are important in modulating both depression and pain, which is illustrated by the pain modulating properties of serotonergic and norepinephrine anti-depressants.[17] Untreated pain may lead to depression, and untreated depression can exacerbate pain. Even brief interventions designed to address emotional components of pain have been effective in decreasing pain severity.[18]

The prefrontal cortex (PFC) is important in pain processing. It interacts with other parts of the brain, such as the amygdala, hippocampus, thalamus, and others. Acute and chronic pain can result in changes to the PFC, including alterations in neurotransmitter release, gene expression, and inflammation, which can impact the PFC's structure, activity, and function.[19] The biopsychosocial model of pain management takes advantage of this interaction between the PFC and other emotion-regulating regions of the brain. Interventions such as cognitive behavioral therapy, mindfulness, music, meditation, exercise, and others may help to regulate the emotional centers of the brain and thus help to manage pain.

Similar regions of the brain are activated by both emotions and pain.[20] Neuroimaging studies have shown that social pain and physical pain are reflected similarly in the brain. In one study, subjects played a virtual game that elicited feelings of being excluded. The anterior cingulate cortex showed an increase in activity during exclusion, including physiologic changes that are similar to those seen with physical pain.[21] In addition, hypnotic suggestion of pain has been shown to create changes on functional MRI in the anterior cingulate cortex, thalamus, insula, prefrontal cortex, and parietal cortex, which are also influenced by pain originating in peripheral tissues.[22] This suggests that pain initiated by the brain has significant similarity to pain originating in the periphery. This concept highlights the mind-body connection and is important for the understanding and treatment of patients with acute and chronic pain.

People with chronic low back pain have an impaired ability to inhibit their pain. This may be related to decreased activation of the anterior cingulate cortex and prefrontal cortex, components of the descending inhibitory system, as well as decreased activation of the nucleus accumbens, which is involved in the dopamine system and thus the release of endogenous opioids.[23] Techniques that enhance active coping and recruitment of certain brain regions may be helpful with pain regulation. Neurofeedback is an example of such a technique. In one study, 28 subjects used fMRI neurofeedback while receiving a heat-induced pain stimulus. Successful pain coping was positively correlated with activation in the anterior cingulate cortex, prefrontal cortex, hippocampus, and visual cortex.[24] Mindfulness meditation (MM) was found to be more helpful for people with higher baseline pain catastrophizing, while mindfulness based cognitive therapy (MBCT) was more helpful for people with lower baseline pain catastrophizing. MM is a breathing practice that encourages focused awareness and attention on the current moment without getting carried away by thoughts, while cognitive behavior therapy (CBT) focuses on how your thoughts, feelings, and behaviors influence one another. MBCT combines dimensions of MM and CBT. Thus certain tools may be more effective for some patients than others, and a multimodal targeted approach is ideal.[25]

Integrative Medicine Modalities and Pain

Varied complementary medicine techniques have shown benefits in the treatment of pain. Domains such as Traditional Chinese Medicine, mind-body medicine, manual medicine, and others have an increasing body of evidence supporting their use in pain management. The most commonly used and well supported modalities are discussed below.

Acupuncture and Traditional Chinese Medicine (TCM)

TCM is an inclusive medical system based on 3000-year-old ancient texts. It incorporates varied treatment modalities, including acupuncture, acupressure, Chinese herbal medicine, meditative movements such as tai chi and qi gong, moxibustion, cupping, and specialized massage techniques referred to as tui na.

Acupuncture and TCM are based on the theory that health is determined by the balance of vital energy flow, called qi (pronounced "chi"), which is thought to be present in all living creatures. TCM utilizes concepts, such as yin/yang, dampness, and wind, which have no equivalents in conventional medicine and are therefore difficult to explain in standard medical terms. "Yin" represents the concept of cold, slow, and passive, while "yang" represents energy that is hot, fast, and active. Health is believed to be based on a balance of these and other opposing forces such as dampness and dryness and require the free flow of qi. Disease is felt to arise from an imbalance in these forces. Imbalance leads to blockage of qi (vital energy) along specified pathways, called meridians. In all organisms, qi is believed to flow through particular channels, called meridians, and TCM therapies are utilized to unblock the flow of qi. Unlike in conventional medicine, treatment plans are highly individualized and are based on an individual's constitution, as assessed by the TCM provider, as well as on their symptoms. Thus two patients with identical complaints might receive entirely unique treatment plans based on their baseline characteristics.

The acceptance of acupuncture in the United States continues to rise, with a 50% increase in use between 2002 and 2012. In that same time period, the number of United States licensed acupuncturists increased 100%.[26] Acceptance is also growing among medical educators. A survey of Pain Fellowship Directors revealed positive impressions of acupuncture in the treatment of common pain conditions. Acupuncture is often included in their treatment planning, is frequently available through the institution, and is integrated into the Fellowship curriculum.[27] Dry needling is also

increasing in popularity. It is a treatment modality that has similarities to acupuncture (thin needles inserted into trigger points) but is performed by non-acupuncturists, such as physical therapists, and does not adhere to the principles of TCM. This has caused consternation for some in the acupuncture community, while others have advocated for a collaborative approach.[28] Acupuncture points (acupoints) are located along the recognized meridians, and the process of acupuncture involves the insertion of thin needles into these points. Although meridians cannot be visualized anatomically, acupuncture points often correspond to depressions in muscles, bones, or neural foramina and may have their neurovascular bundle, which distinguishes the acupoint from surrounding tissue.[29] They are often palpable and may be tender to palpation.

From a conventional medicine point of view, the mechanism of action of acupuncture has not been unequivocally determined. Theories for acupuncture efficacy include the release of endorphins and neurotransmitters, enhanced local immune response, enhanced circulation and smooth muscle relaxation, stimulation of tissue growth and repair, and spinal and peripheral nerve stimulation. Substantial evidence supports the theory that acupuncture creates physiologic change at the site of needle insertion, in the cerebral cortex, and hormone and endorphin release.[29] It may also stimulate neurogenesis.[30] It has been shown to reduce lameness in horses[31] as well as pain and locomotion in dogs with musculoskeletal disorders,[32] suggesting effectiveness that does not rely on the placebo response.

There is abundant evidence to support the use of acupuncture in varied medical conditions, yet there are particular challenges to acupuncture research that may affect results. Acupuncture has no true placebo control, and sham acupuncture has sometimes been shown to be as effective as true acupuncture.[33] Inserting needles in "sham" acupuncture points might elicit physiologic change, and even sham acupuncture needles that press but do not puncture the skin may approximate acupressure effects if they are used at specified acupoints. In addition, standardized acupuncture treatments are often used in research to provide a consistent and replicable approach. That is, all patients with back pain would receive acupuncture at the same acupoints. However, this does not replicate the individualized treatment approach of acupuncture used in practice, thus creating a research environment that does not reflect real life conditions.

Acupuncture is used in various health conditions and is also used by those without specific symptoms to maintain optimal health. It is most commonly used for musculoskeletal pain relief. A 2001 review on acupuncture safety found that minor adverse events were common, but serious adverse events were rare. The most commonly reported adverse events were needle pain (1%–45%), tiredness (2%–41%), nausea or vomiting (0.01%–0.2%), and slight bleeding/bruising (0.03%–38%; Box 61.1). Feeling faint was very rare (0%–0.3%), and pneumothorax was extremely rare—only occurring twice in nearly a quarter of a million treatments.[34] A more recent overview of systematic reviews of acupuncture safety confirmed relatively frequent minor adverse events but rare serious ones.[35] Acupuncture is safe even in people receiving anticoagulation.[36]

Laws concerning the practice of acupuncture are defined by each state. Practitioners may include licensed acupuncturists who have completed over 1,000 hours of training at a college of Oriental Medicine or Masters level program, chiropractors who may receive some training within their professional course of study and may choose to pursue additional post-graduate training, and physicians and dentists who pursue acupuncture training after completing their professional programs. Most programs targeted to physicians, chiropractors, and dentists include approximately 200–400 hours of training. Board certification is available through the NCCAOM National Certification Commission for Acupuncture and Oriental Medicine (https://www.nccaom.org). For physicians, Board certification is available through the American Board of Medical Acupuncture (http://www.dabma.org/requirements.asp). Acupuncture styles differ and can include traditional Chinese acupuncture, five-element acupuncture, Korean or Japanese acupuncture, and auricular acupuncture. Evidence of superiority of one form over the others is not available.

• Box 61.1 Adverse Events Associated With Complementary Medicine Modalities

Treatment	Adverse Event
Acupuncture	Needle pain Tiredness Nausea/vomiting Bleeding/bruising Feeling faint Pneumothorax
Yoga	Soft tissue injury (e.g. overuse) Axial nonbony injury (e.g. degenerative joint disease (DJD) exacerbation)Bony injury (e.g. compression fractures)
Manual therapy	Increased pain Muscle stiffness Headache

A review of Cochrane reviews of acupuncture for pain found that acupuncture was effective for migraines, neck disorders, tension-type headaches, and peripheral joint osteoarthritis.[37] One well-designed randomized controlled trial of acupuncture in the treatment of knee osteoarthritis involved 507 patients recruited from two University outpatient clinics (Box 61.2).[38] The patients were randomized into one of three groups: true acupuncture, sham acupuncture, or education control. The primary measured outcomes were changes in the Western Ontario and McMaster Universities Osteoarthritis Index (WOMAC) pain and function scores at eight and 26 weeks. Secondary outcomes were patient global assessment, 6 minute walk distance, and physical health scores of the 36-Item Short-Form Health Survey (SF-36). Participants in the true acupuncture group experienced significantly greater improvement in WOMAC function scores than both the sham acupuncture and education groups at eight weeks but not in WOMAC pain score or the patient global assessment. At 26 weeks, the true acupuncture group experienced significantly greater improvement than the sham and education groups in the WOMAC function score, WOMAC pain score, and patient global assessment. The authors concluded that acupuncture could be used as adjunctive therapy in the treatment of knee osteoarthritis.[38]

A Cochrane review of acupuncture revealed that sham-controlled trials show statistically significant benefits; however, these benefits are small and may be due partly to placebo effects from incomplete blinding.[39] Acupuncture has been shown to be helpful in the perioperative period to decrease anxiety, and postoperative analgesic requirements,[40] and has been shown to improve chronic low back pain symptoms in some studies,[41] but not others.[42] It shows benefit in some musculoskeletal conditions, such as carpal tunnel syndrome, but no benefit in others, such as

• Box 61.2 Clinical Conditions Where Acupuncture May Be Effective

- Chronic low back pain
- Carpal tunnel syndrome*
- Migraine
- Chronic tension-type headache
- Some neuropathic conditions (Diabetic neuropathy, Bell's palsy)**
- Non-specific musculoskeletal pain
- Peripheral joint osteoarthritis, e.g. knee
- Shoulder pain

* No benefit in patella-femoral pain.
** Probably effective in HIV neuropathy.[45]
See text.

patellofemoral pain.[43] A Cochrane review of acupuncture for the treatment of chronic tension-type headaches suggested that acupuncture could be a valuable non-pharmacologic tool in patients with frequent episodic or chronic tension-type headaches.[44] It has also shown benefit in varied neuropathic conditions.[45] A recent meta-analysis evaluated the efficacy of acupuncture for non-specific musculoskeletal pain, osteoarthritis, chronic headache, or shoulder pain (Box 61.2). The primary outcome measures were pain and function. Data from 39 studies, which included more than 20,000 patients, showed that acupuncture was superior to sham as well as no acupuncture control for each pain condition.[46] Thus although the evidence suggests that acupuncture is beneficial for treating varied pain syndromes, the picture is unclear. Expectation of benefit, possible physiologic action of supposed sham controls, differing styles of acupuncture, and acupuncture research protocols that may not match the "real life" practice of acupuncture all create some uncertainty regarding the effectiveness of acupuncture for the treatment of pain. However, a mounting body of evidence suggests the benefits of acupuncture when added to conventional care and clear evidence of safety.

Mind-Body Medicine

The term mind-body medicine does not refer to a specific treatment modality; instead, it refers to a group of modalities unified by the underlying concept of an intricate connection between the mind and the body. The physical, emotional, spiritual, and social aspects of our lives impact health and wellbeing, and dysfunction in one domain can lead to dysfunction in another. Mind-body medicine asserts that the mind can positively affect the body in the pursuit of health and wellness.
