Practical Management of Pain

Practical Management of Pain

SIXTH EDITION

Honorio T. Benzon, MD

Professor
Department of Anesthesiology
Northwestern University Feinberg School of Medicine
Chicago, Illinois

James P. Rathmell, MD, MBA

Chair
Department of Anesthesiology, Perioperative and Pain Medicine
Brigham and Women's Hospital
Leroy D. Vandam Professor of Anaesthesia
Harvard Medical School
Boston, Massachusetts

Christopher L. Wu, MD

Clinical Professor of Anesthesiology
Department of Anesthesiology
Hospital for Special Surgery;
Clinical Professor of Anesthesiology
Department of Anesthesiology
Weill Cornell Medicine
New York City, New York

Dennis C. Turk, PhD

John and Emma Bonica Professor of Anesthesiology & Pain Research
Department of Anesthesiology & Pain Medicine
University of Washington
Seattle, Washington

Charles E. Argoff, MD

Professor of Neurology
Albany Medical College
Vice Chair Department of Neurology
Director, Comprehensive Pain Center
Director, Pain Management Fellowship
Albany Medical Center
Albany, New York

Robert W. Hurley, MD, PhD

Professor
Associate Dean
Department of Anesthesiology
Department of Neurobiology and Anatomy
Wake Forest University School of Medicine;
Executive Director
Pain Service Line
Atrium Health - Wake Forest Baptist
Winston Salem, North Carolina

Andrea L. Chadwick, MD, MSc, FASA

Associate Professor
Department of Anesthesiology, Pain, and Perioperative Medicine
University of Kansas School of Medicine
Kansas City, Kansas

To my wife, Juliet – thank you for your encouragement and support.
To our children and their spouses – Hazel and Paul, Hubert and Natalie.
To our grandchildren – Annalisa and Jonathan, Hunter and Jackson.
To my co-editors for working with me over three editions.
To all authors who took time off their busy schedules to write their chapters.
To all patients with pain – with basic, translational, and clinical advances, we hope your suffering will be better understood and treated.

Honorio T. Benzon

To Nori Benzon, who, through yet another revision of this text, this one during the course of a pandemic, led the project with patience, persistence, and kindness; it is a great privilege to work with you.
To my wife and children – Bobbi, Lauren, James, and Cara – thank you for your tremendous support.

James P. Rathmell

This work is dedicated to my parents (Shy-Hsien and Tsai-Lien), children (Emily and Alex), partner (Cynthia Cummis), and mentors. I am grateful for their continued support and encouragement.

Christopher L. Wu

To my many mentors, collaborators, and colleagues; way too many to list, but all of whom have contributed greatly to my understanding of the people and especially the plight of people who experience persistent pain. They have truly enriched my journey. And with gratitude to LORRAINE, more than a wife, a partner, and my best friend; for her consistent and unyielding patience, tolerance, and sacrifices throughout our marriage.

Dennis C. Turk

To my wife and best friend Pat – what an adventure we are having together!
To our children David, Melanie, and Emily – it has been a joy to watch you grow into unique and amazing adults.
To Nori Benzon – for asking me to be a part of this project and for his persistence and diligence in assuring its completion in such a dignified manner. To each of the co-editors – I am so grateful to have had the opportunity to work with and learn from you as we completed this venture together.
And to those who experience acute and chronic pain – it is my sincere hope that our ongoing determination to better understand the multiple mechanisms of pain and how to best treat painful conditions will lead to greater pain relief and less suffering.

Charles E. Argoff

To my wife and best friend, Meredith, for her unending support.
To my daughter, Alexandra, and sons, Sebastian and Gibson, my greatest joys.
To my parents, Morrison and Brenda, and my sister, Erin, who have always kept me grounded.
To my mentors, Donna Hammond, Steve Cohen, and Chris Wu, for fostering my interests and, when needed, reining me in.
To my collaborators, for questioning every sentence I put down on paper.

Robert W. Hurley

To my wife and best friend, Carrie, for showing me the power of authenticity and how embodying that principle allows one to fulfill their greatest potential in life and work. You are my why.
To my children, Stellan and Emmett, your support of mommy's "doctor work" is infinitely appreciated. Keep reaching for the stars; there is no limit to what you can achieve if you are true to yourself.
To Nori Benzon, Rob Hurley, Dan Clauw, Nirmala Abraham, Chad Brummett, and Talal Khan, my mentors, sponsors, and cheerleaders. I have nothing but deep gratitude for the support, guidance, and friendship you have bestowed upon me over the years.
To the patients who enrich my life by entrusting me to care for them, thank you for your strength despite adversity, vulnerability, and willingness to embark on a journey of healing with me.

Andrea L. Chadwick

Contributors

Gregory A. Acampora, MD
Faculty Psychiatrist
Department of Psychiatry
Massachusetts General Hospital;

Preface

The *Practical Management of Pain*, first published in 1986, is one of the established textbooks on pain management. In 2008, several of the current editors took over editorial leadership of the fourth edition of the book. As pain is multidimensional, starting in the fourth edition and continuing in the present edition, we the editors, represent several disciplines related to pain: anesthesiology, neurology, and psychology.

The *Practical Management of Pain* has evolved due to our increasing understanding of pain and its underlying mechanisms, which is reflected throughout this volume. Topics such as local anesthetics, neuraxial anesthesia, technique of peripheral nerve blocks, and associated topics were discontinued to focus on pain-related topics. In this updated and expanded edition, we have enlisted an outstanding set of clinicians and researchers with considerable expertise in all facets of pain and its management to provide contemporary information as to why and how best to evaluate and treat patients experiencing pain. We believe that this volume truly represents state-of-the-art knowledge and understanding of pain and its management.

To represent the growing body of knowledge in the field, we have added Andrea Chadwick to this edition. Dr. Chadwick brings particular expertise in the areas of fibromyalgia, non-opioid management of pain, radiation exposure, among other topics.

The production of a textbook involves the contributions, encouragement, and support of a number of people. We thank the authors, Michael Houston, Lisa Barnes, Manikandan Chandrasekaran, Baljinder Kaur of Aptara, and everyone related to the development of this edition.

Contents

Part 1: General Considerations

1 History Is a Distillation of Rumor, 3
Natalie Moryl, Charles Inturrisi

2 Classification of Acute Pain and Chronic Pain Syndromes, 11
Juan C. Mora, Rene Przkora, Matthew Meroney

3 Organizing an Inpatient Acute Pain Service, 16
Preetma Kaur Kooner, Gregory W. Terman

4 Interdisciplinary Pain Management, 39
Steven P. Stanos

5 The Healthcare Policy of Pain Management, 57
Thomas R. Vetter

6 Quality Assessment, Improvement, and Patient Safety in Pain Management, 67
Debra B. Gordon, James P. Rathmell

7 Education, Training, and Certification in Pain Medicine, 87
James P. Rathmell, Anne Marie McKenzie-Brown

Part 2: Basic Considerations

8 Neurophysiology of Pain: Peripheral, Spinal, Ascending, and Descending Pathways, 95
Karin N. Westlund

9 Neurochemistry of Nociception, 110
Tony L. Yaksh, Gilson Gonçalves dos Santos, Lauriane Delay, Elayne Viera

10 Neuroimaging Techniques, 125
Mathieu Roy, Étienne Vachon-Presseau, Markus Ploner, Ariana M. Nelson

11 Individual Differences in Experience and Treatment of Pain: Race, Ethnicity, and Sex, 138
Samantha M. Meints, Dikachi Osaji, Kylie Steinhilber, Robert R. Edwards

12 Communication and Clinician Relationships to Improve Care for Patients With Chronic Pain, 146
David J. Tauben, Mark D. Sullivan

13 Pharmacogenetics in Pain Management, 151
Erica L. Wegrzyn, Himayapsill Batista Quevedo, Jeffrey Fudin, Charles E. Argoff

14 Psychosocial and Psychiatric Aspects of Chronic Pain, 159
Dennis C. Turk, Tasha B. Murphy

15 Comprehensive Approach to Evaluating Patients With Chronic Pain, 173
Dennis C. Turk, Brett R. Stacey, Elisabeth B. Powelson

16 Mechanism-Based Treatment and Precision Medicine, 183
Jianguo Cheng, Yul Huh, Ru-Rong Ji

17 Placebo and Nocebo Effects in Clinical Trials and Clinical Practice, 194
Fabrizio Benedetti, Elisa Frisaldi, Aziz Shaibani

Part 3: Clinical Evaluation and Assessment

18 History and Physical Examination of the Patient With Pain, 207
Charles E. Argoff, Grace Forde, Sayed E. Wahezi, Robert Duarte

19 Electromyography and Evoked Potentials, 219
Andrew Dubin

20 Radiologic Assessment of Patient With Spine Pain, 232
Felix E. Diehn, John C. Benson, Timothy P. Maus

21 Biomarkers of Pain: Quantitative Sensory Testing, Conditioned Pain Modulation, Punch Skin Biopsy, 290
Juliane Sachau, Ralf Baron

22 Psychological and Behavioral Assessment, 299
Jessica Kruse, Robert D. Kerns, Elizabeth K. Seng

23 Disability Assessment, 315
Mohammed I. Ranavaya, Mohammed I . Ranavaya II, Jamila I. Ranavaya

Part 4: Clinical Conditions: Evaluation and Treatment

24 Chronic Post-surgical Pain Syndromes: Prediction and Preventive Analgesia, 333
Nantthasorn Zinboonyahgoon, Yun-Yun K. Chen, Kristin L. Schreiber

25 Evaluation and Pharmacologic Treatment of Postoperative Pain, 347
Lauren K. Dunn, Priyanka Singla

26 Regional and Multimodal Treatments of Perioperative Pain, 355
Ryan S. D'Souza, Rebecca L. Johnson

27 Evaluation and Treatment of Postoperative Pain in Patients With Opioid Use Disorder, 374
Yi Cai, Gregory A. Acampora, T. Anthony Anderson

28 Evaluation and Treatment of Acute Pain in Children, 385
Ravi Shah, Santhanam Suresh, Nicholas E. Burjek

29 Low Back Pain Disorders, 396
Khalid Malik, Ariana M. Nelson

30 Buttock and Sciatica Pain, 413
Graham Wagner, Ariana M. Nelson, Steven P. Cohen, Zachary L. McCormick

31 Facet Pain: Pathogenesis, Diagnosis, and Treatment, 432
Steven P. Cohen, Javier De Andrés Ares

32 Neurosurgical Approaches to Pain Management, 453
Marshall T. Holland, Ahmed M. Raslan, Kim J. Burchiel

33 Evaluation and Treatment of Cancer-Related Pain, 461
Dermot Fitzgibbon, Margaret Hsu

34 Evaluation and Treatment of Neuropathic Pain Syndromes, 479
Christopher M. Lam, Andrea L. Chadwick, Robert W. Hurley

35 Evaluation and Treatment of Complex Regional Pain Syndrome, 500
Frank J.P.M. Huygen

36 Evaluation and Treatment of Pain in Selected Neurologic Disorders, 507
Amir Hadanny, Anna Blanchfield, Olga Khazen, Charles E. Argoff, Julie G. Pilitsis

37 Chronic Widespread Pain, 520
Meredith C.B. Adams, Daniel J. Clauw

38 Headache Management, 530
Stephen D. Silberstein

39 Cervicogenic Headache, Post-meningeal Puncture Headache, and Spontaneous Intracranial Hypotension, 545
Lori-Ann Edwards, Louise Hillen, Deepti Agarwal, Dost Khan, Reda Tolba

40 Orofacial Pain, 560
Aurelio Alonso, Massimiliano DiGiosia, Daniela Vivaldi

41 Visceral Pain, 582
Klaus Bielefeldt

42 Pelvic Pain, 593
Jan Alberto Paredes Mogica, Milana Bochkur Dratver, Elise J.B. De

43 Pediatric Chronic Pain Management, 620
Angelica A. Vargas, Ravi Shah, Bonnie S. Essner, Santhanam Suresh

44 Geriatric Pain Management, 637
Keela A. Herr, Staja Q. Booker, Lynn Nakad, David J. Derrico

45 Managing Pain During Pregnancy and Lactation, 647
Geeta Nagpal, Feyce M. Peralta, James P. Rathmell

46 Rheumatologic Conditions, 663
David Andrew Walsh

47 Pain Management in Patients With Comorbidities, 675
Natalie H. Strand, Andrea L. Chadwick

Part 5: Pharmacologic, Psychologic, and Physical Medicine Treatments and Associated Issues

48 Major Opioids and Chronic Opioid Therapy, 689
David Copenhaver, Rebecca Hoss, Megan H. Cortazzo, Iris Vuong, Scott M. Fishman

49 Minor Analgesics: Non-Opioid and Opioid Formulations, 703
Steven P. Stanos, Mark D. Tyburski, Sagar S. Parikh

50 The U.S. Opioid Crisis and the Legal and Legislative Implications, 720
Jordan Starr, Mohammed A. Issa, Ajay Wasan

51 Evaluation for Opioid Management: Opioid Misuse Assessment Tools and Drug Testing in Pain Management, 727
Robert N. Jamison, Samantha Curran

52 Pain and Addictive Disorders: Challenge and Opportunity, 734
Shannon Nugent, Mark Beitel, Gretchen Hermes, Marina Gaeta Gazzola, Declan Barry

53 Anti-depressants, 743
Anthony H. Dickenson, Ryan Patel, Charles E. Argoff

54 Adjunct Medications for Pain Management, 752
Daniel B. Larach, Andrea L. Chadwick, Charles E. Argoff, Robert W. Hurley

55 Skeletal Muscle Relaxants, 763
Ravneet Bhullar, Evangeline P. Koutalianos, Charles E. Argoff, Andrew Dubin

56 Cannabinoids for Pain Management, 769
Ning Nan Wang, Anuj Bhatia

57 Topical Analgesics, 777
Magdalena Anitescu, Charles E. Argoff

58 Psychological Approaches in Pain Management, 782
Dennis C. Turk, Akiko Okifuji

59 Evidence-Based Rehabilitation Approaches to Acute and Chronic Pain Management, 792
Dana Dailey, Kathleen A. Sluka, Carol G.T. Vance

60 Physical Rehabilitation for Patients With Chronic Pain, 800
Harriet Wittink, Jeanine A. Verbunt

61 The Integrative Approach to Pain Management, 809
Delia Chiaramonte, Brian Morrison, Chris D'Adamo

62 Patient Education and Self-Management, 823
David A. Williams, Silvie Cooper

Part 6: Neural Block and Interventional Techniques

63 Neurolytic Agents, Neuraxial Neurolysis, and Neurolysis of Sympathetic Axis for Cancer Pain, 835
Heather A. Columbano, Amit Gulati, Robert W. Hurley

64 Head and Neck Blocks, 857
Antoun Nader, Jee Youn Moon, Mary Leemputte, Kenneth D. Candido

65 Interlaminar and Transforaminal Therapeutic Epidural Injections, 874
Ariana M. Nelson, Honorio T. Benzon, Magdalena Anitescu, Marc A. Huntoon

66 Radiofrequency Treatment, 892
Koen van Boxem, Maarten van Eerd, Thibaut Vanneste, Xander Zuidema, Jan van Zundert

67 Pain Interventions for the Knee, Hip, and Shoulder, 908
Christine L. Hunt, David A. Provenzano, Kailash Chandwani

68 Myofascial Injections and Fascial Plane Blocks for Perioperative and Chronic Pain Management, 924
Ariana M. Nelson, Carlos E. Guerrero, Andrea L. Chadwick

69 Minimally Invasive Procedures for Vertebral Compression Fractures, 939
Mithun Nambiar, Lee-Anne Slater, Joshua A. Hirsch, Ronil V. Chandra, Julian Maingard

70 Biopsychosocial Pre-screening for Spinal Cord and Peripheral Nerve Stimulation Devices, 950
Andrew J.B. Pisansky, Ajay Wasan, Mohammed A. Issa

71 Spinal Cord Stimulation, Peripheral Nerve Stimulation, Restorative Neurostimulation, Deep Brain Stimulation, and Motor Cortex Stimulation, 957
Leonardo Kapural, James Deering, Christopher Gilmore

72 Intrathecal Drug Delivery, 963
Timothy Furnish, Carlyle Peters Hamsher, Mark S. Wallace

73 Radiation Safety and Radiographic Contrast Agents, 980
James P. Rathmell, Honorio T. Benzon

74 Infection and Anticoagulation Considerations in Pain Procedures, 996
Michael C. Hanes, Honorio T. Benzon, David A. Provenzano

Part 7: Pain Management in Special Situations and Special Topics

75 Pain Management in Primary Care, 1015
Katherine E. Galluzzi

76 Pain Management in the Emergency Department, 1034
Andrew K. Chang

77 Management of Pain in Sickle Cell Disease, 1039
Carlton D. Dampier

78 Burn Pain, 1045
Jatin Joshi, Mohammad Piracha, Christopher L. Wu

79 Pain Evaluation and Management in Patients With Limited Ability to Communicate Because of Dementia, 1052
Thomas Hadjistavropoulos, Una E. Makris

80 Disparities in Pain Care: Descriptive Epidemiology-Potential for Primary Prevention, 1059
Jana M. Mossey

81 Pain Management in the Critically Ill Patient, 1069
Liang Shen, John E. Rubin, James Littlejohn

82 Pain Management at the End of Life and Home Care for the Terminally Ill Patient, 1076
Dalya Elhady, Diane Novy

Part 8: Research, Ethics, Healthcare Policy, and Future Directions in Pain Management

83 Clinical Trial Design Methodology and Data Analytic Strategies for Pain Outcome Studies, 1095
Nebojsa Nick Knezevic, Patrick Schober, Roger Chou, Thomas R. Vetter

84 Outcome Domains and Measures in Acute and Chronic Pain Clinical Trials, 1111
Honorio T. Benzon, Hubert A. Benzon, Dennis C. Turk

85 Ethical Issues in Pain Research, 1123

History Is a Distillation of Rumor

NATALIE MORYL, CHARLES INTURRISI

THOMAS CARLYLE (1795-1881)

Management of pain, such as the management of any disease, is as old as the human race. In the view of Christians, the fall of Adam and Eve in the Garden of Eden produced a long life of suffering pain for men and women. This act allegedly sets the stage for several disease concepts, including the experience of pain in labor and delivery, the concept that hard work is painful, the notion that blood, sweat, and tears are needed to produce fruit; *the introduction of pain and disease to human existence*; establishment of the fact that hell and its fires are painful; and the expectation that heaven is pure, delightful, spiritually pleasing, and of course, pain free. From a historical perspective, humans have deliberately and knowingly inflicted on one another many experiences associated with pain—from the earliest wars to the more recent irrational shooting incidents in Sandy Hook Elementary School in Newtown, Connecticut, and Marjory Stoneman Douglas High School in Parkland, Dallas from the scourging of Jesus to contemporary strife in the Middle East, the Rwandan genocide, the Irish "religious" fratricide, and the conflicts in Bosnia and the Balkans. All wars, including the great wars, World War I and World War II, the American Civil War, the Korean War, and the Vietnam War, have been associated with untold pain, suffering, and death.

In these concepts, pain is viewed as a negative experience and one that is associated with disease and death. Many diseases, including infections, plagues, and genetic and acquired disorders, including cancer and COVID-19, can cause significant pain. In contrast to acute pain that may teach us a lesson, that is, we would not touch a hot stove the second time after the initial touch brings sharp short-lived pain, chronic pain offers no such benefits. It interferes with our quality of life, sleep, work, and enjoyment of life and often causes anxiety, depression, and decreased mobility, which may precipitate or worsen other medical conditions resulting from inactivity. Most recently, social media has created a platform for those who may ordinarily suffer in silence the freedom to share and open up about their suffering and pain. Social media has become a powerful tool for people with pain to share their stories and reach new audiences across the globe, creating new patient communities. This has empowered patients with pain to set up new expectations during treatment of conditions commonly associated with pain, such as cancer, diabetes, HIV, and others.

Medical and technological advances in the 21st century have changed the outcomes of many diseases and the probability of survivorship. Cultural and religious changes in many societies have also changed the way patients view the disease. Various advocacy groups have empowered patients and caregivers to change what is viewed as acceptable during various treatments. Patients' experience has been gaining priority not only for patients but also for research, clinicians, and the medical system overall. Originally conceived in 2001 by the National Institutes of Health, the patient-reported outcomes measurement information system (PROMIS) has involved hundreds of medical researchers and psychometricians and received approximately $250 million in funding.[1,2] Further research showed that not only patients wanted to drive communications by reporting their distress with pain and other symptoms, but both caregivers and clinicians found regular communications from the patient reporting pain and other symptoms useful for clinical care.

This chapter focuses on some of the major historical events that have led to the current conceptualization of pain and its treatment as an independent specialty in modern medicine.

Pain and Religion

The early concept of pain as a form of punishment from supreme spiritual beings for sin and evil activity is as old as the human race. In the book of *Genesis*, God told Eve that following her fall from grace, she would endure pain during childbirth: "I will greatly multiply your pain in childbearing; in pain you shall bring forth children, yet your desire shall be for your husband, and he shall rule over you" (Genesis 3:16). This condemnation led early Christians to accept pain as a normal consequence of Eve's action and to view this consequence as being directly transferred to them. Thus any attempt to decrease the pain associated with labor and delivery was treated by early Christians with disapproval and disapproval. It was not until 1847, when Queen Victoria was administered chloroform by James Simpson for the delivery of her eighth child, Prince Leopold, that contemporary Christians and, in particular, Protestants accepted the notion that it was not heretical to promote painless childbirth as part of the obstetric process.

From the Old Testament, Job has been praised for his endurance of pain and suffering. While Job's friends wondered whether these tribulations were an indication that he had committed some great sin for which God was punishing him (Job x:17), Job was considered a faithful servant by God, not guilty of any wrongdoing. He was described as a man who was "blameless and upright" and one who feared God and turned away from evil.[3]

In the 5th century, St. Augustine wrote that "all diseases of Christians are to be ascribed to demons; chiefly do they torment the fresh baptized, yea, even the guiltless newborn infant," thus implying that not even innocent infants escape the work of demons. In the 1st century, many Christians were rebuked and

suffered ruthless persecution, including death, because of their belief in Jesus as the Messiah. Some who were subsequently described as martyrs endured their suffering in the belief that they did it for the love of Christ, and they felt that their suffering identified them with Christ's suffering on the cross during his crucifixion.[4] This may be the earliest example of the value of psychotherapy as an important modality in managing pain. Thus some present-day cancer patients with strong religious beliefs view their pain and suffering as part of their journey toward eternal salvation. This concept has led to several scientifically conducted and government-sponsored studies evaluating intercessory prayer as an effective modality for controlling cancer pain.

To fully appreciate the historical concept of pain, it is important to reflect on the origins of the term "pain patient." The word *pain* comes from the Latin word *poena*, which means that "punishment." The word *patient* is derived from the Latin word *patior*, meaning "to endure suffering or pain." Thus it is not too outrageous to appreciate that in ancient days persons who experienced pain were interpreted to have received punishment in the form of suffering that was either dispensed by the gods or offered up to appease the gods for transgressions.[5,6]

In some cultures, the tribal concept of pain came from the belief that it resulted from an "intrusion" from outside the body. These "intruders" were thought to be evil spirits sent by the gods as a form of punishment. In this setting, the role of medicine men and shamans flourished because these were the persons assigned to treat the pain syndromes associated with internal disease. Since it was thought that spirits entered the body by different avenues, the rational approach to therapy was aimed at blocking the particular pathway chosen by the spirit.

In Egypt, the left nostril was considered to be the specific site where the disease entered. This belief was confirmed by Papyri and Berlin, who stated that the treatment of headache involved expulsion of the offending spirit by sneezing, sweating, vomiting, urination, and even trephination.[7,8] In New Guinea, it was believed that evil spirits entered via a spear or an arrow, which then produced spontaneous pain.[7] Thus it was common for the shaman to occasionally purge the evil spirit from a painful offending wound and neutralize it with his special powers or special medicines. Egyptians treat some forms of pain by placing an electric fish from the Nile over the wounds to control pain.[8,9] The resulting electrical stimulation that produced relief of pain actually works by a mechanism similar to transcutaneous electrical nerve stimulation (TENS), which is frequently used today to treat pain. The Papyrus of Ebers, an ancient Egyptian manuscript, contains a wide variety of pharmacologic information and describes many techniques and recipes, some of which still have validity.[8,9]

Early Native Americans believed that pain was experienced in the heart, whereas the Chinese and India identified multiple points in the body where pain might originate or might be self-perpetuating.[10] Consequently, attempts were made to drain the body of these "pain points" by inserting needles, a concept that may have given birth to the principles of acupuncture therapy, which is well over 2000 years old.[11]

The ancient Greeks were the first to consider pain to be a sensory function that might be derived from peripheral stimulation.[12] In particular, Aristotle believed that pain was a central sensation arising from some form of stimulation of the flesh, whereas Plato hypothesized that the brain was the destination of all peripheral stimulation. Aristotle advanced the notion that the heart was the origin or processing center for pain. He based his hypothesis on the concept that an excess of vital heat was conducted by the blood to the heart, where pain was modulated and perceived. Because of his great reputation, many Greek philosophers followed Aristotle and embraced the notion that the heart was the center for pain processing.[13] In contrast, another Greek philosopher, Stratton, and other distinguished Egyptians, including Herophilus and Eistratus, disagreed with Aristotle and proposed the concept that the brain was the site of pain perception, as suggested by Plato. Their theories were reinforced by actual anatomic studies showing the connections between the peripheral and central nervous systems.[14]

Nevertheless, controversies between the opposing theories of the brain and the heart as the center for pain continued. It was not until 400 years later that the Roman philosopher Galen rejuvenated the works of the Egyptians Herophilus and Eistratus and greatly re-emphasized the model of the central nervous system. Although Galen's work was compelling, he received little recognition until the 20th century.

Toward the period of the Roman Empire, steady progress was made in understanding pain as a sensation similar to other sensations in the body. Developments in anatomy and, to a lesser extent, in physiology helped establish that the brain, not the heart, was the center for the processing of pain.[15] While these advances were taking place, simultaneous advances were occurring in the development of therapeutic modalities, including the use of drugs (e.g. opium), as well as heat, cold, massage, trephination, and exercise, to treat painful illnesses. These developments led to the establishment of the principles of surgery for treating diseases. Electricity was first used by the Greeks of that era, as they exploited the power of the electrogenic torpedo fish (*Scribonius longus*) to treat the pain of arthritis and headache. Electrostatic generators, such as the Leyden jar, were used in the late Middle Ages, resulting in the re-emergence of electrotherapy as a modality for managing medical problems, including pain. However, there was a relative standstill in the development of electrotherapy as a medical modality until the electric battery was invented in the 19th century. Several attempts have been made to revive its use as an effective medical modality, but these concepts did not catch on and were largely used only by charlatans and obscure scientists and practitioners.

Over the centuries, many modes of anesthesia/analgesia have been developed and refined so that their mortality and morbidity have become negligible. General anesthesia was formally discovered by William Morton in 1846. In 1847, while even the concept of analgesia for the relief of labor pain was considered heretical and unchristian, Simpson used chloroform to provide anesthesia for the labor pains of Queen Victoria during the delivery of her eighth child, Prince Leopold.[9] This action helped legitimize the practice of pain relief during childbirth. Around the same time, a hollow needle and syringe were invented. Many local anesthetic agents have been discovered in this era. In 1888, Corning described using a local anesthetic, cocaine, to treat nerve pain. Techniques for local and regional anesthesia for both surgery and pain disorders have proliferated rapidly.

The history of anesthesia is full of instances wherein attempts to relieve pain were initially met with resistance and sometimes violence. In the mid-19th century, Crawford Long from the state of Georgia in the United States attempted to develop and provide anesthesia, but contemporary Christians of that state considered him a heretic for his scholarly activity. As a result, he had to flee for his life from Georgia to Texas. Although surgical anesthesia was well-developed in the late 19th century, religious controversy over its use required Pope Pius XII to give his approval before anesthesia could be used extensively for surgical procedures.[6] Pope Pius XII wrote, "The patient, desirous of avoiding or relieving pain, may

without any disquietude of conscience, use the means discovered by science which in themselves are not immoral." More recently, the Church endorsed palliative care, including pain management using high-dose opioids or sedatives at the end of life (even if life-shortening) as long as the palliative therapies were proportionate and used to treat refractory symptoms in a terminally ill patient. Pope John Paul II stated: "Moreover, while patients in need of pain killers should not be made to forego the relief that they can bring, the dose should be effectively proportionate to the intensity of their pain and its treatment." (http://www.ldysinger.stjohnsem.edu/@magist/1978_JP2/Addresses/04_11_pal-care.htm).

Pain and Pain Theories

Throughout the Middle Ages and the Renaissance, the debate on the origin and processing center of pain raged. Fortunes fluctuated between proponents of the brain theory and proponents of the heart theory, depending on which theory was favored.

Heart theory proponents appeared to prosper when William Harvey, recognized for his discovery of the circulation, supported the heart as the focus for pain sensation. However, Descartes disagreed vehemently with the Harvey hypothesis, and his description of pain conducted from peripheral damage through nerves to the brain led to the first plausible pain theory, that is, the *specificity theory*.[16] In his 1664 Treatise of Man, René Descartes traced a pain pathway and described pain as "a specific sensation, with its own sensory apparatus independent of touch and other senses."

In the 1850s, by examining the effect of incisions in the spinal cord, Schiff[16] demonstrated that touch and pain were sensations independent of each other. He postulated that pain had its own specific nervous system pathways from the spinal cord that traveled to the brain. Further work along the same lines by Bliz,[17] Goldscheider,[18] and von Frey[19] contributed to the concept that separate and distinct receptors exist for the modalities of pain, touch, warmth, and cold.

During the 18th and 19th centuries, new inventions, new theories, and new thinking emerged. This period was known as the Scientific Revolution, and several important inventions took place, including the discovery of the analgesic properties of nitrous oxide, followed by the discovery of local anesthetic agents (e.g. cocaine). Anatomy has also developed rapidly as an important branch of science and medicine; most notably, the discovery of the anatomic division of the spinal cord into sensory (dorsal) and motor (ventral) divisions. In 1840 Mueller proposed that based on anatomic studies, there was a straight-through system of specific nerve energies in which specific energy from a given sensation was transmitted along sensory nerves to the brain.[20] Mueller's theories led Darwin to propose the intensive theory of pain,[21] which maintained that the sensation of pain was not a separate modality but instead resulted from a sensory overload of sufficient intensity for any modality. This theory was modified by Erb[22] and then expanded by Goldscheider[18] to encompass the roles of both stimulus intensity and central summation of stimuli. Although the intensive theory was persuasive, the controversy continued, with the result that by the mid-20th century, the specificity theory was universally accepted as the more plausible theory of pain.

With this official, though not unanimous blessing of the contemporary scientific community, strategies for pain therapy began to focus on identifying and interrupting pain pathways. This tendency was both a blessing and a curse. It was a blessing in that it led many researchers to explore surgical techniques that might interrupt pain pathways and consequently relieve pain, but it was a curse in that it biased the medical community for more than half a century into believing that pain pathways and their interruption were the total answer to the pain puzzle. This trend began in the late 19th century by Letievant, who first described specific neurectomy techniques for treating neuralgic pain.[23] Afterward various surgical interventions for chronic pain were developed and used, including rhizotomy, cordotomy, leukotomy, tractotomy, myelotomy, and several other operative procedures designed to interrupt the central nervous system and consequently reduce pain.[24] Most of these techniques were abysmal failures that did not relieve pain and occasionally resulted in more pain than previously present.

Pain as a Disease

The cardinal features of disease as recognized by early philosophers included calor, rubor, tumor, and dolor. The English translation is heat, redness, swelling, and pain. One of the important highlights in the history of pain medicine was the realization that even though heat, redness, and swelling may disappear, pain can continue and be unresponsive on occasion to different therapeutic modalities. When pain persists long after the natural pathogenic course of disease has ended, a chronic pain syndrome develops with characteristic clinical features, including depression, disability, disuse, and decreased mobility, causing other medical conditions such as obesity and arthritis to worsen. The risk of another comorbidity of chronic pain increases with chronic opioid exposure that, in some instances, can be complicated by dependency and opioid use disorder, formally known as addiction. John Dryden once wrote, "For all the happiness mankind can gain is not in pleasure, but in rest from pain." Thus many fatal nonpainful diseases are not as feared as relatively trivial, painful ones.

Physicians and healers have focused their attention on managing pain. Thus in managing cancer, an important measure of successful treatment is the success with which any associated pain is managed. Although many technological advances have been made in medicine, it is only within the past 10 to 20 years that significant strides have been made in dealing with chronic pain as a disease entity per se—one requiring specialized assessment, workup, diagnosis, and specialized therapeutic interventions targeting the cause of pain and pain itself.

Pain in the 20th Century

In 1907, Schlosser reported significant relief of neuropathic pain for long periods with the injection of alcohol into damaged and painful nerves. Reports of similar treatment came from the management of pain resulting from tuberculous and neoplastic invasion.[25] In 1926 and 1928, Swetlow and White, respectively, reported on the use of alcohol injections into thoracic sympathetic ganglia to treat chronic angina. In 1931, Dogliotti described the injection of alcohol into the cervical subarachnoid space to treat pain associated with cancer.[26]

One consequence of war has been the development of new techniques and procedures to manage injuries. During World War I (1914-1918), numerous injuries were associated with trauma (e.g. dismemberment, peripheral vascular insufficiency, and frostbite). In World War II (1939-1946), peripheral vascular injuries as well as phantom limb phenomena, causalgia, and many sympathetically mediated pain syndromes occurred. Leriche developed the technique of sympathetic neural blockade with procaine to treat the causalgic injuries of war.[27] John Bonica, himself an army surgeon during World War II, recognized the gross inadequacy of

managing war injuries and other painful states of veterans with the existing uni-disciplinary approaches.[28] This led him to propose the concept of multi-disciplinary, multimodal management of chronic pain, including behavioral evaluation and treatment. Bonica also highlighted the fact that all kinds of pain were being undertreated; his work has borne fruit in that he is universally considered the "father of pain," and he was the catalyst for the formation of many established national and international pain organizations. Bonica's lasting legacy is his historic volume *The Management of Pain*, first published in 1953. The clinic that he developed at the University of Washington in Seattle remains a model for the multi-disciplinary management of chronic pain. As a result of his work, the American Pain Society (APS) and the International Association for the Study of Pain (IASP) were formed. Anesthesiology was developed as a division of surgery and did not reach full autonomy until after World War II. With the discovery of new local anesthetics, regional anesthesia began to flourish in the United States. Bonica's wife had a very difficult delivery, alerting Dr. Bonica to the gap in childbirth analgesia. He played a major role in advancing the safe use of epidural anesthesia to manage the pain associated with labor and delivery in the 20th century. Regional anesthesia suffered a significant setback in the United Kingdom with negative publicity surrounding the 1954 cases of Wooley and Roe, in whom serious and irreversible neurological damage occurred after spinal anesthesia. It took three more decades to fully overcome this setback and to see regional anesthesia widely accepted as safe and effective in the United Kingdom. Several persons contributed significantly to the development of regional anesthesia, including Corning, Quincke-August Bier, Pitkin, Etherington-Wilson, Barker, and Adriani.

An outstanding contribution in the field of research was the development and publication of the *gate control theory* by Melzack and Wall in 1965.[29] This theory, which was built on the preexisting and prevalent specificity and intensive theories of pain, provided a sound scientific basis for understanding pain mechanisms and for developing other concepts on which sound hypotheses could be developed. The gate control theory emphasizes the importance of both ascending and descending modulation systems and provides a solid framework for the management of different pain syndromes. The gate control theory almost single-handedly legitimized pain as a scientific discipline and led not only to many other research endeavors building on the theory but also to the maturity of pain medicine as a science.[30] As a consequence, the American Academy of Pain Medicine (AAPM), the American Society of Regional Anesthesia and Pain Medicine, the IASP, and the World Institute of Pain (WIP) have become serious and responsible organizations that deal with various aspects of pain medicine, including education, science, certification, and credentialing of members of the specialty of pain medicine.

Dr. Jan Sternsward, Chief of the Cancer Unit at the World Health Organization (WHO), collaborated with IASP to focus on cancer pain and palliative care for cancer patients worldwide. In 1982, representatives from IASP, including Drs. Mark Swerdlow, John Bonica, Robert Twycross, Kathleen Foley, and Fumi Takeda met in Italy and developed what eventually became the 1986 report entitled cancer pain relief. With IASP, WHO made a historic statement declaring pain relief a human right issue and called on member states to make pain-relieving drugs available, including oral morphine, which was on the WHO essential drug list.

Memorial Sloan Kettering's James Ewing Hospital (MSK) was a focal point for the main site to evaluate new analgesics in patients with cancer pain. A young internist, Dr. Raymond Houde, with the assistance of a research nurse, Ada Rogers, and a psychologist, Stanley Wallenstein, began work on opioid pharmacology, including equianalgesic opioid doses in 1951. From Henry Beecher at Harvard and from his own experiments with student volunteers at Michigan, he learned that the perception of pain was modified by multiple variables—emotional state, expectations or fears for the future, previous medications or treatments, and the course of the disease itself. Houde's meticulous and patient-sensitive methods were recognized in the late 1950s as the standard for analgesic trials. A neurologist, Kathleen Foley, brought together various programs to form the first designated pain service in a cancer setting in the United States. In addition to Dr. Houde and Ada Rogers, it included Charles Inturrisi, professor of pharmacology at Weill Cornell Medical College, and Gavril Pasternak, professor of neurology, who was developing a laboratory to study opiate receptors in the brain. This program combined basic and clinical research, along with a training program as well as a supportive care program for patients with complicated pain started by a PhD nurse practitioner, Nessa Coyle. Dr. Kathleen Foley published the first taxonomy of cancer pain syndromes.

Pain and the Impact of Psychology

The history of pain medicine is incomplete without acknowledging the noteworthy contributions of psychologists. Their influential research and clinical activities have been an integral part of a revolution in the conceptualization of the pain experience.[31] For example, in the early 20th century, the role of the cerebral cortex in the perception of pain was controversial because of a lack of understanding of the neuroanatomic pathways and the neurophysiologic mechanisms involved in pain perception.[32,33] This controversy largely ended with the introduction of the gate control theory by Wall and Melzack in 1965.[29] The gate control theory has stood the test of time in subsequent research using modern brain-imaging techniques such as positron emission tomography, functional magnetic resonance imaging, and single-photon emission computed tomography have also described the activation of multiple cortical and subcortical sites of activity in the brain during pain perception. Further elaboration of the psychological aspects of the pain experience includes the three psychological dimensions of pain: sensory-discriminative, motivational-affective, and cognitive-evaluative.[34]

Psychological researchers have greatly advanced the field of pain medicine by reconceptualizing both the etiology of pain experience and treatment strategy. Early pain researchers conceptualized pain experience as a product of either somatic pathology or psychological factors. However, psychological researchers have convincingly challenged this misconception by presenting research that illustrates the complex interaction between biomedical and psychosocial factors.[35–37]

This biopsychosocial approach to pain encourages the realization that pain is a complex perceptual experience modulated by a wide range of biopsychosocial factors, including emotions, social and environmental contexts, and cultural background, as well as beliefs, attitudes, and expectations. As the acutely painful experience transitions into a chronic phenomenon, these biopsychosocial abnormalities develop permanency. Thus chronic pain affects all facets of a person's functional universe at great expense to the individual and society. Consequently, logic dictates that this multimodal etiology of pain requires a multimodal therapeutic strategy for optimal cost-effective treatment outcomes.[38,39]

Additional contributions from the field of psychology include therapeutic behavioral modification techniques for pain

management. Techniques such as cognitive behavioral intervention, guided imagery, biofeedback, and autogenic training are the direct results of using the concepts presented in the gate control theory. In addition, neuromodulatory therapeutic modalities such as TENS, peripheral nerve stimulation, spinal cord stimulation, and deep brain stimulation are also logical offspring of the concepts presented in the gate control theory.

The evaluation of candidates for interventional medical procedures is another valuable historical contribution from the field of psychology. Not only is the psychologist's expertise in the identification of appropriate patients valuable for the success of therapeutic procedural interventions for the management of pain, but the psychologist's expertise is also helpful in identifying patients who are not appropriate candidates for procedural interventions. Thus psychologists have contributed positively to the cost effectiveness and utility of diagnostic and therapeutic pain medicine. Psychologists' contribution to the care of patients with cancer pain is invaluable. Psychological research in cancer led by Dr. Jimmie Holland et al., MSK led to the development of a new field of psycho-oncology that is essential in addressing the pain and suffering of patients with cancer pain.

Pain and Pain Organizations

World Health Organization (WHO)

When diplomats met to form the United Nations in 1945, one of the things they discussed was the establishment of a global health organization. A year later, in New York, the International Health Conference in New York approved the Constitution of the WHO. In 1986, the WHO published the first analgesia step ladder and a detailed report on cancer pain relief, highlighting the prevalence and assessment of cancer pain, its undertreatment, recommended therapeutic modalities, and the need to educate healthcare workers and the general public. Among the few countries, the United States was represented by Dr. John J. Bonica, President of the IASP, and Dr. Kathleen Foley, Chair of the Pain Service, Department of Neurology, Sloan Kettering Cancer Center in New York.

The International Association for the Study of Pain (IASP)

The IASP is the largest multi-disciplinary, international association in the field of pain. Founded in 1973 by John J. Bonica, MD, the IASP is a nonprofit professional organization dedicated to furthering research on pain and improving the care of patients experiencing pain. Membership is open to scientists, physicians, dentists, psychologists, nurses, physical therapists, and other health professionals actively engaged in pain and to those who have a special interest in the diagnosis and treatment of pain. The IASP has members of more than 100 national chapters.

The goals and objectives of the IASP are to foster and encourage research on pain mechanisms and pain syndromes and improve the management of clinical pain. One of the instruments used to disseminate new information is the journal *Pain*. In addition, the IASP promotes and sponsors a highly successful biennial world congress, as well as other meetings. The IASP encourages the development of national chapters for the national implementation of the IASP's international mission. In addition, the IASP encourages the adoption of a uniform classification, nomenclature, and definition of pain and pain syndromes.

Special interest groups within the IASP include pain in children, neuropathic pain, herbal medicine, and cancer pain. The IASP also promotes and administers chronic pain fellowship programs for deserving candidates worldwide.

The American Pain Society (APS)

Spurred by the burgeoning public interest in pain management and research, as well as by the formation of the Eastern and Western United States Chapters of the IASP, the APS was formed in 1977 as a result of a meeting of the Ad Hoc Advisory Committee on the Formation of a National Pain Organization. Its main function was to carry out the mission of the IASP at a national level through interprofessional collaborations between basic and clinical pain researchers and clinicians. APS was dissolved in 2019 through Chapter 7 bankruptcy resulting from the OxyContin scandal. APS maintains that it was another victim of the opioid crisis after being "named a defendant in numerous spurious lawsuits related to opioids prescribing and abuse" Although APS has been dissolved, its journal, *the Journal of Pain*, continues independent of the APS that originated it. The United States Association for the Study of Pain is a new professional society for United States-based pain researchers.

Commission on the Accreditation of Rehabilitation Facilities

In 1983, the Commission on Accreditation of Rehabilitation Facilities (CARF) was the first to offer a system of accreditation for pain clinics and pain treatment centers. The CARF model was based on a rehabilitation system that emphasized both physical and psychosocial rehabilitation of patients suffering from pain. CARF promoted multi-disciplinary pain management programs offering not only medical but also mandatory psychological and physical therapy modalities for the management of pain. Its major goals included objective measures such as increased physical function, reduced intake of medication, and return-to-work issues.

The American Academy of Pain Medicine (AAPM)

AAPM was formed in 1983 at a meeting of the APS in Washington, DC, when a group of physicians formed a separate American Academy of Algology, later renamed the AAPM. Their goal was to address the deficiency in evaluating pain physicians' competence by creating uniform standards for training and credentialing. AAPM sponsored the American College of Pain Medicine, which organized, developed, and administered the first credentialing examination in 1992. The American College of Pain Medicine is not now called the American Board of Pain Medicine (ABPM). The goals of the AAPM include the promotion of quality care through research, education, and reimbursement. *The Clinical Journal of Pain*, the initial journal of the AAPM, is not affiliated with any pain medicine society. The AAPMs present journal is *Pain Medicine.* Both journals are well-respected.

The American Society of Regional Anesthesia and Pain Medicine (ASRA)

ASRA is the largest subspecialty medical society in anesthesiology and the leader in regional anesthesia and acute and chronic pain medicine. The society is based in the United States; other societies on regional anesthesia are based in Europe, Asia, and

Latin America. The international societies of regional anesthesia have changed the name of their highly cited journal, *Regional Anesthesia*, to *Regional Anesthesia and Pain Medicine*.

The American Society of Interventional Pain Physicians (ASIPP)

ASIPP is a national organization that represents the interests of interventional pain physicians. The society was founded in 1998 by Dr. L. Manchikanti and associates to improve the delivery of interventional pain management services in various settings, including hospitals, ambulatory surgical centers, and medical offices. ASIPP has become a successful advocate for the political and regulatory aspects of pain medicine. The ASIPP journal is indexed and called *Pain Physician*.

The American Academy of Hospice and Palliative Medicine (AAHPM)

AAHPM was founded in 1988 as an Academy of Hospice Physicians, and in 1996 it changed its name to the AAHPM to reflect a goal of this organization to control pain and other symptoms not only at the end of life but throughout the disease trajectory, from diagnosis through survivorship or end of life. AAHPM works closely with the American Board of Hospice and Palliative Medicine and disseminates its research through affiliation with a well-established *Journal of Pain and Symptom Management*. The goals of the multi-disciplinary AAHPM include providing education and clinical practice standards, fostering research, and sponsoring public policy advocacy for the chronically and terminally ill and their families.

The American Academy of Orofacial Pain

The American Academy of Orofacial Pain (AAOP) is an organization of healthcare professionals dedicated to the alleviation of pain and suffering through education, research, and patient care in the field of orofacial pain and associated disorders. The AAOP goals include the establishment of acceptable criteria for the diagnosis and treatment of orofacial pain and temporomandibular disorders, sponsorship of research, and annual meetings. Their journal, together with the European, Asian, Australian, and New Zealand Academy of Orofacial Pain, is *the Journal of Oral and Facial Pain and Headache*.

The American Academy of Pain Management (AAP Management)

AAP Management was founded in 1988 and changed its name to the Academy of Integrative Pain Management (AIPM) in 2016. The AIPM has promoted an integrative, interdisciplinary model of pain management. The AIPM closed its operations in 2019.

American Society for Pain Management Nursing (ASPMN)

Founded in 1990, ASPMN is an organization of professional nurses dedicated to providing access to specialized care for patients experiencing pain, providing education to the public regarding self-advocacy for their pain needs, and providing a network for nurses working in the pain management field. The ASPMN Journal is *Pain Management Nursing*.

The International Headache Society (IHS)

The International Headache Society is based in London. Its leadership is worldwide and is known for their international classification of headache disorders, now in its third edition. Another notable guideline is their International Classification of Orofacial Pain. In addition, their journal, *Cephalalgia*, has a fairly high impact factor.

The World Institute of Pain (WIP)

The WIP is an international organization that aims to promote the best practice of pain medicine throughout the world through training via international seminars and exchange of clinicians and education via newsletters, scientific seminars, and publications. One of the most important initiatives if the WIP is to develop an international examination process to certify qualified interventional pain physicians. After showing proficiency in both general pain knowledge and safe performance of interventional procedures, successful candidates are awarded the designation of *Fellow of Interventional Pain Practice* (FIPP). In addition, the journal of the WIP, *Pain Practice*, is indexed and has a very respectable impact factor.

The Spine Intervention Society (SIS)

The SIS, formerly called the International Spine Injection Society, is known for its leadership in interventional pain medicine. Their landmark monograph, *Practice Guidelines for Spinal Diagnostic and Treatment Procedures,* is the gold standard for spine interventions. Together with the AAPM, their journal is *Pain Medicine*.

The International Neuromodulation Society (INS)

Founded in 1989, INS is a unique multi-disciplinary, international society that consists of not only clinicians and scientists but also engineers dedicated to the scientific development and awareness of neuromodulation – the alteration of nerve activity through the delivery of electromagnetic stimulation or chemical agents to targeted sites of the body. The INS promotes the field through meetings and its journal *Neuromodulation*.

American Pain Foundation (APF)

Founded in 1997 by the APS (see above for the current status of APS), APF was the first pain organization specifically formed to serve the interests of people with diverse disorders associated with the presence of significant pain. Its goals include patient education, promoting recognition of pain as a critical health issue, and patient access to proper medical care. Regrettably, the organization dissolved in early 2012 because of financial difficulties.

International Association of Hospice and Palliative Care (IAHPC))

IAHPC was founded in 1980. From this, the Academy of Hospice Physicians grew. Two new independent organizations were formed: the AAHPM and the International Hospice Institute and College. IAHPC serves as a global platform to inspire, inform, and empower individuals, governments, and organizations to increase access and optimize the practice of palliative care.

The Worldwide Hospice Palliative Care Alliance (WHPCA)

WHPCA is an international non-governmental organization that includes members from over 100 countries, focusing exclusively on hospice and palliative care development worldwide.

International Children's Palliative Care Network (ICPCN)

The ICPCN is the only global organization working to improve access to palliative care for children. The ICPCN is recognized globally for its leadership, a wealth of educational resources, and a network of members in over 120 countries.

Pain and the Hospice Movement

Hospice is a medieval term representing a welcome place of rest for pilgrims to the Holy Land. The concept of hospice dates back to the reign of Emperor Julian the Apostate, when Fabiola, a Roman matron, created a place for sick and healthy travelers and cared for the dying.[40] In general, hospitals were regarded as Christian institutions, and in medieval times most hospitals were used as hospices and vice versa.[41]

The 17th century Catholic priest St. Vincent DePaul founded the Sisters of Charity in Paris as a home for the poor, the sick, and the dying. The movement grew, and the Protestant pastor Fliedner founded Kaiserwerth 100 years later. Nuns from both Sisters of Charity and Kaiserwerth accompanied Florence Nightingale to Crimea to care for wounded soldiers.[42]

In 1902, the Irish Sisters of Charity founded St. Joseph's hospice. Fifty years later, Cecily Saunders became the founder and medical director of St. Christopher's Hospice in England. She was initially trained as a nurse and served during World War II. After becoming injured, she received training as a social worker. She subsequently developed a keen interest in terminal cancer patients and underwent training in medical school to become a physician. She emphasized the importance of pain control at the end of life, believing patients' pain reports, the need for frequent pain assessments, and the scheduling of opioids for chronic pain instead of administering them on an as-needed basis.[43] For all her efforts and leadership, she is regarded as the "mother of palliative care" and was knighted for her contributions to the hospice movement and care of dying cancer patients. Dame Saunders' teachings are endorsed by medical and nursing schools today.

Pain and Palliative Care

Palliative care is a more recent specialty. The term palliative comes from Medieval Latin palliativus, "under cloak" or to cover, mitigate, or alleviate. Palliative care is provided to improve the quality of life of patients with serious or life-threatening diseases, such as cancer. The goal is to prevent or treat the symptoms and side effects of the disease as early as possible, in addition to any related psychological, social, and spiritual problems. Pain management, research, education, and advocacy are integral parts of palliative care.

Opioid Crisis

While trying to empower the patients to report pain and aiming at pain free outcomes of dental, surgical, and medical interventions and with pharma advertising directly to patients, opioid prescriptions and opioid overdoses started to increase, reaching the peak in 2017.[44] The first wave was from abuse of prescription opioids that was addressed by the Center for Disease Control and state and institutional guidelines.[45] Unfortunately, some of the patients with prescription opioid addiction went on to abuse street drugs, including heroin and illicit fentanyl.

Pharmaceutical companies, sued by several state attorney generals, agreed to a master settlement to defray the cost of the opioid crisis. As a result, the prescription of non-opioids has increased, and the search for non-opioid analgesics has become a priority for research and pharmaceutical companies. Access to the treatment of opioid addiction has become one of the priorities of the federal government, resulting in buprenorphine-naloxone medication-assisted addiction treatment available through primary care and other certified clinicians. This has become an alternative to methadone maintenance clinics that are much more easily accessible to patients. Since COVID-19, there has been an increase in opioid overdose deaths.

Pain and the Future

The contributions of the IASP, WIP, International Headache Society (IHS), AAPM, ASRA, ASIPP, and many other international, national, regional, state, and local organizations devoted to pain and pain management led to research, innovative techniques, new drug development, dissemination of knowledge, and local, national, and international networking. Pain practitioners and investigators are no longer isolated, and a flurry of published manuscripts and textbooks now cover a wide array of topics in pain medicine. Official credentialing is through the certificate of added qualification by the American Board of Anesthesiology. In addition, the WIP offers FIPP certification through examination. Some organizations are now offering certifications on basic knowledge and expertise in the use of ultrasound for interventional pain procedures.

Giving the patient's voice through patient-reported outcomes (PRO) and social networking led to new patient-healthcare provider relationships. Data on PROs and the increasing interest in cost effectiveness made it clear that the scientific community concerned with pain must develop reliable and reproducible outcome measures to maintain high quality, credibility, integrity, and competence in the management of pain.

Key Points

- The word *pain* comes from the Latin word *poena*, which means "punishment." The word *patient* is derived from the Latin word *patior*, meaning "to endure suffering or pain."
- The history of anesthesia is full of instances in which attempts to relieve pain were initially met with resistance and at times violence.
- Developments in anatomy and physiology helped establish that the brain, not the heart, was the center for processing pain.
- The tenet of the specificity theory, proposed by Descartes and revised by Schiff, was that each sensory modality, including pain, was transmitted along an independent pathway.

- The use of chloroform to provide anesthesia for the labor pains of Queen Victoria helped to legitimize the practice of pain relief during childbirth.
- The clinic that Bonica developed at the University of Washington in Seattle remains a model for the multi-disciplinary management of chronic pain.
- The pain program that was developed at the Memorial Sloan Kettering Cancer Center was the first cancer pain program to remain a model for multi-disciplinary pain and palliative care programs for management and research in cancer pain.
- An outstanding contribution in the field of research was the development and publication of the *gate control theory* by Melzack and Wall in 1965.
- Psychological researchers have greatly advanced the field of pain medicine by reconceptualizing both the etiology of pain experience and treatment strategy.
- Several organizations have advanced the science and practice of pain medicine, including the IASP, American Society of Regional Anesthesia and Pain Medicine, AAPM, ASIPP, WIP, SIS, IHS, and INS. Pain medicine practitioners are certified by the American Board of Anesthesiology and the ABPM.

Classification of Acute Pain and Chronic Pain Syndromes

JUAN C. MORA, RENE PRZKORA, MATTHEW MERONEY

Definition of Pain

The International Association for the Study of Pain (IASP) updated the definition of pain in 2020. The previous definition remained unchanged for more than 40 years (originally released in 1979), but it provided a necessary and widely accepted description in the medical field. The 1979 definition of pain was as follows: "An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage."[1] One year later, with a better understanding of pain and new research, the IASP understood the necessity of modifying the definition. They created an expert task force comprising 14 members. After two years of discussion, the 2020 definition was updated to read: "An unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."[2] This new definition includes those unable to articulate their pain verbally, such as infants and the elderly.

It is also important to note a few items to make this definition complete:[2]

1. Pain is a personal experience influenced by biologic, psychological, and social factors.
2. Pain cannot be inferred solely from activity in sensory neurons or nociceptors.
3. Each individual will learn the concept of pain through life experiences.
4. The report of an experience of pain should be respected.
5. Despite having an important adaptive role, pain may have adverse effects on function and social and psychological well-being.
6. A verbal description is only one of several behaviors to express pain, and the inability to communicate does not negate the possibility of experiencing pain.

Taxonomy and Classification

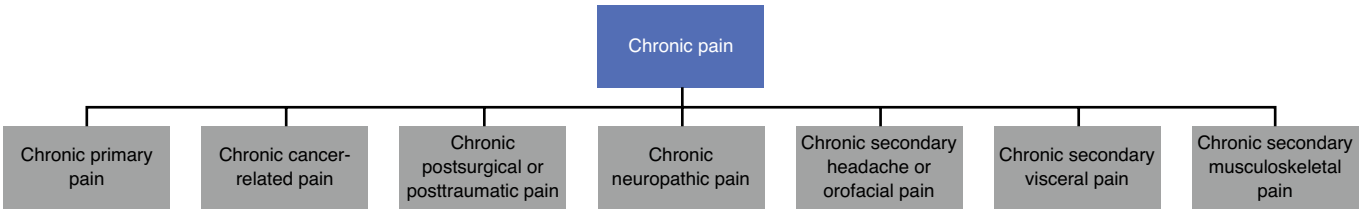
Taxonomy derives from the Greek words *tasso* (arrangement) and *nomia* (rules or law), and it is defined as an organization of concepts arranged using hierarchical relationships. The purpose of creating a medical classification is pragmatic and includes exchanging standardized information, facilitating statistical comparisons, and improving research at national and international levels.[3] An ideal classification should be comprehensive, biologically plausible, reliable, and exhaustive, and each item should be independent and mutually exclusive. However, achieving all of these can be challenging in medical taxonomy.[3]

Currently, there are multiple classifications, groupings, and descriptions of different medical disciplines. Perhaps the most well known is the International Classification of Diseases (ICD), which includes multiple diagnoses and is used worldwide. Classifications related to pain have also been developed. Currently, there is a classification for psychiatric conditions that can be found in the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*, fifth edition (V). The categorization of headaches can be found in the International Classification of Headache Disorders. The classification for acute pain can be found in the ACTTION-APS-AAPM Acute Pain Taxonomy (see Section E, Acute Pain, for more on this workgroup). The classification of chronic pain was provided by the IASP.

International Classification of Diseases (ICD)

In 1793, Dr. Francois Bossier de Sauvages de Lacroix, a French physician and botanist, developed a categorization of 10 main pathologic conditions, subdivided into 2,400 unique diseases. This is believed to be the origin of the ICD.[4] In 1853, a plan was made to create a worldwide system for classifying causes of mortality during the International Statistical Congress. This work was completed in 1893 and named the "International List of Causes of Death." This list was adopted by multiple countries, including the United States, and was updated every decade until 1938. In 1948, it was renamed the ICD when the World Health Organization took over this classification system, expanding the list to include not only mortality but also morbidity.[4] The ICD-6 was the first version to include psychiatric disorders. Starting with the ICD-9 in 1977, the list included 4-digit-level categories and optional 5-digit subdivisions, resulting in a better level of detail. This was advanced in 1992 with the ICD-10 when an alphanumeric code was introduced, dramatically improving specificity and expanding it from 17,000 to approximately 155,000 codes.[4] In this version, the conditions were classified by causal agents, systems of the body, symptom pattern, and type of psychiatric illness.[3] The implementation of the ICD-10 in the United States was officially approved in 2015 with clinical modifications.

The 11th and newest version of the ICD was released in 2018 and approved by the World Health Assembly in 2019. With the contribution of an IASP taskforce, this version is considered more flexible than its predecessor. It has vast advantages in terms



• **Figure 2.1** International Classification of Diseases (ICD)-11 chronic pain terms.

of chronic pain definitions, given that in the past, this type of pain was associated with only a pathophysiologic mechanism, neglecting the psychological and social contributors.[5] In practical terms, chronic pain is still defined as pain that persists over three months.[5] An extremely relevant change is the differentiation of primary versus secondary pain syndromes, with the inclusion of the term "chronic primary pain." This term is intended to group several poorly understood conditions with the important component of emotional distress and/or significant functional disability not accounted for by other diagnoses.[5,6] Chronic pain would then be the parent code of seven children codes that comprise the most relevant groups of chronic pain conditions: chronic primary pain, chronic cancer-related pain, chronic postsurgical or post-traumatic pain, chronic neuropathic pain, chronic secondary headache or orofacial pain, chronic secondary visceral pain, and chronic secondary musculoskeletal pain (Fig. 2.1).[5,6] These changes are promising to improve the acquisition of accurate epidemiologic data, provide adequate billing, and potentiate the development and implementation of new therapies for chronic pain conditions.

IASP Chronic Pain Classifications

The initial attempts to describe the taxonomy of chronic pain came from the IASP and were spearheaded by Dr. John Bonica[7] and Dr. Harol Merskey.[8] This was first published in 1986, followed by a modification in 1994 and subsequent small updates. The group defined the temporality of chronic pain as pain that has been present for more than six months.[8] Their classification method was based on a multiaxis approach, using the five main pain axes (Table 2.1). Combining various pain characteristics and the axes, which are signified by a specific number, would allow most existing pain syndromes to be represented by a five-digit code (Table 2.2).[8]

The first axis addresses the region (anatomic location) where the pain occurs and is chosen for practical purposes. Any chronic pain can be easily identifiable by the region of the body compared to identification by etiology, as the latter has proven very challenging and not always possible. Therefore the etiology was assigned to the last axis of the list.[9] The second axis represents the systems of the body that are involved in the pain (e.g., musculoskeletal, nervous, gastrointestinal) and provides the second digit of the code. The third axis describes the temporal characteristics of pain, with special attention to the pattern of occurrence (e.g., single episode, continuous, recurring, paroxysmal). The fourth axis deals with the patient's statement of intensity and is intended to capture the patient's own experience and report on the severity and duration of the pain. The fifth and last axes refer to the etiology of the pain and are possibly the ones with more challenges given the lack of understanding concerning the etiology of some painful conditions. It is not uncommon that this digit of the code is left unknown. At the end of this five-digit code, a letter can be added to increase the granularity of the taxonomy system. For example, the letter "a" could be added for acute, "s" for spinal pain, and "r" for radicular pain.[8]

TABLE 2.1 Pain Axes

Axis I	Regions
Axis II	Systems
Axis III	Temporal characteristics of pain: pattern of occurrence
Axis IV	Patient's statement of intensity
Axis V	Etiology

Acute Pain

This chapter would not be complete without addressing acute pain. The Acute Pain Medicine Shared Interest Group defines acute pain as "the physiologic response and experience to noxious stimuli that can become pathologic, is normally sudden in onset, time-limited, and motivates behaviors to avoid actual or potential tissue injuries."[10] It is part of the unavoidable core experiences and has been evolutionarily preserved to serve an essential role in protecting the host against multiple threats.[11] Timing differentiation between acute and chronic pain has had multiple definitions in the past, ranging from seven, 14, and 90 days to six months,[11–13] or when it persists past the normal time of healing.[7] However, there has to be an understanding that the transition from acute to chronic pain is a continuum, and they are not completely separate entities. Determining the cutoff time between the two could be very challenging and almost impossible.[11]

Most taxonomy attempts have been performed mainly for chronic pain. However, acute pain has not yet been fully considered. Classifications of acute pain were mainly unidimensional, focusing on sensory experience (pain intensity) and the use of different scales for its measurement.[11] Recent research has discussed that pain trajectories are an important concept and that there are multiple dimensions for acute pain.[11,14–16]

In 2016, the Analgesic, Anesthetic, and Addiction Clinical Trial Translations, Innovations, Opportunities, and Networks (ACTTION) public-private partnership with the US Food and Drug Administration, the American Pain Society (APS), and the American Academy of Pain Medicine (AAPM) collaborated to create the ACTTION-APS-AAPM Acute Pain Taxonomy, which provides a multidimensional classification for acute pain with five dimensions of pain, as described in Table 2.3. They also differentiate between acute pain as surgical/procedural (e.g., general surgery, dental surgery, orthopedic surgery) and nonsurgical

TABLE 2.2 IASP Axes with Codes

Axis I: Regions	
Head, face, and mouth	000
Cervical region	100
Upper shoulder and upper limbs	200
Thoracic region	300
Abdominal region	400
Lower back, lumbar spine, sacrum, and coccyx	500
Lower limbs	600
Pelvic region	700
Anal, perineal, and genital region	800
More than three major sites	900
Axis II: Systems	
Nervous system (central, peripheral, and autonomic) and special senses; physical disturbance or dysfunction	00
Nervous system (psychological and social)*	10
Respiratory and cardiovascular systems	20
Musculoskeletal system and connective tissue	30
Cutaneous and subcutaneous and associated glands (breast, apocrine, etc.)	40
Gastrointestinal system	50
Genito-urinary system	60
Other organs or viscera (e.g., thyroid, lymphatic, hemopoietic)	70
More than one system	80
Unknown	90
Axis III: Temporal Characteristics of Pain: Pattern of Occurrence	
Not recorded, not applicable, or not known	0
Single episode, limited duration	1
Continuous or nearly continuous, nonfluctuating	2
Continuous or nearly continuous, fluctuating severity	3
Recurring irregularly	4
Recurring regularly	5
Paroxysmal	6
Sustained with superimposed paroxysms	7
Other combinations	8
None of the above	9
Axis IV: Patient's Statement of Intensity: Time Since Onset of Pain	
Not recorded, not applicable, or not known	.0
Mild	
- One month or less	.1
Medium	
- One month to six months	.2
- More than six months	.3
- One month or less	.4
Severe	
- One month to six months	.5
- More than six months	.6
- One month or less	.7
- One month to six months	.8
- More than six months	.9
Axis V: Etiology	
Genetic or congenital disorders	.00
Trauma, operation, burns	.01
Infective, parasitic	.02
Inflammatory (no known infective agent), immune reactions	.03
Neoplasm	.04
Toxic, metabolic, radiation	.05
Degenerative, mechanical	.06
Dysfunctional (including psychophysiologic)	.07
Unknown or other	.08
Psychological origin (e.g., conversion hysteria)	.09

(e.g., neuropathic, ischemic, visceral, trauma, musculoskeletal), which allows physicians to identify conditions where it is possible to intervene before the onset of pain or tissue injury, potentially avoiding the progression to chronic pain.[11]

Headache Classification

The *International Classification of Headache Disorders* 3rd edition must be mentioned when evaluating headaches. This classification has created an orderly taxonomy of typically poorly classified neurologic diseases. The intuitive 1- to 5-digit classification code (Table 2.4) caters to general practitioners and headache specialists alike, and it allows for broad or specific diagnoses. The first digit determines the most general type of headache experienced by a patient. For example, (1) migraine, (2) tension-type headaches, and (3) trigeminal autonomic cephalalgias. More specific information leads to a more specific code: 1.2.3.1.1, which indicates familial hemiplegic migraine type 1.[17]

New Pain Classification

Efforts have been made to expand the descriptive factors of chronic pain. Until recently, pain was divided into nociceptive and neuropathic groups. Nociceptive pain is known as pain that

TABLE 2.3 ACTTION-APS-AAPM[a] Acute Pain Taxonomy Acute Pain Dimensions[11]

Dimensions	Description
#1: Core criteria	Specifies the inciting event, time from the event, and tissue involved.
#2: Common features	Characterizes the acute pain condition through common pain variables (symptoms, signs, quality).
#3: Modulating factors	Includes comorbidities (i.e., opioid tolerance) as well as sociodemographic, biopsychosocial, and surgical factors that may modulate the acute pain experience.
#4: Impact/functional consequences	Describes the recovery trajectory, including the interrelationship of the physical, social, psychologic, and vocational consequences resulting from the acute pain condition.
#5: Putative mechanisms	Includes the neurobiologic mechanisms related to the acute pain condition.

arises from actual or threatened damage to non-neural tissue and is because of the activation of nociceptors, and neuropathic pain is defined as pain caused by a lesion or disease of the somatosensory nervous system.[18,19] A growing body of data has begun to show the need for a third descriptor of pain that occurs in patients who do not have acute tissue injury or signs of neuropathy.[20] The term "nociplastic pain" is defined as pain that arises from altered nociception despite no clear evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence for disease or lesion of the somatosensory system causing the pain.[18,19] It has been created to describe dysfunction in nociceptive processing that results in hypersensitivity to seemingly normal sensations. Chronic pain conditions that demonstrate evidence of altered nociceptive processing may include fibromyalgia,[21] complex regional pain syndrome,[22] irritable bowel syndrome,[23] and visceral pain disorders,[24,25] among others. These efforts are meant to address pain that may frequently be classified as "pain of unknown origin," previously known as idiopathic pain. However, a distinction needs to be made that this new descriptor should be used when patients note altered nociception, and it would not be appropriate for a patient who notes pain without hypersensitivity. Critics of this new classification argue that nociceptive and neuropathic pain may be proven by the identification of damage to tissue or nervous structures. Proponents agree that no structural pathology accounts for the pain, but tests such as sensory testing,[22,25–29] sensory-evoked potentials,[30–32] and functional magnetic resonance imaging[21,25,33,34] support altered nociceptive processing.

Psychiatric Aspects of Chronic Pain

The diagnosis of chronic pain related to psychiatric disorders has recently been updated in the DSM-V. The DSM-IV contains somatization disorders, including hypochondriasis, pain disorder, and undifferentiated somatoform disorders that have been removed. These diagnoses were criticized because of their overlap and the resulting lack of clarity regarding the appropriate diagnosis. They required a specific number of complaints from four symptom categories and the need for somatic symptoms to be medically unexplained. The DSM-V replacement states that somatic symptom disorder encompasses somatic symptoms that create dysfunction or distress with significant thoughts, feelings, or behaviors focused on those symptoms for longer than six months. The requirement for medically unexplained symptoms was removed. Therefore the patient's symptoms may be related to other medical conditions. This change aimed to reduce the number of disorders a patient may be diagnosed with while making criteria more straightforward for non-psychiatric care physicians.[35]

The psychiatric aspects of chronic pain have evolved consistent with the changes in the DSM-V described above, psychiatric aspects of chronic pain have evolved. The focus on determining whether the patient's symptoms are medically unexplained, which in itself can be very challenging, has lessened, and more importance has been placed on symptoms. Generally, it is not recommended to give an individual a diagnosis of a mental disorder solely because a medical cause has yet to be established. This contrasts with previous methodologies that sought to categorize a patient's pain as related to a known medical problem versus a psychological origin, as noted in the DSM-IV. Several elements may contribute to somatic symptoms, including biologic vulnerability to increased pain,[20] traumatic experiences, and learned behaviors (care obtained from illness), as well as cultural practices that negatively brand psychological complaints compared to physical ones. Significant data have disproved the mind-body dualism view that the mind and body are distinct and separable. Patients who suffer from both pain and depression have been found to experience reduced physical, mental, and social functioning compared to patients with only depression or pain. Therefore treatments such as cognitive behavioral therapy for a patient with depression may have a significant impact on pain.[36] This being said, there are situations such as conversion disorder where it is possible to conclude that the patient's symptoms are not possible when considering medical pathophysiology.

International Psychiatric Classifications

There are two main entities in world psychiatric classification: the DSM, created by the American Psychiatric Association, and the ICD, created by the World Health Organization. Notably, the DSM is used mainly by psychiatrists in the United States, and the ICD system is used globally and is intended for use by all health practitioners. The ICD-10 classification of mental and behavioral disorders preserves parallel categories to those used in the DSM-V, although the descriptions are often different. However, the ICD-10 classification does not use the "checklist approach," but rather provides a general description and major criteria required.[35,37]

The ICD classification system has often been criticized for its representation of chronic pain.[6,38] Specifically, it has been claimed that the system allows for the documentation of chronic pain but lacks the ability to directly connect it to an additional (i.e., psychological) diagnosis that may be its cause. This could have the effect of confusing other medical providers who may think that the chronic pain condition is not associated with another separate condition. For example, pain because of known or inferred psychophysiologic mechanisms such as muscle tension pain or migraine, which is still believed to have a psychogenic cause, is coded under psychological or behavioral factors associated with disorders or diseases classified elsewhere (e.g. muscle tension pain or migraine). Musculoskeletal pain is organized according to anatomic sites but does not reference the underlying mechanism of pain.[38] The ICD-10 classification does provide a separate category of pain disorder, somatoform disorders F45.41 (pain disorder exclusively related to psychological factors). In essence, this category corresponds to what the DSM-V now calls somatic symptom disorders. In the ICD-10, the predominant complaint is persistent, severe, and distressing pain that cannot be explained fully by a physiologic process or a physical disorder.[37] The next iteration of the ICD, the 11th edition, to be released in 2022, has been created with the goal of further interconnectedness with DSM-V diagnoses to avoid a mismatch of mental pathologizing depending on which classification system is used.

In evaluating disability caused by pain for psychiatric purposes, one can reasonably apply the criteria of the World Health Organization Disability Assessment Schedule, version 2.0. This was created to evaluate a patient's ability to perform activities in six areas: understanding and communicating, getting around, self-care, getting along with people, life activities, and participation in society. This test is based on the International Classification of Functioning, Disability, and Health, and can be used for any medical condition. It may be useful for an initial evaluation to help guide intervention based on high scores in a certain domain or may be repeated to track progress. The World Health Organization Disability Assessment Schedule, version 2.0, is endorsed in the DSM-V and is meant to replace the global assessment of functioning scale previously mentioned in the DSM-IV, which was dropped because of concerns over a lack of clarity regarding symptoms, suicide risk, and disabilities.[35]

Key Points

- Pain is defined as "an unpleasant sensory and emotional experience associated with, or resembling, that associated with, actual or potential tissue damage."
- Taxonomy is the organization of concepts arranged using hierarchical relationships.
- The purpose of creating a medical classification is to exchange standardized information, facilitate statistical comparisons, and improve research at the national and international levels.
- Medical classifications also provide guidance for billing and reimbursement.
- Currently, multiple taxonomy systems classify medical conditions related to pain syndromes: ICD, chronic pain (IASP), ACTTION-APS-AAPM Acute Pain, DSM, and the International Classification of Headache Disorders.
- The ICD-10 is currently used worldwide, and the ICD-11 version is intended to be adopted in the near future.
- The IASP classification of chronic pain uses five axes: anatomic location, systems involved, temporal characteristics, intensity, and etiology.
- Pain can be described as nociceptive, neuropathic, and nociplastic.
- Nociplastic pain is defined as pain that arises from altered nociception despite no clear evidence of actual or threatened tissue damage causing the activation of peripheral nociceptors or evidence of disease or lesion of the somatosensory system causing pain.

Organizing an Inpatient Acute Pain Service

PREETMA KAUR KOONER, GREGORY W. TERMAN

The Rationale

Over the last decade, several surgical practices and public health initiatives, in addition to drug and technology advancements, have impacted inpatient acute pain services worldwide, for example, the continued development and implementation of less invasive surgical techniques, such as arthroscopy. Laparoscopy and robot-assisted surgery have reduced post-surgical pain and allowed nearly two-thirds of surgeries to be performed on an outpatient basis.[1] Nonetheless, moderate to severe pain is common after outpatient procedures as well,[2] and pain is still a leading cause of why patients scheduled for outpatient surgery are unable to go home and remain as inpatients. Indeed, the last minute consults stating that "pain is the only thing keeping [patient name] here" has become an increasingly common refrain. In short, even if outpatient surgery pain is treated effectively in an institution, inpatient post-surgical patients can be expected to have high levels of pain on average, as more patients and procedures are deemed suitable for outpatient surgery. This may explain why pain after inpatient surgery has shown only a marginal reduction in patients suffering from moderate to severe pain, dropping from 80% in 1995[3] to 65% in 2015[4]—despite an increase in inpatient pain services.

Post-operative pain management in both inpatient and outpatient settings has also been complicated by the dramatic increase in opioid-related morbidity and mortality from both illicit and prescribed opioids, which have occurred since the turn of the century (the so called "opioid crisis"). Sometimes conflicting regulatory, legislative, insurance, and institutional policies, largely aimed at outpatient opioid prescribing, have proven, at best, difficult to remember and, at worst, impediments to patient-centered post-operative pain care. Both primary care services and the patients they care for are often reluctant to use opioid analgesics for fear of side effects. In this regard, it is necessary to remember that ineffective post-operative pain management is also associated with a variety of medical and economic "side effects," including readmissions,[5] patient dissatisfaction with medical care,[6] possible transition to chronic pain,[7] and extended lengths of treatment (which has been associated with opioid use disorder diagnoses).[8] Moreover, with or without consistent evidence based policies and guidelines, achieving satisfactory acute pain management is challenging since patient post-operative analgesic requirements vary widely even following the same surgery. Several patient factors have been reported to influence post-operative opioid requirements, including:

- Preoperative pain sensitivity[9]
- Coexisting medical conditions and associated multiple drug administration[4]
- Pre-surgical opioid tolerance or history of drug abuse[10]
- Psychological factors, including catastrophizing, and anxiety[11,12]
- Age[13]
- Type of surgery[10]

Great care must be taken to consider all the characteristics mentioned above when deriving an analgesic plan for managing an individual's response to a surgical insult. Such careful acute pain management does not include opioids and has never been involved. The time is long past when acute or chronic pain caregivers should think of "opioid treatment" and "pain management" as synonyms. However, how can we explain how the 2001 "pain is the fifth vital sign" campaign has, in retrospect, been vilified as a plot to increase opioid prescribing? A "vital sign" implies assessment, not a particular treatment—just as a heart rate of 100 may be treated quite differently in a fetus *in utero* than in a cardiac cripple.

In summary, acute pain, if not pain in general, still suffers from a lack of careful assessment and functional goal-directed multimodal therapy. Despite repeated educational initiatives worldwide, including the International Association for the Study of Pain (IASP) *Global Year Against Acute Pain in 2011,* followed by the *Global Year Against Pain After Surgery in 2017,* and even the *Global Year of Prevention of Pain in 2020.* This chapter posits that investing in an inpatient-based acute pain service is still the best mechanism to ensure effective and safe acute pain care.

General Principles

The sequelae associated with acute pain, including surgical procedures, result from various components of the stress response, including cardiopulmonary, infectious, and thromboembolic complications, cerebral dysfunction, nausea and gastrointestinal paresis, fatigue, and prolonged convalescence. Throughout the process of organizing an acute pain program, it is helpful to remember the following statements:

- The post-operative pain management regimen should be designed with attention to providing patient comfort and

inhibiting nociceptive impulses sufficient to allow appropriate rehabilitation.

- A time-, energy-, and cost-effective acute pain program should optimally provide multimodal and multi-disciplinary interventions, including systemic and regional pharmacologic,[14] and non-pharmacologic treatments,[15,16] including stress reduction, transcutaneous electrical nerve stimulation, music therapy, and acupuncture.
- Surgical stress responses are inhibited most effectively by the neuraxial administration of local anesthetics, and the administration of other agents—systemically, neuraxially, or perineurally—contribute little additional reduction of the endocrine (metabolic and catabolic) stress response following operative procedures.[17,18]
- Parenteral opioids exaggerate the perioperative immune depression already triggered by the neuroendocrine response to surgery, although the clinical relevance of this observation is controversial.[19] Opioids administered into the epidural space have minor suppressive effects on surgically induced proinflammatory cytokines.[20]
- Effective analgesia can reduce post-operative morbidity and improve function. For example, thoracic epidural analgesia has been shown to improve post-operative spirometry and reduce pulmonary infections and atelectasis.[21,22]

The experience of a skilled anesthesiologist lends itself to providing leadership within an acute pain service. Anesthesiologists are proficient in the use of systemic and regional analgesic techniques, including peripheral and neuraxial nerve conduction blockade. They also often understand the surgical techniques and the insults that they impose and are frequently equipped with leadership skills for working within a multi-disciplinary team from their work in the operating room. Nonetheless, an anesthesiologist-based team is not the only service model. Nurse-based, anesthesiologist-supervised, inpatient acute pain services have also been demonstrated to provide safe and effective post-operative pain management.[23,24] Regardless of the service model, nursing involvement in an inpatient acute pain service is essential. Bedside nurses' impressions of a patient's analgesic needs and recovery is an invaluable element in the decision making process for any given patient, and because it is the nurse who will ultimately be delivering the care, nurses must understand the analgesic plan, goals, policies, and procedures that might pertain to their pain care.

Detailed practice guidelines and protocols can help streamline the ordering and implementation of patient care. Well-established protocols have been shown to reduce errors in realms outside pain management[25] and decrease the cost associated with prescribing choices.[26] At the University of Washington Medical Center, we have instituted multiple protocols, including order sets for patient-controlled analgesia (PCA), continuous and patient-administered epidural analgesia, ketamine and lidocaine infusions, and continuous perineural catheter infusions (Figs. 3.1-3.5). PCA and epidural analgesia protocols must include titration and bolus instructions to treat breakthrough or incident pain. Order sets should also include routine and specific monitoring orders, as well as treatment options for common and/or dangerous side effects (e.g. antiemetics and/or antipruritics, and opioid receptor antagonists to reverse respiratory depression). Ketamine, intravenous lidocaine, and perineural anesthetics are most frequently used as adjuncts to other analgesic therapies (e.g. PCA opioids and scheduled acetaminophen and/or nonsteroidal anti-inflammatory drugs). The recovery room, intensive care unit, and medical/surgical floor nurses must be trained to be familiar with the order set parameters. In most cases, nurses can autonomously assess patients and implement changes that successfully achieve adequate analgesia with minimal side effects.

An emerging area of concern for any anesthesiology-based pain service is the complexity of managing invasive pain management techniques (e.g. epidurals) in an era where an ever-increasing number of anticoagulants are given as treatment or prophylaxis for many medical and surgical indications. These indications include treatment of cardiac arrhythmias, valvular disease, and deep vein thrombosis prophylaxis. To aid in treating such patients with the least risk, the University of Washington Medical Center has designed institutional guidelines (based on national guidelines such as those of the American Society of Regional Anesthesia)[27] for the management of indwelling neuraxial and peripheral nerve catheters in patients treated concomitantly with anticoagulants (see Chapter 74). This document was designed to address the placement, maintenance, and removal of catheters in several common anticoagulation scenarios. The intention of such guidelines, which are linked to the electronic medical record, is to distill the existing scientific evidence and opinion into a format that is easy to access and apply in the patient care workflow.

Identifying Service Leadership

It is important to recognize at the outset of establishing a pain service that it is a major endeavor. Planning, design, and implementation of a successful service will require substantial human and material resources. If the need and desire for an acute pain service exist within a hospital facility, one must first elicit support from the anesthesiology department's chairperson. Although multiple design models for acute pain management services are possible, most will require that an anesthesiologist be made available for some level of participation in the service. Unless resources allow an anesthesiologist to be easily released from operating room obligations, the staffing conflict presents a difficult challenge. An agreeable arrangement of service responsibilities must allow the anesthesiologist or his or her delegates to be available to provide safe and consistent care to whomever he or she is responsible, 24 h a day and seven days a week.

Once the intradepartmental resource allocation issues have been discussed with the chairperson, the proposal to begin an acute pain service should be brought to the medical director as a representative of the facility's administrative team. The commitment of the medical director to the project will be necessary to provide resources in the form of personnel and money.

Appropriate leadership for acute pain services must be selected. Operating a service requires a diverse constellation of skills. The service director must have knowledge of the mechanisms of acute post-surgical pain and the methods of treatment, including opioid and non-opioid analgesics, epidural and peripheral nerve catheter placement and maintenance, and ketamine, lidocaine, and other adjuvant drug therapies, as well as treatments for the side effects of these therapies. An anesthesiologist is often the best fit because he or she has experience with these pharmacologic approaches. The recent formation of Accreditation Council for Graduate Medical Studies (ACGME) accredited fellowship programs, combining regional anesthesia and acute pain training, has been in direct response to this understanding that anesthesiology training results in clinicians well suited for providing acute pain management. Indeed, many early acute pain services, like the one started by Dr. Brian Ready at the University of Washington in the 1980s, grew out of the obstetric anesthesia team and the regional anesthetists working thereon. Nonetheless, it is important to distinguish

between a regional anesthetist's goal of keeping a patient comfortable enough to stay *still* for a painful procedure and an acute pain practitioner's goal of keeping a patient comfortable enough to *move* during rehabilitation. Zero out of ten pain is rarely an option or goal for acute pain services. In this regard, as mentioned previously, non-pharmacologic therapies (including physical, psychological, and complementary medicine techniques) also play a role in acute pain treatment, although they are rarely used in the operating room. Acute pain service leaders must be aware of the value and indications for the full panoply of therapeutic strategies for pain.

In addition to expertise in analgesic therapies, the success and stability of any new acute pain service will require that the service director also possess certain nonclinical skills, including strong leadership, organizational, communication, and administrative abilities. The clinical success of an inpatient pain service demands the integration of multiple clinical disciplines, such as nursing, anesthesiology, medicine, physical therapy, and pharmacy. The service director must merge the strengths of these diverse professionals such that their efforts are collaborative—both outside of the normal silos inherent to patient care and without undue power struggles or inefficiencies that can arise within a multi-disciplinary team. In addition, the leader will need to understand the place of the acute pain service within the structure of the health care organization. The service should be seen as efficient and valuable to the hospital and its surgical services.

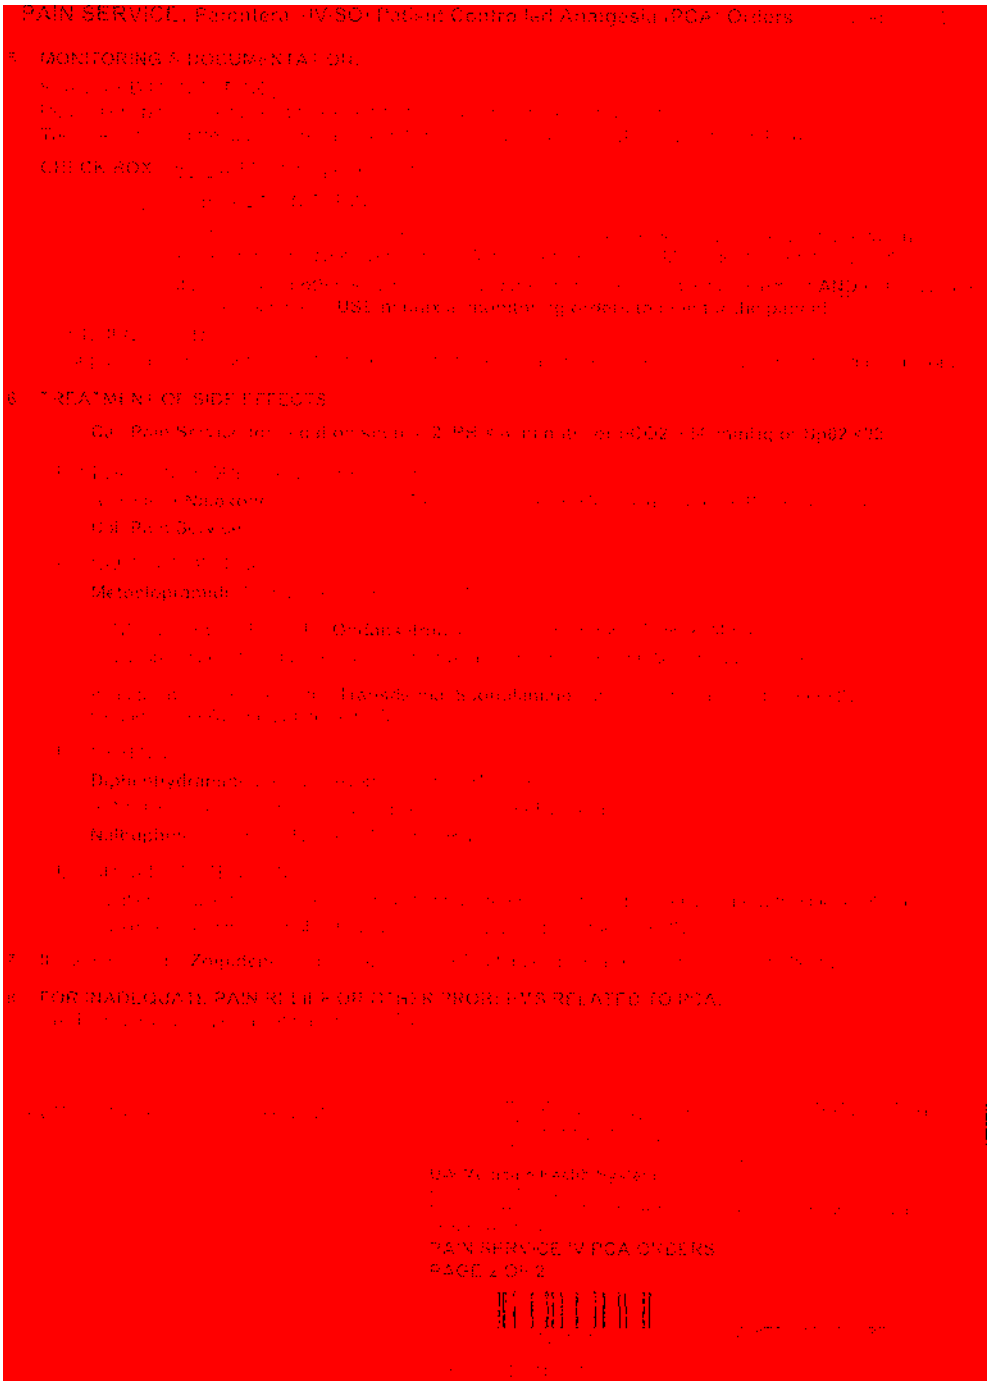
B



• **Figure 3.1, cont'd.**

A clinical nurse specialist (CNS) or equivalent is an additional cornerstone on which to build any new inpatient pain service. The primary responsibility of the CNS is to provide ongoing education for intensive care, recovery rooms, and medical/surgical care nurses concerning pain protocols. At the University of Washington Medical Center, a CNS in pain has been a part of the acute pain service from day one (only four different individuals in 35 years). In addition to nursing education, the CNS is involved in equipment trialing and purchasing, order and policy development, committee work on pain-related (though not necessarily pain service-related) hospital committees, and helps to resolve any conflicts that might arise between nursing and prescribing care team members. Over the years, the CNS's salary has been shared to different degrees between departmental and hospital sources.

More recently, pharmacists have begun to play a valuable role in inpatient pain services. Their understanding of drug actions, metabolism, interactions, and side effects has proven ideal for promoting safe pharmacologic pain management. Moreover, their knowledge of drug costs, prescription drug monitoring program benefits and weaknesses, and electronic health record ordering peculiarities have opened the door for practical teaching of

trainees and more experienced practitioners alike. In our inpatient pain service, pharmacists seem to enjoy patient interactions (including symptom assessment and education) and have become vital parts of our multi-professional team.

Assessment of Need

Once the challenge of implementing an acute pain service is accepted, and leadership is identified, assessment of specific needs for the service is mandatory. This might be accomplished by surveying the patient population, nurses, types of specialty services, procedures commonly performed, and the people performing these procedures. Furthermore, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) has set forth standards declaring the patient's right to adequate pain assessment and treatment and has explicitly acknowledged that pain is a coexisting condition with many diseases and injuries that require explicit attention. Although JCAHO updated its pain-related requirements in 2017,[28] the importance of pain assessment and therapy was not diminished, and the updates were mostly focused on safer opioid prescribing including teaching and practice of multimodal analgesic therapies. This encourages more hospital expertise in

B

• **Figure 3.2, cont'd.**

pain management, and on this basis, the mission statement of the service should be defined.

Those planning the structure of the service might also consider whether they wish to distinguish between different types of pain management challenges or manage them as conglomerates. For example, the University of Washington Inpatient Pain Services is divided into three factions: acute pain, chronic/cancer pain, and interventional pain. The service was separated into these groups to preserve the continuity of care (e.g. inpatient admissions of patients followed by an outpatient cancer pain clinic), and more practically manage the high volume of patients (when only a subset of practitioners on a service have the training or experience to perform certain interventional procedures). Admittedly, the boundaries between these categories are artificial and may overlap. For example, consider a patient with acute post-surgical pain superimposed on long-standing cancer pain or a patient who is now recovering from surgery to place an implanted epidural neuromodulating device for treating chronic pain.

Whatever the organizational structure, an acute post-operative pain management service is likely to require 24 h a day and seven

PAIN SERVICE: Pain Management Ketamine Continuous Infusion Orders

1. Prescription:

Drug:	Ketamine – Non Anesthetic Dosing
Concentration:	1mg/mL Send in 250mL normal saline bag
Route:	IV infusion
Infusion Rate: DO NOT TITRATE, DO NOT BOLUS	_____mg/hour (For Postoperative patients: Do not exceed 8mg/hour infusion rate on medical surgical and oncology floors)
Infusion Device:	Standard pain infusion pump Drug is to be secured in locked box with the pump.

2. Change Ketamine bag every 24 hours (related to stability in IVF bag).
   Order next bag in sufficient time to avoid disruption of continuous ketamine infusion.
3. Monitoring and Documentation:
   Ketamine drip initiation: Blood pressure (BP), respiratory rate (RR), pain score, sedation score every 30 minutes for one hour and then every two hours for 8 hours. After 8 hours, monitor RR, pain score, and sedation score every 4 hours while on infusion.
   Ask the patient if they are having hallucinations or unpleasant, disturbing dreams every 8 hours. Document in the clinical record.

   NOTE: Anticipate decreasing opioid requirement/use.

   Infusion rate increases: BP, RR, pain score, sedation score every 30 minutes for one hour, then every two hours for 4 hours and then every 4 hours.

   Check box if special monitoring is required:
   ☐ if patient has **both** neuraxial route (epidural or intrathecal) pain management and Ketamine infusion, **USE neuraxial (epidural or intrathecal) monitoring orders** for RR, pain score and sedation score. BP every 30 minutes for one hour and then every two hours for 8 hours and then every 4 hours.
4. **Call Pain Service pager 986-3334 if**:
   Systolic BP if > or < 30 mm Hg from pre-infusion baseline parameters Baseline BP = _____
   Sedation score > 2 and/or RR < 8 breaths/minute
   Patient reports hallucinations (auditory or visual); feeling dissociated; or reports of unpleasant, disturbing dreams.
   Inadequate pain management
5. Call Pain Service regarding any new orders for opioids or benzodiazepines not ordered by the Pain Service.
6. Patient also has pain service pain management orders for:
   ☐ PCA
   ☐ Neuraxial analgesia (Epidural or Intrathecal)
   ☐ Other: _____

days a week call coverage, with appropriate medical supervision. Immediate availability is important concerning patient safety and patient satisfaction. Inadequacy of pain relief has been highlighted as a quality-of-care measure and a focus on patients' concerns. In a questionnaire survey, 57% of patients identified pain after surgery as their primary fear.[3] Sadly, the removal of specific questions about pain management satisfaction from the Hospital Consumer Assessment of Healthcare Providers and Systems survey, because of unsubstantiated fears of opioid over-prescribing to improve survey scores, is a step back from incentivizing attention to pain hurdles patients face in recovering from painful conditions or procedures and offers another indication that the multimodal approach to pain management is still not widely appreciated. Nonetheless, the competitive healthcare environment mandates that hospitals focus on the most important issues to patients. Favorable reports of patient satisfaction may encourage patients to seek services in a given hospital facility and encourage patient loyalty in return for additional medical care. Furthermore, according to one multicenter prospective cohort study,[29] immediate post-operative patient satisfaction with care is a predictor of long-term, positively self-perceived health status. In short, for many hospitals, following JCAHO's requirement to have a "leadership team that is responsible for pain management" is also simply put, the right thing to do for their patients.

PAIN SERVICE: Pain Management IV Lidocaine Continuous Infusion Orders

Admit / Tx / Medication

GENERAL GUIDELINES:1. No Titration or bolus. 2. No routine therapeutic drug level monitoring. 3. Generally used for 24-72 hours as an adjunct to existing pain treatments (including epidural, PCA and ketamine for analgesia). 4. Select dose below according to patient weight (MAXIMUM rate = 120 mg/hr

Patient weight < 45 kg = Lidocaine 30 mg/hr IV infusion
Lidocaine 2g in D5W (Dextrose 5% in Water) 250mL
Comments: For PAIN. DO NOT titrate, DO NOT bolus

Patient weight 45-55 kg = Lidocaine 75 mg/hr IV infusion
Lidocaine 2g in D5W (Dextrose 5% in Water) 250mL
Comments: For PAIN. DO NOT titrate, DO NOT bolus

Patient weight 56-67 kg = Lidocaine 85 mg/hr IV infusion
Lidocaine 2g in D5W (Dextrose 5% in Water) 250mL
Comments: For PAIN. DO NOT titrate, DO NOT bolus

Patient weight 68-80 kg = Lidocaine 100 mg/hr IV infusion
Lidocaine 2g in D5W (Dextrose 5% in Water) 250mL
Comments: For PAIN. DO NOT titrate, DO NOT bolus

Patient weight > 80 kg = Lidocaine 120 mg/hr IV infusion
Lidocaine 2g in D5W (Dextrose 5% in Water) 250mL
Comments: For PAIN. DO NOT titrate, DO NOT bolus

Vitals / Monitoring

Vital Signs
Lidocaine initiation: BP, HR, respiratory effort (rate, depth, regularity & effort), 02 sat, visual analogue scale (VAS) pain score q1h × 2, then q2h × 2, then q4h if stable

Cardiac Monitoring
It is the responsibility of the ordering provider to assure that a 12 lead EKG has been obtained within the previous 7 days and showed no contraindications (including 1st and 2nd degree heart block)

Neuro Checks
Neuro checks and monitoring for adverse effects/toxicity signs including: disorientation,or confusion, slurred speech, dizziness, sedation, seizure q1h × 2, then q2h × 2, then q4h if stable

Pt Care / Nursing

Call Provider for the Following Vital Signs
SBP> 160, SBP< 90, DBP< 50, RR< 8, and/or sedation scale > 2, if systolic BP is > or < 30 mm Hg from pre-infusion baseline parameters. New development of arrhythmia. CALL or page the Acute PAIN SERVICE (APS) and Primary Service

Call Pain Service for the following signs or symptoms (see order comments) and STOP infusion immediately.
Comments: Patient Assessments: 1) seizure 2) tremor 3) diplopia 4) metallic taste 5) numbness of tongue 6) tinnitus 7) muscle twitching. Provider should consider drawing lidocaine level STAT if side effects are severe. (Please note: this has no therapeutic consequence and is to rule out other etiologies)

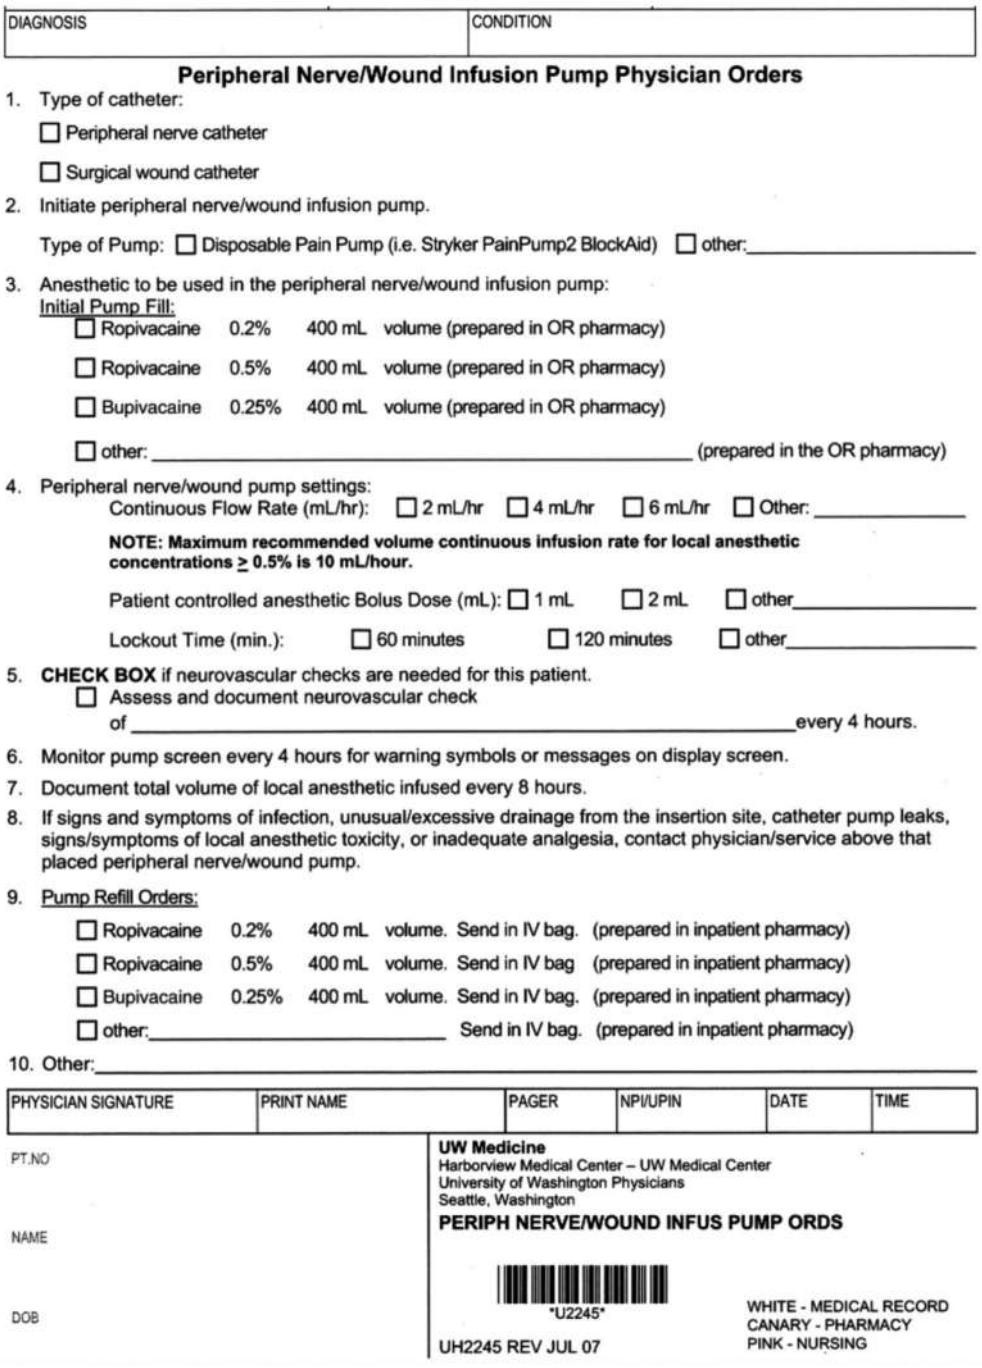
In the very rare event of Local Anesthetic-induced Systemic Toxicity (LAST) call a CODE BLUE immediately and implement: 1. Airway management to deliver Oxygen, 2. Seizure suppression with benzodiazepines, 3. Cardiopulmonary stabilization/resuscitation

• **Figure 3.4** University of Washington Medical Center intravenous Lidocaine infusion standardized order set. Courtesy of University of Washington Medical Center, Seattle, Washington.

Definition of the Service

Once the pain service mission statement has been formulated in response to the perceived institutional and community needs, leadership must define the resources that will be required to meet the needs. The resources and modalities that an acute pain service may use are diverse and depend on the patient population, the skills of the personnel, and the service's therapeutic approach. Ideally, an evidence based approach to the selection of treatment modalities that specifically evaluates the efficacy and cost-effectiveness of each therapy is used. The resources required to implement and operate an acute pain service will represent a synthesis of characteristics of the patient population, evidence based selection of therapeutic modalities, and consistency with the service's mission.

The feasibility of various treatment plans based on the availability of resources was defined by the IASP task force for the management



DIAGNOSIS	CONDITION

Peripheral Nerve/Wound Infusion Pump Physician Orders

1. Type of catheter:
   - ☐ Peripheral nerve catheter
   - ☐ Surgical wound catheter
2. Initiate peripheral nerve/wound infusion pump.
   Type of Pump: ☐ Disposable Pain Pump (i.e. Stryker PainPump2 BlockAid) ☐ other:_____
3. Anesthetic to be used in the peripheral nerve/wound infusion pump:
   Initial Pump Fill:
   - ☐ Ropivacaine 0.2% 400 mL volume (prepared in OR pharmacy)
   - ☐ Ropivacaine 0.5% 400 mL volume (prepared in OR pharmacy)
   - ☐ Bupivacaine 0.25% 400 mL volume (prepared in OR pharmacy)
   - ☐ other: _____ (prepared in the OR pharmacy)
4. Peripheral nerve/wound pump settings:
   Continuous Flow Rate (mL/hr): ☐ 2 mL/hr ☐ 4 mL/hr ☐ 6 mL/hr ☐ Other: _____
   NOTE: Maximum recommended volume continuous infusion rate for local anesthetic concentrations ≥ 0.5% is 10 mL/hour.
   Patient controlled anesthetic Bolus Dose (mL): ☐ 1 mL ☐ 2 mL ☐ other_____
   Lockout Time (min.): ☐ 60 minutes ☐ 120 minutes ☐ other_____
5. **CHECK BOX** if neurovascular checks are needed for this patient.
   ☐ Assess and document neurovascular check
   of _____every 4 hours.
6. Monitor pump screen every 4 hours for warning symbols or messages on display screen.
7. Document total volume of local anesthetic infused every 8 hours.
8. If signs and symptoms of infection, unusual/excessive drainage from the insertion site, catheter pump leaks, signs/symptoms of local anesthetic toxicity, or inadequate analgesia, contact physician/service above that placed peripheral nerve/wound pump.
9. Pump Refill Orders:
   - ☐ Ropivacaine 0.2% 400 mL volume. Send in IV bag. (prepared in inpatient pharmacy)
   - ☐ Ropivacaine 0.5% 400 mL volume. Send in IV bag (prepared in inpatient pharmacy)
   - ☐ Bupivacaine 0.25% 400 mL volume. Send in IV bag. (prepared in inpatient pharmacy)
   - ☐ other:_____ Send in IV bag. (prepared in inpatient pharmacy)

of acute pain (Table 3.1). Individualized treatment of patients should ideally be evidence based (Table 3.2), and several organizations have published guidelines for acute pain treatment.[30,31] A useful, more dynamic resource for evidence based post-operative pain management is the PROSPECT database[32]—hosted and updated by the European Society of Regional Anesthesia and Pain Therapy. This website (https://esraeurope.org/prospect/) offers procedure specific post-operative pain management (PROSPECT) recommendations based on evidence detailed on the site. Such recommended care mixes maximal improvements in patient outcomes with the most cost-effective care available. Indeed, many of the leaders of the PROSPECT project have also spearheaded the so called ERAS (Enhanced Recovery After Surgery) movement to facilitate safe and efficient post-surgical rehabilitation, minimizing hospital stays and thus reducing costs.[33] For example, Dr. Henri Kehlet (a general surgeon) has developed ERAS principles for more than 35 years—emphasizing rapid re-feeding after bowel surgery, including, in part, the use of neuraxial local anesthetics for post-operative pain. Such techniques require special resources in the form of medications, equipment, and personnel, and these must be anticipated and negotiated with the institution's administrative, business, and clinical departments when designing the service structure.

TABLE 3.1 **Options for Acute Pain Treatment Based on Available Resources**

TABLE 3.1A **Attention! When can you Safely do Neuraxial/Peripheral Nerve Procedures or Give Antithrombotic Agents?**
NOTE: For Concerns Related to Bleeding or Traumatic Procedures, Contact Pain Service.

Precautions:

Do NOT give MULTIPLE anticoagulants, including antiplatelet agents, concurrently in patients undergoing Neuraxial/Nerve Procedures.
Delay restarting anticoagulants for 24 h after traumatic needle placement.

MEDICATION	PRIOR TO NEURAXIAL/NERVE PROCEDURE Minimum time between the last dose of antithrombotic agent AND neuraxial injection or neuraxial/nerve catheter placement	B. WHILE NEURAXIAL/NERVE CATHETER IN PLACE Restrictions on the use of antithrombotic agents while neuraxial/nerve catheters are in place and prior to their removal	AFTER NEURAXIAL/NERVE PROCEDURE Minimum time between neuraxial injection or neuraxial/nerve catheter removal AND next dose of antithrombotic agent
ANTICOAGULANTS FOR VTE PROPHYLAXIS			
Heparin unfractionated 5000 units SQ Q8H or Q12H	Maybe give; no time restriction for neuraxial injection or neuraxial/nerve catheter placement **Does not require Pain Service approval**		
* **Heparin** unfractionated 7500 units SQ Q8H	12 h	**CONTRAINDICATED while catheter in place. May NOT be given unless approved by Pain Service or Obstetric Anesthesia Attending**	4 h
* **Dalteparin** (Fragmin) 5000 units SQ QDay * **Enoxaparin** (Lovenox) 40 mg SQ QDay	12 h - CrCl ≥30 mL/min 24 h - CrCl <30 mL/min	**May be given BUT:** • **Must wait for 8 h after catheter PLACEMENT before giving the dose** • **Must wait for 12 h after the last dose before REMOVING catheter**	4 h
* **Enoxaparin** (Lovenox) 30 mg SQ Q12H or 40 mg SQ Q12H	12 h - CrCl ≥30 mL/min 24 h - CrCl <30 mL/min	**CONTRAINDICATED while catheter in place. May NOT be given unless approved by Pain Service or Obstetric Anesthesia Attending**	4 h
Fondaparinux (Arixtra) 2.5 mg SQ QDay	48 h - CrCl ≥30 mL/min CrCl <30mL/min: Call Hematology		6 h
Apixaban (Eliquis) 2.5 mg bid	48 h - CrCl ≥50 mL/min 72 h - CrCl ≥30–50 mL/min CrCl <30 mL/min: Call Hematology	**May be given BUT:** • **Must wait for 8 h after catheter PLACEMENT before giving the dose** • **Must wait for 12 h after the last dose before REMOVING catheter**	6 h
Rivaroxaban (Xarelto) 10 mg po QDay	48 h - CrCl ≥50 mL/min 72 h - CrCl ≥30–50 mL/min CrCl <30 mL/min: Call Hematology		
Betrixaban (Bevyxxa) 80 mg QDay	72 h - CrCl ≥30 mL/min 96 h - CrCl ≥15–30 mL/min CrCl <15 mL/min: Call Hematology		

IM, Intramuscular; *IV*, intravenous; *vPCA*, patient-controlled analgesia; *PO*, by mouth; *PPV*, positive pressure ventilation; *PR*, by rectum; *SQ*, subcutaneous; *TENS*, transcutaneous electrical.

TABLE 3.1B Agents Used for Full Systemic Anticoagulation

Apixaban (Eliquis) 2.5 mg bid - 10 mg bid	48 h - CrCl ≥50 mL/min 72 h - CrCl 30–50 mL/min CrCl <30 mL/min: Call Hematology	**CONTRAINDICATED** **While catheter in place.** **May NOT be given unless approved by Pain Service or Obstetric Anesthesia Attending**	6 h
Rivaroxaban (Xarelto) 15–20 mg po QDay or 15 mg bid	48 h - CrCl >50 mL/min CrCl <50 mL/min: Call Hematology		
Edoxaban (Savaysa) 30–60 mg QDay	48 h - CrCl ≥50 mL/min CrCl <50 mL/min: Call Hematology		
Dabigatran (Pradaxa) 75 mg bid - 150 mg bid	72 h - CrCl 50 mL/min 120 h - CrCl 30–50 mL/min CrCl <30 mL/min: Call Hematology		
Fondaparinux (Arixtra) 5–10 mg SQ QDay	72 h - CrCl ≥30 mL/min CrCl <30 mL/min: Call Hematology		
Dalteparin (Fragmin) 200 Units/kg SQ QDay or 100 Units/kg SQ Q12H	24 h - CrCl ≥30 mL/min 48 h - CrCl <30 mL/min		4 h
Enoxaparin (Lovenox) 1.1–1.5 mg/kg SQ QDay or 1 mg/kg SQ Q12H	24 h - CrCl ≥30 mL/min 48 h - CrCl <30 mL/min		
Heparin unfractionated IV infusion	when aPTT normal or anti-Xa activity is undetectable		
Heparin unfractionated full dose SQ	when aPTT normal or anti-Xa activity is undetectable		
Warfarin (Coumadin)	when INR ≤1.5		
DIRECT THROMBIN INHIBITORS, INJECTABLE			
Argatroban IV continuous infusion	when DTI assay <40 or aPTT <40 s	CONTRAINDICATED While catheter in place. May NOT be given unless approved by Pain Service or Obstetric Anesthesia Attending	4 h
Bivalirudin (Angiomax) IV continuous infusion	when DTI assay <40 or aPTT <40 s		

TABLE 3.1C Antiplatelet Agents Pages 285–286

Aspirin or NSAIDs	**May be Given; No Time Restrictions for Neuraxial Injection or Neuraxial/Nerve Catheter Placement Does Not Require Pain Service Approval**		
Abciximab (Reopro) IV continuous infusion	48 h	CONTRAINDICATED while catheter in place. May NOT be given unless approved by Pain Service Attending	6 h
Aspirin/ dipyridamole (Aggrenox)	24 h		
Cangrelor (Kengreal) IV continuous infusion	3 h		
Clopidogrel (Plavix)	Seven days		
Prasugrel (Effient)			
Ticagrelor (Brilinta)			
Tirofiban (Aggrastat) IV continuous infusion	8 h-CrCL > 50 mL/min CrCl < 50 Call Hematology		
Eptifibatide (Integrelin) IV continuous infusion			

TABLE 3.1C Antiplatelet Agents Pages 285–286—cont'd

Aspirin or NSAIDs	**May be Given; No Time Restrictions for Neuraxial Injection or Neuraxial/Nerve Catheter Placement Does Not Require Pain Service Approval**		
	THROMBOLYTIC AGENTS		
Alteplase (TPA) 1 mg dose for catheter clearance	May be given; no time restriction for neuraxial injection or neuraxial/nerve catheter placement Does not require Pain Service approval (Maximum dose 4 mg/24 h)		
Alteplase (TPA) full dose for stroke, MI	48 h	CONTRAINDICATED while catheter in place. Mat NOT be given unless approved by Pain Service Attending	Ten days

Neuraxial block	A,C	Dose, range, side effects, anatomy	M, N, P, Q, R, S	T, U, W, X, Y, Z	1, 2, 3, 5, 6, 7, 8
Interpleural	A,C,D,E	Dose, range, side effects, anatomy	M, N, P, Q, R, S	T, U, W, X, Y, Z	1, 3, 7
Cryoanalgesia	E, D	Anatomy		Delivery system	1, 3, 7
Psychological support	A, B,C, D, E, F	Coping strategies	Relaxation, breathing exercises	All the above	Time-consuming, adjunct
Acute pain service	A, C, D, E, F, G	All of the above	M, N, O, P, Q, R, S, leadership		Policies, procedures, education, quality assurance

After the resources are defined, the range of therapeutic services to be offered can be determined. The principles of post-operative pain therapy that must be implemented in each patient interaction on the service include:

1. Evaluation of the source and severity of the pain.
2. Understanding the relationship between pain and other components of suffering (e.g. poor prognosis creating reactive depression or anxiety).
3. Achieving and maintaining adequate pain relief and incorporating it into the acute rehabilitation scheme.
4. Refining therapies based on individual needs.

These goals can be achieved through pain services built on different therapeutic emphases. For example, a *single-modality service* allows the provision of analgesia with intravenous opioid systems to all inpatients and the provision of regional analgesia in select instances. This model can be nurse-based with physician supervision and offers a safe, limited, and cost-effective method for the treatment of post-operative patients. On the other hand, a multimodal service includes diverse healthcare professionals from a variety of domains. Extracting and integrating the relevant expertise from these professionals on such services is critical for individualized and optimized pain management. Professionals commonly utilized include psychologists, pharmacists, physical and occupational therapists, nutritionists, and spiritual care providers, in addition to physicians and nurses. The comprehensive approach of multi-disciplinary pain service functions is ideal for inpatients with the most complicated pain issues. Examples include patients with chronic pain suffering from acute exacerbations and post-surgical patients with severe opiate tolerance following long-term opioid treatment. This multi-professional model has been most frequently used in the context of inpatient palliative care consultation at the end of life, but this approach, or some mild modification of it, has utility in the acute care arena as well.[34]

Ongoing quality assurance can be managed on a service, departmental, and/or institutional level but should be transparent to participants and provide an opportunity for feedback and improvement for team members (including trainees and faculty) and service policies and procedures. We have used multi-professional team meetings—no less frequently than every two months as forums to communicate new or updated policies or procedures, clinical questions or concerns, cases of morbidity or mortality, and upcoming or ongoing research updates.

Financing and the Business Plan

The next step in the process of organizing an inpatient acute pain service is to construct a business plan. This is often the most challenging phase because the financial and business skills needed may not be innate to clinical anesthesiologists and are rarely covered in their training. The value analysis of this type of service is not entirely monetary. It should be emphasized that although the cost of delivering care may be considerable, the calculation of the cost analysis is a more complicated determination. The ideal measurement of the utility for pain management is controversial. Researchers have examined outcome measures, including hospital stay, hospital readmissions, quality of life, and clinical productivity.[35] However, regardless of the cost analysis, there is a cultural expectation and ethical imperative supporting the philosophy that appropriate treatment of pain is independently valuable. The JCAHO has emphasized this sentiment in their statement that appropriate pain management is "good medicine" and that pain assessment and pain management should be "an organizational priority."[28,36] With that acknowledgment, the purpose of an acute pain service business plan is to describe the inner workings of the proposed service, including its organizational strategy, marketing plan, tentative schedule for implementation, and overall cost. This must occur before the first cent is spent on the project. The business plan has two primary components.

The first arm of the plan is a narrative that includes the mission statement, its structure, and the responsibilities of the service. Here, the job descriptions of the involved personnel are outlined, facility requirements are listed, and the marketing plan is presented. This document should clarify the role, responsibilities, duties, and expectations of various personnel that are key to a successfully operating service. Guidelines and manuals for nurses and house staff are key to this first portion of the business plan.

The second primary component of the business plan is prepared as a spreadsheet that outlines the finances of the business endeavor, and these estimates must be as accurate as possible. Estimates of fixed and variable incomes, startup capital necessary until revenue produces profit, and a month by month expenditure estimate for at least the first year must be among the data provided in this document.

The plan should also consider the acquisition costs of analgesic medications and other pharmacy costs. Macario and McCoy reviewed the records of 298 patients who underwent hip or knee replacement surgery and found that pharmacy costs accounted for only 3% of the total hospital cost. However, the costs of post-operative analgesics represented 31% of the total pharmacy cost.[37] Intravenous acetaminophen is an example of a useful addition to our analgesic armamentarium, but its absolute indications are few. Studies have demonstrated that intravenous and oral acetaminophen are equally effective for pain,[38] despite their hundred-fold difference in cost. In our hospital, intravenous acetaminophen is to be administered only after acute pain team discussion, and indications for use include only functionally significant pain, patients who can have nothing by mouth including medications, and a contraindication or insufficiency of nonsteroidal anti-inflammatory drugs. If intravenous acetaminophen is approved by the pain team (including the pain service pharmacist), it is only approved for 24 h, at which time indications are assessed again. Similarly, in the last few years, millions of doses of liposomal bupivacaine have been infiltrated by surgeons and anesthesiologists (at hundreds of dollars per dose). However, third-party payers have had very restricted reimbursement policies for the drug, and initial meta-analyses demonstrated limited evidence of clinical advantages over plain bupivacaine (at 1/100th its cost).[39,40] Liposomal local anesthetics may well be found to be efficacious and cost effective in their pain-relieving effects for certain inpatient and/or outpatient procedures or patients. However, it is unlikely that anyone is better positioned to help hospital administrators balance hospital cost and evidence based analgesic efficacy in such therapeutic decision making than acute pain service leadership.

Other cost drivers include human resources in the form of pharmacists and nurses, as well as equipment, including PCA and epidural pumps. Medication errors are another rarely considered factor that increases the cost of post-operative analgesia. Adverse drug events, for example, have been shown to result in extending hospital stay by 4.6 days at a cost of $5857 per patient.[41]

Finally, in this section of the business plan, it is ideal to have an estimate of the anticipated monthly patient load and the minimum number of patients required to support service expenses. This is not as easy a calculation as it might seem and needs to include a discussion of anticipated challenges to reimbursement

either within or outside the institution. For instance, it is necessary to examine the insurance characteristics of the patient population that the acute pain program will serve. Based on the payer mix or the percentage of the population that is served by health maintenance (HMO), preferred provider (PPO), and medical care (MCO) organizations, it may be necessary to arrange plans for the preauthorization of acute pain services with the administrators of local health plans. Additionally, there may be geographical region-specific rules for billing pain services. Post-operative pain services are bundled under Medicare surgical services fees. In our Medicare region, we must provide evidence of a request from the attending surgeon for help with pain management and why such services are requested. For this reason, we have created a pain service consult "order" with several common reasons for pain consultation listed (e.g. opioid tolerance, and regional analgesia evaluation) and have provided this electronic list both as a freestanding order and embedded in the pre-operative surgical order set. We ask our surgical colleagues to fill out this request for service but have thus far chosen not to withhold pain treatment from patients with extreme pain when awaiting electronic referral.

In the construction of the business plan, the total revenue minus the total cost will produce a *predicted* financial position. This calculation begins with the estimation of the approximate charge per patient for each therapeutic modality to be used. With this revenue in mind, the cost of providing the service and various therapeutic modalities can be determined. Ideally, the financial design of the acute pain service should include elements promoting flexibility as the patient loads waxes and wanes. This is best accomplished by shifting fixed costs (e.g. permanent employees) to variable costs (e.g. temporary employees) as much as possible. Note that the result of this calculation will fluctuate over time. The financial solvency of the service will be most protected by hoping for the best while planning for the worst-case scenario.

Billing and Collection

A well-organized structure for billing and collecting services is imperative to ensure the solvency of any medical organization. Knowledgeable personnel, the necessary hardware, and efficient software for data collection are necessary if the service's business plan includes an internal billing and collection group. As medical coding and billing accelerate in complexity and specificity, many organizations have elected to employ outside billing and collection services that operate on percentage-based contracts.

It is crucial to be aware of the current Centers for Medicare and Medicaid Services (CMS) guidelines for documentation and billing and to remain informed about modifications as they occur. Accurate documentation of services will facilitate correct and timely reimbursement, as well as represent what was actually done in the medical record. Furthermore, accurate documentation will clarify what was not done for the reference of both other healthcare professionals and third-party payers, thereby avoiding time-consuming changes in documentation, fines, and even criminal charges if discrepancies between CMS guidelines and physician billing are judged to be fraudulent. Example reference guides regarding chart notation and current CMS-required documentation can be found in the Appendices F. At our particular teaching institution, we have found it useful to "bake" some of the billing criteria into the electronic medical record pain consult note and progress note templates with the use of "hard stops" for vital assessment fields. Documentation of appropriate pain assessments, including analgesic-related side effects, often ensures that suitable levels of billing are accomplished.

Over the last several years at the University of Washington Medical Center, we have transitioned from a resident home night call model to using a team of trained nurse practitioners and physician assistants working in the hospital at night with pain attending home availability for questions (as before). This arrangement has improved patient and nursing satisfaction with a member of the pain team in house and available 24/7 despite only a minimal increase in net personnel costs because we can now bill for post-operative day zero pain assessment and treatment. This additional billing is appropriate, and perhaps even overdue, as, often, the most important pain assessments and treatments occur in the first few hours after surgery,[29] when the pain team might have previously been at home.

Marketing Plan

Once the design and planning of the new acute pain service have been completed, a marketing plan will be important to promote its utilization. Potential referring providers and patients will need to be introduced to the concept and the benefits that the service offers. Although conventional medical education often leaves physicians naive to the business and marketing dimensions of medicine as an industry, help can be garnered from the hospital's public relations office or a private marketing firm. Implementation of the marketing plan is another cost that must be considered in the service budget. Marketing strategies must be designed carefully. It should present a consistent image of the mission and services offered by the budding acute pain service in light that emphasizes the added value to patient care. The marketing strategy may also delicately make a case for the potential cost and convenience of using the new service. Methods for circulating such information may include announcements and brochures, professionally prepared stationary, logos, newsletters, and websites.

Internal education is another vital part of the marketing of acute pain services. Frequent positive interactions between the acute pain service and other departments and their personnel (e.g. presentations at interdepartmental case conferences) are crucial for increasing the visibility of the service and expanding its referral base. In an academic institution, this might also include the involvement of non-anesthesiology residents in the service. When residents rotating from other specialties participate, particularly from the surgical department, they can learn about the treatment modalities offered and the advantages that they provide. Furthermore, several years ago, when we began having anesthesiology residents rotate on the pain service for a month during their pre-anesthesia intern year, we were surprised at the interns' adeptness and seeming enjoyment of the service but also by how we benefited from having "under-cover pain experts" on teams throughout the hospital during the interns' other 11 months. In addition, the importance of education and involvement of nursing and pharmacy colleagues (and their students) cannot be overestimated in helping to grow a pain service since these colleagues are often in a position to suggest that a patient be referred to the acute pain service.

Finally, the marketing plan of an acute pain service should align itself with the JCAHO and its standards and expectations previously described.[28] Implementation and compliance with these standards should serve to propel an acute pain service toward success, given that both aim to make safe pain management a top priority.

Future Service Flexibility

Even after the implementation of an acute pain service, leaders of the service must remain attentive and responsive to changes in the pain care needs of patients, colleagues, or the institution. For instance, recent advances in disposable pump technology have allowed us to offer peripheral nerve blocks on an outpatient basis as surgeries have shifted increasingly to an outpatient setting. Our inpatient acute pain nocturnist team is available at night by telephone should there be any questions or concerns from these patients. On the other hand, our daytime regional anesthesia team educates these patients before discharge (including a written instructional document) and routinely contacts them by phone on post-operative day one to inquire about patient questions and level of satisfaction with their pain care. Whether future advancements in treatments or technology will allow us to provide further evolution of services provided by our inpatient pain team remains to be determined. However, public health and individual complexities in pain management have already prompted us (and others) to use expertise gained from the inpatient pain service to influence safe pain management practices throughout the healthcare system.

Perioperative Pain Clinic

Some inpatient acute pain services have recently been used to provide additional outpatient perioperative pain clinic services as a way of educating, planning, and helping our surgical colleagues manage the most complex post-operative pain patients. Although rules and guidelines by various national societies, legislatures, and insurance carriers have been incorporated into institutional protocols for the management of post-operative pain (sometimes based on actual evidence [30,32.42,43]), there is a subset of patients for whom the standard plan of care is still inadequate. Patients with a history of chronic pain or addiction, who have a history of pain that is difficult to control, or who are at risk for developing chronic post-surgical pain might require a more involved multi-tiered approach to pain in the surgical setting.[44] The development of a perioperative pain management service is one way to improve care for such patients.

Perioperative pain management seeks to bridge the pre-operative, intraoperative, and post-operative periods through patient education and expectation management, enhanced interdisciplinary communication, and expert specialist care throughout the perioperative period. The general principles for treating post-operative pain apply to the rationale for such a service:

- First, as previously mentioned, surveyed patients rate pain control, especially immediately after surgery, as one of their highest concerns and priorities.[45]
- Second, safe and adequate pain control has been shown to reduce post-operative opioid consumption, decrease inpatient hospital length of stay, and prevent the development of chronic pain after surgery.[46]
- A perioperative pain service (in contrast to a more limited inpatient pain service) can give a more structured methodology for treating acute post-operative pain in a specific "at risk" group of patients.[47]
- Finally, a perioperative pain clinic provides another layer of care and safety for the patient, their outpatient providers, and surgeons in the management of perioperative opioid consumption.

In fact, at this time, there are currently few perioperative pain clinics or services nationwide.[49] Therefore the ideal model for such services has yet to be established, and such clinics' long-term effectiveness awaits further study. However, reports from perioperative clinics that are currently operating suggest an improvement in patient outcomes with this intervention and share several characteristics.[48]

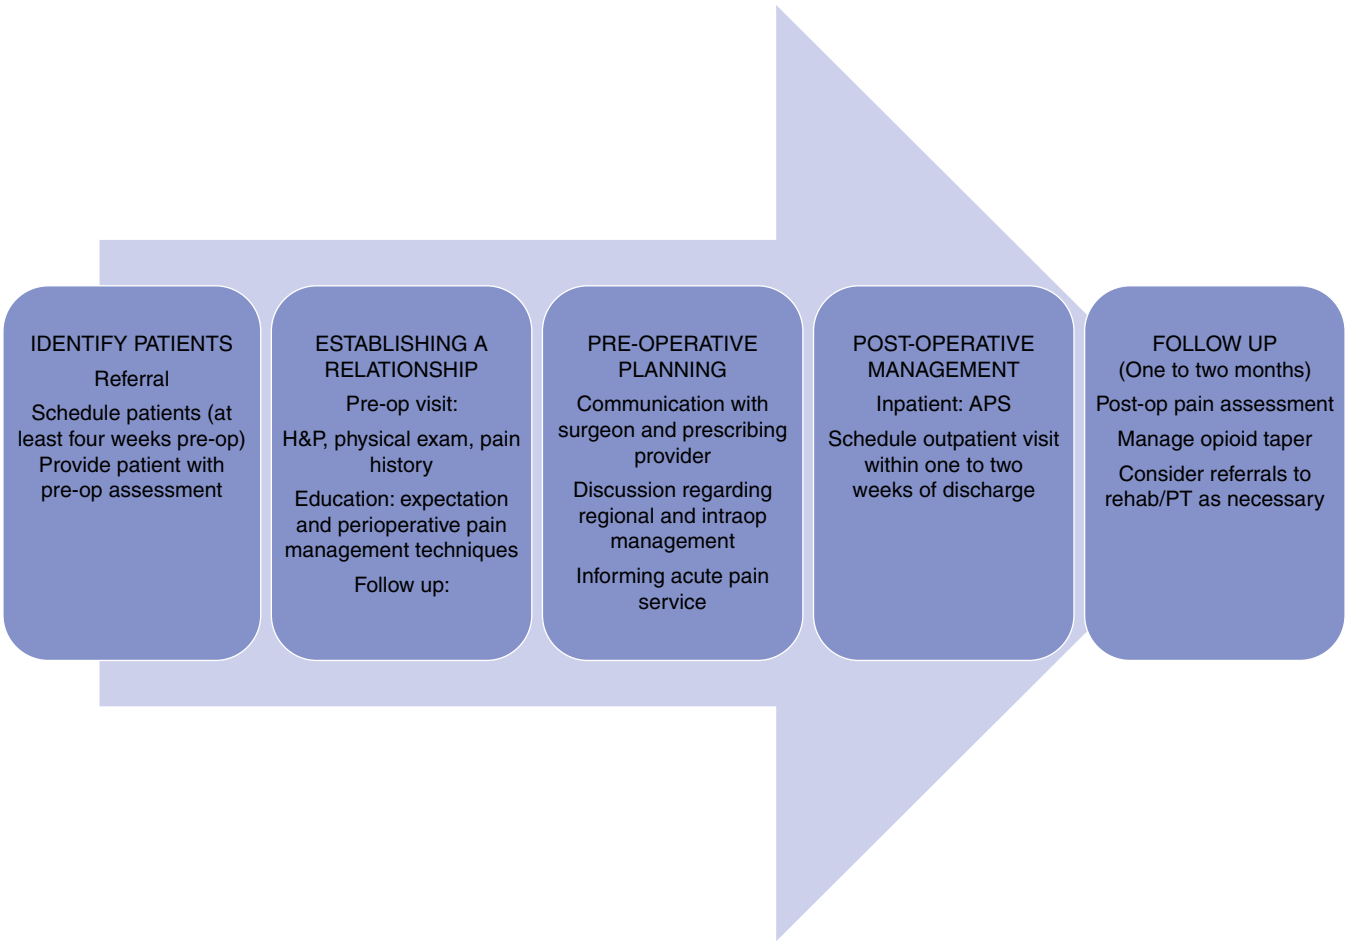
Institutional support for building perioperative pain services is mandatory. The benefits extend across departmental lines impacting surgical and anesthetic planning and treatment from pre-operative outpatient assessment and preparation, intraoperative management, post-operative inpatient care by all disciplines, and finally discharge and limited post-discharge therapy. As such, a perioperative pain clinic must be seen as an institutional resource or none at all. A multi-disciplinary approach is crucial in the development of perioperative pain services. Just as a multimodal approach to pain, using various pharmacologic and non-pharmacologic techniques is the standard of care for post-operative patients (allowing decreased reliance on opioids). The utilization of providers with different areas of expertise is crucial for perioperative pain management. Therefore caregivers from nursing, pharmacy, and pain medicine with close ties to surgery and anesthesiology will be needed to implement a successful perioperative pain service. Clinic patients should be those likely to have (1) post-operative pain that is difficult to control, (2) high dose post-operative opioid use requirements, and/or (3) risk factors for developing chronic pain after surgery, that is, largely mirroring the patients who already find their way into an inpatient acute pain service. At the University of Washington Medical Center, we used the following recommendations for patients undergoing inpatient surgery to be referred to the perioperative pain clinic:

- Pre-operative daily morphine equivalent dose of greater than 90 mg for three months
- Any daily opioid use > one year
- Use of daily extended release long-acting (ERLA) opioids for any length of time
- Patients on Suboxone (buprenorphine/naloxone)
- Patients on methadone
- Concurrent opioid and benzodiazepine use
- Known/active history of opioid use disorder (OUD) or other substance abuse
- History of difficult to control pain (for a similar type of surgery)

Surgeons should identify these patients as early as possible prior to scheduling surgery to allow for pre-operative assessment and interventions as needed. Ideally, the patient's pre-operative visit would include time with a pain provider, pain psychologist, and physical therapist to optimize evaluation and education. Specific evaluation should include risks of opioid misuse, psychological measures (including depression, anxiety, and catastrophizing), and functional disabilities, in addition to a thorough history of past pain problems and their treatment.

Perioperative pain clinic patient care should include (Fig. 3.6):

1. Intake (identify patients): Surgery referral; Schedule patient at least four weeks pre-operatively; Provide pre-visit assessment.
2. Visit (establish relationship): H&P focusing on pain history; assessment: including opioid risk tool, catastrophizing, and functional impairment testing; education and expectation management about post-operative pain and multimodal pain treatment: patient-provider agreement; communication with current pain provider, if any, and surgeon; form acute pain service +/- the regional anesthesia team; Start pre-operative medications if necessary.



• **Figure 3.6** Perioperative pain clinic patient flow.

3. Communicate with the inpatient social worker and/or pain psychologist if appropriate.
4. Group visit/education.
5. Intraoperative and post-operative care (therapeutic relationship): Relay intraoperative recommendations to the operative anesthetic team via acute pain service; Acute pain service follows as usual, including discharge recommendations; Schedule follow up with clinic if needed.
6. Follow up: Provide opioid therapy taper (two weeks- two months) in consultation with patients' pre-operative pain provider/prescriber; Consult with surgeons concerning referrals to physical therapy/occupational therapy and rehabilitation services.

Patients with past or current treatments with buprenorphine or methadone are prime examples of those who may benefit from pre-surgical consultation with the perioperative pain clinic. This is particularly true given the increase in medication-assisted treatment for OUD by the "opioid crisis" and the rapidly evolving literature on the management of these drugs in the perioperative period.[48,49,50]

Buprenorphine

Each patient on buprenorphine requires an individualized perioperative plan that should take the following into account: the reason they are on buprenorphine, the type of surgery and expected recovery period, the dose they are on, the social context, and access to appropriate providers available during the perioperative period. The literature on the management of buprenorphine pre- and postoperatively varies and is often contradictory. Various institutional protocols exist and continue to evolve as thinking and experience with buprenorphine evolves. For patients on buprenorphine, a well-constructed pain management plan is necessary to ensure safe and adequate post-operative pain control.[49]

The perioperative period can be very challenging for patients with OUD who are on maintenance therapy with buprenorphine. Pain can be more challenging to control, and they are at a high risk for relapse during this period. Patient education, coordination between providers, and detailed planning are necessary.

Key components in post-operative management for patients on buprenorphine:

1. The likely severity of post-operative pain is based on surgery type. For example, for outpatient surgeries with minimal post-operative pain anticipated, buprenorphine can and should be continued as is.
2. The reason patients were taking the medication: OUD vs. chronic pain. If the patient is taking buprenorphine for OUD, continuing daily dosing to avoid perioperative relapse (regardless of post-operative opioid tolerance).
3. Daily dose of buprenorphine: Consider outpatient tapering of doses >12 mg/day pre-operatively for surgeries expected to produce severe pain to avoid antagonism of full opioid

agonists (i.e. to avoid full μ-opioid receptor occupancy by the high doses of buprenorphine).
4. Collaboration between the patient, prescribing provider (pain/addiction specialist), and surgeon regarding the perioperative plan should always be done.

In general, past recommendations of completely discontinuing buprenorphine pre-operatively have fallen out of favor (particularly for normal starting doses of 18 mg/day or less).[51] As buprenorphine treatment at OUD doses has become more common, intravenous short-acting full opioid agonists (e.g. hydromorphone or fentanyl) have been reported to provide effective analgesia in the post-surgical setting while continuing buprenorphine, although with expected analgesic tolerance similar to patients treated preoperatively with other ERLA opioids.[52] Regional anesthetic techniques should be employed whenever possible and appropriate and non-opioid adjuncts in the post-operative period are of even greater value than usual in these patients. Discharge opioid medications also require careful coordination with the surgeon and outpatient buprenorphine prescriber with very close follow up within or separate from the perioperative pain clinic.

Methadone

As with buprenorphine, there are several reasons why patients might be on methadone, and there is a difference in approach to the patient on methadone maintenance therapy for OUD versus patients who are on methadone as an ERLA medication for chronic pain. In either group, the dose of methadone used for maintenance therapy is rarely adequate for treating any acute post-operative pain.[50] Therefore it is expected that such patients require higher opioid doses initially postoperatively. It is best not to chase such acute increases in pain with methadone. However, because of its long half-life and shorter onset, analgesics are preferable. As with buprenorphine, there is also an important role for post-operative regional anesthetic and multimodal pharmacologic treatments in these patients.

In patients with OUD, methadone maintenance is usually administered once a day to dampen cravings and ease dosing at methadone clinics. Pre-operatively, every effort should be made to ensure that the patient's OUD treatment program is aware of upcoming surgery if it will mean an inpatient hospital stay. It is recommended that patients either coordinate to obtain their daily dose from their maintenance program or receive their normal oral dose separately pre-operatively on the day of surgery.

For acute post-operative pain, methadone dosing, whether administered pre-operatively for OUD or pain, should be administered in divided doses (every 6 or 8 h at the same total daily dose) to optimize its analgesic window. If the patient is kept strictly NPO, consider administering methadone IV to avoid long "wash-in" times when restarting methadone. Although this is admittedly conservative with the high bioavailability of oral methadone, we used an intravenous dose equal to half the calculated oral dose. This IV methadone dose, nonetheless, keeps blood levels from falling too dramatically and certainly avoids withdrawal symptoms as supplemental short-acting opioids are always provided (usually by IV PCA) for breakthrough pain in the post-operative period.[53] The goal should be to taper off short-acting opioids in the subacute post-operative period (no more than six weeks and usually much less) as appropriate recovery, and for tissue healing to occur. As short-acting opioid use diminishes, the patient should then be returned to their methadone dosing once a day if they remain hospitalized, or a follow up appointment should be coordinated with the outpatient maintenance program upon discharge. Guidance from an addiction specialist or the patient's maintenance program can help inform decisions on discharge medications.[54]

A Different Kind of Service

An ironic advantage of the tragic "opioid crisis" that has gripped North America (and to a lesser extent the rest of the world), costing many thousands of lives, is an increase in interest in the appropriate management of pain. This is because the opioid crisis is not so much a "problem" as it is a "dilemma"—less in need of a solution (like banning all opioids) as it is a management strategy. Thus, agencies, commissions, societies, and institutions that would never have shown any interest in pain treatments in the 20th century are suddenly publishing opioid prescribing guidelines—the best of which (for example, the Centers for Disease Control and Prevention [CDC] guidelines),[55] when examined closely, are really pain management guidelines. As mentioned earlier, the fight to discard the notion that "pain management" equals "opioid therapy" is still rampant—a fight that, at its core, is probably the primary "raison d'etre" for the development and existence of pain services. As a result, leaders of an inpatient acute pain service will now have a huge opportunity to teach other medical professionals about pain assessment and management skills that they never had before, even though pain management specialists may have been practicing these skills for decades.

ERAS Opportunities

These teaching opportunities are no longer confined to lectures at Grand Rounds or trainee didactics. Educators in other departments or professions may reach out to pain service leaders, asking them to allow their trainees to spend time on the pain service. In our service, the visitors to rounds from around the world (common in the 1990s) have been replaced by nursing, nurse practitioners, physician assistants, pharmacy students, and even residents from other medical disciplines within the institution, though not yet from surgery. On the other hand, long overdue interest in post-operative pain management among surgeons has also grown rapidly with skyrocketing protocols and guidelines appearing in the literature on appropriate durations of post-operative opioid prescription; for example,[42,56,57] Perhaps the most useful resource in this regard for evidence based procedure specific data on opioid use after surgery is the Michigan Opioid Prescribing and Engagement Network (OPEN)and their website (https://michigan-open.org/prescribing-recommendations/). In combination with knowledge of the PROSPECT recommendations mentioned earlier,[32] concerning evidence based pain treatments found to reduce pain and improve function after specific surgeries—and their own experiences, pain service leaders can be a valuable resource as additions to committees crafting their institution's ERAS protocols. Although one could conceivably argue that this might negatively impact consult volume and thus billing, a role in developing ERAS protocols gives pain service leaders an influence, never before possible, on the pain and opioid risks of inpatients and outpatients with surgery who would never have come to our service anyway and at the same time improve the quality and efficiency of our colleagues and health care systems.

Opioid Stewardship Activities

Another recent teaching opportunity for acute pain team members seeking to improve institutional pain management is involved in opioid stewardship activities. Modeled on hospital antibiotic

stewardship programs required by the JCAHO, opioid stewardship is described by the Canadian Institute for Safe Medication Practices as "coordinated interventions designed to improve, monitor and evaluate the use of opioids to support and protect human health."[58] It is hard to imagine professionals who are better positioned to be involved in these efforts than acute pain service leaders. By definition, opioid stewardship is a multi-disciplinary and multi-professional endeavor (drawing on pharmacy, nursing, surgical, primary care, emergency medicine, pain medicine, and addiction medicine expertise), and again, acute pain service leaders, by necessity, are experienced in such endeavors. If your institution has not yet implemented an opioid stewardship committee, you can be assured that one is planned as JCAHO has already gone on record as supporting such initiatives.[59] More and more case studies of institutional programs are being published, and the National Quality Forum has suggested seven fundamental steps needed to support opioid stewardship in health care organizations:[60, 61]

- Promote leadership commitment and culture.
- Implement organizational policies.
- Advance clinical knowledge, expertise, and practice.
- Enhance patient and family caregiver education and engagement.
- Track, monitor, and report performance data.
- Establish Accountability.
- Support community collaboration.

In our system, the opioid stewardship committee is a subcommittee of the pharmaceutics and therapeutics committee and provides part-time administrative support for our monthly meetings. We used a workgroup approach to underpin the complex and far-reaching activities of the opioid stewardship committee. These workgroups have evolved over the years and will continue to do so, but currently include addiction services, education, metrics, and documentation groups—all held together by invaluable information technology support for each group (without which, in this day and age, would make most of the work of the committee impossible). As with most committees, most of the time is spent by a handful of dedicated individuals composing the leadership team. This currently comprises the chairs of the various workgroups as well as the two co-chairs of the larger opioid stewardship committee (a pain specialist and an addiction specialist). As it happens, many of our leaders are active in advocacy work at the state and national levels, including the development of several opioid-related rules and guidelines. However, this is neither necessary nor sufficient. The goal of opioid stewardship activities, as is the case with most pain service activities, is implementing local policies and procedures to help ourselves and our colleagues more safely care for our patients in an evidence based more efficient, and more effective manner.

Conclusion

Although healthcare providers acknowledge that providing analgesia to acute post-surgical patients is important, this task is often easier said than done. Challenges to meeting this aim include opioid tolerance, acute-on-chronic pain scenarios, and a great variety of surgical procedures and techniques. An acute inpatient pain service can often offer insight and experience when dealing with complex clinical issues. However, the design, planning, and implementation of an acute inpatient pain service must be performed with great care, and intention with an eye toward flexibility as pain problems and solutions evolve. Only through thoughtful construction will a successful service emerge that can meet and exceed the needs of the hospital, its surgical and medical services, and the patients whom they serve.

Key Points

- Acute post-operative pain remains widely undertreated, even though it is a primary concern for patients anticipating planned surgery.
- An optimal post-operative pain management program will integrate multimodal and multi-disciplinary interventions.
- Several systems for organizing an inpatient acute pain service have been described, although most use a partnership between nursing and anesthesiology.
- Detailed practice guidelines, protocols, and order sets can streamline and simplify care.
- Enlisting the support of hospital administration and defining resources is a vital first step in organizing an inpatient acute pain service.
- Treatments provided by the pain service should be individualized and evidence based.
- The business plan of the service must include a cost analysis, although the delivery of pain relief is inherently valuable beyond a calculable measure.
- The business plan should be flexibly constructed by shifting fixed costs to variable costs whenever possible.
- Accuracy in documentation and billing is crucial to facilitate timely and correct reimbursement.
- A marketing plan introduces potential referring providers to the concept and benefits of the service.
- Flexibility for improving pain care based on technologic innovations, health systems, or regulatory changes related to pain is essential for providing long-term, safe, and efficient pain care.

Appendix A

History

HPI (history of present illness): Characterize HPI by considering either the status of chronic conditions or the number of elements recorded. ☐ One condition ☐ Two conditions ☐ Three conditions or ☐ Location ☐ Severity ☐ Timing ☐ Modifying factors ☐ Quality ☐ Duration ☐ Context ☐ Associated signs and symptoms	☐ Status of one to two chronic conditions	☐ Status of one to two chronic conditions	☐ Status of three chronic conditions	☐ Status of three chronic conditions
	☐ Brief (one to three)	☐ Brief (one to three)	☐ Extended (four or more)	☐ Extended (four or more)
ROS (review of symptoms) ☐ Constitutional (weight loss) ☐ Ears, nose, mouth, throat ☐ GI ☐ Integumentary (skin, breast) ☐ Endo ☐ Eyes ☐ Cardiovasc ☐ GU ☐ Musculo ☐ Neuro ☐ Me/lymph ☐ Resp ☐ Psych ☐ All/immuno ☐ Psych	☐ N/A	☐ Pertinent to problem (one system)	☐ Extended (Pert and others) (two to nine systems)	☐ Complete (Pert and all others) (ten systems)
PFSH (past, family, social history) ☐ Past history (the patient's past experiences with illnesses, operations, injuries, and treatments) ☐ Family history (a review of medical events in the patient's family, including diseases that may be hereditary or place the patient at risk) ☐ Social history (an age-appropriate review of past and current activities)	☐ N/A	☐ N/A	☐ Pertinent (one history area)	☐ *Complete (two or three history areas)
*Complete PFSH: two history areas: (a) established patients—office (outpatient) care, domiciliary care, home care; (b) emergency department; (c) subsequent nursing facility care; and (d) subsequent hospital care three history areas: (a) new patients—office (outpatient) care, domiciliary care, home care; (b) consultations; (c) initial hospital care; (d) hospital observation; and (e) initial nursing facility care	Problem focused	Exp. problem focused	Detailed	Comprehensive
	Final history requires all three components above met or exceeded			

Appendix B

Examination			
CPT Examination Description	**1995 Guideline Requirements**	**1997 Guideline Requirements**	**CPT Type of Examination**
Limited to affected body area or organ system	One body area or organ system	One to five bulleted elements	Problem focused examination
Affected body area or organ system and other symptomatic or related organ systems	Two to seven body areas and/or organ systems	Six to 11 bulleted elements	Expanded problem focused examination
Extended examination of affected body area or organ system and other symptomatic or related organ systems	Two to seven body areas and/or organ systems	12–17 bulleted elements for two or more systems	Detailed examination
General multisystem	Eight or more body areas and/or organ systems	18 or more bulleted elements for nine or more systems	Comprehensive examination
Complete single-organ system examination	Not defined	See requirements for individual single-system examinations	

CPT, Current Procedural Terminology.

Appendix C

Data Reviewed or Ordered		Point Value
Order and/or review medically reasonable and necessary clinical laboratory procedures. Note: Count laboratory panels as one procedure.	One to three procedures	1
	≥ Four procedures	2
Order and/or review medically reasonable and necessary diagnostic imaging studies in the radiology section of CPT.	One to three procedures	1
	≥ Four procedures	2
Order and/or review medically reasonable and necessary diagnostic procedures in the medical section of CPT.	One to three procedures	1
	≥ Four procedures	2
Discuss tests results with the performing physician.		1
Discuss the case with other physicians involved in the patient's care or consult another physician (i.e. true consultation meaning seeking opinion or advice of another physician regarding the patient's care). This does not include referring the patient to another physician for future care.		1
Order and/or review old records. Record type and source must be noted. Review of old records must be reasonable and necessary based on the nature of the patient's condition. Practice or facility protocol-driven record ordering does not require physician work and thus should not be considered when coding E/M services. Perfunctory notation of old record ordering/review solely for coding purposes is inappropriate, and counting such is not permitted.	Order/review without summary	1
	Order/review and summarize	2
Independent visualization and interpretation of an image, ECG, or laboratory specimen not reported for separate payment. Note: Each visualization and interpretation is allowed one point.		1
Review of significant physiologic monitoring or testing data not reported for separate payment (e.g. prolonged or serial cardiac monitoring data not qualifying for payment as rhythm ECGs).		1
	Total points	

CPT, Current Procedural Terminology; *ECG*, electrocardiogram; *E/M*, evaluation and management.

Appendix D

Risk for Complications and/or Morbidity or Mortality			
Level of Risk	**Presenting Problem(s)**	**Diagnostic Procedure(s) Ordered**	**Management Options Selected**
Minimal	One self-limited or minor problem, e.g. cold, insect bite, tinea corporis	Laboratory test requiring venipuncture Chest x-rays ECG/EEG Urinalysis Ultrasound, e.g. echocardiography KOH preparation	Rest Gargles Elastic bandages Superficial dressings
Low	Two or more self-limited or minor problems One stable chronic illness, e.g. well-controlled hypertension or non-insulin dependent diabetes, cataract, BPH Acute uncomplicated illness or injury, e.g. cystitis, allergic rhinitis, simple sprain	Psychological test not under stress, e.g. pulmonary function tests Non-cardiovascular imaging studies with contrast, e.g. barium enema Superficial needle biopsies Clinical laboratory tests requiring arterial puncture Skin biopsies	Over-the-counter drugs Minor surgery with no identified risk factors Physical therapy Occupational therapy IV fluids without additives
Moderate	One or more chronic illnesses with mild exacerbation, progression, or side effects of treatment Two or more stable chronic illnesses Undiagnosed new problem with an uncertain prognosis, e.g. lump in the breast Acute illness with systemic symptoms, e.g. pyelonephritis, pneumonitis, colitis Acute complicated injury, e.g. head injury with brief loss of consciousness	Physiologic tests under stress, e.g. cardiac stress test, fetal contraction stress test Diagnostic endoscopy with no identified risk factors Dee needle or incisional biopsy Cardiovascular imaging studies with contrast and no identified risk factors, e.g. arteriogram, cardiac catheter Obtain fluid from the body cavity, e.g. lumbar procedure, thoracentesis, culdocentesis	Minor surgery with identified risk factors Elective major surgery (open, percutaneous, or endoscopic) with no identified risk factors Prescription drug management Therapeutic nuclear medicine IV fluids with additives Closed treatment of fracture or dislocation without manipulation
High	One or more chronic illnesses with severe exacerbation, progression, or side effects of treatment Acute or chronic illnesses or injuries that may pose a threat to life or bodily function, e.g. multiple trauma, acute MI, pulmonary embolus, severe respiratory distress, progressive severe rheumatoid arthritis, psychiatric illness with a potential threat to self or others, peritonitis, acute renal failure An abrupt change in neurologic status, e.g. seizure, TIA, weakness, or sensory loss	Cardiovascular imaging studies with contrast Cardiac electrophysiologic tests Diagnostic endoscopy with identified risk Diskography	Elective major surgery (open, percutaneous, or endoscopic) with no identified risk factors Emergency major surgery (open, percutaneous, or endoscopic) Parenteral controlled substances Drug therapy requiring intensive monitoring for toxicity Decision not to resuscitate or to de-escalate care because of poor prognosis

BPH, Benign prostatic hyperplasia; *ECG*, electrocardiogram; *EEG*, electroencephalogram; *IV*, intravenous; *MI*, myocardial infarction; *TIA*, transient ischemic attack.

Interdisciplinary Pain Management

STEVEN P. STANOS

"Chronic pain is a complex biopsychosocial phenomenon that may interfere with many aspects of a person's life—ability to work, personal relationships, and both physical and mental health".[1]

The National Pain Strategy

"Pain for me, arrives as a complete package, and that demands a team approach."

Patrick Wall, PhD

Introduction

Interdisciplinary pain rehabilitation incorporates a team-based approach based on a biopsychosocial model of care. This chapter will review the history of multi- and interdisciplinary care, functional restoration, and the various treatment disciplines involved that contribute to the success of chronic pain rehabilitation programs. The chapter will review the author's interdisciplinary program in the Pacific Northwest as an example and means for a deeper discussion of program philosophy, workflow, and processes. This section also highlights additional federal, academic, and private programs across the United States, including recent outcomes studies. This overview of interdisciplinary care will help represent where a strong interdisciplinary pain rehabilitation model can be integrated into a traditional comprehensive pain center at a healthcare system level or as an independent freestanding entity. Most importantly, an explanation of specific therapeutic disciplines and treatment focus provided by physical therapy (PT) and occupational therapy (OT), pain psychology, relaxation training (RT), medical management, and pain education will be reviewed along with the unique synergies a team-based approach provides helping patients struggling to manage chronic pain decrease their pain and suffering, better understand their condition, and improve psychosocial function and quality of life.

History of Pain Rehabilitation

Pain rehabilitation and treatment of injured workers go back to the Egyptians under Ramses II in 1500 BD. The modern development of more formal rehabilitation models of care evolved after both World Wars, with the birth and advancements in the fields of rehabilitation medicine and OT. The advancement of various medical specialties and health psychology helped advance further growth in the mid-twentieth century. Dr. John Bonica championed a "multi-disciplinary" approach and formalized a consultation-based program in the early 1960s at the University of Washington.[2] Patients were assessed by a multi-disciplinary group of providers, discussed in a multi-disciplinary manner where patient specific treatment plans and recommendations were made. Over time, the consultation-based multi-disciplinary clinic has evolved into providing more structured inpatient programs in collaboration with anesthesia, physical medicine and rehabilitation, and health psychology. Wilbert Fordyce, a psychologist and early leader in the field of behavioral medicine, joined Bonica and applied operant conditioning and behavioral interventions in what was initially an inpatient eight week program. Fordyce had a primary interest in operant conditioning principles that shape both pain-related and healthy behaviors, noting several learned processes that maintained "pain behaviors," those behaviors that can be positively and negatively reinforced.[3] The approach was a sharp contrast to the more contemporary practiced biomedical model, which emphasizes physiologic pathology shifting to a more comprehensive and patient-centered "biopsychosocial" approach. The biopsychosocial model, championed by George Engel, has been used to treat medical conditions, including cardiovascular and gastrointestinal disorders and infectious diseases.[4]

In 1983 John Loeser and Bill Fordyce at the University of Washington formalized a more "structured program," three weeks in duration, that become a model of "interdisciplinary" treatment around the word.[5] In Texas, Mayer and Gatchel in the 1970s and 1980s incorporated "functional restoration" into the interdisciplinary model to better address deconditioning and prolonged disability associated with low back pain with injured workers. The interdisciplinary functional restoration approach focused on physical reconditioning and cognitive behavioral "crisis intervention" for helping patients manage related psychosocial problems.[6] The functional restoration model grew from a sports medicine approach to work related injuries focusing on endurance training and strengthening. Along with cognitive behavioral support and didactic teaching about the nature of pain, pain management principles, and disability avoidance, functional restoration programs are also highly interdisciplinary, with a focus on the progressive increase in levels of task-oriented rehabilitation and work simulation, with ongoing objective and functional assessments.

These interdisciplinary functional restoration programs have been shown to improve pain and function and improve spine surgical outcomes when integrated as a "prehabilitation" intervention prior to surgery.[7] Over time, "interdisciplinary treatment" and "functional restoration" have become terms synonymous with structured rehabilitation-based programs. Okifuji et al. described

three common elements of interdisciplinary treatment, including medication management, graded physical exercises, and cognitive and behavioral techniques for pain and stress management.[8]

With a strong emphasis on interdisciplinary care, pain program treatment facilities grew in the 1980s and the 1990s worldwide, including in the United States. Accreditation by the Commission on Accreditation of Rehabilitation Facilities (CARF) and other organizations led to the growth of these programs in the United States, many of which focused on rehabilitating injured workers and returning them to work. Unfortunately, despite evidence of interdisciplinary treatment efficacy, a significant decline in CARF accredited programs began in the early 2000s. However, in the federal health system, the availability of these programs grew significantly in 2009 because of the Veterans Health Administration (VHA) Directive in response to the growing opioid epidemic and an increase in the prevalence of chronic pain.[9] The directive outlined a new standard of multimodal pain care at all levels of clinical care by formally establishing a more seamless population-based, patient-centered, stepped care model of pain management. The model includes "Step One: Primary Care," "Step Two: Secondary Consultation," and "Step 3: Tertiary Interdisciplinary Care" with Step 3 helping to better the needs of more complex patients requiring advanced pain medicine diagnostics and pain rehabilitation.[10]

In 2011, the Agency for Healthcare Research and Quality (AHRQ) published a technical brief on multi-disciplinary pain programs, which included reviews of interdisciplinary programs describing programs that provide medical therapy, behavioral therapy, physical reconditioning, and education. The AHRQ report reviewed the literature on the positive efficacy of interdisciplinary care and described the growth of programs in Europe while declining the number of programs in the United States.[11] Efforts to curb the growing drug overdose epidemic and increased reported prevalence of chronic pain and high-impact chronic pain have led to greater support for comprehensive pain care, including interdisciplinary care. In the near future, the development of value-based care models and payer systems in the United States healthcare system may offer an opportunity for greater integration of a continuum of team-based approaches to improve comprehensive pain care. An interdisciplinary care model is the foundation of this care system.

Legislative and Federal Initiatives Highlighting the Need for Interdisciplinary, Team-Based Care

Initiatives and legislative acts supporting multi- and interdisciplinary care include the National Pain Strategy, the Centers for Disease Control and Prevention (CDC) Chronic Opioid Management Guideline,[12] the National Academies of Medicine report,[13] Health and Human Services (HHS) Pain Management Interagency Task Force report,[14] and National Governor's Association report.[15]

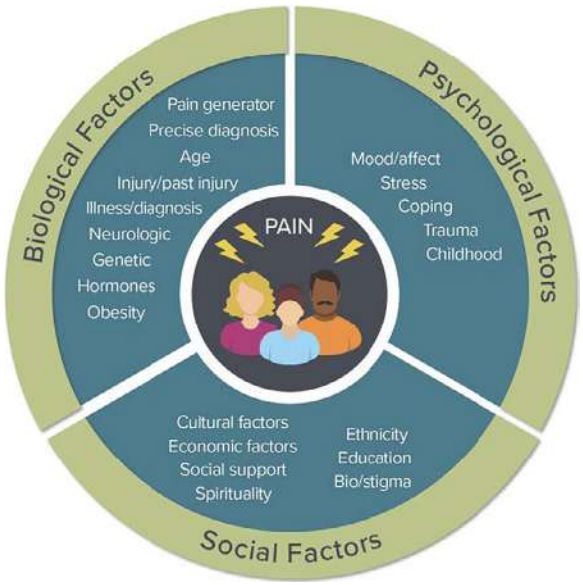
The 2010 Patient Protection and Affordable Care Act (ACA) required the Secretary of HHS to coordinate through the Institute of Medicine (IOM) a strategy to increase awareness and recognition of pain as a significant public health problem. The IOM report included several recommendations for improvements in pain spanning data collection, education, research, and delivery of care, leading to a congressionally mandated federal effort into a comprehensive population health-level strategy, the National Pain Strategy (NPS). The NPS, released in 2017, and endorsed "a population-based, biopsychosocial approach to pain care that is grounded in scientific evidence, integrated, multimodal, and interdisciplinary while, at the patient level, is tailored to individual needs." The NPS lays the foundation for greater integration of team-based interdisciplinary care and better delivery strategies and integrates this type of care into current treatment models, payers, and healthcare systems. The report included definitions that will help guide this overview of interdisciplinary care.[12] The ACA, which increased access to medical coverage for the uninsured, has also helped to support the growth of interdisciplinary and comprehensive care within state Medicaid systems, including novel team-based programs that may help to more widespread use of programs within Medicare and commercial payor programs.

The National Academy of Sciences and the HHS Interagency Task Force report emphasized a multi-disciplinary approach based on a biopsychosocial model and included an endorsement of multi-disciplinary care as a critical part of biopsychosocial-based care. Besides behavioral health approaches, interventional procedures, medications, and complementary and integrative health, the range of restorative therapies (physical and OT, therapeutic exercise, and movement modalities) are critical components of interdisciplinary, multimodal pain care.[13,14]

As shown in Figure 4.1, response to the drug overdose epidemic highlighted the need for states to examine current evidence, coverage, and access for non-opioid therapies and explore innovative, coordinated, interdisciplinary care delivery models "that function as best practice models for patients experiencing complex high-impact chronic pain."[15] In 2020 the National Governor's Association report addressed strategies to expanding access to non-opioid pain management in the context of the COVID-19 pandemic. The report also highlighted progress in several states through waivers, health home programs, and performance improvement projects to promote evidence-based non-opioid therapies, including interdisciplinary rehabilitation, and improve how chronic pain is addressed in primary care.[16]

Models of Care

A few important definitions are reviewed to describe the models of care. The terms "multi-disciplinary" and "interdisciplinary" as models of care are commonly used interchangeably, although they



• **Figure 4.1** Biopsychosocial factors impacting pain. HHS: Interagency Task Force report. 2019.

represent treatment models across a continuum of care in modern clinical practice. Heterogeneity in the terminology used to describe pain management programs in the literature may lead to some confusion. "Multi-disciplinary" implies multiple disciplines being used for a clinical purpose but not necessarily delivered in one setting. "Interdisciplinary" implies the use of multiple disciplines, such as occupational and PT, behavioral medicine, RT, vocational services, and nursing education in one setting or facility.[17]

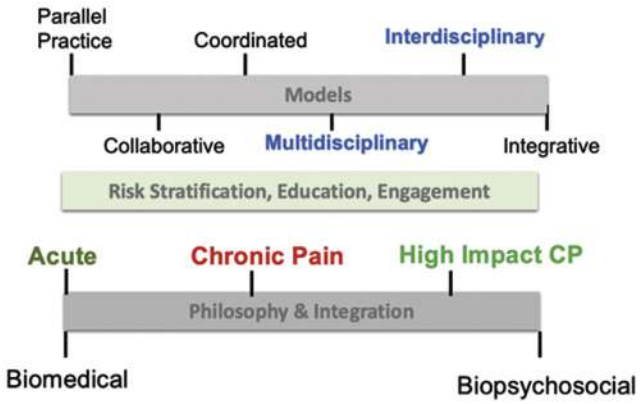
Boon et al. described a conceptual framework of models of care in order of increasing comprehensiveness and philosophical complexities, starting with a more biomedically based model parallel to a collaborative, coordinated care. This is followed by a multi-disciplinary, then interdisciplinary biopsychosocial model, and finally, a fully integrative one,[18] which could include acute medical care, such as an emergency room, where different team members have defined roles (i.e. phlebotomy, nursing, radiology technician, and emergency medicine provider). A "collaborative" or "coordinated" model may include practitioners acting independently and sharing medical records facilitated by a case manager. Across the models, there is an increasing need for communication, less individual autonomy, increased goals, and shared philosophy. "Multi-disciplinary" in pain management may commonly include a patient being managed by a pain medicine specialist who is directing care, a physical therapist providing care at an outside facility, and a vocational counselor working with the patient individually. At an even higher level of integration, "interdisciplinary" care, a basic tenet of functional restoration, includes multiple disciplines providing care at one facility. This is often led by a pain management specialist or behavioral health specialist, with multiple allied health disciplines (physical and OT, behavioral health [pain psychology, counseling, social work], nursing education) working together, agreeing upon treatment goals, and ongoing active communication, including formal team conferences or meetings. Integrated pain management programs are centered in and integrated into primary care with some embedded or easy access to multi-disciplinary providers and services. This arrangement has been described primarily in the federal healthcare system, including the Veterans Administration and the Department of Defense. This continuum starts with a more biomedical, pathology-focused approach, progressing to more multi-disciplinary, then interdisciplinary and integrative models more heavily dependent on a biopsychosocial team-centered approach. The continuum and progression in philosophy can similarly be appropriate for how a person with pain is treated, starting with acute pain, chronic pain, and finally high-impact chronic pain, but all models equally consider individual patient risks, values, engagement, education, and knowledge (Figure 4.2). The following important definitions better define the population and scope of treatment:

High-impact chronic pain: Pain associated with substantial restrictions on participation in work, social, and self-care activities for six months or more

Integrated care: The systematic coordination of medical, psychological, and social aspects of healthcare includes primary care, mental health, and, when needed, specialist services.

Interdisciplinary care: Care is provided by a team of health professionals from diverse fields who coordinate their skills and resources to meet patient goals.

Multimodal pain treatment: Addresses the full range of an individual patient's biopsychosocial challenges by providing a range of multiple and different types of non-pharmacologic (active therapy, behavioral health, interventional procedures) and pharmacologic therapies as needed.



• **Figure 4.2** Models of care, philosophy, and biomedical to biopsychosocial continuum. Adapted from Boone, et al.

Continuum of Care: Pain Rehabilitation

A continuum of pain rehabilitation approaches for chronic pain can include various models, including back schools, primary care integrative programs, and interdisciplinary functional restoration. A consistent emphasis on education and self-management was seen at varying levels with these approaches. A brief description of these models helps put into context the most comprehensive pain rehabilitation continuum, interdisciplinary care.

Back Schools

Back schools have been defined as interventions that include group education, training, and exercise, often delivered by a physical therapist or other healthcare provider organized in an occupational setting or part of a multi-disciplinary treatment program. Programs include brief education by a single provider within a management-based group. Back schools encourage self-management, advice to stay active, and reduce potential concerns about low back pain.

Low back pain education programs were championed by Lidstrom, Zachrisson, and Forsell in the late 1960s as the "Swedish Back School" model. Swedish back school classes focus specifically on biomechanics, ergonomics, exercise, and skill acquisition.[19,20] Studies have demonstrated efficacy in treating low back pain.[21] The content of back schools has varied over time, and endorsement of these programs in treatment guidelines has waned. Recent reviews found limitations, including insufficient studies and low quality evidence, although more effective than placebo on work status, and may be more effective as an added treatment versus provided alone.[22] Other reviews have demonstrated conflicting evidence that schools are better than waiting lists or no intervention for reducing disability or improving return to work.[23]

Integrative Primary Care

Collaborative care models for chronic pain, conceptually based on treating chronic illnesses such as diabetes and depression, based on primary care have demonstrated efficacy.[24,25] Focus areas for collaborative care for chronic pain include patient identification and population management, a defined care team with access to specialty pain and behavioral health with standard workflows and system supports, coordinated and collaborative care management,

and evidence-informed care (that is trauma-informed, addressing pain amplifiers like sleep problems, appropriate use of integrative health such as massage and acupuncture, and movement and body awareness strategies). Finally, patient-supported self-management is provided by a team member where goals are identified, and barriers to making progress toward goals are addressed (Table 4.1).[26]

Primary care-based integrative pain management programs are often based on medical home models. Various primary care models exist but often include coupling a decision-support component such as an algorithm-guided treatment (such as analgesic optimization) or stepped care with proactive treatment monitoring, stratifying patients based on the extent of their medication management, psychosocial, and/or comorbid medical illness factors. Programs are commonly led by case managers who communicate with patients via phone or other automated symptom monitoring (apps, internet). Education was delivered in multiple weekly group sessions. In some cases, primary care-based integrated programs also include physicians, pharmacists, dieticians, and physical therapists who provide group or individual care. A recent review of primary care models found clinically relevant improvements in pain intensity and function, with variable improvement in other core outcomes such as mood, sleep, and medication use.[27] Additional trials are ongoing with the integration of interdisciplinary pain care within primary care, including models that include comprehensive evaluations, cognitive behavior therapy (CBT)-based pain coping skills training, and adaptive movement training provided over a 12-week period in group sessions (led by a trained nurse and behavioral specialist), and primary care consultation.[28]

Interdisciplinary Pain Rehabilitation and Functional Restoration

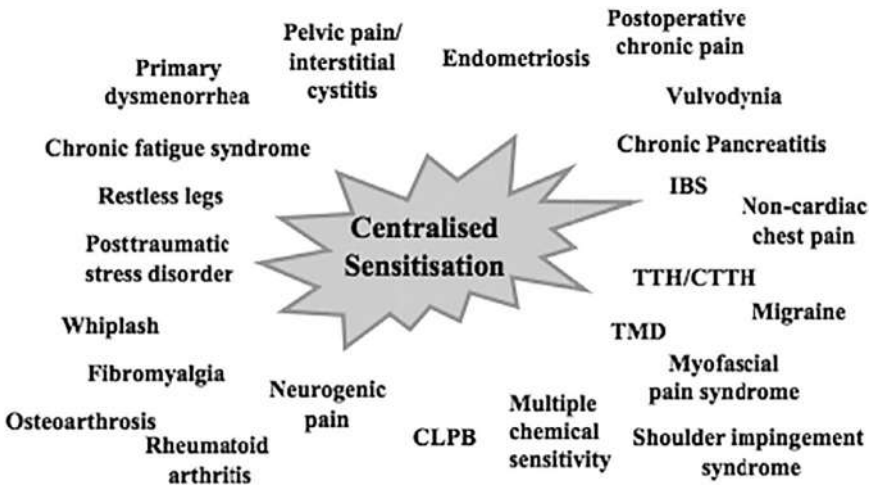
Interdisciplinary models are based on a biopsychosocial approach to pain and pain-related loss of function (i.e. disability). The biopsychosocial approach emphasizes pain and disability as complex and dynamic interactions among physiologic, psychological, and social factors that may perpetuate each other, leading to complex pain and prolonged disability.[29] Importantly, in contrast to a biomedical model, chronic pain is understood as a disease, making the traditional biomedical model often inadequate at addressing the complexities of pain unique to each patient.[30] The evidence for interdisciplinary pain rehabilitation programs as effective interventions for reducing pain and pain-related disability is well established in the literature.[31,32,33]

Important in this complex biopsychosocial relationship underscoring pain and affective distress is evidence supporting neurophysiologic changes, including neurophysiologic activation, and more recent evidence of chronic pain perpetuating central sensitization. Central sensitization has been defined as "a process of abnormal and intense enhancement of pain caused by increased neuronal responses to stimuli in the central nervous system."[34,35] Central sensitization is associated with psychosocial and cognitive behavioral factors.[36] Central sensitization plays an important role across many chronic pain conditions and contributes to the transition process from acute to chronic pain, amplification of pain in many chronic pain conditions, and in the development of chronic post-operative pain (Figure 4.3).[37]

TABLE 4.1 Primary Care Collaborative Care for Chronic Pain Focus Areas (Bree Collaborative)

Patient Identification and Population Management	• Identifying patients with persistent pain with life activity impacts • Preventing the transition from acute to chronic pain with life activity impacts • Through screening with a brief, validated instrument for psychosocial barriers • To recovery (e.g. STarT Back Tool for low back pain) • Tracking patients in a registry and participating in performance improvement • Based on the aggregation of data for collaborative care performance • Use of a dashboard for patient progress • Patient-reported outcome measures at the initial visit and follow up
Care Team	• Defined roles for care team members, care team • Communication expectations • Access to specialty pain or behavioral health consultation, if needed • Patient point of contact for the care team • Standard workflow with planned interactions • System supports (e.g. technology, training) • Identifying, supporting, and enhancing what patients are already doing to manage chronic pain with life activity impacts
Care Management	• Coordination of the collaborative care process, including facilitation of care team access • Identifying diverse resources and interventions that patients can use in managing chronic pain with life activity impacts, depending on motivations and preferences • Facilitation of referrals, if needed • Management of medication • Proactive outreach
Evidence-Informed Care	• Trauma-informed care • Developing and improving pain management skills (e.g. relaxation) • Conventional medical treatment options (e.g. nonsteroidal anti-inflammatory drugs as first line treatment rather than opioids, topical, heat, and ice) • Addressing pain amplifiers (e.g. sleep problems) • Integrative health practices (e.g. massage, acupuncture) • Movement and body awareness strategies
Supported Self-Management	• Helping patients identify goals for resuming life activities and addressing barriers to making progress toward goals

Collaborative care for chronic pain: report and recommendations. *Bree Collab*. 2018.



• **Figure 4.3** Chronic pain conditions and central sensitization.[37]

In addition to sensitization, neurophysiologic changes may be closely linked to psychological and behavioral factors. The classic cognitive activation theory of stress links neurophysiologic activation and an individual's innate stress alarm, where there is a discrepancy between what is expected and experienced by the individual with chronic pain.[38] The resulting sustained state of anxiety and sustained neurophysiologic activation may be reduced by improved coping behaviors or decreasing feelings of hopelessness. Many of these related psychological factors are targets for fear avoidance training for persistent pain. Sensitization to pain processing also contributes to elevated pain perception and affective distress. Decreasing "sensitization" of the nervous system serves as a useful broad or shared target for pharmacologic, behavioral, and active non-pharmacologic interventions (exercise, movement-based therapies) for pain management. It remains an important and growing area of clinical focus and patient-directed education within interdisciplinary and multidisciplinary treatments.

Interdisciplinary Care and Functional Restoration

Over 30 years ago, Kinney et al. described the basic elements (i.e. nine core attributes") of interdisciplinary functional restoration programs.[6] With advancements in understanding persistent pain, pain pharmacology, health psychology, and integration of mind body techniques, these nine core attributes remain, but with updated modifications. These nine core attributes will help describe the continuum of interdisciplinary care (Table 4.2).

Interdisciplinary functional restoration can be best described as involving four phases:

1. Comprehensive interdisciplinary assessment: Multiple specialists (pain medicine, pain psychologist, and/or vocational counselor) evaluate the patient, help clarify the underlying pain and psychological diagnoses, and consider candidacy for interdisciplinary care.
2. Pre-programing: Pre-programing as needed to complete workup, complete related assessments, and/or stabilize psychiatric or medical issues and program orientation.
3. Formal interdisciplinary management.
4. Post-program: Follow up care, outcome assessments, and maintenance classes.

TABLE 4.2 Core Attributes of a Functional Restoration Program: Swedish Pain Services/Swedish Health System)

1. Pain medicine assessment and management: Review of past treatment, diagnostic workup, comprehensive musculoskeletal, neuromuscular examination, assessment of neuropathic, nociceptive, and nociplastic pain; discussion with the patient regarding treatment plan; rationale for treatment program specific to patient needs; and ongoing visits reviewing progress.
2. Pain Psychology Evaluation and Treatment; psychosocial functioning: semi-structured pain psychology assessment, completion of psychosocial packet questionnaires.
3. PT directed reconditioning, strengthening, stabilization, and wellness, and pain education, many times including a model based on PNE.
4. OT directed work and home physical functioning assessment, pacing and ergonomic training, integration of relaxation techniques and mindfulness, Tai Chi, and Qi Gong training.
5. Behavioral health, including pain psychology and RT CBT, mindfulness, acceptance and commitment therapy (ACT) approaches, biofeedback-assisted RT, and nervous system education.
6. Pharmacologic interventions targeting analgesia, mood, and sleep, including detoxification or opioid tapering when appropriate, medication trials, and medication optimization, are usually led by a pain medicine specialist, physiatrist, and psychiatrist.
7. Interdisciplinary, medically-directed team approach with formal weekly team conference meetings, including structured report generation from all disciplines.
8. Work and avocational reintegration guided by nurse educators, pain medicine specialists, OT, PT, and behavioral health teams include a return to work plan, work release, and flare up management.
9. Ongoing outcomes assessments.

The intensity of treatment, disciplines involved, and how the four phases are delivered can vary widely across programs. An overview of four interdisciplinary programs in the United States is included in Table 4.3, highlighting program setting, specific disciplines used, treatment duration, integration of integrative therapies, billing structure, outcome measures used, payer mixes, and unique features of individual programs. The table helps represent an example of the variability of program structure, components, and payer mixes across successful programs in the United States. The five programs highlight a shared philosophy of

biopsychosocial patient-centered care focusing on education and learning new skills (Table 4.3).[39]

The author will describe below more specifics related to his teams' interdisciplinary program presently provided at the Swedish Health System in Seattle, Washington. This will serve as an example and represent the four phases of interdisciplinary care in more detail. Many of these same principles and treatment philosophies can be applied to the programs in Table 4.3 and interdisciplinary programs in the United States and across the world.

Swedish Pain Services: Functional Restoration Programs Overview

Swedish Pain Services (SPS) is a comprehensive outpatient pain management center in Seattle, Washington, and is part of the Swedish Health System and Providence St. Joseph Health. The functional restoration space, including treatment rooms, gym space, and group rooms, comprises approximately one-third of the clinic's 14,000 square foot facility, including an interventional procedure suite, outpatient clinic space, and support staff offices. SPS offers various outpatient-based interdisciplinary pain rehabilitation programs of various lengths, the most comprehensive being the four week structured functional restoration program (SFRP). The SFRPM program provides care for Medicare, Medicaid, and commercially covered patients referred by primary care and specialty care providers within the healthcare system and externally. The SFRP is a four week, 5 h per day, three day per week program (60 h total). Each program cohort included four patients who received both group and individual treatment with 1 h sessions of physical and OT, RT, and pain psychology. Patients were also seen weekly by a pain medicine specialist, and team conferences were completed every week, where the patient's progress was reviewed, and the rehabilitation team made treatment adjustments. Additional pain education is provided by a nurse pain educator and includes a comprehensive workbook-based and web-based curriculum.

Patients were followed up four weeks after completion of the program and continued to be followed by a pain medicine specialist after discharge. Because of current billing guidance, all disciplines of treatment (PT, OT, pain psychology, RT) are charged on a fee for service basis. Pain education group sessions led by our nurse educator were provided but not a billable service. A less intensive weekly program includes 3-4 h per week of individual and group based PT, OT, pain psychology, and RT. This is offered over a six to eight week period and includes medical visits and scheduled team conferences where patients' progress and adjustments in treatment focus are made by the interdisciplinary team.

Four Phases of Interdisciplinary Care

Comprehensive Interdisciplinary Assessment: The "Comprehensive Evaluation"

Commonly, patients are evaluated by a 2 h "comprehensive evaluation," which includes a 1 h pain psychology assessment followed by a 1 h pain medicine evaluation by a pain medicine specialist. Many programs that treat injured workers may also include a third assessment by a vocational counselor to help assess and guide work related issues, including the return to work and more objective functional capacity assessments. After the individual assessments, the patient's case is discussed in an interdisciplinary manner, and the treatment recommendations are then communicated with the patient. Factors that may preclude a patient from participating in a structured program may include the need to stabilize psychiatric functioning, referral for substance use treatment including opioid detoxification or transition to buprenorphine, or patients' inability to agree with the treatment plan or philosophy, including patients' readiness or willingness to accept a self-management approach. Additional practical barriers may prevent patients from participating, including lack of insurance coverage, excessive out-of-pocket costs, travel restrictions, and inability to take time away from work or other personal responsibilities.

Pre-programming Phase

Prior to starting a structured program, many patients may benefit from short trials in time-limited physical and OT, behavioral health, and RT. These "pre-programing" visits may help to "trial" the program for patients and assess compliance and willingness to comply with treatment philosophy and self-management approach. Trial therapy sessions can include weekly sessions for three to four weeks and include informal team conference discussions with the treating disciplines and the pain specialist where decisions for continuing care are made. This also offers the treating team additional time to work with the patient and familiarize themselves with their individual needs. The pre-programming phase is often necessary for patients with a maladaptive understanding of their pain condition and unstable psychiatric problems that may need to receive more focused behavioral health interventions, including referrals for depression, anxiety, or post-traumatic stress disorder (PTSD). Stabilizing these psychosocial factors will help set up the patient for success in a formal program and ensure a greater likelihood of patient compliance with active and behavioral interventions. Coordination of pre-programming treatments and follow ups was completed with the treating pain medicine physician. The final stage of pre-programming includes a 1 h orientation to the program coordinated by the nurse educator and is done in individual or group format. Patients are given an overview of the program, expectations for care, the importance of individual compliance, and practical questions are answered, including scheduling and parking. The nurse educator can also review the treatment manual and help coordinate how additional online web-based educational materials can be accessed.

Interdisciplinary Care: Formal Treatment Program

Interdisciplinary functional restoration programs combine individual and group based sessions and include physical and OT, behavioral health (i.e. cognitive behavior therapy, mindfulness training), RT, pain education, and aerobic conditioning. The most intense program involves the four week SFRP [60 h of treatment total] and less intense weekly program [18-32 h]. For the SFRP patients, in cohorts of four, they participated in three sessions per week, two session days involved 1:1 therapy sessions and a third session day in groups. Separate from current Covid-19 restrictions, two cohorts or a total of eight patients participated in group sessions. The group setting offers a therapeutic option for patients to learn from each other, provide a sense of validation of their pain, provide an environment to share common concerns, help to increase self-reliance, and be a source of inspiration from other patients in the program.[40] Studies have found that patients participating in groups may help to improve engagement, understanding, share their experiences, and express themselves in a safe and non-threatening atmosphere. The group process can enhance treatment success and patient satisfaction through cognitive

TABLE 4.3 Interdisciplinary Pain Rehabilitation Programs in the United States—cont'd

Name of Program, System of Care	Mayo Clinic Pain Rehabilitation Center	Pacific Rehabilitation Centers	Savas Health Unitized Transdisciplinary Care™	Stanford University School of Medicine Pain Management Clinic	Swedish Health System, Swedish Pain Services
Unique features:		Only full service interdisciplinary telehealth CARF program in the region	– Scalable transdisciplinary solution based on a proprietary software platform – Use of proprietary assessment system to allow for easy communication among disciplines and goal tracking (Patient Global Health Score™) – Use of artificial intelligence driven predictive modeling for optimal treatment planning and execution – Regular Systematic Case Review by the treatment team for all participants	Pain Psychology and MD Fellowship programs, only med-behavioral inpatient pain experience in the western United States (SCIPP), Bi-weekly interdisciplinary case conference	Pain rehabilitation programs integrated within physical space and cost center of comprehensive pain center hub for the large health system. Behavioral health co-treatment with integrated behavioral health services in the system's primary care clinics helps stabilize patients prior to and provide additional behavioral health support after completing structured programs.
Program Content Contributors	Wesley Gilliam, PhD	Michael D. Harris, PhD	Tobias Moeller-Bertram, MD	Kristen Slater, PhD Heather Poupore-King, PhD	Becca Taylor, RN, PhD Wilson Chang, MD

AUDIT, Alcohol Use Disorders Identification Test;
BESS, Balance Error Scoring System;
CES-D, Center for Epidemiological Studies Depression;
COPM, Canadian Occupational Performance Measure;
CPAQ-8, Chronic Pain Acceptance Questionnaire-8;
CHOIR, Collaborative Health Outcomes Information Registry;
DAST-10, Drug Abuse Screening Test-10;
GAD-7, Generalized Anxiety Disorder-7;
NPRS, Numeric Pain Rating Scale;
ODI, Oswestry Disability Index;
ODQ, Oswestry Low Back Pain Disability Questionnaire;
PASS-40, Pain Anxiety Symptoms Scale-40;
PCL-5, PTSK Checklist for DSM 5;
PCS, Pain Catastrophizing Scale;
PEG, Pain, Enjoyment in Life and General Activity [PEG] Scale;
PDI, Pain Disability Index;
PHQ-9, Patient Health Questionnaire-9;
PGIC, Patient Global Impression of Change;
PROMIS, Patient-Reported Outcomes Measurement Information System;
PSEQ, Pain Self-Efficacy Questionnaire;
PSFS, Patient Specific Functional Scale;

TSK, Tampa Scale of Kinesiophobia;
WHODAS-2, WHO Disability Assessment Schedule 2.0;

behavior interventions applied by all members of the treatment team.[41]

The program was led by a pain medicine specialist (physiatrist or anesthesiology pain medicine specialist) along with a nurse educator, who helps to coordinate the patients' treatment program, guide progress, and provide any needed interventional therapy, medication management, or ongoing explanation of the complex nature of the patients' pain. Patients are seen for medical follow up visits every week and at scheduled visits after completion of the program. The emphasis during medical visits is on assessing progress in the program, reviewing patient compliance across disciplines, sharing feedback from the treating team on patient progress, and any change in treatment recommendations. The structured environment provides an opportunity for time-limited medication trials, including opioid tapering and detoxification, analgesic and adjuvant medication adjustment, and medication regimen simplification.[42,43] Pharmacotherapy commonly focuses on analgesia, mood, and sleep.

Most importantly, the pain medicine specialist role focuses on understanding the complexities of the patients' past treatments, diagnostic workup, related psychosocial and vocational factors, and clarifying and educating about the treatment diagnoses. During and after formal participation, the pain medicine specialist helps to motivate the patient to integrate techniques and skills learned in the treatment program across all disciplines (Table 4.4)

The following short summary highlights the skills and techniques used in interdisciplinary care for PT and OT, behavioral health, and RT, many times more specialized than more unimodal therapy approaches. Many patients may also present with "yellow flags" traditionally thought to be unhelpful beliefs, avoidance of activities, and psychologic factors of distress that are risk factors for long term distress and disability. Common yellow flags include psychological factors such as fear avoidance behavior, catastrophizing, depression, and heightened anxiety.[44] Their initial assessment needs to lay the foundation for a positive-clinician-patient therapeutic alliance that can foster a sense of collaboration, understanding, and support between the patient and team member.[45]

Physical Therapy

Physical therapy (PT) recommendations for exercise may be challenging for patients undergoing interdisciplinary treatment. Many patients have poor prior experiences with active PT in the past and may not have remained compliant with previous PT recommendations and exercises because of increases in pain. In addition to integrating techniques from other disciplines while participating in interdisciplinary-based PT (such as meditation, diaphragmatic breathing, mindfulness, and pacing concepts), several key points concerning an exercise prescription of chronic pain include reassuring patients that it is safe to move, exercise should be time, as opposed to pain contingent, using a tolerable or intolerable dichotomy. In addition, the physical therapist helps patients develop a comprehensive home program that also includes flare up exercise plans, the importance of self-monitoring exercise, and an emphasis on developing and retaining movement confidence and quality (Table 4.5).[46]

PT involves an initial comprehensive assessment based on a diagnostic classification system. Therapy combines manual therapy, strengthening, and joint stabilization exercises, and an additional emphasis on the nervous system and pain education based on clinical practice guidelines.[47,48] The Swedish Health System program has integrated staff certified and trained in chronic pain education based on evidence-based work by physical therapists Lorimer Mosely, David Butler, and Adrianne Louw, Pain Neuroscience Education (PNE). PNE includes an understanding by the therapists (and treatment team) of contemporary pain biology concepts that help patients better engage in a meaningful and constructive dialog as the "explain pain" to patients.[49]

PNE de-emphasizes pathoanatomic educational content focusing on teaching patients about the complex neurologic, psychological, and physical contributors to the development of pain. Some examples of content within a PNE program may include the purpose of pain (i.e. pain as an alarm system warning of actual or potential tissue damage, pain's influence on thoughts, emotions, actions, and activities), peripheral nerves (i.e. signal transmission including synapses and neurotransmitters, ability to modify the excitability of peripheral nerves), the central nervous system (i.e.

TABLE 4.4 Pain Medicine Physician's Role on the Interdisciplinary Team: Goals and Responsibilities

- Clarify the diagnoses, explain the roles and goals of treatment team members
- Educate and explain treatment philosophy
- Pharmacotherapy focusing on analgesia, mood, and sleep
- Simplify medication regimen, guide tapering of opioids when appropriate
- Put the patient's reported history or "story" together and shift their focus to the present and learn new skills
- Prioritize and help patients establish realistic goals, set the context for success
- Help engage patient to change and embrace a biopsychosocial model
- Be flexible, use motivational interviewing techniques
- Guide, encourage, give feedback on progress, and review team conference notes
- Provide conflict resolution between patient and team members
- Celebrate successes and help patients to manage setbacks
- Reassess the need for additional diagnostic workup, referrals to other specialists and therapists before, during, and after formal interdisciplinary treatment

TABLE 4.5 Key Points About Exercise Prescription for Chronic Pain

- Understanding contemporary pain biology and "explaining pain" are key competencies required for biopsychosocial treatment
- Frequently reassure patients it is safe to move/pace despite their symptoms
- Exercise prescription should be time, as opposed to pain, contingent on a tolerable/not tolerable dichotomy
- Have ready-made responses to flare-ups can reduce the severity
- Exercises should be individualized, enjoyable, related to patient goals, and with a level of supervision specific to the patient
- Many patients with chronic pain will respond to a lower exercise dosage than recommended for healthy individuals (i.e. graded low to moderate intensity)
- Closely observe and monitor exercise practice, seek and provide feedback, and correct poor technique
- Encourage patients to self-monitor exercises (diaries, activity trackers)
- Emphasize developing/restoring movement confidence and quality

Booth J, Moseley GL, 2017.[46]

the brain's role in the production of pain and the influence of beliefs, emotions, and attention on pain production), chronic pain (i.e. dissociation between pain and tissue damage, and the maladaptive nature of chronic pain), and treatment strategies (i.e. benefits of pain knowledge, stress relief, sleep hygiene, graded exercise, and activity).[50]

Over the four week program, a patient-centered home exercise program was developed based on patient needs and clinical areas of focus. The "home program" includes aerobic conditioning (daily walking, treadmill), joint and core muscle stabilization, neurodynamic training, stretching, and instruction on manual muscle self-release. Techniques and strategies from other disciplines (i.e. pacing, deep breathing, mindfulness) and concepts of PNE and graded exercise dosing are integrated into how a patient will self-progress and self-modify their PT regimen daily (Table 4.6).

Occupational Therapy

Occupational therapy (OT) focuses on posture assessment and training, pacing, and goal setting to improve instrumental activities of daily living (IADLs), including homemaking, yard work, shopping, driving, sleeping, hobbies, and traditional joint protection and compensatory strategy training. Initial assessment includes COMM and completion of daily activity "time pies," providing a visual report of how patients spend the day on an hourly basis, including self-care, work, family, friends, work, housework, and leisure/recreational activities. Over the four week SFRP program, patients complete their own self-management activities "tool box" that includes pacing, setting realistic daily goals, work simplification, prioritizing, and delegating as needed.

Pacing

A central component of OT in the SFRP program and many interdisciplinary programs is the concept of pacing, a skill that is often overlooked in traditional biomedically based pain treatment. "Activity pacing" may be considered part of time management training to find a balance between overdoing and underdoing activities built around a patient's own more structured daily schedule. Activity pacing is used clinically to describe behavioral strategies taught or encouraged to help patients, in the context of pain management, to better cope and function with chronic pain.[51] Pacing includes determining the amount of activity that can be done without causing a pain flare up. It allows one to be more productive, conserve energy for doing goal-oriented activities, and better manage their pain (Table 4.7).

Fordyce classically identified two types of maladaptive activity pacing patients: (1): recliners, "recliners," who tend to rest when pain increases and are more likely to rest in response to pain, and (2): "pacers," whom Fordyce described as those who "paced" or walked back and forth unable to decrease or stop activity.[3] In this example, Fordyce's "pacer" or walked back and forth unable to decrease or stop activity. The more recent use of the term "pace" or "pacer" is a positive and more adaptive use of the term. Interestingly, both maladaptive patterns (recliners and pacers) can be problematic and lead to more pain and more pain flare-ups. The "recliner" may become more deconditioned and weaker and, when faced with an increase in activity, may experience increased pain. The "pacer" may overdo an activity and experience a subsequent delay in the aversive effects of over-activity, making it difficult to appreciate any connection between over-activity and subsequent pain. Fordyce's approach focused on gradually increasing activity with behavioral strategies where positive reinforcement of activity becomes time-contingent or goal-contingent in distinction from pain contingent. Keefe et al. expanded on Fordyce's quota-based interventions with interventions focused on activity management or "appropriate pacing," where patients not only focus on goal-related activities, like increasing walking distance or sitting and standing tolerances but also increasing general activity throughout the day by a percentage of a safe "baseline" in a systematic manner with the use of activity-rest cycling. This approach includes the use of activity diaries.[52,53] The SFRP OT curriculum focuses on these concepts. It helps patients individually assess and understand how to apply these skills and strategies to understand that activity pacing is "a regulation of activity level and/or rate in the service of an adaptive goal or goals" based on an updated definition of activity pacing. Many patients may continue to struggle to apply the pacing technique after formal treatment and like other skills learned in an interdisciplinary program, follow up, and reassessment, re-encouragement of applying techniques remains an important aspect of ongoing follow up to maintain patient engagement.[54]

TABLE 4.6 PT Exercise Evolution With Pain Education Techniques

Progress Over Time	Modify When Pain Is High
Start with two sets, build to three	Decrease number of sets
Build more repetitions (>ten repetitions) to increase endurance	Add rests between each repetition
Improve coordination and control	Decrease range of movement to within comfort
Improve body awareness and sensation connection	Decrease the total time in activity
Add weight or resistance if necessary or possible	Use relaxation breathing to support movement and breathe between sets while resting
	Practice imagery of movement with no pain while resting

Swedish Pain Services, Structured Functional Restoration Program. Tim Zepelak, DPT, 2020.

TABLE 4.7 Swedish Pain Services Functional Restoration Program: OT Pacing

1. Deciding on reasonable activity goals based on what you value.
2. Establish time baselines of your present time limits and tolerances for activities on both a "good" day and a "bad" day to determine a present baseline.
3. Gradually increase the time spent doing a task.
4. Planning your daily activity level on pre-set realistic goals.
5. Prioritizing, organizing, and breaking up your daily activities.
6. Delegating less important tasks to others.
7. Breaking activities up into smaller tasks or parts.
8. Taking rest breaks between tasks.
9. Working at a slower, less intense pace.
10. Breaking up high and low intensity tasks during the day or over the week.
11. Use the best hours of your days for the most demanding task.
12. Vary or change tasks often, so you use different parts of the body.

Additional clinical focus within OT individual and group sessions includes educating and training in movement therapies. Movement therapy includes a range of Eastern and Western mindful-based practices that helps to promote a patient-centered proactive participation in one's health by innately promoting health and wellness and commonly include the practice of Tai Chi, Qigong, Yoga, Pilates, and the Feldenkrais Method.[55] The SFRP program focuses primarily on teaching Tai Chi, which has strong evidence for improving pain and mood in several chronic diseases, including chronic pain.[56] Tai Chi is based on an ancient Chinese system of meditative movement that has evolved to provide low-impact exercises, joint mobilization, and improve body awareness, balance, and posture.[57] Tai Chi includes a series of movements or "forms" that can be practiced from 5 to 20 min per session (Table 4.8).

Compliance and integration into patients' daily routines with Tai Chi, as well as other movement-based therapies, has significantly improved with the more recent ability to provide web-based videos, program content on video link platforms (i.e. YouTube), and the increase in community availability for patients to continue with movement-based therapies at local gyms and exercise facilities.[58]

Pain Psychology

Many chronic pain patients present with varying levels of psychosocial distress, such as depression and anxiety, elevated catastrophic thinking, maladaptive ideas about their pain condition, and previous or active physical or psychological trauma. Pain psychology emphasizes CBT, mindfulness training, and acceptance and commitment therapy provided in individual and group therapies.[59,60,61] The reader is directed to Chapter 58 on behavioral interventions for pain.

All patients were evaluated by a treating pain psychologist prior to starting the structured program. Patients are often scheduled for a "comprehensive evaluation," a 2 h assessment, where the patient is first evaluated by the pain psychologist followed by the pain management specialist. Patient specific needs, including the need for stabilization or initiation of related psychological therapies, are assessed at the evaluation and may include referral for psychiatric and psychological counseling, treatment of substance use disorder, or treatment for more specific disorders such as PTSD offered within the hospital system, external community private practices, or community mental health clinics.

Behavioral health interventions at SPS include mindfulness-based cognitive therapy that helps to address pain amplification and maintenance provided over the four week program, including eight individual and four group sessions.[62] MBSR has been shown to be an effective intervention for several medical conditions, psychological disorders, chronic pain, improving pain, and reducing psychological distress.[63] Mindfulness-based CBT includes sessions addressing automatic pain habits, facing the challenge of chronic pain, using the breath as an anchor, staying present, acceptance, understanding thoughts, taking care of myself, and harnessing the power of the mind (Table 4.9).

Besides a focus on cognitive behavioral factors such as depression, anxiety, catastrophizing, and pain coping, the mindfulness-based cognitive therapy training addresses extreme thinking, selective attention (overgeneralization, filtering, disqualifying the positive, magnification/minimization), relying on intuition (emotional reasoning, mind reading), and blaming (personalization, labeling and mislabeling), and helps patient practice mindful movement and other "mindful" exercises, teaching patients to be present in the sensations of one's body, pleasant experiences diary taking, using the breath as an anchor, and meditation. Additional group lectures include education and discussion of the gate control theory of pain, pain neuromatrix, stress-pain connection, and sleep.

TABLE 4.8 Key Characteristics of Tai Chi

Tai Chi Characteristics	Brief Description
Circular	All movements flow in a circular path, promoting dynamic stretching and balance
Relax	Deep breathing facilitates relaxation throughout the entirety of the practice. Overexertion is avoided
Calm	Calmness in movement and mind, meaning no excessive movements and the mind is clear of superfluous thoughts
Continuous	Smooth transitions with one movement flowing to the next
Intent	Mind is present and fully focused on moving with purpose
Energy	Movements are biomechanically efficient, using the least amount of effort to execute

Phuphanich ME, Droessler J, Altman L, Eapen BC. Movement-based therapies for rehabilitation. *Phys Med Rehabil Clin N Am.* 2020;31:577-591. doi:10.1016/j.pmr.2020.07.002.[57]

Relaxation Training

Relaxation therapy (RT) uses evidence-based techniques to help patients release or reduce mental, emotional, and physiologic tension. Studies have shown the benefits of relaxation and biofeedback in several medical conditions, including pain conditions such as low back pain, headache, and chronic musculoskeletal pain.[64,65,66] The goals of relaxation therapy at SPS include learning nervous system balancing techniques, maintaining a physiologic balance, increasing a sense of calm, and decreasing overall tension. The "relaxation response" was defined by Benson et al. in the 1970s as a physiologic and homeostatic state that counteracts stress.[67] Relaxation response can be achieved by several techniques, including visualization, muscle relaxation, massage, breathing techniques, meditation, and mind body exercises such as yoga and Tai Chi. Teaching patients various techniques to induce a relaxation response is a key focus of RT.

Formal biofeedback training includes measuring various physiologic responses such as auditory, visual, or tactile feedback about physiologic processes from the autonomic nervous system, including muscle tension, heart rate, and skin conductance. Patients learn to self-regulate their physiologic processes with the help of "feedback" of their physiologic functioning that is provided while in session with the relaxation therapist, often inducing or facilitating a relaxation response. Feedback may include surface EMG-measured muscle tension, skin temperature, heart rate variability, or respiratory biofeedback.[68]

Patients are taught basic concepts of nervous system physiology, including unique features of the parasympathetic (calms

TABLE 4.9 Mindfulness-Based Cognitive Behavior Therapy (CBT)

	Mindfulness-Based CBT Sessions	Clinical Context and Example
1	Stepping out of Automatic Pain Habits	Pain can seem unpredictable to many patients. Helping them identify habitual behaviors contributing to the pain-stress cycle is an important first step for treating pain
2	Facing the Challenge	Managing pain is stressful, and reacting to stress can be a powerful habit. Mindfulness meditation can help patients learn to respond rather than react to stress
3	The Breath as an Anchor	Stress, pain-related or not, may stem from dwelling on the past or the future. Learning how to ground oneself using one's breath is the best way to connect to the present moment, which can reduce stress
4	Learning to Stay Present	Pain- and stress-related self-talks can occur without awareness. Improving awareness allows patients to choose how to respond to unhelpful self-talks
5	Active Acceptance	Many patients have a hard time accepting pain, which leads to poor self-management. Breathing with pain during meditation promotes acceptance and reduces pain-related stress
6	Seeing Thoughts as Just Thoughts	Buying into unhelpful, habitual self-talks may lead to the same disappointing results for pain management. Learning how to pause, become aware, and respond is the key to obtain a different result
7	Taking Care of Myself	Struggling with pain management may indicate a lack of self-care. Practicing key elements of mindfulness meditation—awareness, acceptance, and compassion—may promote better self-care
8	Harnessing the Power of Mind for Chronic Pain Management	Sitting with strong sensation, thoughts, and emotion can be challenging, regardless of how long one has been practicing mindfulness meditation. Session eight draws on the body scan meditation and 3 min breathing space meditation, two foundational practices, to promote mind body awareness and to help patients reflect on progress made during the program

Adapted from Melissa Day, Ph.D. "Mindfulness-based cognitive therapy for chronic pain: a clinical manual and guide" (Ref. 64), and Sharon Hsu, PhD, Swedish Pain Services, Seattle, WA.

the body to conserve and maintain energy) and sympathetic (i.e. arouses body to expend energy) nervous system.[69,70]

Additional training context is provided with a focus on vagus nerve action and physiology, the primary driving force of parasympathetic tone, as an important regulator of stress, anxiety, and anger.[71] This helps to explain to patients the physiology behind creating a relaxation response. Patients are also introduced to the concept of the "fight or flight" stress response, including various unhelpful consequences that develop with chronic or persistent pain. The four primary relaxation tools taught include diaphragmatic breathing, progressive and passive muscle relaxation, autogenic training, and guided imagery (see Table 4.10: RT techniques). Patients are encouraged to integrate RT with other skills taught in other disciplines, such as Tai Chi in OT, during exercises or stretches in PT, and mindfulness training with pain psychology. Over the four week treatment program, emphasis was placed on integrating relaxation at home, work, during their daily routine, and during flare-ups. Patients are also given resources to continue their daily integration of RT, including personal recorded sessions on their smartphone or iPads, various breathing training apps (Breathe2Relax; Breath+), and relaxation therapy videos provided via links to our hospital YouTube site and other commercial platforms.

Nursing Education

A full-time nurse educator helps to coordinate all aspects of patient care from the initial assessment, pre-programming, during formal interdisciplinary care, and post-treatment. The nurse educator's role as a nurse navigator helps to provide ongoing and consistent messaging around program goals and procedures. The nurse educator also provided educational support and additional RT for patients. Lectures provided in group sessions of four to eight patients included topics such as orientation to self-management programs, sleep, nutrition, medication pharmacology, and side effects (Table 4.11).

Post-program: Follow Up Care, Outcome Assessments, and Maintenance Classes

Four weeks after completing the four week SFRP program, patients were re-evaluated by the pain rehabilitation team, which included 30 min round-robin like scheduled visits with their treating PT, OT, pain psychologist, relaxation therapist, and pain medicine specialist. Progress and compliance across all disciplines were re-assessed, and home programs were adjusted. Medical follow up helps assess core outcomes related to pain, pain flare-ups, mood, and sleep quality. Patients may be referred back to their referral provider or continue medical management with a program pain medicine specialist. Additional "maintenance" aftercare classes are provided to patients and are usually delivered in a group format monthly or quarterly. Time-limited follow ups with PT, OT, psychology, and relaxation are also provided for patients who need upgrades in their current self-management program and are coordinated by their managing pain medicine specialist. The integration of virtual health into the functional restoration program has included pain psychology and pain medicine virtual visits, pain psychology virtual individual and group visits. As a hospital-based outpatient clinic, our center cannot provide physical and OT through our virtual platform.

Outcome measures tracked pre-program at time of comprehensive evaluation, after the treatment program, and at the four week follow up team visit. Assessments and questionnaires include the average pain, enjoyment in life, and general activity (PEG),[72]

TABLE 4.10 Relaxation Training Techniques

Exercise	Technique (example)
Diaphragmatic breathing (DB)	Breathe through your nose (inhale) while pushing abdomen out; breathe out (exhale) while pushing abdomen in
Progressive muscle relaxation (PMR)	Tense and release muscle groups, distally to proximally; hands (clench); wrists and forearms (extend and bend hands back); shoulders (shrug toward ears); cheeks and jaws (smile as widely as you can); hips and buttocks (press buttocks together tightly). Hold tension for 4-10 s, then release and relax for 15-30 s
Grounding exercises	"5-4-3-2-1"; five things you see, four things you feel, three things you hear, two things you smell, and one thing you taste
Autogenic training (AT)	Six step sequence allows patients to observe sensations in the body passively. Examples: limbs feel heavy, limbs feel warm, breathing is comfortable, abdomen feels warm, forehead feels cool, and heart is beating calmly or regularly
Guided Imagery	Guided experience encourages mentally generated images that simulate or re-create the sensory perceptions: sight, sound, taste, smells, and touch

Swedish Pain Services: Structured Functional Restoration Program Patient Program Resources, Katie Kapugi, Relaxation Therapist, 2020.

disability (ODI),[73] affective distress (depression [PHQ-9],[74] anxiety [GAD-7],[75] activity engagement [Chronic Pain Acceptance Questionnaire (CPAQ]),[76] catastrophizing (Pain Catastrophizing Scale [PCS]),[77] fear of movement (Tampa Scale for Kinesiophobia [TSK]),[78] and physical activity tolerance (6 min walk test).[79]

Patient Challenges: Need for a Team Approach and Stakeholder Coordination

Practical challenges to providing this type of service despite the powerful clinical outcomes include significant out-of-pocket expenses for many patients, limitation of coverage for multiple group sessions, multiple co-pays, and poor reimbursement even for those "covered" services. In many cases, "pain rehabilitation" programs were not considered covered services under their respective plans and/or behavioral health, and RT coverage is limited or covered by a third party insurer. Many patients could not participate in the treatment program because of similar out-of-pocket expenses and coverage issues.

Central to the success of interdisciplinary care is the importance of a well-functioning team and ongoing communication between caregivers, usually structured within weekly team conferences.[80]

TABLE 4.11 Topics: Pain Education Classes (See Table 4.11)

Pain Education: Class Curriculum	Group Session (four to eight patients): Led by Nurse Educator
PROGRAM ORIENTATION – Prior to the program: Virtual & in-person orientation – First day: Rules of the program, expectations – Preparing your own "Pain Toolbox"	NUTRITION – Anti-inflammatory diet – Pain triggers in your diet – Healthy eating habits
SLEEP AND CHRONIC PAIN – How is sleep regulated? – Co-occurring conditions: insomnia, sleep apnea, mood disorders, PTSD – Sleep Hygiene: Habits for sleeping better	MEDICATIONS FOR CHRONIC PAIN – Managing your medications effectively (how to track, one pharmacy, safe storage, communication with Doc) – Over the counter medications (ASA, NSAIDs) – Anti-depressants, Anti-convulsants – Opioid Therapy: dependency, tolerance, addiction, tapering, benefits, harms – Benzodiazepines & Muscle Relaxers

*Swedish Pain Services, Seattle, WA. Structured functional restoration program patient workbook (Becca Taylor, RN).

Attributes of a well-functioning team include members of the treatment team working in a collaborative, integrative environment, with open communication, and the ability for consensus building and resolution of any conflict relating to a patient's treatment program

Patients may be resistant to taking a more active role in self-management after many failed interventions, ongoing impact, and chronic pain. Readiness for change and accepting a biopsychosocial philosophy is an early challenge for patients starting a program. Early in the program, besides learning many different and new skills, a focus includes increasing compliance with practicing techniques (i.e. diaphragmatic breathing, stabilization exercises, Tai Chi), applying skills (i.e. pacing, setting limits), and "unlearning" maladaptive thoughts or ideas about their pain. Ongoing dialog between the patient and the pain management specialist and individual therapists is an important part of the journey patients take part in the course of treatment. Consistent messaging and the openness to reassess and modify short and long term treatment goals are critical to the success of patients benefiting from the program and maintaining and applying skills, being compliant with "their program" after discharge from formal treatment.

The common core components of CBT described by McCracken and Turk, and Hatchell and Mayer can be shared and reinforced by the entire interdisciplinary team and include promotion of self-management approach, relaxation skills training, cognitive restructuring, behavioral activation (goal setting and pacing), problem solving, skills training, habit reversal (i.e. identifying and unlearning maladaptive ideas and behaviors), and maintenance and relapse prevention.[81]

Outcomes for Interdisciplinary Care

Multiple studies, including systematic reviews and meta-analyses, have demonstrated the efficacy of interdisciplinary treatment programs for many chronic pain conditions, including

low back pain, fibromyalgia, musculoskeletal pain, and chronic headaches.[82,83,84] Chou et al. reviewed the evidence for non-pharmacologic therapies for chronic low back pain, finding evidence for interdisciplinary care along with CBT and spinal manipulation were moderately effective.[85] A systematic review of multidisciplinary rehabilitation programs, which included less intense interdisciplinary treatment programs, examined randomized placebo-controlled studies of any intensity that included a physical component and one or both of a psychological component or social work, finding multi-disciplinary more effective than usual care (moderate quality evidence) and physical treatments (low quality evidence) in decreasing pain and disability.

A recent large-scale study of interdisciplinary pain treatment programs found short and long term effect sizes but moderate long term effect sizes for pain, pain interference, and perceived health. In this study, patients with higher levels of perceived disability and suffering showed greater treatment improvement,[86] while other studies have demonstrated improvements in pain, mood (depression and anxiety), medication usage, activity level, and return to work.[87,88]

Murphy et al. examined outcomes across six interdisciplinary pain programs across the Veterans Affairs system (Albuquerque, Cleveland, Puget Sound, San Francisco, Tampa inpatient, Tampa outpatient). The diverse group of programs primarily included group based treatments, with some offering individual psychotherapy, goal setting, and medical visits.[89] Program intensity, disciplines offered, and scope from daily to two/three days per week, 3–6 h per session, and 5–12 weeks. One program site offered both outpatient and inpatient programs, the latter incorporating opioid detoxification and services for veterans from out of state.[89] Overall, all programs demonstrated significant improvements from pre-treatment to post-treatment in nearly all outcomes (consistently with all programs for pain-related functioning, reduced sleep difficulties, and pain catastrophizing). Many programs have demonstrated improved vitality, negative affect, and reduced pain. Effect sizes ranged from medium to large and were positive despite differences in structure, duration of treatment, and resources.

Interdisciplinary Care: A Place for Reduction or Tapering of Opioids

Murphy et al. also examined veterans participating in a three week inpatient interdisciplinary pain program comparing subjects using opioids and agreeing to an opioid taper (average morphine equivalent of 61 mg/day) compared to subjects not receiving opioids for primarily low back, neck, and extremity pain.[90] Individuals in both groups experienced significant improvement in all areas of treatment, including pain reduction, ADLs, mobility, negative affect, pain-related fear, pain-symptom amplification, coping skills, catastrophizing, and sleep. Gradually tapering opioids while participating in an interdisciplinary program, even for those who perceived opioids as beneficial, did not negatively impact treatment outcomes.[90]

Gilliam et al. reported outcomes for a three week interdisciplinary pain program with a supervised opioid taper (average MME = 40) compared to non-opioid users. At discharge and at six months, irrespective of opioid use status, both groups demonstrated improvements in pain, mood, and physical function.[91] In a similar tertiary based interdisciplinary program, high dose opioid patients weaned from opioids showed improvements in pain, depression, anxiety, and pain-related function versus lower dose or no opioids. Seventy three percent of weaned patients remained off opioids, and although treatment benefits declined at six and 12 months after completion, benefits remained clinically significant.[92] A recent study of functional MRI imaging changes following interdisciplinary treatment showed significant improvements in standard outcomes measures, increases in total brain volume, and changes in more specific brain volume that correlated with patient perception of change. Differential program effects were found between opioid and non-opioid use in patients with changes in specific brain areas.[93]

Economic Analysis of Interdisciplinary Treatment

Sletten et al. analyzed the economic outcomes of a three week, five day per week, daily SFRP and found a significant reduction in medical costs between 64% and 90% from three to 18 months post-treatment.[94] Proctor et al.'s prospective study of 1440 patients with chronic work related musculoskeletal disorders compared outcomes of those patients completing and not completing interdisciplinary care.[95] Non-completers of interdisciplinary rehabilitation for chronic pain were found to have poor socioeconomic outcomes one year after discharge from treatment, including poorer work status and greater utilization of healthcare. Patients who did not complete the program were also seven times more likely to undergo post-treatment surgery. Those who completed the program were ten times more likely to return to work and seven times more likely to continue working after 12 months of treatment. Non-completers, as a group, had a greater prevalence of comorbid health problems, greater rates of smoking, ongoing financial disputes related to disability, negative relationships with their employer, and longer pre-treatment length of disability time. Gagnon et al. studied a similar intensity interdisciplinary program and found operant factors contributing to early discharge for injured workers (31%) participating in a functional restoration treatment program and included inconsistencies in performance, noncompliance with self-management techniques, disagreement with goals, and distressful or belligerent behavior.[96]

Interdisciplinary Pain Program Accreditation

International commissions, state workers' compensation bodies and mandated legislative acts, and specific insurance payer groups or plans may certify or accredit interdisciplinary programs or deem specific program centers of excellence, enabling patients to receive treatment as a covered benefit of service. CARF accredits thousands of aging services, behavioral health, opioid treatment programs, and medical rehabilitation programs, including inpatient and outpatient interdisciplinary pain programs across the United States and Canada. CARF describes interdisciplinary pain rehabilitation programs (IPRPs) that provide outcomes focused, coordinated, goal-oriented team services, with strict criteria related to the medical director, behavioral health, and team member training, including specialty certification in pain management and experience in team-based care. CARF IPRPs should focus on the unique needs of persons with persistent pain, including minimizing impairments and secondary complications, reducing activity limitations, maximizing participation and quality of life, and decreasing environmental barriers.[97] CARF standards also include admission and discharge criteria, program components, integration of team conferences, communication with stakeholders involved in an individual's care, as well as community-directed interventions of the interdisciplinary team, including education and training for external stakeholders; and strict ongoing assessments of ongoing

programs, program development, resource utilization management, financial planning, and decision making. After the proliferation of IPRPs in the 1980s, a decline was seen from over 200 accredited CARF programs in the late 1990s to 87 in 2019 and 74 in 2020. Several programs may voluntarily choose not to be accredited for various reasons, including financial or administrative burdens, but CARF accreditation remains a proxy for the relative number of programs available. An increase in CARF accredited programs has been seen in the VA/DoD (currently 20 programs) and now accounts for almost one-fourth of all programs in the United States. This may be related to the 2009 Directive, realizing the value of these programs in a closed system and providing valuable, comprehensive, and patient-centered care for veterans.

The availability of interdisciplinary care may vary depending on the state where care is being provided, including the state and injured workers' benefits system, insurance structure, and fee schedules. The State of Washington Labor and Industries Department, for example, provides and coordinates care for injured workers and describes specific interdisciplinary pain programs for patients covered by the state workers' compensation insurance plan and/or covered under self-insured and managed care plans.[98] The "Structured Intensive Multidisciplinary Programs" or SIMP's are "structured" in that they deliver care through regularly scheduled modules of assessment education and treatment. They are "intensive" and include daily treatment, six to eight hours per day, five days per week, for up to four weeks. They are "multi-disciplinary" or interdisciplinary, including medical management, behavioral health, physical and OT, and vocational services depending on the worker's needs. SIMPs are a "program" in that they provide outcomes focused, coordinated, goal-oriented team treatment. Similar programs and rules are found across the United States in many states, where the treatment of injured workers is legislated, managed, and delivered at the individual state level. Many programs may or may not need to be accredited by CARF or other accrediting bodies. The state of Ohio, for example, requires ongoing re-accreditation by CARF to provide care for injured workers.[99] Providers need to be familiar with their state laws and potential interdisciplinary program availability and resources.

Conclusion

Interdisciplinary care is a true team-based approach based on a patient-centered biopsychosocial model of care. Programs have evolved since the early years of "multi-disciplinary" rehabilitation programs started by John Bonica, Wilbert Fordyce, and others in the 1970s. Functional restoration and structured interdisciplinary treatment evolved and was later championed by Loeser, Mayer, Gatchel, and many others, along with developments in the fields of health psychology and evolution of knowledge around the underlying and complex nature of persistent pain and high-impact chronic pain. Comprehensive pain management relies on an appreciation for complex physiologic changes, including central nervous system sensitization and behavioral and psychosocial factors, necessitating a biopsychosocial approach. This chapter reviewed the SFRP at the Swedish Health System as an example and as a point of reference. The chapter only included an overview of other academic and private interdisciplinary programs from around the United States, demonstrating variability in scope of practice, disciplines used, payer mixes, and novel delivery models.

Interdisciplinary treatment can be described as involving four phases: the comprehensive interdisciplinary assessment, usually provided by a pain medicine specialist, pain psychologist, and vocational counselor; the pre-programing phase, where patient issues are clarified and patients are stabilized for formal self-management training; formal interdisciplinary treatment in a structured program; and finally, the post-program follow up care and maintenance phase.

Pain medicine specialists are commonly the leader or co-leader of the treatment team, helping to coordinate care, setting realistic goals, providing feedback on an individual's progress, and identifying and clarifying pain-related diagnoses. Team disciplines, in general, include physical and OT, behavioral medicine (pain psychology, RT, counseling), nurse education, and vocational services. A key concept of interdisciplinary management is an emphasis on patients learning self-management skills, a greater understanding of persistent pain, the nervous system, sensitization, and how to integrate and apply self-management skills (i.e. exercises and stretching, activity pacing, relaxation, mindfulness, aerobic exercise, and therapeutic movements, such as Tai Chi and yoga) into an individual's daily routine, work, and leisure pursuits. Programs offer a positive treatment milieu to help support patients and guide them to learn new skills to better manage their high-impact chronic pain condition along with traditional multimodal treatments such as medication approaches and interventional procedures, to better and more safely decrease pain and improve function and quality of life. The programs also provide a structure to help clarify issues around opioid use and other controlled substance problems and are an ideal environment to assist patients who need tapering and detoxification as they learn other non-pharmacologic skills to manage their pain and return to higher levels of function.

Efforts to improve patient-centered comprehensive pain care in response to the growing prevalence of high-impact chronic pain, behavioral health disorders, substance, and opioid use disorders, and the drug overdose epidemic should focus on increasing access to interdisciplinary care. In the future, these programs should be a more integral part of typical pain management service lines and pain treatment centers to help patients learn new skills to manage pain better and return to greater levels of function.

IPRPs have been shown to be effective in returning patients to work and have been positioned clinically within the continuum of care for injured workers, including work conditioning and work hardening treatment programs. The reader is referred to other resources more specific to the rehabilitation of injured workers, as this important area was not specifically emphasized in this chapter.[100]

Key Points

- Interdisciplinary pain rehabilitation incorporates a team-based approach, built on a biopsychosocial model of care delivered to patients in structured, primarily outpatient settings that incorporate PT and OT, pain psychology, RT, medical management, and pain education.
- A: multi-disciplinary" team-based approach was developed by John Bonica in the 1960s and advanced in collaboration with Bill Fordyce, incorporating behavioral approaches. Programs were formalized into structured interdisciplinary programs later by John Loeser and many others and expanded to include

functional restoration approaches led by Tom Mayer and Robert Gatchel, all of whom focused on a patient-centered, biopsychosocial approach.

- A growing area of PT directed education within an interdisciplinary pain rehabilitation program includes PNE. PNE deemphasizes pathoanatomic educational content with a focus more on teaching patients about the complex neurologic, psychological, and physical contributors to the development of pain such as pain as an "alarm system" warning of actual or potential tissue damage; pain's influence on thoughts, emotions, actions, and activities; signal transmission, including synapses and neurotransmitters, ability to modify the excitability of peripheral nerves, and the brain's role in the production of pain and the influence of beliefs, emotions, and attention on pain production.
- The four phases of interdisciplinary care include the comprehensive assessment: pre-programming, where necessary workup or stabilization of medical issues or psychiatric function; formal interdisciplinary pain management participation; and post-program or maintenance classes.
- The primary clinical focus of OT within an interdisciplinary program includes ergonomic and posture training, IADLs assessment and training, and learning new skills related to activity pacing. Pacing includes determining the amount of activity that can be done without causing a pain flare up, allowing one to be more productive, conserve energy for goal-oriented activities, and be able to manage their overall pain better.
- Movement therapies may also be included in many interdisciplinary programs and may include a range of Eastern and Western mindful-based practices that help to promote patient-centered proactive participation in one's health and may include the practice of Tai Chi, Qigong, Yoga, Pilates, and the Feldenkrais Method.
- Many chronic pain patients present with varying levels of psychosocial distress, such as depression and anxiety, elevated catastrophic thinking, maladaptive ideas about their pain condition, and previous or active physical or psychological trauma. Pain psychology emphasizes CBT, mindfulness training, acceptance, and commitment therapy provided in individual and group sessions.
- Relaxation therapy uses evidence-based techniques to help patients release or reduce mental, emotional, and physiologic tension. Common relaxation techniques that patients may learn in interdisciplinary treatment include diaphragmatic breathing (DB), progressive muscle relaxation (PMR), grounding exercises, and autogenic training (AT).
- Recent initiatives and legislative acts supporting multi- and interdisciplinary care include the NPS, the CDC Chronic Opioid Management Guideline, the National Academies of Medicine report, the HHS Pain Management Interagency Task Force report, and the National Governor's Association report.
- Several meta-analyses and individual studies have demonstrated the efficacy of IPRPs to decrease pain, improve psychosocial function, and decrease and/or help taper off chronic opioids and return patients to work.

The Healthcare Policy of Pain Management

THOMAS R. VETTER

Rationale for Pain Management Being a Healthcare Policy Priority

Chronic pain is a major cause of suffering, disability, lost productivity, and diminished quality of life across the entire life span and around the world.[1] The global burden of chronic pain is increasing in parallel with the aging worldwide population and the greater prevalence of pain-associated medical conditions like diabetes and obesity.[2]

In its seminal report, "Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research," the Institute of Medicine (IOM) observed that more Americans suffer from chronic pain than the combined prevalence of heart disease, cancer, and diabetes.[3]

According to the United States Centers for Disease Control and Prevention, based upon 2016 National Health Interview Survey data, an estimated 20.4% (50.0 million) of adults in the United States have chronic pain, and 8.0% (19.6 million) of adults in the United States have high-impact chronic pain.[4] Similarly, 27% of the European adult population are affected annually by a chronic pain condition.[5]

The individual and societal costs of chronic pain are multifaceted and extensive. It is essential that well-informed healthcare providers and health policymakers are fully cognizant of these costs (Table 5.1).[6,7] Notably, chronic pain-related costs borne by individual patients and their families—such as uninsured treatments, informal care, and intangibles related to loss of quality of life—are unquestionably substantial but difficult to measure, and hence often under recognized and underappreciated.[6,7]

The societal impact of nearly 30% of American adults having a chronic pain condition includes associated (1) annual direct medical costs of US$261–$300 billion and (2) lost productivity costs of US$297-$336 billion—totaling upwards of $US635 billion dollars per year.[1,8,9]

The estimated direct and indirect healthcare costs for chronic pain disorders in the European Member States vary between 2% to 3% of gross domestic product across the European Union. For 2016, this estimate would correspond up to 441 billion Euros.[10]

Even in a country like Canada, with its more constrained, government-controlled, universal health insurance, the most recently estimated mean total yearly expenditure of CDN$5177 per adult with chronic pain equates to an estimated total annual economic burden of chronic pain of CDN$7.2 billion for all of Canada.[11]

Based upon a series of focus groups of key stakeholders from across the United States, the Pain Action Initiative: A National Strategy (PAINS) originally identified six major themes regarding chronic pain (Table 5.2)[12]—all of which speak to interconnected ethical, economic, and healthcare policy aspects of chronic pain.

Subsequently, the Pain Management Best Practices Inter-Agency Task Force was convened by the United States Department of Health and Human Services in conjunction with the United States Department of Defense and the United States Department of Veterans Affairs, along with the Office of National Drug Control Policy, to address acute and chronic pain, especially in light of the ongoing opioid crisis. This Task Force was mandated both (a) to identify gaps, inconsistencies, and barriers and (b) to make updated recommendations for current best practices in managing chronic pain (Table 5.3).[13]

A greater prevalence of chronic pain in the United States has been reported among women, older adults, previously but not currently employed adults, adults living in poverty, adults with public health insurance, and rural residents.[4] Furthermore, such vulnerable groups of patients—specifically, children, the elderly, the indigent and uninsured, certain racial minorities, and those with major chronic comorbidities (including mental health disorders)—are also at higher risk of inadequate pain management.[12,14]

By many accounts, patients with chronic pain in the United States and around the world continue to face a major burden, and often an attendant health crisis, because of persistent major challenges in obtaining adequate care—resulting in profound physical, emotional, and societal costs.[3,15,16] Pain management thus has a myriad of major healthcare policy factors and implications, some of which will be discussed further in this chapter.

Corporatization of American Pain Medicine: Its Implications for Widening Pain Care Disparities

In his January 1961 farewell address to the country, United States President Dwight D. Eisenhower warned the nation of the widely unrecognized threat to American democracy from the emerging military-industrial complex.[17] In a similar vein, Arnold Relman, the former editor of *The New England Journal of Medicine*,

TABLE 5.1 The Multifaceted and Extensive Individual-Borne and Societal Costs of Chronic Pain[6,7]

Costs of interventions and therapies for treating pain and securing pain relief
Costs incurred for additional primary care and specialty consultations as a result of ineffective interventions being provided
Costs for patients and their families to access conventional or alternative therapies because of a lack of appropriate facilities within their localities
Costs resulting from inappropriate self-medication and treatment by patients
Costs of treating and preventing adverse events that arise as a result of prescribing decisions
Costs of disability claims resulting from an individual's inability to work
Costs to employers and economy of reductions in productivity and absenteeism
Costs of providing social support, home care, and respite care to people suffering with pain
Costs of informal care provided to patients by families, including loss of earnings
Costs of intangibles associated with deterioration in the quality of life of patients and their families

TABLE 5.2 Continued Major Themes in Chronic Pain Management[12]

Reducing disparities in access to pain care among the young, elderly, and lower socioeconomic groups
Defining quality of care in pain management
Need to train qualified providers and training programs in pain medicine
Need for evidence-based public policy regarding opioid use and diversion
Need to raise awareness about chronic pain as a disease to prevent stigmatization and discrimination
Promotion of multimodal therapies for pain care as a way of diverting attention from opioid abuse problem

TABLE 5.3 Dependencies for Achieving Current Best Practices and Excellence in Chronic Pain Care[13]

An emphasis on an individualized, patient-centered approach for diagnosis and treatment of pain is essential to establishing a therapeutic alliance between patient and clinician.
A multidisciplinary approach for chronic pain across various disciplines, using one or more treatment modalities, is encouraged when clinically indicated to improve outcomes.
Effective multidisciplinary management of the potentially complex aspects of chronic pain should be based on a biopsychosocial model of care.
Health systems and clinicians must consider the pain management needs of the special populations that are confronted with unique challenges associated with chronic pain.
Risk assessment is one of the four cross-cutting policy approaches necessary for best practices in providing individualized, patient-centered care.
Stigma often presents a barrier to pain care and is often cited as a challenge for patients, families, caregivers, and providers.
Improving education about pain conditions and their treatment for patients, families, caregivers, clinicians, and policymakers is vital to enhancing pain care.
Addressing barriers to access to care is essential in optimizing pain care, including the workforce gap for all disciplines involved in pain management and improved insurance coverage and payment for different pain management modalities.

opined in 1980, the emergence of what he labeled as the "medical-industrial complex" and presciently observed:

> *This new "medical-industrial complex" may be more efficient than its nonprofit competition, but it creates the problems of overuse and fragmentation of services, overemphasis on technology, and "cream-skimming," and it may also exercise undue influence on national health policy. Closer attention from the public and the profession, and careful study are necessary to ensure that the "medical-industrial complex" puts the interests of the public before those of its stockholders.*

The subsequent inexorable rise of this medical-industrial complex has resulted in an immense for-profit American healthcare industry—ranging from proprietary hospital systems, skilled nursing facilities, and nursing homes to diagnostic services, medical devices, hemodialysis, pharmaceutical industry ("Big Pharma"), the insurance industry, home health care, and many other related brand-named activities.[18–20]

The well-established phenomena of corporatization, consolidation, and commoditization are based on the fundamental business principle of maximizing profitability, primarily through improved economies of scale, greater efficiency, and cost containment. These phenomena can apply to the overall healthcare sector through its individual healthcare companies and medical professional practices (Table 5.4).[21–23]

Over the past 40 to 50 years, there has been a widespread corporate transformation in American healthcare.[18,22,24] The original motivating ideology for the corporatization and proprietization of healthcare was a commitment to excellence of care. However, this impetus has been replaced by cost containment and profitability.[21,25] With the concomitant concentration and centralization of healthcare delivery in the United States, the pursuit of profit has become central.[21]

The primary goal of health corporations has become to earn profits, with their justifying mantras of "no margin—no mission" or "no income—no outcome." However, ironically, their corporate product is health care, for which the poor and vulnerable populations have an equal or greater need but often limited or no access. Thus the corporatization of medicine presents a complex moral dynamic across the variables of access, cost, efficiency, and quality of care.[26]

As the corporatization of health care has become more pronounced in the US, it has paradoxically been in part responsible for not only the high cost but also the inconsistency and fragmentation of the medical care and services that Americans receive.[27] Health care in the United States has thus become dominated by a business philosophy whose primary concern is increasing share-

TABLE 5.4 Basic Definitions Used in Corporate Transformation Among Its Financial Stakeholders[22,23]

Corporatization: The acquisition of part or all of the assets of a healthcare company or medical professional practice by private equity firms, venture capital firms, or publicly traded companies
Consolidation: Merger and acquisitions of many smaller healthcare companies into fewer larger ones
Commoditization: Widespread availability of a healthcare related good or service that has reduced the basis for patient-consumer decision making to simply price

holder value rather than providing optimal care and experience for patients.[28] Furthermore, vulnerable groups become more vulnerable when profit becomes the driving force in conceptualizing, organizing, and delivering health care.[26]

The writ large corporate systematization and commodification of medicine has had a knock-on effect on pain medicine.[25,29] Scientific progress continues to increase the understanding of pain mechanisms and availability of effective pain therapeutics. However, the administrative and economic infrastructure that supports—or just as often denies—providing indicated medical services leaves clinicians ever more disempowered to use this knowledge to effectively care for all individuals who are experiencing chronic pain—thus threatening the moral obligation to treat all pain patients safely, effectively, and equally.[29]

There has been an accompanying transformation (devolution) of the "profession" of pain medicine into the "business" of pain medicine,[30] which has been marked by:

- physician complicity in the transformation of pain medicine from a profession to a business;[31]
- the refusal by the health insurance industry to cover multidisciplinary/interdisciplinary pain management programs;[32]
- the increase in pain management spending without any evidence of improved patient outcomes;[33]
- the overutilization of interventional procedures and spine surgery by physicians who have questionable relationships with industry;[34]
- the innate, continued conflict of interest relating to industry and its impact on pain education;[35] and
- the corporatization of American pain management and the resulting benefits to certain special interests and concomitant increases in disparities in pain care.[26]

Ideally, pain medicine depends upon patients having ready access to freestanding or hospital-based clinics, interdisciplinary care teams with diverse providers and specialty services, diagnostics, interventions, medical products and devices, as well as pharmaceuticals—but each vital component poses layers of bureaucratic, financial, and non-access related barriers.[26]

The biopsychosocial model of pain has been well-recognized as an optimal approach to the assessment, treatment, and prevention of pain.[36–39] This comprehensive, multidimensional approach to chronic pain equally considers the multiple biologic, psychological, and social factors frequently associated with chronic pain (Table 5.5).[40]

However, a narrow-minded vision of pain treatment in the United States—once again, more driven mainly by market forces than evidence—has resulted in a decreasing number of multidisciplinary pain management programs. The practice of pain care that focuses predominantly on pharmaceutical agents and biomedical interventions is inaccurately redefining pain as a nociceptive phenomenon—thus undermining the perceived importance

TABLE 5.5 Factors Associated With The Development of Chronic Pain[40]

Factor	Elements
Demographic	Age Gender Ethnicity and cultural background Socioeconomic background Employment status and occupational factors
Lifestyle and behavior	Smoking Alcohol Physical activity Nutrition Sunshine and vitamin D
Clinical	Pain Multi-morbidity and mortality risk Mental health Surgical and medical interventions Weight Sleep disorders Genetics
Other	Attitudes and beliefs about pain History of violent injury, abuse, or interpersonal violence

of its psychosocial dimensions, which are direct determinants of the tremendous direct and indirect costs of pain to the individual and society.[26] Therefore many pain medicine practices in the United States have become nothing more than profit-driven, "block shops" and "pill-mills" that are staffed and owned by entrepreneurial "needle jockeys" and "pill-pushers" who enjoy very large profit margins and high professional incomes.[41]

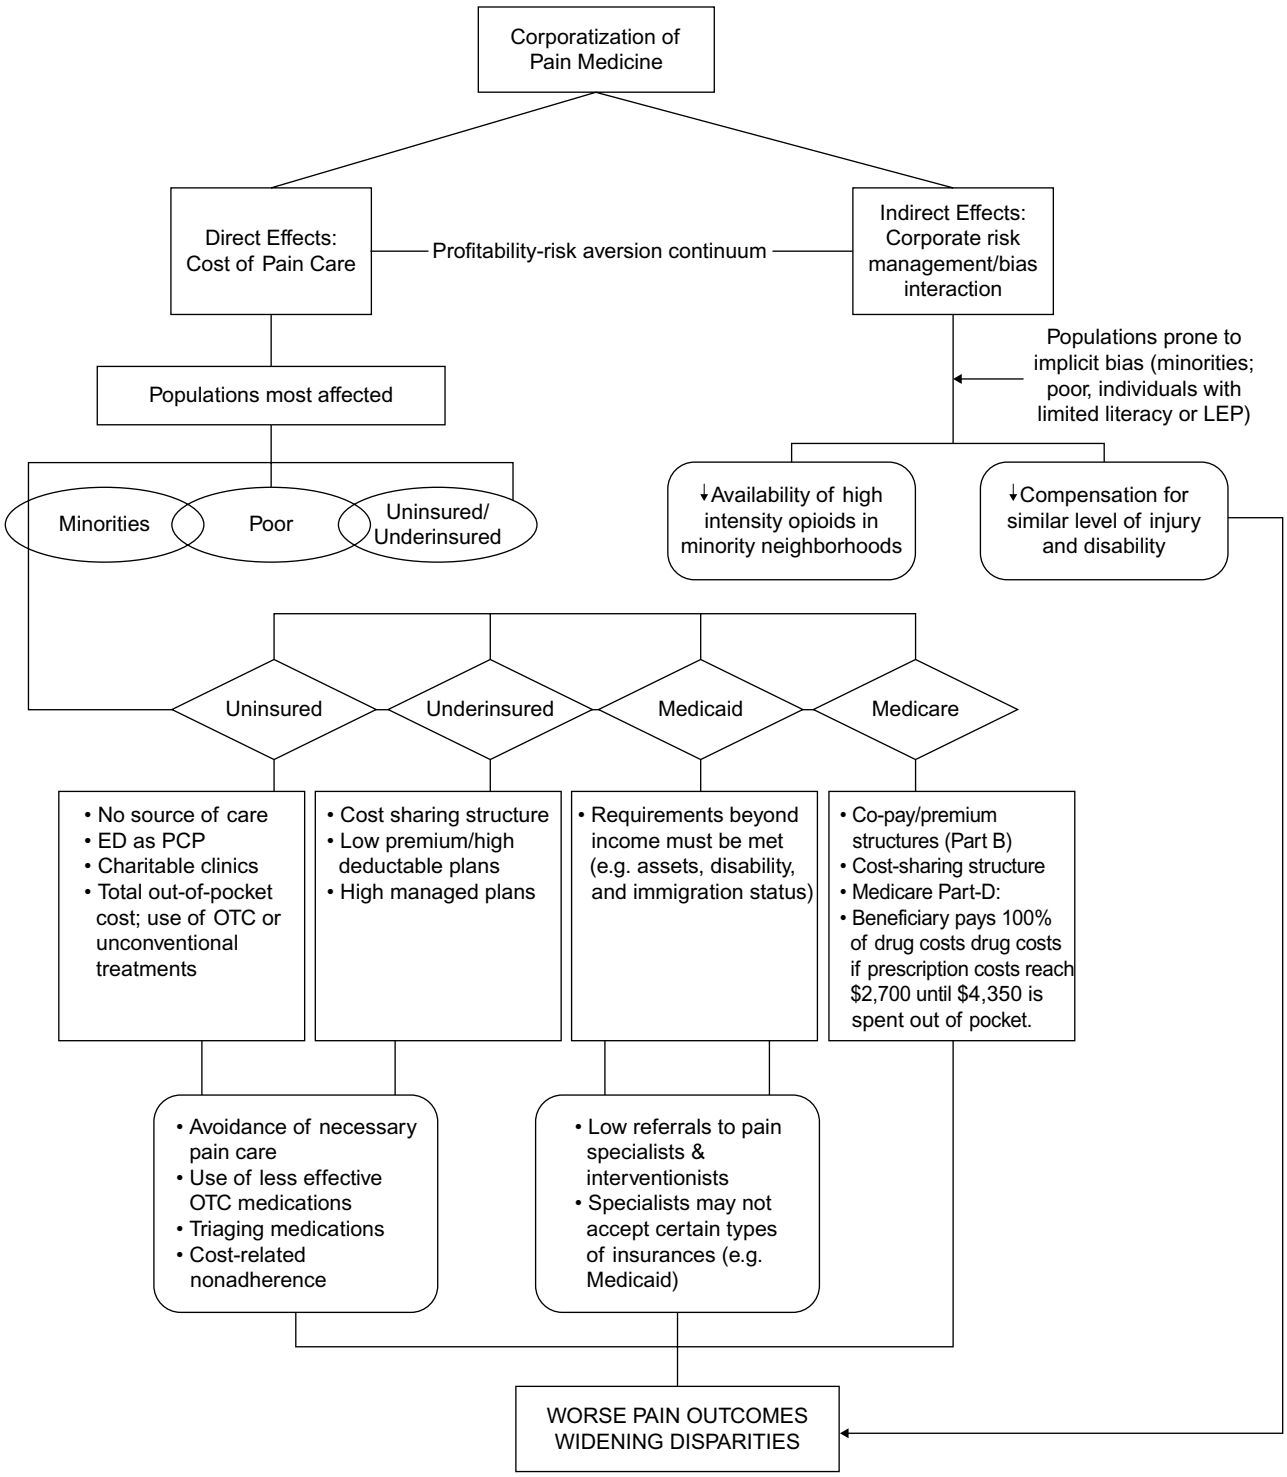
While the corporatization, consolidation, and commoditization of pain medicine have implications for many populations, three groups are the most vulnerable to its effects: the poor, minorities, uninsured, and underinsured. The corporatization of pain medicine in the United States has had major implications, especially in widening the disparities in pain care (Fig. 5.1).[26] Specifically, the highly profit-oriented mindset and culture within the current practice of pain medicine has resulted in the amplification of the already-existing disparities in care by driving up its costs and limiting options, thereby making comprehensive pain treatment inaccessible to more Americans.[25]

Although the corporatization of American medicine may originally have been well-intended—ostensibly, to promote competition, and thereby to drive down healthcare costs—the actual consequence of this widespread phenomenon has been an increase in human pain and attendant suffering.[25]

Pain Management as a Global Public Health Priority and a Human Right

The initial 2013 Global Burden of Disease Study,[42] and its subsequent updates undertaken in 2015, 2016, and 2017,[43–45] have provided valid, consistent, and striking evidence of the substantial, global morbidity and disability burden of pain, and diseases associated with pain, in both the developed and developing countries.[46]

Quite importantly, although some infectious diseases have decreased in prevalence since 1990, the burdens associated with chronic pain are overall increasing. This is partly because of dominant



• **Figure 5.1** How poverty, minority status, and un/underinsurance widen pain treatment disparities in the United States (Reprinted with permission:[16] *ED*, Emergency department;*LEP*, limited English proficiency; *OTC*, over-the-counter; *PCP,* primary care provider.

demographic forces like the aging of populations across the developed countries and similarly increased survival into middle and old age in the developing countries—resulting in not only a growing population size but also a mounting prevalence of chronic diseases.[46]

Humans are thus living longer, but with more chronic disease and disability. An unprecedented transition is occurring from a world with predominantly communicable diseases to one with chronic disease and disability, with implications for the welfare of people worldwide. However, health systems and economies are not prepared for this transition. Instead, the discordance between health system responses and the changing population needs is worsening, as are health inequalities.[47]

Not surprisingly, the World Health Organization (WHO) and the United Nations (UN) have estimated (1) that over 75% to

80% of the world's population receives inadequate treatment for moderate to severe pain and (2) that at least 5 billion people live in countries with minimal to no appropriate access to governmental controlled analgesics like opioids and psychotropics.[48–50]

Given this enormous worldwide burden, pain should presumably represent a continued major global public health concern.[51,52] Yet until only recently, pain management has been relatively neglected by national governmental agencies and international non-governmental organizations (NGOs).[53–59]

Acute, chronic, and cancer pain collectively represent the often unreported and hence silent dimension of many of the worldwide causes of adult and pediatric morbidity and mortality.[46,55] Although acute pain may reasonably be considered a symptom of disease, illness, or injury, chronic and recurrent pain is a specific healthcare problem—a disease in its own right.[52,60] It has been persuasively posited that this pervasive view of chronic pain as a symptom of disease, rather than a disease state in itself, has contributed to the paucity of public health and health policy attention and funding that chronic pain has historically received.[12,51]

Consequently, the WHO, the International Association for the Study of Pain (IASP), and the European Federation of the IASP Chapters jointly declared in 2004 that such widespread, inadequately treated chronic pain must not be tolerated and that the relief of pain should be a universal human right.[53–55,61] In 2010, the IASP issued its "Declaration that Access to Pain Management is a Fundamental Human Right" ("Declaration of Montreal") (Table 5.6), which in addition to emphasizing that chronic pain is a disease entity, reaffirmed the basic human right to access effective pain management and the obligation of governments and healthcare institutions to establish laws, policies, and processes that help promote—not inhibit—access to pain management.[60,62]

Fortunately, the concept of access to pain management as a human right has recently gained increasing currency.[63] Beginning as individual-level advocacy ("cries in the dark"), this concept was embraced by the disciplines of pain medicine and palliative care and by mainstream human rights organizations (e.g., Human Rights Watch). By 2019, the UN and regional human rights bodies had accepted the concept and incorporated it into their key human rights reports, reviews, and standards.[63]

The two ultimate aims of this sustained global pain initiative have been (1) to inform international, regional, and national health policymakers about the personal burden and the economic costs of chronic pain and (2) to educate physicians and allied healthcare professionals about pain assessment and treatment to promote higher standards of care worldwide.[54,60] Similar attention has been focused on receiving effective palliative care being a universal, international human right.[58,64–66] Lastly, the denial of adequate pain treatment, when used as a form of punishment or torture, is a grossly egregious human rights violation.[67]

The Continued Need to Achieve a More Equitable and Balanced, Worldwide Access to Analgesics and Effective Analgesia

Pain is a universal, multicultural experience that affects all people, regardless of demographics or geography. However, its inadequate treatment and adverse effects are not equally distributed worldwide.[51,63]

Despite international human rights laws, calls for the reform of laws and policies inhibiting local, regional, and national access to pain treatment—as well as the attendant obligation of sovereign states to provide their citizens access to pain relief medicine—barriers still commonly exist to patients' accessing effective pain treatment and palliative care globally (Table 5.7).[68,69]

TABLE 5.6 International Association for the Study of Pain "Declaration that Access to Pain Management is a Fundamental Human Right" ("Declaration of Montreal")[60]

Article 1. The right of all people to have access to pain management without discrimination.

Article 2. The right of people in pain to acknowledgment of their pain and to be informed about how it can be assessed and managed.

Article 3. The right of all people with pain to have access to appropriate assessment and treatment of the pain by adequately trained health care professionals.

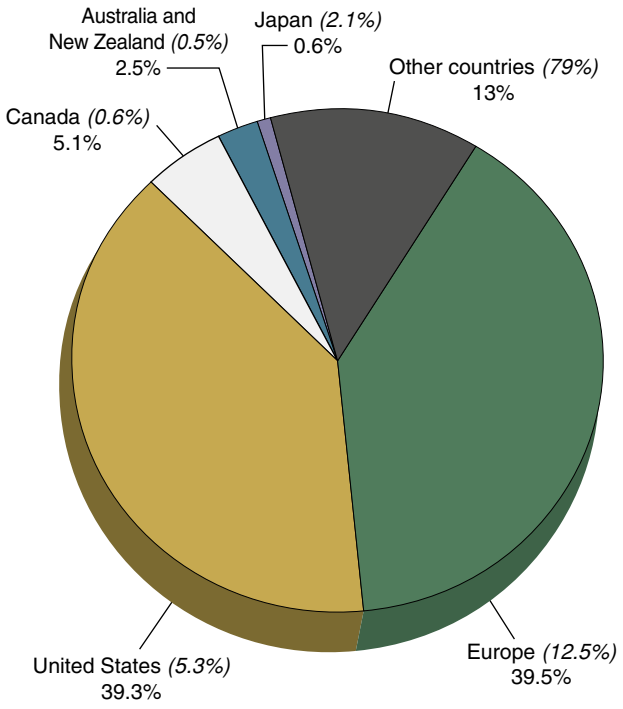
As a result of these barriers, receiving even basic treatments, like oral analgesics, including opioids (e.g. morphine) for cancer pain, and anti-epileptic and anti-depressant drugs for neuropathic pain, remain widely disparate and commonly deficient worldwide.[16,70]

Even though such simple, cost-effective treatments exist, a major gap still continues between the increasingly sophisticated understanding of the mechanisms and pathophysiology of pain and its continued widespread inadequate management.[16,70] As poignantly observed by the authors of the 2018 Lancet Commission on Global Access to Palliative Care and Pain Relief report:[70]

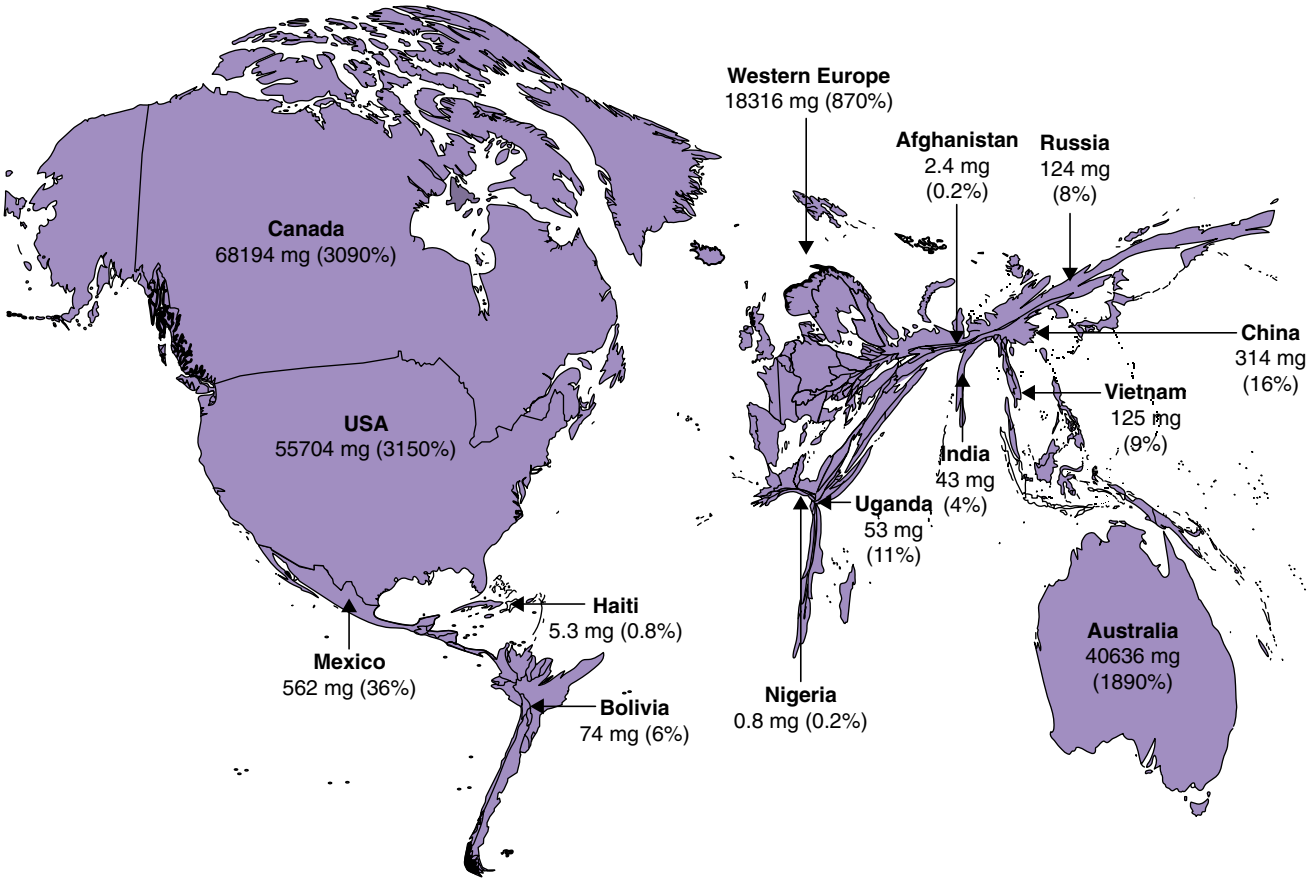
> *"Poor people in all parts of the world live and die with little or no palliative care or pain relief. Staring into this access abyss, one sees the depth of extreme suffering in the cruel face of poverty and inequity. The abyss is broad and deep, mirroring relative and absolute health and social deprivation… The fact that access to…inexpensive, essential, and effective intervention is denied to most patients in low-income and middle-income countries (LMICs) and in particular to poor people—including many poor or otherwise vulnerable people in high-income countries—is a medical, public health, and moral failing and a travesty of justice."*

Greater than 61 million people worldwide experience about 6 billion days of serious health-related suffering annually, which could be alleviated with proper and adequate access to analgesics, palliative care, and pain relief. However, palliative care, in particular, is limited or nonexistent in most parts of the world.[71] The "access abyss" called out by the 2018 Lancet Commission is so stark that 50% of the poorest populations in the world live in countries that receive only 1% of the opioid analgesics distributed globally. By contrast, 10% of the richest populations in the world live in countries that receive nearly 90% of the opioid analgesics distributed globally.[71]

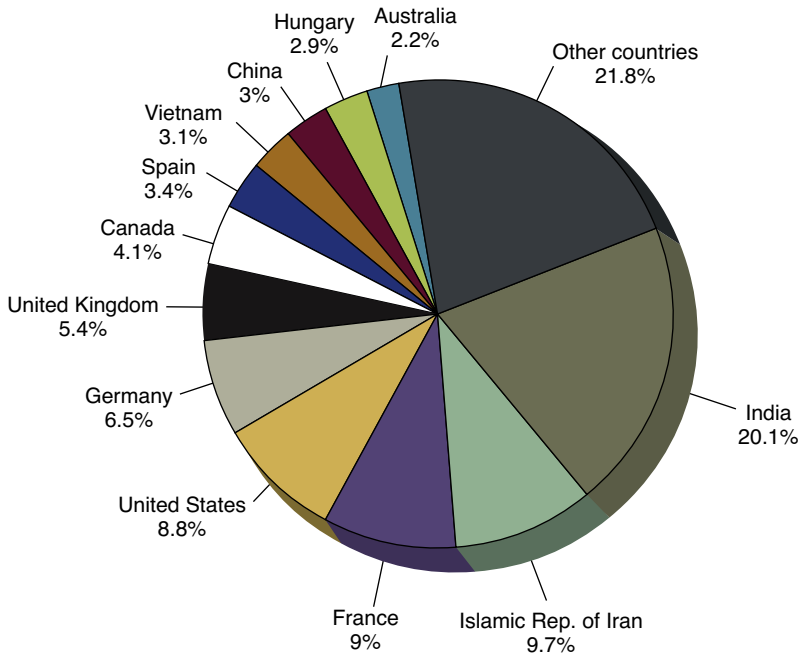
According to the International Narcotics Control Board (ICNB), the country-level differences and maldistribution in the consumption levels of opioids continue to be very significant. In 2018, the greatest share of morphine consumed legally worldwide occurred in the European countries as a whole (39.5%) and the United States (39.3%), followed by Canada (5.1%), Australia and New Zealand (2.5%), and Japan (0.6%) (Fig. 5.2).[72] In stark contrast, 79% of the world's population—mainly people living in low-income and middle-income countries—consumed only 13% of the total amount of morphine used for the management of pain and suffering in 2018, or 1% of the 388 tons of morphine manufactured worldwide (Fig. 5.3).[72]



• **Figure 5.2** Distribution of nation-level, legal morphine consumption in 2018 according to the International Narcotics Control Board (INCB) <http://www.incb.org/>. Note: The percentage in parentheses refers to the share of the total population of all the countries that submitted data on morphine consumption. (Reprinted with permission: **Will need to obtain permission to reprint**).[72]



• **Figure 5.3** Distributed opioid morphine-equivalent (morphine in mg/patient in need of palliative care, average 2010-13), and estimated percentage of need that is met for the health conditions most associated with serious health-related suffering, based upon data from International Narcotics Control Board (INCB) <http://www.incb.org/>. (Reprinted with permission: **Will need to obtain permission to reprint**).[70]



• **Figure 5.4** Distribution of nation-level, legal codeine consumption in 2018 according to the International Narcotics Control Board (INCB) <http://www.incb.org/>. (Reprinted with permission: **Will need to obtain permission to reprint**).[72]

In 2018, the country with the highest percentage of the global consumption of hydrocodone (99.1%), oxycodone (63.4%), and hydromorphone (44.9%) continued to be the United States.[72] In 2018, only codeine consumption was more evenly distributed worldwide (Fig. 5.4).[72] This is ironic given that codeine is a prodrug, which lacks intrinsic analgesic properties without its variable hepatic conversion, because of genetic polymorphism, into morphine.[73]

While opioids remain the mainstay for the treatment of moderate and severe pain, in many countries, the legal availability and legitimate consumption of these analgesics appear grossly insufficient. Historically, various NGOs, including experts from the WHO and ICNB, have published opioid analgesic metrics. These organizations have advocated for legal, legitimate opioid consumption at a level considered adequate, as based on the actual consumption in the most developed countries.[74]

A recent study examined the current adequacy of clinical opioid consumption.[74] The authors analyzed data for 18 controlled opioid medications, primarily used as analgesics, and developed an Adequacy of Opioid Consumption (AOC) Index. The average consumption of the 20 most developed (highest income) countries for 2015 was equated to an AOC Index of 100. An AOC Index of 100 or higher was considered indicative of adequate consumption.[74] The average opioid analgesic consumption of the 20 countries with the highest Human Development Index increased from 84 morphine milligram equivalents per capita in 2000 to 256 morphine milligram equivalents per capita in 2015. The extremes in 2015 were Germany (AOC Index of 304) and Nigeria (AOC Index of 0.0069), with a 44,000-fold difference, further evidence of the continued very problematic disparity in worldwide opioid analgesic consumption.[74]

Nevertheless, as promulgated now for over two decades by the Pain & Policy Studies Group at the University of Wisconsin Carbone Cancer Center, School of Medicine and Public Health, improving global pain relief requires achieving a more pragmatic yet balanced access to opioids worldwide. "Balance in the [health] policy context refers to international, national, and state policies that strive to ensure both the adequate availability of pain medication for patient care and the avoidance of their diversion and abuse."[69]

The Need for a More Rational Strategy and Equitable Approach to Prescribing Chronic Opioids in the United States

While many worldwide needlessly suffer, prescribing opioids for chronic non-cancer pain has tremendously but irrationally escalated in the United States.[49,50,72] Furthermore, this exponential use of opioids for chronic non-cancer pain in the United States has outpaced the availability of rigorous scientific and epidemiologic evidence of the benefits versus harms of these medications.[75–78]

There has certainly been an abundance of attention focused on the ensuing "opioid epidemic" ("opioid crisis") in the United States.[79–84] The still expanding opioid epidemic in the United States lies at the intersection of two major public health challenges: (1) reducing the continued and unnecessary suffering and burden from pain and (2) containing the rising toll of harms associated with the aberrant use of opioid medications.[85] Successfully addressing both these pressing challenges requires a substantial investment in surveillance and research on several fronts—in addition to a well-coordinated healthcare policy response by federal, state, and local agencies along with other stakeholder organizations.[85]

Initially fueled by greater availability and consumption of prescription pharmaceutical opioids, an increasing number of opioid overdoses in the United States are now resulting from less expensive heroin and illicitly manufactured fentanyl and fentanyl analogs.[82] Effectively addressing this current second wave of the opioid epidemic in the United States requires (1) mitigating the

stigma associated with an opioid use disorder and its treatment, (2) increasing access to efficacious treatment options—specifically, methadone and buprenorphine, and (3) reducing opioid overdose fatalities via the wide distribution of the opioid antagonist and overdose reversal agent naloxone.[82]

The escalating overdose deaths and attendant declines in life expectancy in the United States mandates the adoption of a comprehensive public health approach to the opioid epidemic.[86] Successfully addressing the challenges posed by the opioid epidemic requires an integrated, translational approach that combines the contributions of neuroscience, pharmacology, epidemiology, treatment services, and prevention strategies. It also is crucial to integrate interventions across settings—including health care, justice, education, and social service systems.[86] This innovative approach[86] has four interconnected goals:

- recognizing and addressing the social determinants of health and disease;
- applying person-centered approaches for prevention and treatment;
- bridging the gap between implementation science and practice; and
- using data to build learning systems of care relevant to public health approaches to address the opioid crisis.

A sustained and coordinated effort is thus warranted, which is (1) comprised of multipronged, aligned federal and state policies and initiatives and (2) manifested via regulations, laws, funding, and guidelines.[87] Furthermore, population health research is needed to evaluate the impact and potential unintended consequences of any increased legislation and regulation.[87,88] Ultimately, new pain management-related policy and funding can provide the path to new treatments and models of care that can reduce the impact of pain and opioid proliferation as a dual, interdependent public health crisis in this country.[87]

As it evolved from the Pain Action Initiative: A National Strategy (PAINS),[12] the National Pain Strategy (NPS)[89] aimed to serve as the first comprehensive approach to address pain and provided a roadmap with broad and specific broad policy implications.[87] Released in 2016, the NPS[89] focused on six primary areas for improvement:

- population research
- prevention and care
- disparities
- service delivery and payment
- professional education and training
- public education and communication

Although much has been accomplished to date across all six of these NPS domains, the intercurrent transitions in federal and state political power and priorities, available data and funding, and opioid epidemic continue to hamper implementation of the NPS. To their credit, the NPS collaborators have undertaken a thoughtful, interim, comprehensive strengths-weaknesses-opportunities-threats self-analysis, which provides a transparent progress report and valuable experiential, programmatic insights.[87,90]

Even in countries like the United States with its at least ample, if not overabundant, supply of opioids, there are inconsistent prescribing patterns and thus frequently disparate and inadequate access to opioids. As with many other elements of the United States healthcare system, there are racial, socioeconomic, and age disparities in pain assessment and opioid prescribing patterns, with minorities, the poor, and the elderly less likely to access needed controlled substances.[91–95] In many large United States medical centers, such marginalized patients with a legitimate need for opioids are customarily passed around from clinic to clinic. Thus, out of necessity, such patients frequently visit emergency departments, where pain assessment and treatment are widely variable and inadequate, and where racial disparities in opioid prescribing also exist.[96–100]

An innovative, pharmacy-primary care–based chronic opioid management program (an "Opioid Renewal Clinic") for such high-risk patients was successfully implemented at Philadelphia Veterans Affairs Medical Center.[101–103] To be more widely applied, this comprehensive practice model requires close collaboration between primary care physicians and pain medicine specialists.[104] However, there is little apparent support for such a labor-intensive, comparatively low margin program among non-governmental healthcare administrators, interventional pain practitioners, and for-profit health corporations.

This notwithstanding, in a 2017 themed issue of *Anesthesia & Analgesia* focused on the opioid epidemic (crisis),[84] Brown and Sloan[105] very insightfully observed in their editorial:

> *In light of this public health problem, chronic pain physicians have often been maligned as the root cause of addiction and death because of good faith efforts to treat selected patients suffering long-standing pain with opioids. But, anesthesiologists practicing chronic pain medicine do not prescribe the most opioids, and the multidimensional management most often practiced by these clinicians appears to be a paradigm for responsible opioid treatment of patients with all types of pain. Chronic pain physicians must take the lead as educators of the entire field of medicine on the appropriate and comprehensive management of acute and chronic pain.*

Pain is fundamentally a significant personal and public health problem, which calls for policy, regulatory, statutory, and funding changes at the national, state, and local levels to reduce the prevalence of insufficient, ineffective, and disparate pain treatment while concomitantly mitigating the risk of inadvertently increasing the use of treatment like opioids that can result in personal and public harm.[87]

The Need for a More Comprehensive Approach to Chronic Pain-Related Mental Health in the United States

As noted earlier, the biopsychosocial model of pain has been well recognized as an optimal approach to pain management.[36–39] Such a comprehensive, multidimensional approach to chronic pain equally considers the multiple biologic, psychological, and social factors that are frequently associated with chronic pain (Table 5.5).[40]

Moreover, mental illness, despair borne of economic hardship and uncertainty, and societal pressure, especially among adolescents and young adults, also contribute to the misuse and abuse of opioids.[105] Specific risk factors for opioid misuse or addiction include past or current substance abuse, untreated psychiatric disorders, younger age, and social or family environments that encourage misuse.[106] These factors further complicate the rather dismal current picture of the national opioid epidemic as a personal and public health quagmire.

Chronic pain patients often have a psychiatric disorder that negatively influences their response to treatment. Even if they do not meet the formal diagnostic criteria for a psychiatric disorder, many chronic pain patients also have dysfunctional pain-related beliefs and pain coping strategies.[107]

TABLE 5.7 Barriers to Patients' Accessing Effective Pain Treatment and Palliative Care Globally[68]

The failure of governments to put in place functioning drug supply systems
The failure to enact policies on pain treatment and palliative care
Poor training of healthcare workers
The existence of unnecessarily restrictive drug control regulations and practices
Fear among healthcare workers of legal sanctions for legitimate medical practice
The unnecessarily high cost of pain treatment

Studies analyzing data from pain clinics, general population surveys, and health insurance administrative databases have reported that not only traditional adult but also adolescent and younger adult patients with a common psychiatric problem like depression, anxiety, and substance use disorder, are more likely to be prescribed opioids for chronic non-cancer pain than patients without a mental disorder.[108–110]

The current opioid epidemic in the United States has highlighted the substantial yet largely unfunded and unmet need for more consistent and effective psychiatric and psychosocial services—the so-called presently "missing p"—in chronic pain care.[108]

Valid psychosocial screening for depression, anxiety disorder, and substance use disorder should be routine components of the initial assessment for all patients who present for chronic pain management. The initial clinical evaluation should also include an assessment of the patient's functional status, specifically, daily physical activities, personal environmental and social wellbeing, and occupational status.[108] When implemented in conjunction with physical rehabilitation modalities, the timely treatment of any identified psychiatric comorbidities with appropriate pharmacotherapy, cognitive behavioral, and supportive therapy can often lead to improvements in a patient's physical and psychosocial functioning—thereby avoiding the problems associated with long-term opioid use.[108]

Conclusions

Given the widespread and substantial human and financial impact and burden of pain, pain management economics and health policy are inextricably linked. As noted earlier, all healthcare systems—across the entire socioeconomic spectrum and around the world—are confronting the same fundamental health economic and health policy dilemma: How best to allocate finite resources to satisfy seemingly infinite healthcare demands.[111] Ultimately, as observed by a leading healthcare economist, "In a world of budget constraints there are no easy solutions."[112] Nevertheless, clear guidance and recommendations are needed to prioritize and to address these ever-expanding healthcare needs.

Cited at the outset of this discussion, it is fitting to conclude by revisiting the still quite relevant 2011 IOM report, "Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research." It offers a set of underlying principles (Table 5.8), a series of 16 salient recommendations, provides a timeline for implementing them and designates the groups responsible for doing so.[3,113] While focused on the healthcare system in the United States, these IOM findings and recommendations are universally applicable and represent an urgent call for continued action.

TABLE 5.8 Underlying Principles Institute of Medicine (IOM) "Relieving Pain in America: A Blueprint for Transforming Prevention, Care, Education, and Research"[3]

A moral imperative: Effective pain management is a moral imperative, a professional responsibility, and the duty of people in the healing professions.
Chronic pain can be a disease in itself: Chronic pain has a distinct pathology, causing changes throughout the nervous system that often worsen over time. It has significant psychological and cognitive correlates and can constitute a serious, separate disease entity.
Value of comprehensive treatment: Pain results from a combination of biological, psychological, and social factors and often requires comprehensive approaches to prevention and management.
Need for interdisciplinary approaches: Given chronic pain's diverse effects, interdisciplinary assessment and treatment may produce the best results for people with the most severe and persistent pain problems.
Importance of prevention: Chronic pain has such severe impacts on all aspects of the lives of its sufferers that every effort should be made to achieve both primary prevention (e.g., in surgery for broken hip) and secondary prevention of the transition from the acute to the chronic state through early intervention.
Wider use of existing knowledge: While there is much more to be learned about pain and its treatment, even existing knowledge is not always used effectively, and thus substantial numbers of people suffer unnecessarily.
The conundrum of opioids: The committee recognizes the serious problem of diversion and abuse of opioid drugs and questions about their usefulness long term but believes that when opioids are used as prescribed and appropriately monitored, they can be safe and effective, especially for acute, postoperative, and procedural pain, and for patients near the end of life who desire more pain relief.
Roles for patients and clinicians: The effectiveness of pain treatments depends greatly on the strength of the clinician-patient relationship. Pain treatment is never about the clinician's intervention alone, but about the clinician and patient and family working together.
Value of a public health and community-based approach: Many features of the problem of pain lend themselves to public health approaches—a concern about the large number of people affected, disparities in occurrence and treatment, and the goal of prevention cited above. Public health education can help counter the myths, misunderstandings, stereotypes, and stigma that hinder better care.

Key Points

- Chronic pain is a major cause of suffering, disability, lost productivity, and diminished quality of life across the entire life span and around the world.
- The individual and societal costs of chronic pain are multifaceted and extensive.
- It is essential that well-informed healthcare providers and health policymakers are fully cognizant of these costs.
- Patients with chronic pain in the United States and around the world face a major burden because of persistent major challenges in obtaining adequate care, resulting in profound physical, emotional, and societal costs.
- The corporatization of American pain medicine has major implications for widening pain care disparities.
- Pain management is a global public health priority and a human right.
- It is vital to achieve a more equitable and balanced, worldwide access to analgesics and effective analgesia.
- There is a mandate for a more rational strategy and equitable approach to prescribing chronic opioids in the United States.
- There is a substantial need for a more comprehensive approach to chronic pain-related mental health in the United States.

Quality Assessment, Improvement, and Patient Safety in Pain Management

DEBRA B. GORDON, JAMES P. RATHMELL

This chapter covers challenges in defining, measuring, and improving quality in pain management as well as patient safety issues. These are in some cases distinct and in others inextricably interrelated. They are each debated on national and international levels, and both are fundamental elements of the daily practice of pain management. The first section considers quality assessment and improvement programs and practical steps to measure quality and create a quality improvement (QI) program in pain practice. The second section discusses the patient safety movement, both on a national scale and in terms of how each pain practitioner can expect to be involved.

SECTION I QUALITY ASSESSMENT AND IMPROVEMENT IN PAIN MANAGEMENT

Quality is a nebulous concept, especially in the realm of healthcare. Within the field of pain medicine, healthcare quality becomes even more challenging to define because pain itself is a highly individualized, subjective biopsychosocial experience that does not easily lend itself to standardized measurement or treatment. Further, pain medicine itself is practiced in many different ways (e.g. pharmacologic, interventional, rehabilitative, interdisciplinary) and many different settings. Whether one examines healthcare at the micro-level (e.g. encounters between patients and providers) or the macro-system (e.g. processes across large academic healthcare organizations), quality is a property of the system. The healthcare system is laden with quality problems related to underuse, overuse, and misuse of services that impact patient safety.[1] In the ensuing two sections, we discuss the topics of quality and patient safety separately. These sections review the practical efforts each pain care provider can make to address those issues at the level he or she can influence.

What Is "Quality" in Healthcare?

Healthcare quality is generally defined in terms of the attributes and outcomes of care provided by practitioners and received by patients.[2] A more specific definition emphasizes the technical aspects and characteristics of interactions between provider and patient.[3] Important attributes of the provider-patient interaction include communication, trust, empathy, sensitivity, and honesty. Technical quality consists of "doing the right thing right."[1] In other words, performing the right tests or providing the right services at the right time in the right way to accomplish the desired outcomes. Outcomes refer to the patient's health status (e.g. changes in pain, physical function, affect, social roles) after treatment concludes.[4] Avedis Donabedian, a physician and founder of the study of quality in healthcare, stated,[5] "quality cannot be judged by technical terms, by healthcare practitioners alone; that the preferences of individual patients and society at large have to be taken into account as well." Donabedian added, "As such, the definition of quality may be almost anything anyone wishes it to be, although it is, ordinarily, a reflection of values and goals current in the medical care system and in the larger society of which it is a part."

Donabedian is also known for developing a practical "structure-process-outcome" framework for conceptualizing quality.[6] Structure is defined as the physical and organizational properties of the setting in which care is provided; the process is what is done for patients, and the outcome is what is accomplished for patients. This three-prong model provides a more comprehensive definition of healthcare quality if we add that which is suggested by Bowers and Kiefe:[7] "quality being the extent to which structure and process maximize the likelihood of good outcomes." Note, the emphasis is on the "likelihood" of good outcomes because high quality care and good outcomes are not necessarily directly linked. As Chassin has described, the vagaries of the human condition mean that good quality medical care can be followed by poor outcomes, and excellent outcomes can occur despite poor care.[8]

In 1990, Donabedian enumerated seven attributes, or "pillars," of healthcare quality:[9]

1. Efficacy-the ability of care to actually improve health.
2. Effectiveness-how well care achieves improvement in health in the circumstances of "everyday practice."
3. Efficiency-the cost of any given improvement in health.
4. Optimality-the point at which incremental increases in care begin to diminish in their return on investment, such that health may be improved, but in a less efficient manner.
5. Acceptability of care to patients-accessibility, the practitioner-patient relationship, amenities of care, patient valuations of care outcomes, patient estimation of care's economic worth.
6. Legitimacy-considerations of the value of care by others than the patient receiving that care, the aspect of societal valuation as mentioned above.
7. Equity-the balance between what individuals and what society considers the appropriate distribution of care and resources.

The degree of attention given to any attribute will vary depending on the aspect of quality being assessed. In any given instance of healthcare delivery, the patient, the provider, and the payer may have very different opinions as to what healthcare quality constitutes. This last lesson should be kept in mind in choosing any single definition of "quality" as most appropriate.

Lohr crafted a definition that the Institute of Medicine (IOM), now termed the National Academies of Medicine, included in its discussion of quality:[10] "quality is the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge." The IOM National Roundtable on Healthcare Quality revisited this statement in 1998, redefining the phrase "desired health outcomes" to specifically include the health outcomes that patients desire,[11] ushering in the consideration of patient and family satisfaction as a factor in evaluating the quality of healthcare services. However, in the context of pain management, interpreting patient satisfaction is complex. High satisfaction scores are not consistently correlated with traditional outcome and safety indicators and may be associated with increased costs of care.[12,13] Concern over the potential receipt of low patient satisfaction scores impacting pay for performance formulas may have contributed to the overprescribing of opioids[14] in the United States even though opioid prescribing has not been correlated with consumer satisfaction.[15] Patient satisfaction surveys are almost always skewed toward the positive and may be more representative of the quality of the interpersonal relationship between patient and caregiver than the quality of the actual services or their outcomes. Interviews of primary care patients with chronic pain revealed that high patient satisfaction was driven by concrete behaviors including listening, maintaining communication with patients, acting as an access point to comprehensive pain care, providing an honest assessment of the possibilities of pain care, and taking time during consultations with patients.[16]

Drivers of Attention to Quality in Healthcare

Several noteworthy historical influences have led to sustained attention on quality assessment and management in healthcare.

Development of Standards of Care and Accreditation Programs

The debate about the quality of care began more than 100 years ago when a surgeon named Ernest Codman (1869-1940) first proposed standardized outcomes data collection to determine whether care was effective.[17] Codman's ideas swayed the American College of Surgeons to establish a Committee on the Standardization of Hospital Care, ultimately leading to the formation of The Joint Commission (TJC).[18] Interest in care standards grew among public and private insurers as the basis for better and presumably more cost effective coverage policies and quality measurement. Care standards began to be used to shape policy, assess utilization of services, and define and identify inappropriate medical care. In the 1960s, Medicare and Medicaid were established to broaden the population that received healthcare coverage, improve access to care, expand the array of healthcare providers, and decrease cost while improving the quality of care.[19] To help ensure delivery of healthcare in a manner consistent with available standards, accreditation programs such as TJC and the Commission on Accreditation of Rehabilitation Facilities (CARF) became prerequisites for participation in the Medicare program.

Growth of Epidemiology, Information Technology, and Outcomes Research

Growth in clinical epidemiology, information technology, and outcomes research has strongly accelerated the progress of healthcare quality.[20] Use of information and communications garnered from these technological advances helped identify wide variation in the practice and outcomes of care among patients treated for the same healthcare problems in different places and healthcare settings.[2] The awareness of practice variations led to the need to better understand their effect on outcomes. Geographic variations have been uncovered in cost and care, often without linkage between more care and better quality.[21,22] This information fueled interest in outcomes research resulted in new measures of quality, especially in the treatment of chronic illness such as pain, where patient reported outcomes that impact physical, emotional, and social function are important.[23]

The Triple Aim Campaign and Related Concerns over the Cost of Healthcare

In 2007, the Institute for Healthcare Improvement (IHI) created a framework for optimizing health system performance termed the "triple aim" focused on the health of a population, experience of care for individuals within that population, and per capita cost of providing that care.[24] The IHI triple aim entails improvement at all levels of the system and includes identification of target populations, the definition of system aims, and rapid scale testing of models of care and scale up adapted to local needs and conditions. The Patient Protection and Affordable Care Act, passed in March 2010, was designed to address triple pain concerns through a myriad of reforms in healthcare insurance markets.[25] Though the legislation remains controversial, one important objective is to better orient the nation's healthcare system toward health promotion and disease prevention.

The triple aim supports efforts to focus on value for money invested rather than solely on reducing growth or cost reduction. The healthcare spending in the United States grew 4.6 percent in 2018 and accounts for 17.7 percent of the nation's gross domestic product.[26] Ninety percent of the national $3.5 trillion in annual healthcare expenditures are for people with chronic and mental health conditions, many of which include a significant component of pain. It is the perception of many in business, government, and among the public that there is much waste of money in these figures.[27] One example of increased expenditures being disabling low back pain that is partly iatrogenic because of harmful consequences associated with exposure to healthcare.[28]

Malpractice Litigation and For-Profit Healthcare

As an indicator of poor quality, medical malpractice litigation is viewed by others as a driving force for the defense of over utilization of services, leading to increased spending and exposure to unnecessary risk for the patient.[29] Malpractice litigation might also inhibit error disclosure and be counterproductive to efforts to improve quality. Findings from a review of 37 studies in 2020 found no association between measures of malpractice liability risk and healthcare quality and outcomes.[30] The authors concluded that malpractice liability risk might not be an effective deterrent in preventing substandard care.

Additionally, the increase in for-profit healthcare delivery systems, specialty ("boutique") hospitals, and increased office-based

surgery is a concern for some regarding cost and waste in the system. There is a fear that such practice modes "skim" the most profitable segment of income from the traditional hospitals, leaving the larger nonprofit and public entities at risk for financial ruin. There is also a potential conflict of interest when the providers are stakeholders in these healthcare entities. However, a cross-sectional study of 31 provider-led health plans (PLHPs) reported higher Medicare Advantage program star ratings, effectiveness, access, and patient satisfaction among PLHPs compared with non-PLHPs, and lower procedure rates.[31] The association between PLHPs and outcomes did differ by plan size, nonprofit status, and region. This heterogeneity is likely attributed to multiple factors, including population needs, enrollment policies, and leveraging of health system resources.

Politics and the National Pain Strategy

Finally, the politicization of decisions affecting healthcare through the expanding role of government and big business in scrutinizing and regulating its practice is a huge force impacting quality and cost.[32] Examples include potential implications of United States Supreme Court appointments, political influence from industry campaign donations that influence decision makers on a range of issues, including coverage for new technology, payment levels for a care sector, interpretation of a Medicaid regulation, classification of a hospital as "rural" or "critical access," measurement and reporting of quality, or even coverage for physician counseling on end-of-life care options. The toxicity of politics perpetuates enormous waste.

In 2010 the National Institutes of Health (NIH) contracted with the IOM to make recommendations to increase the recognition of pain as a significant public health problem. In response to the final report,[33] the Department of Health and Human Services asked the Interagency Pain Research Coordinating Committee to oversee the creation of a National Pain Strategy (NPS). Evidence from this report suggests that wide variations in clinical practice, inadequate tailoring of pain therapies to individuals, and reliance on relatively ineffective and potentially high risk treatments such as inappropriate prescribing of opioid analgesics or certain surgical interventions that contribute to poor quality care for people with pain and increase healthcare costs.[34] The NPS aligns with the triple aim and recommends improvements in standard methods and metrics that can reveal the pattern of health services, including over and under treatment, costs, and quality of care. The NPS provides a roadmap with substantial broad and specific political implications, including concrete steps to transform pain education, models of care, and payment structures. However, transitions in political power, available data and funding, and the opioid epidemic continue to impact implementation progress.[35]

What Is "Quality" in Pain Management?

Few explicit definitions of quality pain management can be found in the literature. This is partly because, in the history of medicine, views on pain have only relatively recently changed from that of a mere symptom to a field of study and practice specialty. As well, definitions of quality have historically been couched in quality assurance (QA) paradigms popular in the 1970s and 80s that relied mainly on inspection and audit activities aimed at identifying and isolating performance problems. In QA, standards of care are used as yardsticks, focused on identifying adverse outcomes, reducing providers' errors in the care of individual patients, and censuring responsible parties. The difficulty with the QA model is that feedback comes too late in the process and does little to explain differences in practice or outcomes. Also, medical records, a primary source of this type of quality review data, are notoriously incomplete and are often missing information important to evaluate the quality of pain management. In 1990, Mitchell Max, then chairman of the American Pain Society's (APS) Quality of Care Committee, suggested that the traditional formula of QA and education was insufficient to improve pain management and treatment outcomes.[36] Citing the failure of these efforts to change practice, Max suggested that a series of background factors must be addressed in the context of the clinical setting bringing attention to QI in the field of pain management.

In 1996, Sanders and colleagues forwarded guidelines for a uniform approach to a quality assessment of programs that treat persons with chronic non-cancer pain syndromes hinting at a definition of chronic pain care quality.[37] The guidelines were meant to be used as a complimentary document to those published by the CARF and to evaluate interdisciplinary chronic pain programs based on eight basic outcomes objectives including:

1. Reduction in the misuse of medications (if present)
2. Increase in physical function
3. Increase in productive activity at home, socially, and/or at work
4. Improvement in overall mood
5. Reduction in patients' subjective pain intensity
6. Reduction in use of and expenditures for healthcare
7. Where applicable, achievement of case settlement
8. Minimizing pain treatment program costs without compromising the quality of care.

Given the evolution of the healthcare system, frequent updates were recommended, but to date, there have been no visible coordinated efforts to further specify quality definitions for chronic pain programs until the development of the NPS.[34]

Under the leadership of Max, the APS provided QI guidelines for acute and cancer pain.[38] The recommendations specify that all care settings formulate structured, multilevel systems approaches that are sensitive to the type of pain, population served and setting of care that ensure prompt recognition and treatment of pain, involvement of patients and families in the pain treatment plan, improved treatment patterns, regular reassessment and adjustment of the pain management plan as needed, and measurement of processes and outcomes of pain management. This work helped shaped one explicit definition of quality pain management to include appropriate assessment (screening for the presence of pain, completion of a comprehensive initial evaluation when pain is present, and frequent reassessment of patient response to treatment); interdisciplinary, collaborative care planning that includes patient input; appropriate treatment that is efficacious, cost conscious, culturally and developmentally appropriate, and safe; and access to specialty care as needed.[39] A more recent concept evaluation of quality pain management in adult hospitalized patients concluded that pain management quality is a multidimensional concept that encompasses several subconcepts (Box 6.1), and valid, reliable, and operational measures of structure, process, and outcomes are needed.[40]

Quality Assessment and Measurement

Demand for measurement of healthcare quality continues to grow from all fronts, including managed care plans, healthcare consumers, accreditors, and clinicians. The national quality forum (NQF)

• BOX 6.1 Characteristics of Quality Pain Management According to the Donabedian Model[40]

Structure

- system-wide efforts and organizational commitment
- policies and standards supportive of effective pain management
- monitoring effectiveness and appropriateness of pain management
- staff education and training
- interprofessional care
- competent staff
- access to specialized care
- accountability

Process

- prompt recognition of pain
- screening, standardized assessment, and reassessment of pain, based on self-report
- documentation of pain assessment
- appropriate, safe, individualized, evidence-based pain treatment
- patient and family education
- identification of patient groups at risk for inadequate pain treatment
- patient participation
- caring attitude and trust in patient/provider relationship
- continuity of care

Outcomes

- reduced pain severity
- acceptable pain relief
- minimal pain interference on physical and psychosocial function, and quality of life
- minimal suffering from pain
- minimal side effects/adverse effects from treatment
- satisfaction with pain management

was created in 1999 by a coalition of public and private sector healthcare leaders with representatives from providers, purchasers, and consumers as well as the agency for healthcare research and quality (AHRQ), the Centers for Disease Control and Prevention (CDC), the Centers for Medicare & Medicaid Services (CMS), and the Health Resources and Services Administration.[41] Under legislated authority, the NQF-convened Measure Applications Partnership advises the federal government and private sector payers on the optimal measures for use in specific payment and accountability programs. There are five major hospital quality measurement sets endorsed by the NQF,[42] that were developed for a variety of purposes, including QI, pay for performance, and public health monitoring, including:

1. AHRQ Quality Indicators
2. National Hospital Quality Measures
3. Consumer Assessment of Healthcare Providers and Systems Hospital Survey
4. TJC's performance initiative ORYX®
5. Leapfrog Group's Measures

These measurement sets focus on quality and safety and utilize administrative data, patient medical records, and patient surveys.

Recognition of the differences in measures for performance (accountability), research, and QI is important because the **measurement is not a neutral activity, meaning there can be unintended consequences. One example being attempts to quantify pain using the** zero to ten **scale combined with the infamous campaign to make pain a "**fifth **vital sign" that contributed to the overprescribing of opioids.**[43]

Performance Measures

Accountability measures are performance indicators used by purchasers of healthcare to compare services. Performance indicators are typically public and intended to measure variations and improvements in performance and reflect the concerns of patients, providers, regulators, accreditation bodies, and other stakeholders. These indicators are often rate-based and reported as fractions or percentages of a total number of eligible events. The theory is that performance measures create competition in the marketplace, which will lead to improvements in healthcare quality and service. However, **success in improving quality and safety through the use of public performance reports has been mixed.**[44–46] **This is** partly because of **the choice of comparison measures with insufficient evidence of validity and how the measures are used. Measures should be carefully chosen for attributes (Box 6.2) that make them appropriate for the purpose used and support the intended goal.**[47,48] **Use of poorly designed measures may lead to misinterpretation of findings.**

The use of performance measures and the report cards that derive from them to rate institutional, practice, and individual physician performance continues to grow and be tied to payment models. Financial incentives to reward performance measures

• BOX 6.2 National Quality Forum (NQF) Criteria for Evaluating Measures Suitable for Public Reporting[48]

- **Standardization**: The measures are standardized at the national level, which means that all healthcare providers will be reporting the same kind of data in the same way.
- **Comparability**: If appropriate, the results are adjusted for external factors that could make a healthcare organization's performance appear better or worse than it really is; such factors include age, education, gender, income, and health status.
- **Availability**: Data will be available for the majority of healthcare organizations that you are profiling.
- **Timeliness**: The results will be available in time for you to produce and distribute a report when it is most needed by consumers.
- **Relevance**: The measures address the concerns of your audience.
- **Validity**: The measures have been adequately tested to ensure that they consistently and accurately reflect the performance of healthcare organizations.
- **Experience**: Healthcare organizations have experience with these measures to be confident that the measure reflects actual performance and not shortcomings in information systems.
- **Stability**: The measures are not scheduled to be "retired," e.g. removed from a measurement data set to make room for better measures.
- **Evaluability**: The results can be evaluated as either better or worse than other results, in contrast to descriptive information that merely shows how healthcare organizations may be different from each other. For example, a complication rate is an evaluable measure because we know that a lower rate is always better; in contrast, a Caesarian-section rate is not evaluable because we do not necessarily know whether a higher rate or a lower rate is desirable.
- **Distinguishable**: The measures reveal significant differences among healthcare organizations.
- **Credibility**: The measures are either audited or do not require an audit.

include accountable care organizations and bundled payments, value-based purchasing, or pay-for-performance (P4P) programs. All are complex, with limited evidence from which to draw conclusions.[49] Participation has been somewhat voluntary, and the financial incentives have been either paltry, easily gained, or both. Regardless, legislation has accelerated a shift to value-based payments, as evidenced in 2015 when the Department of Health and Human Services announced their intent to tie 85% of all traditional Medicare payments to quality or value by 2016 and 90% by 2018.[50]

Physicians have been reported to support the use of evidence-based measures that are congruent with provider expectations for clinical quality, targeting areas of poor performance and de-emphasizing areas that have achieved high performance.[51] Thus measures targeting process-of-care or clinical outcomes that are evidence-based and viewed as clinically important may inspire more positive change than programs using measures targeted to efficiency or productivity or those that do not explicitly engage providers from the outset. As mentioned, a challenge is that the correlation between process measures that tend to be those most easily measured, and outcome measures that are more difficult to measure, remains controversial. In addition, the use of composite indicators that combine performance measures presents challenges to interpretation distortions and the ability to guide improvement efforts.[52]

Research Measures

In contrast to performance measures, the purpose of measurement for research on quality is to generate new knowledge, though often with limited generalizability. Research on quality may focus on methods of implementation for new processes or outcomes. Measurement for research requires control of all possible variables, yet the study of quality of care must often rely on pragmatic and hybrid study designs because of the complexity of the interventions and context of the clinical arena.

Quality outcomes research has resulted in new measures of quality to help improve clinical practice, especially in the treatment of chronic illnesses such as back pain, where improved function is a primary objective.[53,54] Methods required for selecting or developing a psychometrically validated measure for quality research are beyond the scope of this chapter. Much has been written about the validity and reliability of the current pool of clinical outcome measures, including debate about use as a reference standard in responsiveness studies or as an accurate overall assessment of change. Greater consistency is needed in research measures, hence the development of the NIH Pain Consortium PROMIS® (patient reported outcomes measurement information system), a set of person-centered measures that evaluates and monitors physical, mental, and social health in adults and children.[55] Drawing heavily on the PROMIS methodology, the NIH pain consortium has developed research standards for chronic low back pain, including recommendations for definitions, a minimum dataset, reporting outcomes, and future research.[54]

Quality Improvement (QI) Measures

Measurement for QI is intended to understand a process, the attitudes of key process workers and customers, and to motivate all relevant personnel to improve and to evaluate changes that have been made. Measures chosen for QI must be few and easy to collect because there are often limited resources and time to collect them. Measurements should be made over a short period so that data can be collected periodically and, most importantly, be available to provide timely insight into a problem. A criticism of QI has been the lack of rigor in the methodologies used to generate data with resultant doubts about the validity and reliability of QI measures.[56] However, there are no gold standard methodologic approaches to QI measurement development. A more thorough description of QI approaches follows.

Continuous Quality Improvement (CQI) or Total Quality Management Approaches

Used for years in the manufacturing industry, QI is a compilation of methods adapted from psychology, statistics, and operations research to avert predictable human errors, eliminate unnecessary and harmful variations in practice, and improve the production of goods and services.[57] Of note, many assessment techniques developed in engineering and used in QI (e.g. statistical process control, time series analysis) have more power to inform about processes and context than randomized controlled trials.[57] Continuous QI (CQI) is a philosophy and involves enlisting an entire organization to work toward a goal of continuous improvement in quality by carefully studying the process one is attempting to improve and changes the responsibilities and power of frontline workers. There are numerous approaches to QI, but the general principles are similar.[58] All focus on reducing unnecessary variation in production processes, standardization, and continuous improvement in outcomes rather than on the identification and elimination of "defects." The following four major frameworks for CQI share the philosophy that quality problems are process problems rather than people problems and base decisions on data, not hunches or opinions.

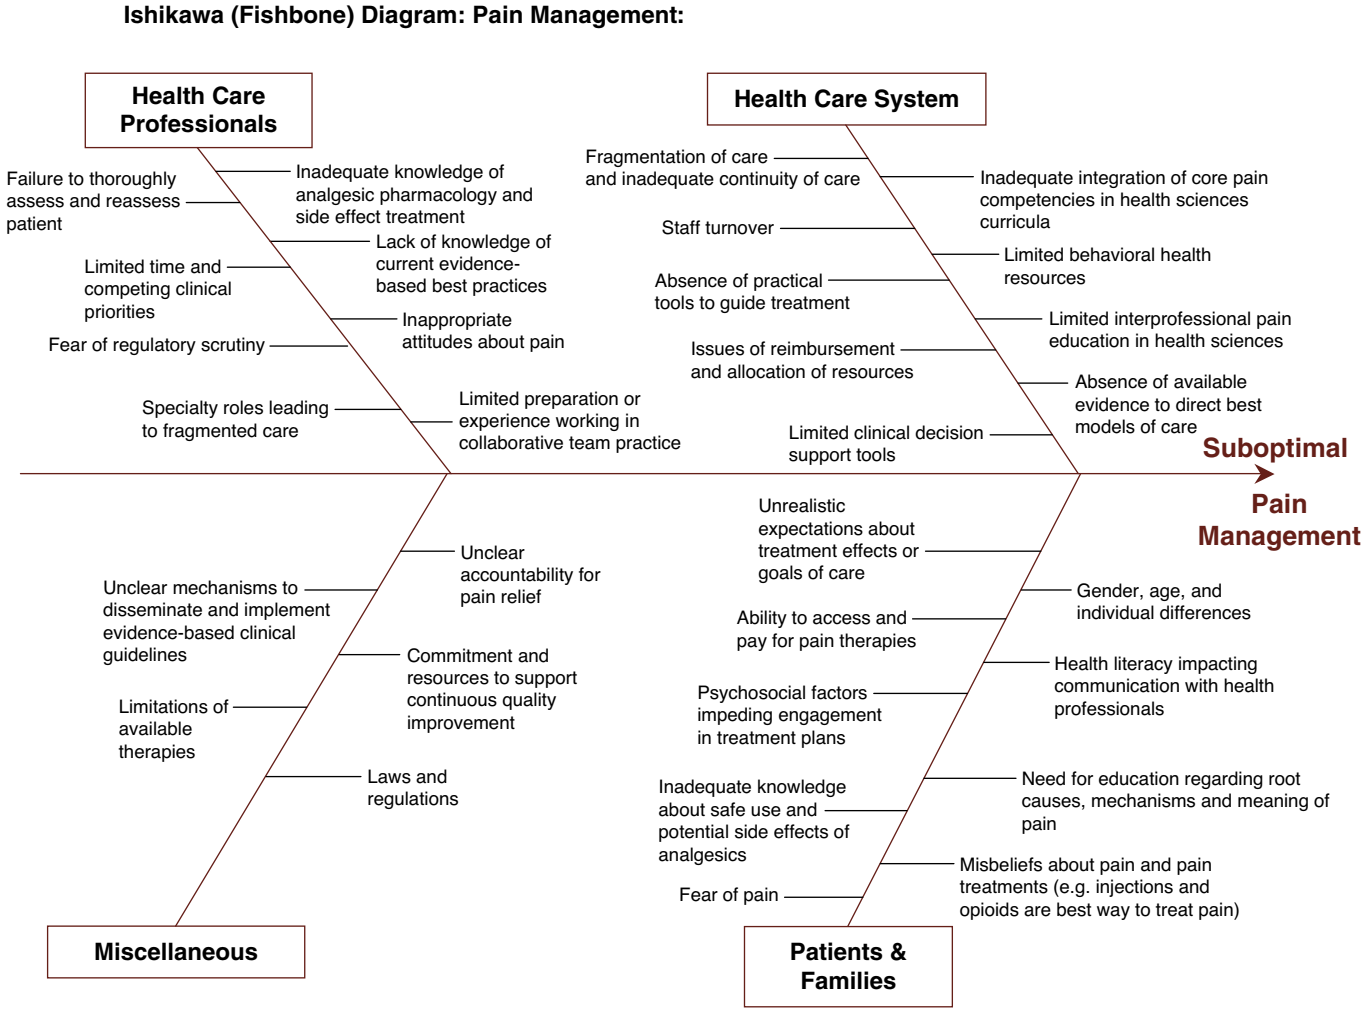
1. **The PDSA approach** (an acronym that stands for Plan, Do, Study, and Act) was first popularized by Edwards Deming (1900 to 1993), an electrical engineer, and is a rephrasing of the scientific method.[59] This method is driven by three primary questions: (1) what are we trying to accomplish, (2) how will we know that a change is an improvement, and (3) what changes can we make that will result in improvement. Continual improvement is made through repetitive iterations of the PDSA cycle. Deming is also known for his "profound system of knowledge,"[60] composed of four interrelated parts:
   1. Appreciation for a system
   2. Understanding variation
   3. Theory of knowledge or how people's view of what is meaningful impacts their learning and decision making
   4. Psychology

   Deming's work was influenced by Walter A. Shewhart, a physicist known for his developments in using statistics such as upper and lower control limits set at three standard errors above and below the mean to identify major causes of variation.
2. **Total Quality Management (TQM)**, attributed to Joseph M. Juran (1904 to 2008), builds on the work of Deming to prioritize customer expectations and team-based approaches to improve products and customer satisfaction.[61] Juran is attributed with the development of the Pareto principle (the 80-20 rule), which states that 80% of the effects in a system arise from 20% of the causes. TQM integrates all employees into the common goal of QI. Adapted by the IHI, team-based improvements are accomplished by using analytical

tools (e.g. flowcharts, statistical charts) and process techniques (e.g. brainstorming, nominal groups, consensus decision making).

3. **Six Sigma** is a management system developed by Motorola in 1986 to reduce variability within work processes by reducing error rates.[62] A five step methodology known as DMAIC (define, measure, analyze, improve, control) is followed using histograms, run charts and Pareto charts, and Ishikawa or "fishbone diagrams" most relevant to the variables to be addressed by the QI team. An example of a pain management fishbone diagram can be seen in Figure 6.1.
4. Finally, **Lean** emerged from the Toyota Production System in the 1990s and is aimed at reducing waste or non-value-adding activities. Value stream mapping[63] is used to visualize materials and information in a process and identify excess steps and bottlenecks such as wait times, motion, and cost of quality. Value stream mapping helps analyze the current state and design a future state for the series of events that take a product or service from the beginning of the specific process until it reaches the customer.

TJC has constructed a framework utilizing Lean and Six Sigma methods along with a systematic approach to change management to help healthcare organizations create a culture of high reliability for quality and safety.[64] Medical students from the Columbia-Bassett Medical School used a Lean Six Sigma approach to pain management when Hospital Consumer Assessment of Healthcare Providers and Systems survey data revealed opportunities for improvement.[65] Analysis of patient survey data revealed timeliness of addressing pain and feeling the care team understood their pain significantly correlated with being "very satisfied." These two variables were identified in a Pareto analysis as accounting for 71% of defects. Process mapping helped identify root causes, and a successful procedure was created to focus on response time for pain-related calls from patient call to nursing contact.



• **Figure 6.1** Ishikawa (Fishbone) Diagram: Pain management example
Also called a cause-and-effect diagram, the Ishikawa or fishbone diagram helps staff track down the reasons for imperfections, variations, defects, or failures. This tool can be useful when identifying possible causes for a problem. The diagram looks just like a fish's skeleton with the problem at its head and the causes for the problem feeding into the spine. Brainstorm all the possible causes of the problem. Ask, "why does this happen?" Consider all major categories of causes of the problem or use generic headings: methods; machines (equipment); people (manpower); materials; measurement; environment. As each idea from a person is given, writes it as a branch from the appropriate category. Causes can be written in several places if they relate to several categories. Continue to ask "why?" and generate deeper levels of causes. Layers of branches indicate causal relationships.

Though the evidence supporting these CQI methodologies in healthcare is positive, it remains limited and may only have modest effects on outcomes at best.[66]

Reducing Unnecessary Variation by Understanding Root Cause Analysis

The process of reducing variation or eliminating misuse, underuse, or overuse of treatments is inherent in the standards of evidence-based medicine. It is important to recognize that variation may be good or bad, or neither. It may indicate significant overuse or underuse of a therapy and thereby signal that either the science of the therapy is poor or that it is being applied haphazardly. However, before practice data can truly be defined as significant variation, it must be assayed for any underlying reasons. This includes exploring potential root causes and associations of multiple factors influencing diverse practices, such as dissimilarities in supply and demand because of geographic economics and climate. For instance, findings in the variation of inappropriate use of MRI for occupational low back pain showed significant associations based on gender, state workman's compensation policy not limiting initial treating provider choice, higher state orthopedic surgeon density, and lower state MRI facility density.[67] The reader is reminded that associations are not causation. In reality, a deeper inquiry into actual root causes is needed focusing on systems and processes in an organization to identify potential targets for improvements.

Statistical control charts are often used to determine if a variation is because of chance or special causes. Common-cause variation is chance or random variation where no one or combination of factors is affecting the process variation, whereas special-cause variation is when one or more factors influence the process variation in a non-random way. Five root cause analysis tools (Box 6.3) are commonly used in QI efforts, each appropriate for different situations.[68–70] The value in finding variation in care is to provide a signal that there may be best practices that can be emulated, but best practices can only be determined if variation is understood. Again, not all variation is misuse, overuse, or underuse.

Implementation Science and Toolkits

Because simply becoming aware of or being educated about the need to improve quality rarely produces the type of behavior changes required, more is needed. Improvement science overlaps with implementation science and other commonly used terms (e.g. translational research, knowledge transfer) to refer to dissemination and implementation strategies for new knowledge or information.[71] All use the scientific approach to systematize changes using social sciences to provide a conceptual and methodologic framework for the complexity of the phenomena at stake.[72,73] These methods have moved healthcare from more intuitive approaches to improve quality of care to the acknowledgment of the need for more planning and systematization with greater incorporation of the social sciences and enhancement of the role of context.[74] Improvement science identifies the intervention's technical component, the implementation strategy, and the context within which the intervention is implemented. Critical contextual factors include the impetus for change, leadership commitment to quality, professionals' engagement in problem solving, organizational alignment of objectives, resource allocation and action at all levels of the organization, and overcoming barriers.[75] Though the task may seem overwhelming, it merely emphasizes the need for teamwork, planning, and appreciation for the interrelated parts of the system.

To aid individuals with a practical approach to implement systematic changes, toolkits have been developed to address several topics, including pain management with reports of positive effects on clinical processes. However, robust research is needed.[76] Toolkits typically include introductory and implementation materials (e.g. research summaries), healthcare provider tools (e.g. care plans), and materials for patients. The American Academy of Family Physicians has a toolkit designed to help family physicians identify gaps in practice flow,[77] standardize evaluation and treatment of chronic pain patients, and facilitate conversations surrounding pain and treatment goals, as well as identify and mitigate risk. It contains primary care, patient centered resources that highlight key workflow features to streamline delivery and offer best-care medicine. The Veteran's Health Administration designed a tool as part of its NPS to assist healthcare providers and facilities to devise methods and implement processes to measure pain treatment outcomes based on focus (patient or process), type of pain (acute, chronic, or pain at end of life), and practice setting.[78] As well, the Society of Hospital Medicine (SHM) has produced an implementation guide[79] to provide practical advice to hospitalist physicians and other leaders who are developing programs to improve pain management in their services and facilities. The focus is on medical patients, though many of the principles described are relevant to patients recovering from surgical care who are increasingly co-managed by hospitalists.

Benefits and Steps in Constructing a CQI Program for a Pain Practice

There are several ways that a CQI program can help a pain practice, including the approbation of accreditors and P4P programs that tie some portion of provider income to either process or outcome achievements. Additionally, benchmarking to elucidate best practices can add value to the community through sharing lessons learned in the "real world" of clinical practice with others in the form of scholarly projects.[80–83]

CQI programs may improve pain treatment quality by simply inducing a more extensive review of a patient's history. For instance, inquiry about patient risk adjustors may lead to the recognition of mental health issues that could significantly affect the outcomes of any pain treatment plan. The use of baseline patient measures can direct care and provide an understanding of the likely potential for meaningful improvement in function and pain severity by identifying risk factors for long term treatment failure. Studies with longitudinal designs of persons with chronic pain indicate associations between measures of baseline self-efficacy and pain severity, functional impairment, and affective distress at follow up, as well as potential moderating effects of sociodemographic characteristics.[84] Considerations for risk adjustment also come into play when measuring opioid utilization and risk of opioid use disorder; for example, geographic epidemiologic work demonstrates variations in opioid-related overdoses that are presumed to be related to differences in opportunities and resources at the United States county level, which include rates of disability, employment, housing crowding, insurance, and racial and ethnic diversity.[85]

The use of a clinical database for monitoring patient outcomes provides a sense of participation in the process for the staff whose work is being assessed, a key factor in their acceptance and

• BOX 6.3 Common Root Cause Analysis Tools[69,70]

1. Pareto Chart

A Pareto chart is a histogram or bar chart combined with a line graph that groups the frequency or cost of different problems to show their relative significance. The bars show frequency in descending order, while the line shows cumulative percentage or total as you move from left to right.

Hypothetical example

2. 5 Whys

This method uses a series of questions to examine and peel away surface layers of a problem to get to the root cause. Each time you ask why the answer becomes the basis of the next why. This tool is most useful for problems where advanced statistics are not needed. A deeper analysis may incorporate the results of a Pareto analysis. It may take more than five times to uncover the problem.

For example

- *Why is the patient not seeing the right provider in a multidisciplinary pain clinic?* According to a Pareto chart of contributing causes, the biggest factor is the scheduling center's routine to calendar a patient for the earliest available appointment.
- *Why does the call center schedule for earliest available appointments?* Because they have no triage or screening criteria or information to do otherwise.
- *Why is there no triage or screening criteria?* Because the pain clinic has not created triage criteria that can easily be used by a scheduler.
- *Why hasn't the clinic created triage criteria?* Because historically, the workflow involved a nurse triage of incoming referrals.
- *Why is the nurse triage no longer happening?* **Because the need to clarify triage criteria with the appointment scheduler was not captured in a reorganization of the pain clinic and change in nursing roles.**

3. Fishbone Diagram (see Fig. 6.1)

Also called an Ishakawa or "cause-and-effect" diagram, a fishbone sorts the possible causes into various categories that branch off from the original problem. Multiple sub-causes branch off each identified category.

4. Scatter Plot Diagram

A scatter diagram plots your suspected cause (or independent variable) on the x-axis and the effect (or your dependent variable) on the y-axis. This scatter plot or diagram helps uncover relationships. If the patterns show a clear line or curve, you know the variables are correlated and can proceed to correlation or regression analysis.

Legend: Correlation between RMDQ scores and pain intensity. Scatter plot showing the relationship between disability (RMDQ scores) and pain intensity scores measured with visual analog scale. The many small circles represent the plotted values obtained for each of the variables, while the line represents the best fit for the correlation between them.

RMDQ = Roland Morris Disability Questionnaire

Doualla M, Aminde J, Aminde LN, et al. Factors influencing disability in patients with chronic low back pain attending a tertiary hospital in sub-Saharan Africa. *BMC Musculoskelet Disor.* 2019;29(1):25.

5. FMEA

This is a proactive assessment tool and qualitative analysis method used during the process or product planning to identify potential systematic failures, consequences, and causes before events occur. The FMEA process focuses on causes and opportunities for preventing negative effects and involves scoring for severity, occurrence, and detection ratings that allow calculation of a risk priority number to determine further action.

Potential FMEA [system, product or process]

Background				Rating				Countermeasure			Results			
Description of Process	Potential Failure Mode	Potential Effect(s) of Failure	Potential Root Causes	SEV	OCC	DET	RPN	Owner	Due	Recommended Actions	SEV	OCC	DET	RPN

SEV = severity (1-10), OCC = occurrence (1-10), DET = detection (1-10), RPN = risk priority number

enthusiasm for the benefits of CQI. An active CQI program will also allow practitioners to evaluate the effects of introducing new therapies or treatment algorithms into their practices and either prove or disprove their value.[86]

The most significant hurdle in CQI for pain practices is a lack of apparent benchmarks or national "best practices" that providers emulate. Using the literature to establish benchmarks is prone to error because of the significant positive bias in the reporting of the success of techniques there. Overall, the evidence is not clear as to which, if any, interventions improve many chronic pain states.[87,88] The analysis of practice patterns among either partners or an unassociated local group of pain practitioners is a potential source of evidence in those situations where there is a lack of randomized controlled trials in the peer-reviewed literature. Assessment programs under the mantel of "peer review" statutes will allow participating pain practices more timely and open means of sharing their own best practices to attempt to increase the quality of the community's pain care.

Creating a CQI Program for a Pain Practice

There are several steps in creating a CQI program for pain:

1. Identify and engage front line practitioners (physicians, nurses, therapists, case managers) who will be involved.
2. Gather those caregivers together to align their information goals and to craft a set of measures toward which all can agree that the program should be directed. A good starting point is the list put forth by the IOM's *Crossing the Quality Chasm* IOM,[89] with six specific targets for improvement:[89]
   a. Care should be *safe*.
   b. Care should be *effective* and based on proven *evidence and science*.
   c. Care should be *efficient* and *cost effective with no waste*.
   d. Care should be *timely*, with no waits or delays.
   e. Care should be *patient centered*: respect patient preference and give the patient control.
   f. Care should be *equitable* with no unequal treatment.
3. Pick outcome measures that will allow accurate assessment of the problem. Any evaluation of the overall quality of care needs to consider a patient's perception of quality and understand it is a cumulative process that develops over time, as the different attributes of the services available and their outcomes are revealed.[90] Indicators are of three types:
   a. *Structure measures* assess the characteristics of the practice or a facility, such as staff-to-patient ratios, presence of evidence-based policies, or continuing education supports. Structure measures may simply be the absence or presence of system supports but can be used to prioritize limited resources and standardize that which can be standardized.
   b. *Process measures* assess how care is provided in the practice. For instance, documentation and communication of critical steps in the workflow surrounding referrals and billing. The disadvantage to process measures is primarily in determining a link with the outcome. These must be considered surrogates for outcome in the many situations in which direct measurement of the outcomes is impeded by difficulty with risk adjustment or other barriers. Another limitation is that process measures are frequently used because they are relatively easy to measure, but they may have little connection to true clinical outcomes. An example is how long it takes for a patient to be roomed after arrival.
   c. *Clinical outcome measures* include using repeated patient health status testing to determine health status longitudinally after interventions. In most practices, it would be expected that some sort of evaluation of patients in this regard would be collated and sorted by diagnosis, demographics, and intervention. This is a critical step to monitor for overuse or underuse of medical therapies.
4. The chosen measures should have the following characteristics:[91,92]
   a. *Relevance*. They should directly relate to the goals of the group, and it should be true that the interventions of the group have an effect upon them.
   b. *Timeliness*. The measures should be collected in a timely manner to relate them as closely as possible to the interventions that the practitioners wish to assess.
   c. *Reliability*. The measures should be accurate and consistent no matter when or who is assessing and recording them.
   d. *Validity*. The valid measure is sensitive to changes that the practitioner can effect.
   e. *Precision*. The measures should be clearly defined and leave little potential for individual or erroneous interpretation.
   f. *Cost effectiveness*. A CQI program costs money, and the measures should be significant enough to your patients and your practice that they are worth the time and money expended on the process of collection and analysis.
   g. *Provider control*. The variable measured must be one that the provider or organization can control, or it is not worth measuring. For instance, measuring patient self-reported pain levels one year after intervention for a chronic pain condition is unlikely to reflect a process that the provider can control because of the impact of the intervening healthcare and patient activity over the course of one year.
   h. *Clear meaning*. The measure must be one that is easily understood by all concerned.
5. Terminology-once the practitioners have chosen the measures. The terms may need to be adjusted to be in congruence with standard nomenclature. The accepted standard is a somewhat moving target, but SNOMED-CT (systemized nomenclature of medicine-clinical terms) is the designated unified medical language systems by the NIH and National Library of Medicine (NLM) to promote the creation of more effective and interoperability between computer systems, including electronic health records in the United States. Thus all practitioners should make sure their own terms are "cross-walked" to SNOMED terms so that they report data that, where possible standardized for accreditation and certification bodies and payers. One can download all of SNOMED at the NLM site, which has licensed SNOMED for use by any entity within the United States. This site is www.nlm.nih.gov/research/umls, but the data sets are raw, and most practitioners would need help manipulating them. This crosswalk process may be accomplished by several vendors.
6. *Risk adjustment* must be included in the design of the monitoring system for the measurements to have any utility for identifying high quality and best practice. Risk adjustment uses multivariate regression methods to measure performance by removing between-clinic differences associated with factors outside of a clinic's control and constructs a measure that reflect a clinic having comparable patients. Risk adjustment is still a confounding science, with many controversies but has been used for several purposes, including prediction of concurrent and future healthcare utilization levels of insured patients who receive some care from complementary and alternative medicine providers compared with those who receive care only from conventional practitioners to provide spine surgeons and hospitals a basis to make informed decisions for elective single-level posterior lumbar spine fusions.[93,94]

The vagaries of risk adjustment recommend that practitioners use tools of measurement that are already validated. If a pain practitioner or group decides to create a completely new measure, careful attention to risk adjustment theory and its evaluation in the literature or appropriate texts is recommended.[95] Risk adjustment in chronic pain practice poses very significant challenges, in view of the diversity in the types of adjustors that are operant in the widely diverse population of persons with chronic pain conditions, including multiple comorbid conditions ranging among physical disabilities, economic and social burdens, and mental health disorders. Nonetheless, small groups of clinical experts can choose risk adjustment indices with validity if the process is done with bias controls and if there is the involvement of biostatisticians and epidemiologists. The use of a standardized pain classification is important. For instance, the analgesic, anesthetic, and addiction clinical trial translations, innovations, opportunities, and networks

(ACTTION)-APS Pain Taxonomy (AAPT) reflects common features and comorbidities, including psychosocial factors that influence the diagnosis and trajectory of chronic pain disorders.[96]

Use of Outcome Measurement Tools for your Pain Practice CQI Program

Validated quality of life or condition-specific assessment tools used in clinical practice (e.g. EQ-5D-5L, SF-12 or 36 measures, Roland Morris back pain, Waddell disability index, the fibromyalgia impact questionnaire, others) might be considered for a pain CQI program.[97–99] These have been used in scientific studies to measure some of the variables that would be valuable to a pain program. However, the reader is cautioned that a great deal of variation exists in the versions of some of these instruments published in the literature.

Gathering data is ideally managed in part by using patient surveys before and after the provision of services, with timing appropriate to the nature of the patient's condition and the expected effective duration of the intervention. The use of both a short general health assessment and a specific pain evaluation tool are probably the most basic approach. Reviews of the relative merits of acute and chronic pain measurement tools advocate well for certain tools in certain patients or for certain conditions.[100] Brevity and speed of both information entry (either by the patient or staff) and data analysis are salutatory aspects of an outcome measurement system, and these should all be considered in determining which instruments will be used.

The desire for universal measures of self-reported health, including the ability to compare disease burden and treatment impact across various chronic conditions, and to be able to measure patient-relevant outcomes, using a common metric, with people who have more than one disease or medical condition led to the development of NIH PROMIS measures.[101] The current body of clinical validity evidence for the nine PROMIS measures (self-report measures for adults for functions, symptoms, behaviors, and feelings) indicates that they too are effective across a range of chronic conditions,[102] though the practicality of using in clinical practice is debatable. Using computerized surveys that leverage item response theory (e.g. in the waiting room or online prior to a clinic visit) holds the potential to reduce staff and patient burden and improve data integrity by maximizing accuracy.[103]

One important issue is the significance of any change observed in the various measures over time in each patient. Some of the recommended tools were developed primarily to look at patient cohorts rather than for point-of-care decision making with individual patients. This area of research is still emerging, and the reader is encouraged to monitor the literature closely to help be sure that his or her use of the tools is valid.

Standard Nomenclature and Pain Registries

Many organizations are still attempting to codify and make uniform the "dictionary" of terms that are used in quality databases. A source of guidance in this endeavor is the document from the American Society of Anesthesiologists (ASA) titled "Guiding Principles for Management of Performance Measures by the American Society of Anesthesiologists," available on the ASA website www.asahq.org. Several organizations are involved in the effort to codify terminology in addition to the ASA, including the Anesthesia Patient Safety Foundation (APSF) and its Data Dictionary Taskforce, and international groups such as the World Health Organization (WHO). The number of societies, the importance of the task, and the lack of certainty in the area means that any database will be mutable over time. The benefit of such malleability of design, which will always cost money, is that the practitioners who use it will be better assured that they will be in compliance with the requirements of the accreditation agencies (e.g. TJC, Accreditation Association for Ambulatory Healthcare (AAAHC), and others), which will also be set and amended in the years to come.

Active learning is critical to continuous improvement and requires a means of quickly harvesting internal and external best practices and creating multiple feedback loops.[104] Utilizing communities of practice across the health system encourage participation in shared learning. While many still strive to implement CQI in individual pain management practices, Stanford has taken this a step further by aggregating data in the form of a national pain registry that can be utilized for QI purposes in a "real world" clinic setting. The Collaborative Health Outcomes Information Registry (CHOIR) is an example of a learning health system developed to collect information on pain patients and the effectiveness of therapies.[105] CHOIR is an open source, open standard, free, secure, electronic, learning health system designed to capture detailed, longitudinal patient reported outcomes data on physical, psychological, and social health. CHOIR was developed to inform point-of-care decision making, provide software-based decision making, and act as a platform for comparative effectiveness research, longitudinal outcomes research, and practice-based evidence trials. CHOIR also integrates NIH PROMIS measures to capture 15-20 domains of physical, psychological, and social functioning.[106] This effort exemplifies the broader view that is required to improve patient care and facilitate the discovery of novel solutions for pain management. The registry is currently shared by numerous pain centers nationwide, and data has been used for formative evaluations that allow for distinction between intervention and implementation failure, by identifying at an early stage whether desired outcomes are being achieved and if they are not, using the formative evaluation data to develop or refine implementation strategies to improve implementation success, as needed.[106,107]

An example of a web-based information system used by hospitals for an acute postoperative pain quality database is the international QI registry project termed "PAIN OUT."[108] Patient reported outcome data is collected using the validated International Pain Outcomes Questionnaire (IPOQ)[109] along with other clinical data in a standardized way. Following input of data, hospitals receive online feedback and can compare their results with other participating hospitals to help identify deficits to direct improvement efforts. Initially funded by the European Commission's 7th Framework Programme (Grant Agreement no. 223590), participating hospitals have to pay a moderate annual fee for the services provided.

Such megadata systems exist in other forms online as not-for-profit and profitable entities that collect quality assessment data on behalf of providers. The practice generally has access to their individual data and its analysis, but the business essentially "owns" the collective database. This information can then be subject to countless analyses. Thus it is not only used by the provider to assess and improve the quality of care in their private clinic but can be pooled for research purposes. Comparative effectiveness between distant practices and longitudinal data analyses are examples of the many uses of web-based data collection programs like these.

Still, further, the incorporation of new technologies in pain assessment systems using smartphones or smartwatches continues to grow.[110] Studies have shown that pain "apps" are workable and well-liked by patients and healthcare professionals.[111] Patients

are already participating in studies using telephone-based health coaching sessions supported by an internet-based application and an accelerometry activity tracker that remotely reports to the provider and, by extension, to a registry.[112,113] This information will allow the provider to track a patient's progress, evaluate the ongoing treatment and gather data that can later contribute to evidence-based practice, and document accountable care.

Summary

This chapter separates patient safety and QI as independent sections. However, both must be considered when reviewing strategies to improve either of them. A primary objective in the delivery of quality pain care is to make pain management accessible, optimal, and personalized for all. Practitioners must be scrupulous in evaluating procedures and therapies with rigorous doubt, eliminating those that do not prove valuable compared to alternatives that may be more banal and less lucrative. This is hindered by many challenges, including the need for payment reform to foster coordinated interdisciplinary care, pain self-management programs, patient education, psychological counseling and complementary and integrative health approaches, and access to medications. However, individual pain practitioners can impact quality by fostering methods to improve pain assessment and delivery of integrated, multimodal, interdisciplinary care that is effective and safe.[34]

SECTION II–PATIENT SAFETY

To Err Is Human and the Prevention of Harm

Patient safety is, based on the WHO definition, "the absence of preventable harm to a patient during the process of healthcare."[114] Patient safety, with its fundamentals of collecting and analyzing events as well as prevention of adverse events in a confidential environment, has become an indispensable discipline and element of healthcare quality.[115] There is reasonable debate as to whether or not a specific patient may be safe and whether or not a specific error contributes to real morbidity.[116] However, the public, legislators, and payers are convinced that both patient safety and human error are significant problems in today's healthcare delivery system. The healthcare industry is now urged to create a "culture of safety" at all levels of practice, which will put in place processes that will eliminate or decrease the impact of human error. A significant hurdle to the effort to improve safety is that there is insufficient data to assess healthcare safety or even definite identification of uniformly valid indicators of safety in healthcare.[117] Therefore which solutions, which information, and which technology will be of value in improving patient safety are still disputable.

Standardized and reliable definitions are needed to measure harm accurately and evaluate the result of patient safety. First, a medical error has to be distinguished from an adverse event. There are two major types of errors: (1) errors of omission occur because of actions not taken and (2) errors of the commission occur because of the wrong action taken.[118] Medication errors are among the most common medical errors,[119] and events reported in TJC sentinel events database.[120] Most errors in patient care do not arise from an individual but from conflicting, incomplete, or suboptimal systems and have the potential of being harmful.[121] An adverse event is a harmful injury resulting from a treatment and is not caused by the underlying medical problem and can be classified as preventable or non-preventable. These events, such as those associated with opioid treatment for chronic non-cancer pain, can be lethal, life-threatening, disabling, prolong hospital stay, and require additional monitoring.[122]

The publication of "to err is human" in 1999 was the IOM public alarm about patient safety and error in the healthcare delivery system.[123] The IOM recommended the creation of safety centers and organizations and motivated hospitals as well as professional societies to focus on patient safety. As an effect of the IOM, the government was one of the first to support safety research. Further, the 2005 Patient Safety and Quality Improvement Act stimulated the development of Patient Safety Organizations (PSO) and defined their role. The act called for a confidential culture of patient safety and for the establishment of a Network of Patient Safety Database to provide an interactive evidence-based management resource.[124] In the two decades since the IOM landmark report, additional areas of safety risk have been identified and targeted for intervention, such as outpatient care, diagnostic errors, and the use of health information technology.[125,126] Health information technology can improve patient safety, but its implementation and use have led to unintended consequences and new safety concerns (e.g. unavailable or malfunctioning hardware or software, failure to use health IT appropriately, alarm fatigue).[127]

The frequency of preventable harm remains high, and new scientific and policy approaches to address both prior and emerging risk areas continue to be needed. Based on different facets of patient safety and with varied scopes, several prominent groups have emerged:

1. **The WHO** launched the World Alliance for Patient Safety in 2004 in all member states to improve safety in healthcare.[128] Patient safety is not only a problem in industrialized countries but also a global problem. Prevention of healthcare-associated infections, hand hygiene, surgical safety, and patient engagement are targeted safety issues. The WHO emphasizes prevention, detection, and risk reduction through guideline implementation and establishment of a uniform classification of patient safety concepts, The WHO also aims to reduce iatrogenic harm from medications. Many patients may be exposed to risks from a combination of adverse reactions, polypharmacy, and miscommunication, and the WHO recommends national medication safety plans that focus on engaging patients and the public; medication as products; education, training, and monitoring of healthcare professionals; and systems and practices of medication management.[129]
2. **The AHRQ** has the federal lead in patient safety. It supports research of causes and the development of new strategies in patient safety, including integration within the healthcare industry. This center coordinates the PSOs and distributes knowledge about effective practices. The AHRQ offers the Patient Safety Network (PSNet),[124] a web-based resource of news on patient safety, as well as the Web M&M,[130] a morbidity and mortality round on the internet.
3. **The NQF** (discussed in part 1 of this chapter) helps improve the quality of healthcare in the United States by building, endorsing, and promoting national consensus about priorities, measurements, and their education. NQF oversees a patient safety measure portfolio and in 2017 endorsed new measures for the use of opioids from multiple providers and at high dosage in persons without cancer.[131]
4. **TJC,** advised by a panel of safety experts, has published national patient safety goals since 2002.[132] These goals are provided as clear, actionable statements, such as "use at least two patient identifiers when providing care, treatment, or services"

or "mark the procedure site," with the rationale behind these goals and the elements of performance. The main topics are identify patients correctly, improve staff communication, use medicines safely, prevent infection, identify patient safety risks, and prevent mistakes in surgery. Each year information is gathered about emerging patient safety issues to inform sentinel event alerts, standards and survey processes, performance measures, and educational materials.

5. **The IHI** is an independent non-profit organization founded in 1991. IHI initiated the 100,000 Lives Campaign (2004-2006), which was designed to save lives by introducing six safety problems in healthcare.[133] The campaign aims to reduce harm and deaths by the deployment of rapid response teams, evidence-based care for acute myocardial infarction, prevention of adverse drug events, central line and surgical site infections, and ventilator-associated pneumonia. The National Patient Safety Foundation (NPSF), initially created in 1997, merged with the IHI in 2017. The NPSF published *Free from Harm,*[134] 16 years after the IOM report, and called for a total systems approach to patient safety to replace piecemeal interventions. Challenges remain to address several major concepts for system-level action including[115]:
   - Medical education must be redesigned to prepare new physicians and other health professionals to function in these new safety cultures.
   - Care must be delivered by multi-disciplinary teams working in integrated care platforms.
   - Healthcare workers need to work in safe environments and find joy and meaning in their work.
   - Patients must become full partners in all aspects of designing and delivering healthcare.
   - Transparency must be a practiced value in everything we do.
6. **The Leapfrog Group** is a national nonprofit organization founded in 2000 by large employers and other purchases of healthcare.[135] They aim to reduce preventable medical mistakes, improve quality and affordability of healthcare and encourage healthcare providers to publish their quality and outcomes, and reward them for improving quality. This group focuses on four "leaps," including computerized physician order entry (CPOE), evidence-based hospital referral, ICU physician staffing, and a Leapfrog patient safety composite score that assesses a hospital's progress.[136]

Understanding the Components of Patient Safety

As the healthcare system has become more complex, communication breakdowns are common. Creating a culture where healthcare workers speak up candidly about concerns before problems occur is critical. TJC's sentinel event database identified communication as a leading root cause of sentinel events in the United States.[137] Past studies have indicated more than 65% of medical errors are caused by problems in interpersonal team communication citing seven categories of conversation that are especially difficult and at the same time essential for patient safety.[138] These include broken rules, mistakes, lack of support, incompetence, poor teamwork, disrespect, and micromanagement.

There is no single reason why a safety event happens. Instead, it is a combination of individual and system factors. This may include inattentive or carelessness leading to mistakes, procedural violations, or bearish behavior directly causing adverse events. The system can provoke an environment initializing errors based on organizational decisions, also called latent conditions.[139] While active errors are attributed to the immediate action of a human to cause an error, latent conditions allow active errors to occur, leading to an adverse event or harm to the patient. Latent conditions can be undetected for a long time before leading to a problem when combined with active failures. In creating safer processes, it is best to focus on system changes rather than on scrutiny of individual practitioner errors, as system errors are most causative of an adverse event.[140]

Culture of Safety and Safety Climate

The terms patient safety culture and climate are often used interchangeably in practice, but there are conceptually meaningful differences in their scope and depth. The notion of a patient safety culture originated from the experience in hazardous industries such as aviation and nuclear energy.[141] A safety culture depends on attitudes, beliefs, behaviors, perceptions, values, and practices shared by employees. Safety climate is the quantitative description or a way of measuring safety culture by taking a closer look at adverse events (outcomes measures), analyzing adherence to practices (process measures), or tuning of healthcare teams' attitudes about issues relevant to safety. Clinicians may feel that medical care is not amenable to the safety monitoring systems of other industries, yet emulation of highly reliable organizations within these other industries does lead to improvements in safety in healthcare.[142,143]

Across the globe, there are differences in the way that patient and occupational safety culture is perceived among different health professional groups, particularly between managers and bedside clinicians.[144] Healthcare providers define safety climate using three attributes: (1) creation of safe working environment by senior management in healthcare organizations; (2) shared perception of healthcare providers about safety of their work environment; and (3) the effective dissemination of safety information.[145] Evidence suggests that interventions such as team training, interdisciplinary rounding, or executive walk rounds can improve perceptions of safety culture and potentially reduce patient harm.[146]

The IOM not only proposed to build centers and organizations but also the creation of a culture of safety. Engaged senior leaders are important to an organization's successful development of a culture of safety. A just culture where providing safety-related information in a blame-free environment is rewarded, and people have the will and the knowledge to learn from mistakes (learning culture) are essential to develop a safety culture.[147] Teamwork and collaboration such as open communication have been defined as a second important behavior to support a culture of safety, especially considering the increasing complexity of today's patients.[148] As well, the use of standardized, evidence-based processes together with patient centered medicine has an important influence on patient safety culture.[149,150]

Strategies to Reduce and Improve Safety Events

Patient harm can be reduced in the same way engineers manage dynamic complexity as a system problem requiring interdisciplinary systems solutions.[151] Anticipating and preventing predictable risks and hazards through standard routines and protocols removes uncertainty, reduces information processing requirements, and, thereby, decreases possible memory lapses, judgment errors, or biases that can lead to adverse outcomes. Individual pain practitioners need to work together with others to understand the nature of the work, create detailed operating procedures and

contingency plans, and use the tools of science and technology (e.g. failure mode effects analyses, or hazard and operability studies) to shape the behavior of organizational members to avoid mishaps.

There is a retrospective (reactive) and a prospective (proactive) way to measure and improve safety. The retrospective way is the root cause analysis (RCA), described in part 1 of this chapter and commonly used in QI, error reporting systems, morbidity and mortality conferences, or malpractice claims. These methods seek to answer the question of what went wrong and why. We widely use these techniques to understand the causes of harm and to improve safety. A group of anesthesiologists from Seattle and Boston, for example investigated conditions and patterns in malpractice claims after interventional pain treatment at the level of the cervical spine. They found that injuries leading to malpractice claims were most often caused by direct needle trauma to the spinal cord; that these injuries were often severe, and they appeared more frequently in unresponsive patients.[152] RCAs increase the awareness of faulty processes and are more likely to detect latent errors and adverse events but bare the risk of spending resources on unnecessary interventions if not performed correctly or comprehensively. For example, errors in the use of patient controlled analgesia pumps or epidural line misconnections; remedial actions may be aimed at the wrong level of the healthcare system, such as education of individuals instead of innovations in pump or tubing connection designs.[153]

Though the strength of evidence may be low, a systematic review of varied interventions to promote patient safety in an inpatient environment reported several useful types of interventions such as team training and team communication tools, executive and interdisciplinary rounding, and the Comprehensive Unit-Based Safety Program (CUSP).[148] CUSP is a multifaceted strategy that pairs "adaptive intervention" use as a continuous learning strategy with technical interventions and application of best available evidence-based clinical care algorithms to improve patient safety and quality.[154] Adaptive intervention is based on the premise that systems can learn adaptively by reacting to a change in the environment and can learn by generating new knowledge and conditions.

Healthcare is continuing to organize for higher safety and reliability. Standardized protocols and checklists, pre-procedural and post-procedural briefings, incident reporting, and daily huddles all hold promise for enhancing safer care.[155] These types of activities are part of a comprehensive, organization-wide integrated approach to manage risk and to achieve safe and reliable performance, similar to the systems found in other industries. Checklists provide a means to translate evidence-based best practices to the bedside for a wide range of care processes. Well-constructed checklists codify interventions, remove ambiguity, and increase the reliability of care processes.[156] The American Society of Regional Anesthesia and Pain Medicine (ASRA) showed in a randomized simulation study that checklists improved not only medical management of local anesthetic systemic toxicity but also augmented non-technical performance.[157] Surgical safety checklists are widely used and associated with better postoperative outcomes, but this could reflect the wider quality of care in hospitals where checklists use is routine.[158] Clearly, no checklist has all the required interventions, and patients often require multiple checklists. Blindly following the rules can be deadly if it reduces the ability to adapt or react swiftly to surprises.

Failure Modes and Effects Analysis (FMEA)

FMEA is a proactive assessment tool and qualitative analysis method to identify potential systematic failures and their effects before events occur. The FMEA process focuses on causes and opportunities for preventing negative effects and involves scoring for severity, probability, and detection of failure reasons, as shown in Box 6.3. FMEA has been applied to assess risk with intrathecal drug (IT) delivery for pain management.[159] Human error, catheter issues, pump failure, and granuloma formation were considered severe safety concerns during IT therapy. Among 17 top failure modes, the methodology identified appropriate patient selection as the most critical component for the successful management of pain with IT therapy.

In 1974, Jick introduced a prospective concept based on trigger events.[160] Trigger tools such as the Global Trigger Tool is a form of medical record review often used as an adjunct to patient safety event reporting to reduce the number of adverse events that are undetected during hospitalization and primary care.[161] This tool seems more reliable than other methods to detect possible events, often discovering at least ten times more confirmed, serious events than other methods.[162] Searching for triggers typically associated with the most frequent and harmful adverse events allows for detection and measurement of "all-cause harm." This method has lower resource intensity through the use of sampling and has been shown to identify more than 90% of harm in hospitalized patients.[163] It is recommended that hospitals should report all adverse events as all-cause harm, meaning any event during the care process that results in harm to a patient, regardless of cause.[164] There is a strong relationship between all-cause harm and safety culture, employee engagement, and patient experience, indicating that when there is a positive patient safety culture, a more engaged employee, and a more satisfying patient experience, there may be less all-cause harm.[165]

Healthcare Education

Healthcare education has altered significantly over the years, with many professional societies adapting their curricula to focus on safety. The American College of Surgeons has integrated six core competencies defined by the Accreditation Council for Graduate Medical Education (ACGME) and the American Board of Medical Specialties, which include listings of patient safety topics, teaching and learning strategies, and assessment methods. Learners and experts agree that topics within the domains of improvement science and nontechnical skills should be included in a formal curriculum.[166] Yet, there is wide variation on how well these topics are currently included in graduate medical education training programs. Since 2019, the ACGME also endorsed the disclosure of adverse treatment events as a common program requirement for resident education and experience. However, a survey of medical residents at the Yale Primary Care Residency Program endorsed the need for the design of a more specific and effective educational program.[167]

Professional education has not kept pace with increasing demands for collaboration-ready health workers in part because of disjointed and outdated curricula and a glaring mismatch of competencies to patient and population needs.[168] Interprofessional education is a growing trend across health professions and has been defined as when two or more professions learn with, from, and about each other to improve collaboration and the quality of care.[169] For interprofessional learning to occur, all three "with, from, and about" must be present. The Lancet Commission calls for education reform that is guided by the desired outcomes of transformative learning and interdependence in education.[168] Transformative learning has been called for in the field of pain medicine and involves fundamental shifts from fact memorization to the synthesis of information for decision making; from

seeking professional credentials to achieving core competencies for effective teamwork in health systems; and adaptation of global resources to address local priorities.[170]

Education is tightly linked with the introduction of new technologies. There are different ways to adopt new techniques and technologies into clinical use through education. Peyton's Four-Step Approach (1. trainer demonstrates, 2. talk the trainee through, 3. trainee talks trainer through, and 4. trainee does), and the traditional training model of "see one, do one" have both been shown to be effective though effects are variable.[171,172] Healthcare simulation can provide an opportunity to practice technical and nontechnical skills in a patient-safe environment, particularly the skills most required in dynamic and crisis situations. Simulation-based education is expensive, but it is cost effective if utilized properly and increases patient safety. Simulation-based training complements medical education in patient care settings but does not replace educational activities based on real patient care experiences.

In addition to simulation, several team training models and practical tools, and organizational interventions are available to help reach safety goals.[173] These include team strategies and tools to enhance performance and patient safety (TeamSTEPPS),[174] SBAR (situation, background, assessment, and recommendation) communication and patient handoff tool,[175] debriefing checklists, rounds, and redesigning structures to stimulate team processes and team functioning. Other important sources aimed at providing the evidence to improve patient safety and outcomes are clinical guidelines and practice advisories, like those published and steadily updated for regional anesthesia and pain medicine.[176] Based on current literature, expert opinion, and clinical data, these systematically formulated advisories aim to improve patient safety by reducing the incidence and severity of adverse outcomes in daily practice. These recommendations usually focus on clinical topics where treatment is as yet unclear. Consensus statements based on opinions today may be rewritten and changed when overruled by new scientific facts, and readers and writers are encouraged to continuously re-evaluate these recommendations.

Finally, in regard to education, patient centeredness is an essential element of quality and safety. Education and training programs should emphasize shared decision making with patients regarding realistic goals, expectations, and preferences to inform the pain care plan. Patients are uniquely positioned to provide important information potentially unavailable from other sources such as medical records and to engage in certain practices that may improve their safety. Interventions include patient and family education, encouraging patients to remind healthcare workers of safety practices such as hand washing, and to participate in reporting clinical errors. However, patient engagement is often low, and there is insufficient high quality evidence to exactly inform how to facilitate this in the clinical arena.[177]

Technology

The use of technology has facilitated many steps in patient care. The calculation of medication doses, imaging modalities, exchange of patient data between geographically or temporally separated practitioners, providing references such as guidelines for care and monitoring patient outcomes, adverse events, and practice patterns can help improve patient safety. Information technology can reduce error and the negative impact of error by the provision of critical information at the point-of-care, improved speed of response once an error has occurred and tracking the occurrence of errors to allow monitoring for trends and allow feedback to providers.[178] Importantly, though technology in the form of electronic health record best practice notices and other warnings can help alert clinicians to safety issues, alarm fatigue can also jeopardize patient safety.[179]

Smartphones have become one of the most rapidly adopted technologies with onboard technologies, such as Wi-Fi, Bluetooth, lights, microphones, cameras, accelerometers, and even barometers. Patient-facing apps may help engage patients with chronic pain in between (or perhaps instead of) traditional outpatient visits and empower them to take a more active role in the management of their ailment, to improve pain relief, to facilitate functioning, and to return to daily living.[180] Telemedicine, smartphone, or tablet that allows Health Insurance Portability and Accountability Act of 1996 (HIPAA)-compliant text messaging or camera images may serve as a means to monitor patient wound status and be of value to a pain practice in which patients with invasive catheters are cared for at home.

It appears increasingly desirable to have a nationwide, internet-based monitoring program, such as the prescription drug monitoring program (PDMP), to avoid multiple prescriptions for opioids, improve patient safety, and distribute important information about patients' health.[181] Another example of the promise of safety improvement through innovative technology is in patient identification. Correct patient identification and elimination of wrong-site surgery have been identified by the WHO and TJC as a significant opportunity for improved safety.[182] The use of a bar coding system can virtually eliminate the potential for patient misidentification and can also diminish medication errors.

Imaging Technologies

Bedside administrative technologies are increasing in the field of healthcare. Imaging modalities in interventional pain medicine help accurately identify relevant structures, which intuitively appears to ensure safer interventional therapy in pain medicine. Ultrasound techniques, fluoroscopy, and computed tomography imaging are being used. There are indirect ways like nerve stimulation that help identify nerves and increase the likelihood of a successful neural blockade. However, they have limited sensitivity.[183] There are also direct methods to differentiate the properties of the target and those of the surrounding tissues. The safe use of ultrasound techniques has increased in the past years for performing nerve blocks. However, its impact on patient safety has been less clear.[184] Fluoroscopic guidance, with or without radiographic contrast, helps to assure extravascular catheter location or to detect intravascular needle perforation, and it can be used to prevent unintentional intravascular or subarachnoid injection of local anesthetics or steroids.[185] Techniques, like the use of an "optical" spinal needle that provides spectrophotometric information from the tip of the needle, can safely identify the epidural space and may be complementary to fluoroscopic imaging of the epidural space.[186] Brynolf et al. have shown that the detection of nerves with this optical reflectance spectroscopy is complementary to ultrasound and might replace nerve stimulation. It might also lower vascular complications while detecting intra-arterial needle tip placement.[187] Although image guidance has become a routine in pain medicine, there still insufficient evidence to prove that it increases the safety of the procedures.

Next Steps for the Pain Practitioner

Practitioners should work to discern practical ways to improve patient safety and the most efficient and economic means of practicing in congruence with the regulations and legislation now growing out of the public safety campaign. Whatever safety

improvement programs are chosen, they should be repeatedly evaluated for efficacy and abandoned if they are not efficient and effective. "Mistake-proofing" care will require minimizing variation in its delivery, monitoring every patient's course of care for error and adverse outcomes, and making care delivery systems within the clinic or practice setting as simple as possible to avoid the complexities that lead to variation and error.

Organizations that are considered "highly reliable" utilize five principles to achieve and maintain exemplary levels of safety that can be used by individuals:[188]

1. Preoccupation with failure, never being satisfied that they have not had an accident for many months or years
2. Resisting the temptation to simplify their observations and their experience of their environment
3. Sensitivity to operation, recognizing that the earliest indicators of threats to organizational performance appear in small changes
4. Commitment to resilience, recognizing that despite all best efforts and past safety successes, errors will occur, and safety will be threatened
5. Deference to expertise; when confronted by a new threat having mechanisms in place to identify individuals with the greatest expertise relevant to the situation

Box 6.4 lists specific targets that the pain practitioner can focus on to improve patient safety. It is critical to document these efforts and their results to ensure that resources are not wasted and portray the diligence of the practice when payers and regulators inquire about safety efforts.

• BOX 6.4 Interventions That May Improve Patient Safety in the Pain Clinic

Facility Procedures and Structure

- Routinely and repetitively conduct drills for emergency situations by assigning specific roles to personnel in the case of patient medical emergencies, facility emergencies (e.g. power outage, fire, earthquake, severe weather), and selected adverse events in patient care.
- If relocating or creating a new facility, locate it as near a hospital as possible. Arrange to create a legal transfer agreement with that hospital.
- Furnish the facility with in-wall piped oxygen and suction, and adequate lighting and space to allow full access to patients by sufficient personnel in the case of an emergency.
- Consider accreditation by the AAAHC, TJC, CARF, or another agency. If accreditation is not possible, consider an annual inspection by one of these agencies for evaluation of your facility and practice regarding safety.
- Daily cleaning should include bactericidal cleansing of all surfaces contacted by staff, patients, or family members of patients in all parts of the facility.
- Place hand cleanser dispensers in multiple locations readily available to all clinical and nonclinical staff.
- Drawers and supply cabinets should be clearly organized and standardized in their organization between rooms.

Medication Management

- Utilize available prescription drug monitoring programs (PDMP) to monitor and the frequency of renewals for opioids and sedatives.
- Monitor and document patient response to medication treatment.
- Use and adhere to written treatment agreements with patients for opioids and controlled substances.
- All medications used at the facility should be labeled (including an outdate once opened) and carefully read aloud before being drawn up and before administration.
- All syringes should be labeled in a standard manner regarding label color, font, size, and information on outdate.
- The facility should be regularly inventoried (weekly or monthly) for outdated medications and other supplies.
- Use medication reconciliation techniques to confirm doses and the frequency of all medications when there is a transition in caregiver, location, or date.
- Use computer technology to monitor for potential adverse drug events.
- Contract with a clinical pharmacist for consultation services as needed.
- Use protocols for monitoring the prescription of any medication that may lead to significant morbidity with continued use, such as non-steroidal anti-inflammatory drugs, opioids, tricyclic anti-depressants, and so on. These protocols should include timely and repetitive monitoring for known risks via either laboratory or electrocardiographic studies or mandated office visits.
- Communicate prescriptions of all medications to all practitioners providing care to your patient.
- Any adverse drug events should be reported immediately and recorded in a database that is regularly reviewed for trend analysis. The patient should be notified about the adverse event. The patient's other caregivers outside the practice should be notified about the adverse drug event.
- Prompt attention by staff should be focused on open discussion and adjustment of protocols and policies by the end of the day to avoid any repetition of errors that occurred either with or without an adverse drug event.

Technology

- Track the outcomes of all care. Use relational database technology to allow evaluation of outcomes for trends, both positive and negative. Do not make this a punitive system but provide information on outcomes to staff regularly to invite input on changes in the system that may avert negative events.
- Consider the use of an electronic medical record.
- Use technology to allow the integration of clinical and laboratory systems to ensure that all critical information is available at the point-of-care.
- Use a CPOE system that includes the transmittal of outpatient prescriptions directly to a pharmacy.
- Use a computer system to track patients' medications that has automated alerts regarding potential drug interactions and anticoagulant use.
- Use technology to provide practitioners with all necessary reference material for decision support (e.g. medication dose, cross-reaction, and toxicity information).
- Use technology to ensure accurate matching of patient identity, medication history, and current medications at each point-of-care. Consider the use of a bar code system.
- Create or obtain audiovisual (e.g. DVD) material about procedures and medications to allow patients to review them before obtaining informed consent for procedures or before beginning a new medication.

• BOX 6.4 Interventions That May Improve Patient Safety in the Pain Clinic (Continued)

Staff

- Establish a pattern of regular use of hand cleansing by all personnel.
- Create and enforce protocols for handoff of patients between practitioners.
- Create and enforce protocols for two-person patient identification interaction.
- Use standard teams with assigned roles for medical and invasive procedures.
- Involve all staff in discussions of quality and safety issues and invite open and non-punitive reviews of adverse events and trends with the freedom of each staff member to contribute ideas for the improvement of the system.
- Create a plan in advance to respond to adverse events, including honest discussions with patients and family and support for the staff involved.
- Do not allow employees to work beyond the limits of their education and training.
- Monitor, track, and report all practitioner work hours and do not allow them to extend beyond 80 h per week or for more than 16 consecutive hours.
- Maintain sufficient staffing to ensure adequate care for sedated or recovering patients. These staff levels should be equivalent to or more intensive than the local standard of care as used in hospitals in the area.

Procedures

- Use full barrier protection during invasive procedures.
- Administer appropriate prophylactic antibiotics.
- Use imaging technology when appropriate during invasive procedures.
- Use the minimum necessary contrast material.
- Develop and enforce the use of standard protocols for medical and invasive procedures, including sterile preparation and critical medication checks, such as anticoagulants.
- Use guidelines, checklists, or both.
- Develop and enforce protocols to ensure that invasive procedures are carried out at the correct site, including marking the patient's body area before preparation and a pause for verbal confirmation among all staff present of patient identification and procedural intent.
- Follow state and other applicable regulations regarding radiation safety.
- Avoid patient sedation beyond the loss of the ability to discern and communicate paresthesia or other changes in sensation during neuraxial or perineural procedures.
- Refer procedures that you rarely or never perform to higher-volume practitioners or facilities. Monitor the outcomes of these patients.
- Provide both written and audiovisual informed consent material and give patients time to review them and ask questions before obtaining informed consent for procedures.
- Use supplemental oxygen and monitor oximetry whenever sedation is used.
- Use supplemental oxygen and monitor oximetry whenever the prone position is used.
- Mandate and enforce that all patients have a driver before beginning either sedation or any procedure.
- Obtain written agreement from patients that they will not drive for 8 h following a neuraxial procedure, sedation, or any procedure that could impair their motor skills.

Extra Facility Considerations

- Maintain close interaction with any provider also involved in your patient's care.
- Provide information about prescriptions of all controlled substances that you have begun and any other medication or treatment interventions that you have made.
- Make direct phone contact with written confirmation regarding significant changes in condition or the treatment plan.
- Create a transfer agreement with a hospital to prepare for a patient emergency.
- Participate in the exchange of regular peer review of procedures and standards with other practitioners who have no economic stake in your practice or facility.

Treatment Outcome Databases: Recording Adverse Events

Practitioners can help ensure their patients' safety by recording their outcomes and all adverse events in a database. There are many ways to measure outcomes, which are important to adequately reflect the provided quality. SF-36 or more comprehensive S-TOPS (Treatment outcome in pain survey) is used, among others.[189,190] Such an outcomes database or registry is vital for practitioners to discover their own best practices and to monitor for any trends that would reveal a lack of efficacy of therapeutic interventions. Simple recording of adverse events without affixing blame can provide opportunities for solo physicians and large groups to spot trends in which certain care patterns are associated with significant rates of error or even injury. Box 6.5 lists some of the adverse events that might be monitored in a pain medicine practice.

Some Practical Tips to Improve Patient Safety

In the environment of national safety initiatives that emphasize significant investment in information technology, some of the simpler steps in improving patient safety may be overlooked. For an office that engages in interventional therapy, there are parallels to the safety features needed in offices that perform any kind of surgery. Bridenbaugh[191] offered recommendations regarding safer office care, which include improved office emergency equipment, routinely updated and maintained by biotechnical personnel; training and certification of personnel in the delivery of medication and resuscitative techniques; use of written practice policies and procedures that are routinely reviewed with the staff, including emergency procedures; use of monitoring that conforms to the same levels as would be expected in an accredited ambulatory surgical center or hospital; guidelines for sedation and anesthesia

• BOX 6.5 A List of Potential Adverse Events to Be Monitored in a Pain Practice Safety Program

Procedural Events

Procedure on the wrong body part or location
Procedure performed on the wrong patient
Wrong procedure performed
Unintended retention of a foreign object in a patient
Product or device events
    Contamination
    Function other than intended
Intravascular air embolism
Infection following a procedure
Unexpected death following a procedure
Unexpected hospitalization within 24 h of a procedure
Unintentionally compromised nerve function following any procedure
Lack of consent or incongruous consent
Allergic reaction
Anaphylaxis
Abortion of a procedure-anxiety
Abortion of a procedure-other
Burn
CV-angina
CV-arrest
CV-congestive heart failure
CV-dysrhythmia
CV-electrocardiographic changes
CV-hypertension
CV-hypotension
CV-infarction
Death
Dehiscence of wound
Dizziness
Electrolyte abnormality
Failure to follow up or communicate laboratory, pathology, or radiology test results
Fainting
Fall
Fever-not malignant hyperthermia
Headache
Hemorrhage
Increased pain
Itching
IV site pain
IV site infection
Malignant hyperthermia
Neurologic change
No home care
No instructions given
No ride available
Physician delay
Patient delay
Respiratory arrest/apnea
Respiratory asthma
Respiratory pneumothorax
Respiratory pulmonary edema
Return to the operating room
Sepsis
Signed out against medical advice
Somnolence
Transient neurologic syndrome
Urinary retention
Viscus perforation

Non-procedural Care-Related Adverse Events

Serious adverse event secondary to a medication prescription
Any medication prescription error requiring follow up by a pharmacist or physician
Serious injury to a patient or other person secondary to misuse of a device or medication
Nerve injury, fall, or skin breakdown in an anesthetized body part following treatment
Hypoglycemia
Allergic reaction to medication or other treatment
Patient fall while on site at the facility for treatment
Patient fall while taking medication that may impair balance or mentation
Patient involvement in a motor vehicle accident subsequent or consequent to treatment
Any staff or patient injury while on site at the facility for treatment
Patient misidentification
Release of any patient to an inappropriate or incorrect caregiver
HIPAA privacy or security rule violation
Incomplete medication list documentation
Incomplete allergy list documentation
Incomplete problem list documentation
Incomplete or incorrect "other provider" list
Inability to access health records at the point-of-care

CV, Cardiovascular; *HIPAA*, Health Insurance Portability and Accountability Act; *IV*, intravenous.

that conform to those of the ASA; and compliance with any local or state standards of office safety and quality standards.

Accreditation

It is strongly recommended that every practitioner invite an independent agency to inspect their practice annually to provide advice about improving the quality and safety of care delivered there, even if formal accreditation does not ensue. Options include state health departments, and either TJC,[192] or the AAAHC.[193] Both of the latter will certify multiple- and single-specialty ambulatory surgical centers and physician practices and offices that practice pain medicine. If the program in question is a multi-disciplinary program, another accrediting organization to consider is the CARF,[194] which is willing to accredit what it terms "interdisciplinary pain rehabilitation programs."

Indeed, full accreditation or even just a letter from an inspector describing a practice's positives and negative attributes-assuming the former outweigh the latter-can be valuable in contracting with third party payers as a means of proving a salutatory commitment to patient safety and practice quality. Such accreditation has been used successfully to decrease liability insurance for a facility and malpractice insurance for both a facility and the physicians who are part of its practice or ownership group. Such documentation would be of value in the event of any later tort action concerning a patient's safety.

Avoidance of Provider Fatigue

Operator fatigue has been recognized as a potential source of error in many industries; the United States Congress and the IOM asked for work hour limitations to improve patient safety. Practitioners who have completed their training tend to work longer hours with less rest than is considered appropriate in almost any other work setting. This should be particularly concerning for those pain practices that employ interventional therapies. All

aspects of cognition are adversely affected by fatigue, although there is insufficient evidence to pinpoint a specific amount of rest as "enough" in medicine. Each practitioner is encouraged to create and follow personal and practice wide policies regarding continuous time spent in clinical activity.

Caution Patients Regarding Potential Impaired Ability to Drive

A controversial topic is the role a prescriber plays in the determination of the ability of his or her patients to drive an automobile. Most state regulations require healthcare practitioners to report any patients who have a medical or surgical impairment that would make them unsafe if they have not voluntarily given up driving.[195] This is a significant concern for practitioners whose practice has a large percentage of older patients, many of whom may have vision, hearing, or developing cognitive impairments that warrant concern about safety while driving a car.

Additional concerns for the pain practitioner are those patients who are using opioid medication, other psychoactive medications, or who undergo procedures that may impair their motor skills or mentation.[196,197] The real risk of driving in the setting of long term use of opioids is unclear, but there is likely impairment present for some patients.[198,199] Evidence exists that a subset of chronic noncancer pain patients has worse highway driving performance than matched health controls despite rating their subjective driving quality to be normal.[200]

Patients Undergoing Injection Therapy: Should They Have a Driver?

There have been no controlled studies of adverse consequences of driving post pain procedures, but there are several theoretical risks of driving, such as sensorimotor impairment after epidural steroid injection.[201] Many practitioners require all patients undergoing interventional therapy to have a driver for the following reasons:

1. Often, the patient's original diagnosis entails some degree of neural dysfunction. Therefore driving capability is probably already impaired.
2. Pain, which may increase during the initial treatment period, can cause mental distraction and muscle spasms that could impair driver focus and function.
3. The activity of driving very frequently will serve to exacerbate muscle spasm and is often among the activities that patients complain worsen their pain so that driving is on the list of activities that we ask our patients not to practice any more than is absolutely necessary during the days that treatment is in progress.
4. Theoretically, even those procedures that do not intentionally block neural transmission (e.g. an epidural steroid injection with only steroid and normal saline) may cause a diminished motor response because of either volumetric compression on nerve tissue or increased pain after the injection.
5. Patients are often asked to engage in therapeutic activities the day of their procedure, including the use of massage, bath, and relaxation therapy. The efficacy of these measures is opposed by the stress associated with the activity of driving.
6. Patients required to organize a driver for their return home may be less likely to immediately return to work after the procedure or ignore post procedure instructions.
7. Finally, with no definitive study in the literature showing that driving post injection therapy is safe and with plausible theoretic reasons to consider that such patients might be more prone to accidents, it is a reasonable and prudent precaution.

Opioid Stewardship

From 1999-2017, nearly 400,000 people in the United States died from an overdose involving an opioid, including prescription and illicit opioids,[202] becoming one of the most urgent public health threats of the country. Many factors across the healthcare system contributed to the problem, including the desire of clinicians and accrediting bodies to effectively manage patients' pain, third party payment issues, and a lack of knowledge of and/or access to a broader array of pain management options.[203] Although appropriate indications exist for prescribing opioids, including acute pain, active cancer treatment, palliative care, and end-of-life care, there is little evidence for long term use of opioids for the treatment of chronic, non-cancer pain.

Opioid Stewardship may be described as coordinated interventions designed to improve, monitor, and evaluate the use of opioids to support and protect human health.[91] Regardless of the setting or indication for opioid prescribing, individuals directly responsible for the treatment of pain and healthcare organizations should coordinate commitment and actions with the community to protect patients and the public through opioid stewardship efforts. A comprehensive system-level strategy that extends beyond education efforts toward opioid stewardship is warranted.[204–206] In 2018, the NQF developed a national opioid stewardship "playbook" outlining seven fundamental actions to support opioid stewardship in healthcare organizations:

1. Promote leadership commitment and culture.
2. Implement organizational policies.
3. Advance clinical knowledge, expertise, and practice.
4. Enhance patient and family caregiver education and engagement.
5. Track, monitor, and report performance data.
6. Establish accountability.
7. Support community collaboration.

The NQF Playbook is unfortunately available for purchase only but provides concrete and practical implementation examples, potential barriers, and suggested solutions and sample tools and resources from basic to advanced approaches that can be adapted to individual, organizational contexts. The Centers of Disease Control (CDC) and others have also issued guidelines for chronic opioid prescribing and data tracking tools to bring awareness, resources, and expertise to opioid stewardship efforts.[207,208]

An acute injury or a procedure is a common source of a patient receiving his or her first opioid prescription that may lead to long term use. The concept of a comprehensive opioid stewardship program at the systems level is growing and supported by TJC.[209] In 2019, a multi-professional group used literature review and consensus to develop a set of 19 valid and feasible quality indicators for opioid stewardship interventions in the hospital and emergency department settings.[210] Among the top priorities were naloxone administration, average dose of morphine milligram equivalents per day, use of long acting or extended release opioid in opioid-naïve patients, and length of prescriptions.

What to do When an Adverse Event Does Occur

This section intends to promote the use of methods to diminish the likelihood of error and avoid adverse events. Nonetheless, adverse events will happen. How should the practitioner respond? The initial impulse will most often be to deny the event, to "cover up" any role that error played in the outcome and at, all costs, not implicate any practitioner as culpable when communicating with

the affected patient. However, it is widely recommended that disclosure of medical errors be done as quickly as is reasonable with a sincere apology and a statement regarding how the healthcare team will avoid similar incidents in the future, even if not all of the details of the event are available at that time.[211]

The APSF emphasizes the importance of open and frank communication with the patient and family involved, with open answers to even difficult questions.[212] An attitude of learning and correcting error rather than blaming the practitioners involved, combined with complete honesty about the events that occurred, is suggested. Above all, a strategy for dealing with patient injury should be worked out in advance among all the practice participants. The APSF has placed an "adverse event protocol" on its website at www.apsf.org that is oriented toward an anesthetic adverse event (see drop-down list under "resource center" and click on "clinical safety tools"). It would provide guidance in the pain clinic and a clear statement that an error has occurred, details regarding that error, and how it will affect the patient's health.

The practice's adverse event plan should also include discussions with malpractice carriers and practice attorneys in advance of any events. Having a plan and confidence in it is the best approach to the management of any breaches of patient safety. Invariably, such events should be examined closely to find the system flaws that led to errors and improvement opportunities.

Conclusions

"Mistakes are a fact of life. It's the response to the error that counts. The only real mistake is the one from which we learn nothing."

~John Powell

Among these larger forces of business, government, and society, a lesson sometimes lost is that the individual practitioner *can* improve healthcare quality and safety. If practitioners identify those outcomes that are desired, employ the tenets of evidence-based medicine to find "best practices," and measure both their delivery of those therapies (process) and the results of those therapies (outcomes), then it is more likely that quality will improve.[213] Adherence to evidence-based "best practice" begins with the individual practitioner and is associated with significant improvement in patient outcomes, including mortality.[214]

QI initiatives can be fragmented, short-term, and challenging to sustain. In 2018, the WHO, The World Bank and the Organization for Economic Cooperation and Development, the National Academies of Science, Engineering and Medicine in the United States, and the Lancet Global Health Commission issued publications emphasizing the need to implement an infrastructure for learning to understand root causes and continually improve the quality of healthcare.[215] Pain medicine practitioners should align individual efforts with defined safety and quality strategies and plans at the national, regional, facility, and community levels to close the fragmented approach and facilitate the update of the national policy and strategy. Use active learning to quickly harvest internal and external best practices and create multiple feedback loops to enable a rapid response to improve care processes. Institutionalizing a culture of quality and patient safety through active learning to scale up evidence-based interventions increases awareness and diligence, contributing to the development of standards and measures to monitor and improve quality with team-based strategies and coordinated partner efforts.

Safety in medicine is a very complex problem, and progress may remain uncertain. For long term improvement in patient safety, we need a benevolent culture of safety in which healthcare providers can get an adequate education, including education on all available sources and technologies, with an understanding that the costs must be monitored.

Key Points

- The quality movement in healthcare continues to evolve. It is being driven by alarm among the public, payers, regulators, and the business community spurred by widespread evidence of unnecessary variation and potential unsafe care.
- The various stakeholders in healthcare define quality in different ways, and practitioners must consider these alternative attitudes as they work to improve and prove the value of their practices.
- At each clinic, a "culture of safety" must be established by creating new systems that will decrease the impact of human error on patient outcomes.
- If quality and safety are to be improved, they must be measured. Monitor and respond to measures of structure, process, and clinical outcomes using active learning strategies.
- Use QI and implementation science theories and tactics to apply practical approaches to continuous improvement in quality and safety.

Education, Training, and Certification in Pain Medicine

JAMES P. RATHMELL, ANNE MARIE McKENZIE-BROWN

The Evolution of Pain Medicine as a Subspecialty

As medical knowledge expands, there is a natural progression toward specialization. No physician can become an expert in every field, yet there is discomfort with this inevitable narrowing of focus. The urge to both specialize and remain unspecialized dates back to the earliest recorded history in medicine. The first specializations were between barber surgeons and internists; a rivalry of sorts remains to this day. Writing about Ambrose Paré, the 16th century physician who elevated the role of barber surgeons to that of other physicians, the present-day surgeon and historian Sherwin Nuland reflected on the ongoing distinction between internist and surgeon[1]:

> *Surgery is an exercise in the use of the intellect. Heckling internists, with tongues barely in check, would prefer that surgical specialists be viewed merely as dexterous craftsman who carry out the routing errands assigned to them by their more cerebrally endowed medical overseers. I attribute this teasing raillery to a kind of good-natured fraternal envy, not so much of our celebrity status, but rather of the visibility of the cures we surgeons achieve and the particular personal gratification we have while doing it.*

In the United States, anesthesiology has progressed toward further specialization, first with the establishment of critical care, then pain management (now pain medicine), and more recently pediatric anesthesiology, cardiothoracic anesthesiology, regional anesthesia, and acute pain medicine. With specialization comes a conscious effort to focus practice so that one becomes intricately familiar with a more limited realm. The obvious result is the loss of the skills and knowledge needed to practice in the broader parent specialty. In pain medicine, many now view this as a full-time vocation. The scientific meetings and journals that keep pain medicine specialists up to date have little overlap with those designed to serve anesthesiologists practicing in the operating room. A common thread between the technical skills needed in the pain clinic and those required for anesthesiology in the operating room is expertise in neural blockades. With the advent and portability of ultrasound guided blockade, procedures initially reserved for the perioperative setting, e.g. transversus abdominus plane (TAP) blocks, are now being adapted for use in the treatment of chronic pain conditions.[2] The pain medicine practitioner must acquire a vastly different skillset from those practicing anesthesiology, including expanding their skills as diagnosticians. Pain physicians need to be able to distinguish between conditions appropriately treated with injections and those requiring surgical intervention, e.g. lumbar radicular pain associated with rapidly progressive neurologic deficits. They need to know when to hold off on interventional therapies and pursue further diagnostic testing in patients who display "red flag" signs or symptoms consistent with malignancy, infection, and other serious disorders. The skills of a pain physician must also include expertise in having difficult conversations and the ability to coordinate and collaborate with other specialists.

Much has been written about the origins of pain medicine as a distinct discipline, and anesthesiologists have played a primary role since its inception.[3] It started with the introduction of effective general anesthetics in the mid-19th century, when surgical pain could be separated from surgery. Almost 100 years later, the late John Bonica, an anesthesiologist and recognized father of the specialty that we now call pain medicine, developed his career by promoting multi-disciplinary pain care and formal training of specialists. From his life's work, we now have extensive ongoing efforts to recognize and treat pain effectively, train subspecialists, and conduct basic and clinical research to understand pain and its treatment further. The International Association for the Study of Pain, founded in 1974, its United States chapter, the (now dissolved) American Pain Society, and the journal *Pain* are legacies left by Dr. Bonica for our patients.

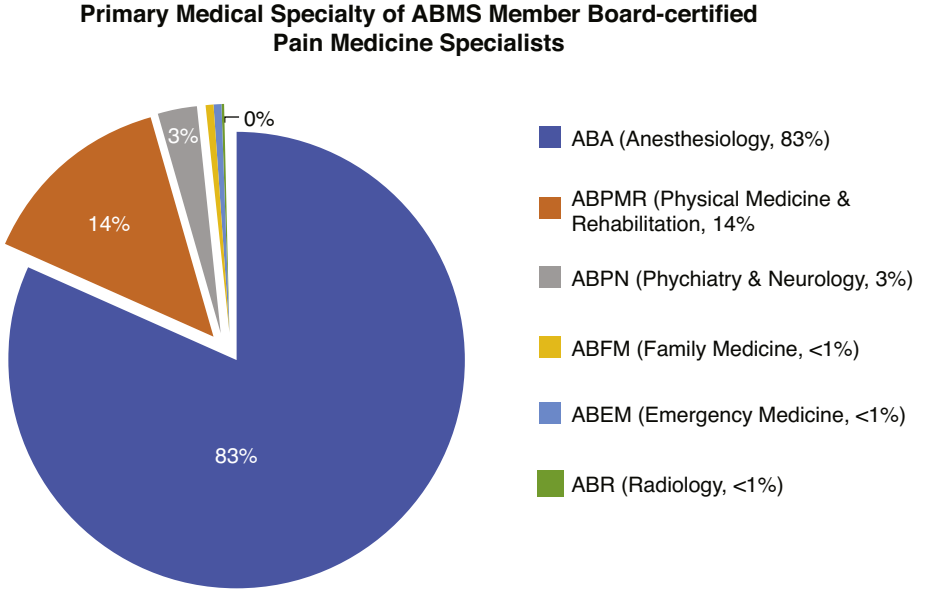
Accredited fellowship training in pain medicine is a relatively recent development. Before 1992, training was frequently obtained in academic anesthesiology departments, including those of Bonica, Bridenbaugh, Carron, Haugen, Moore, Raj, Winnie, and others, and subsequently in programs run by their trainees. These unaccredited programs advanced the specialty, widened interest in pain medicine as a career, and propagated pain care in smaller and smaller communities across the country. Outside the United States, this type of informal training remains the rule for those seeking expertise in pain medicine. In the United States, the American Board of Anesthesiology (ABA) developed an interest in certifying pain medicine specialists following their training. Through the leadership of Dr. William Owens in his roles in both the ABA and the Accreditation Council on Graduate Medical Education (ACGME) and through his representations of the subspecialty to the American Board of Medical Specialties, formal training programs were accredited, and physicians were certified. Drs. Stephen Abram and John Rowlingson were both key members of the group that assisted Dr. Owens in moving the new subspecialty forward.

The first programs were accredited by the ACGME in 1992. The number of ACGME-accredited programs and trainees in accredited programs has grown steadily over the past decade, and there are now more than 100 training programs that turn out about 300 new pain specialists each year. Working in parallel with ACGME, the ABA developed a subspecialty certification examination in pain medicine, first named the "Certificate of Added Qualifications in Pain Management" and now titled "Subspecialty Certification in Pain Medicine." The first examination was given in 1993. This examination is written and edited by a multi-disciplinary group of experts in the fields of anesthesiology, physical medicine and rehabilitation, neurology, and psychiatry. The number of candidates taking the examination has grown steadily since the initial examination (see Fig. 7.1). The fastest growing cohort of examination candidates have been from the specialty of physical medicine and rehabilitation (see Fig. 7.2).

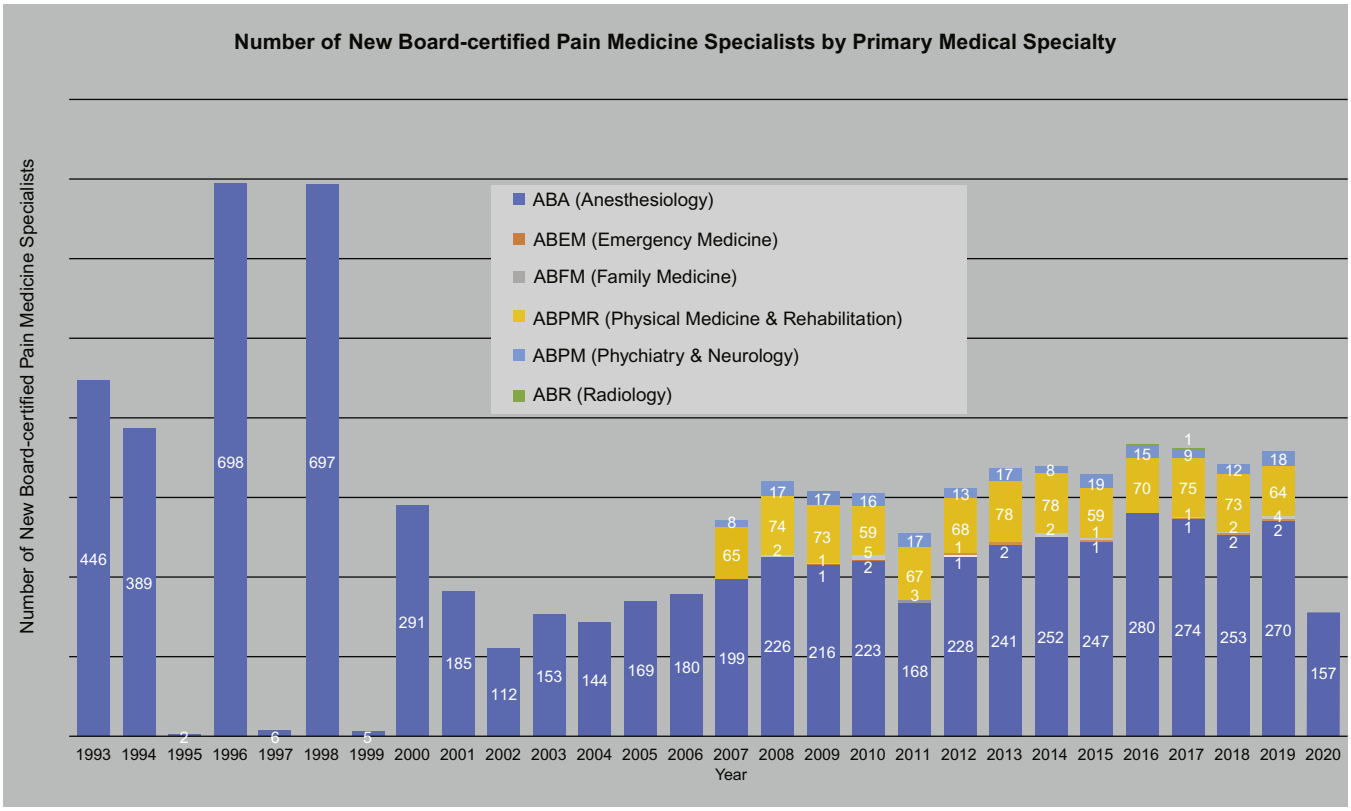
Dr. Bonica's original push to develop multi-disciplinary pain care recently evolved into a collaboration between four specialties that agreed to a single and unified set of program requirements for all ACGME-accredited pain fellowships, regardless of the sponsoring specialty. The ACGME Residency Review Committees for Anesthesiology, Neurology, Physical Medicine, and Rehabilitation and Psychiatry agreed on these requirements in late 2005, and the ACGME board approved their implementation for 2007.[4] These requirements have standardized pain fellowship training programs. After the introduction of new training requirements in 2007, several programs closed because of unwillingness to adopt a multi-disciplinary approach, and thus only the more comprehensive programs were left to continue the training of physician pain specialists (see Fig. 7.3). Programs have begun to produce more comprehensive and multi-disciplinary focused physicians from a broader range of primary disciplines. Other groups also encourage a more comprehensive approach to pain care, with the linked American Academy of Pain Medicine and the American Board of Pain Medicine likewise devoting energy to a multi-disciplinary approach. Equally important in the evolution of the discipline is the creation of academic physicians within the fellowships who undertake research programs to add new knowledge to guide clinical practice in this area of medicine.

Pain and its consequences draw on resources from all medical disciplines. Dr. Bonica's experiences during World War II suggested that each medical specialist had unique expertise to bring to patients suffering pain, hence his consistent and effective promotion of a multi-disciplinary process for pain care. Thanks largely to Dr. Bonica, anesthesiology has led the development of formal training programs. Indeed, most currently accredited programs reside within academic anesthesiology departments, and most program directors are anesthesiologists. Specialists from other disciplines have also focused their clinical and research efforts on pain. The most obvious example is neurology, from which the majority of clinical treatment and research on headache has arisen. The field of physical medicine and rehabilitation has also had a focus and expertise on functional restoration, and physiatrists lead many chronic pain rehabilitation programs. The pain expertise of these specialties brings together complementary concepts for overlapping areas in expertise, e.g. in the treatment of low back pain and chronic headache, the most common causes of chronic pain in the United States and internationally.[5] Moreover, psychiatrists and psychologists have been closely involved when pain, depression, and substance abuse overlap. During the last decade, specialists from these other disciplines have been seeking subspecialty training in pain medicine with increasing regularity. Close interaction with fellows from specialties outside their own has led some fellowship graduates to join or start multi-disciplinary pain practices upon graduation, continuing the collaborative care they learned in their training. Pain societies, such as the American Society of Regional Anesthesia and Pain Medicine and the American Society of Interventional Pain Physicians, once anesthesiology based, are now multi-disciplinary.

The range of practitioners declaring themselves pain medicine specialists is extraordinary, from clinics that provide largely or solely cognitive-behavioral approaches to chronic pain through functional restoration programs all the way to the type of clinic that offers nothing more than injections of various sorts. "Interventional pain medicine" is a phrase that has been coined for techniques that involve minimally invasive treatments and minor surgery as part of their application, including neural blockade and implantable analgesic devices. Despite the paucity of scientific evidence to guide pain practitioners, particularly evidence to support the use of many interventional modalities, many techniques with efficacy based on limited observational data have been adopted into widespread use. Many organizations have published guidelines on the appropriate use of interventions and other therapies to treat pain conditions.



• **Figure 7.1** Primary specialty of board certification of diplomates receiving subspecialty certification in Pain Medicine through a member board of the American Board of Medical Specialties (ABMS). ABA, American Board of Anesthesiology; ABEM, American Board of Emergency Medicine; ABFM, American Board of Family Medicine; ABPMR, American Board of Physical Medicine and Rehabilitation; ABPN, American Board of Psychiatry and Neurology; ABR, American Board of Radiology (Data courtesy of the American Board of Anesthesiology, July 2021).



• **Figure 7.2** Trends in the number of new subspecialty board-certified diplomates in pain medicine recognized by the American Board of Medical Specialties (ABMS) and their primary discipline of ABMS board certification. ABA, American Board of Anesthesiology; ABEM, American Board of Emergency Medicine; ABFM, American Board of Family Medicine; ABPMR, American Board of Physical Medicine and Rehabilitation; ABPN, American Board of Psychiatry and Neurology; ABR, American Board of Radiology (Data courtesy of the American Board of Anesthesiology, July 2021).

Still, there is no single practice pattern that pain specialists can point to as being the correct way to treat patients with chronic pain. Training programs vary widely in the scope of what they train practitioners to do. The best pain medicine practitioners strike a reasonable balance between interventional and non-interventional management. This practice pattern is sustainable, and those adopting a balanced style of practice will be able to adapt to the evolving scientific evidence that appears in support of pain treatment, regardless of the type of treatment. A balance between treatment modalities also allows practitioners to switch from one mode to another or to incorporate multiple treatment approaches simultaneously. The use of these interventional modalities is just one part of the expanding armamentarium of a skilled pain practitioner, which now also includes complementary and alternative therapies.

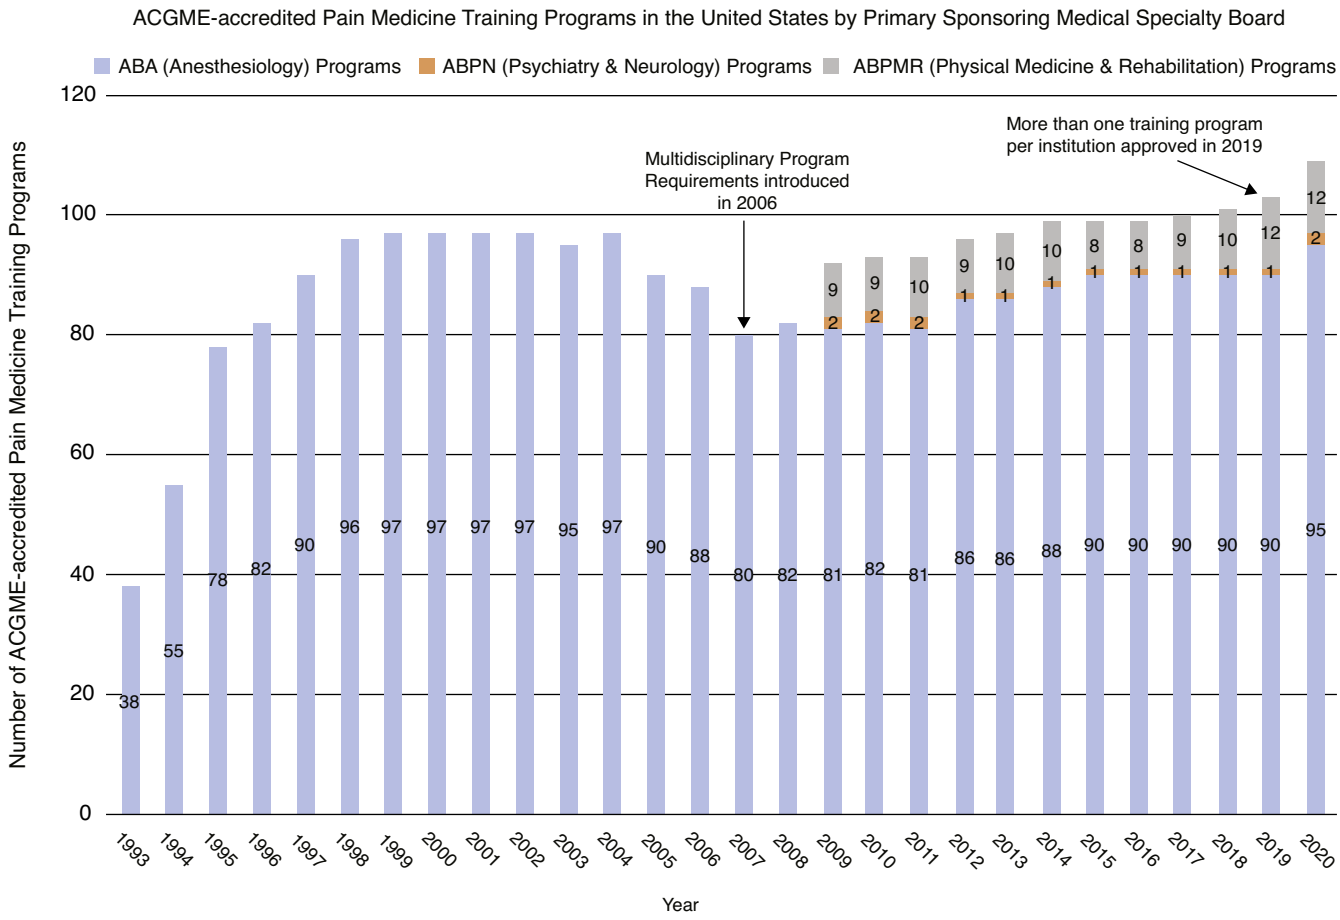
Training and Credentialing in Interventional Pain Medicine

In our rapidly changing world of modern health care, new technologies are appearing at a dizzying rate. Many of these new treatments require physicians to acquire detailed new knowledge and technical skills. The introduction of new techniques typically extends from centers in the public or private sector, where the ideas are conceived and tested in a limited realm among innovators. From there, anecdotes can often take over, and many techniques in pain medicine have blossomed into widespread use with nothing more than word of mouth to propagate their use. The use of pulsed radiofrequency and intradiscal electrothermoplasty[6] for the treatment of pain are examples where clinical application preceded detailed clinical testing.[7]

In the United States and Europe, industry often leads innovation by testing and initiating the introduction of new devices. When the innovation appears to have merit in limited trials, many devices are introduced to the market with approval through the Food and Drug Administration's 510K "substantially similar device" process with little or no data regarding efficacy. Once on the market, the means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and—of great importance—the means by which practitioners gain enough expertise to introduce new techniques into their own practice are all highly variable and seemingly without any rational or consistent approach.

Interventional pain medicine is evolving as a distinct discipline that requires detailed new knowledge and expertise. Familiarity with radiographic anatomy for performing image-guided injections and the minor surgical skills needed to implant devices such as spinal cord stimulators and intrathecal drug delivery systems are just a few of the techniques that practitioners must master. As we set out to introduce new interventional techniques into our own pain practices, we must be sure that we have been properly trained to perform these techniques in a manner that ensures safety and success.

Adequate exposure to these newer treatment alternatives during the fellowship training period is necessary to ensure appropriate application and optimize patient outcomes. ACGME requires demonstration of competence for peripheral nerve blocks, neurolytic and neuraxial procedures, and neuromodulation. For techniques that are now widely accepted as a core element of pain practice, we must ensure that our trainees gain enough experience to conduct



• **Figure 7.3** Trends in the number of pain medicine fellowship training programs accredited by the Accreditation Council for Graduate Medical Education (ACGME) since the first program were established in 1992 (Data courtesy of the American Board of Anesthesiology, July 2021).

these procedures independently. One key element of the ACGME deliberations about unified pain training is to acknowledge that not all pain fellows will have experience in the wide variety of interventional techniques. Acquisition of competence in these procedures may be more easily acquired in those with a background in an interventional primary specialty. Instead, it is hoped that these fellows will gain an understanding of all available options for patients with pain and yet demonstrate and have competence documented in only techniques for which formal training is made available during fellowship training.

It is difficult to define the techniques that are core for a pain practitioner. However, it does seem that detailed knowledge of the radiographic anatomy of the spine and the minor surgical expertise required to implant spinal cord stimulators and permanent intrathecal drug delivery systems are among the skills that most practicing pain physicians would expect a new graduate from a pain fellowship program to have. New techniques are appearing at a staggering rate, and we cannot rely on pain fellowship programs to provide all the technical training needed. More robust standards for documentation of minimum training following fellowship programs are also urgently needed. Some pain practitioners believe that too many of their colleagues find it perfectly acceptable to attend a single brief weekend course and then introduce a highly technical new treatment into practice without additional study, training, or oversight.[8] Practitioners themselves must take the lead in obtaining adequate training *before* proceeding with any new and unfamiliar technique. A weekend workshop is just a start, often a good start, particularly in the years following fellowship training. The best workshops will give practitioners a detailed understanding of anatomy, pathophysiology of disease related to use of the new technique, patient selection, conduct of the procedure, outcomes, and avoidance, management, and recognition of complications. These workshops are increasingly accompanied by links to training videos that may be viewed and reviewed at a later date. In Spring 2020, during the COVID pandemic, the use of telehealth dramatically increased, and organizations offered a variety of educational webinars, often free of charge, discussing techniques and strategies for interventional procedures such as ultrasound-guided neural blockade and neuromodulation. Box 7.1 is a suggested method for practitioners to introduce a new technique into clinical practice.[9]

Future Directions

The field of evidence-based medicine has emerged as a new paradigm to guide practicing physicians. This field aims to educate practitioners on how to frame specific questions based on the clinical problems that they encounter every day. They then venture to the published scientific literature with focused questions on prevention, treatment, and diagnosis of a specific clinical condition. Many evidence-based medicine centers offer concise and periodically updated summaries on specific clinical conditions. The idea is to get the best information available to practicing clinicians.

• BOX 7.1 Suggested Training and Experience When Introducing a New Technique Into Clinical Practice

Study the new technique and the published literature and gain detailed knowledge of all aspects of the technique.

Attend a workshop, preferably a hands-on cadaver-based workshop that allows the introduction of the technique in as realistic a setting as can be assembled. Review the post workshop videos, if available.

Plan adequate time for your initial procedures.

Get help at the bedside during the initial performance of new procedures—perhaps another experienced practitioner at your institution or an invited expert to assist or team up with a colleague in a related discipline.

Inform your patients that you are introducing a new technique and include this discussion as part of the informed consent process.

Scrutinize your outcomes in the initial stages of using any new technique and compare them with those of your colleagues and the published literature.

They describe the best available evidence, and if there is no good evidence, they say so. In pain medicine, we are faced with an expanding array of treatment options that strike us as logical developments that s*hould* provide pain relief for our patients. However, there is a dearth of clinical evidence to guide rational choice and application of many emerging treatments. So how are we to decide when to apply them?

In 2003, Merrill[10] presented an analysis of the state of evidence guiding the use of interventional treatments in the field of pain medicine. He pointed out the frequent flaws in existing studies (largely the lack of valid comparators, such as no treatment) and concluded that "the practice of invasive pain medicine teeters at a particularly critical juncture…crippled by a lack of vigorous self-evaluation of its role in the treatment of chronic pain." Merrill explained the means by which we, as scientists and clinicians, can build a better body of evidence for the treatments we are using. A recent publication also addressed this lack of scientific rigor for interventional therapies. They commented that poor research results might in part reflect the inherent challenges in blinding and patients refusing the possibility of not receiving an intervention.[11] However, the field of pain medicine is relatively young, and although randomized clinical trials are still lacking for many treatments, some are starting to emerge. The Minimally Interventional trial failed to demonstrate long term efficacy for radiofrequency denervation compared to exercise for low back pain.[12] With the advent of paresthesia free spinal cord stimulation, randomized controlled trials showing promise for neuromodulation in certain pain populations are now in publication.[13,14]

New treatments evolve slowly. Application of the scientific method in clinical medicine begins with observation, perhaps a chance observation that a certain drug typically used for another purpose provides analgesia to a given patient. If the drug is readily available, a clinician may choose to treat other patients with similar conditions. If academically minded, the clinician may choose to report the limited success in a case series. Case series are a valuable beginning, the very beginning of emerging new ideas. If the problem is uniform and prevalent enough, the new treatment may gain the attention of investigators willing to assemble a randomized clinical trial. All too often, sound treatments are never tested because of a lack of interest or funding. Those that are tested tend to be under patent, and the manufacturer proceeds with large trials understandably in the hope of financial return in the event that the treatment proves useful. Patients who are suffering from severe and intractable pain are desperate and can easily be convinced that desperate measures, however new or unproven, are warranted.

How then are we to proceed? Our patients are begging for us to try anything that offers a glimmer of hope in reducing their pain, and we as scientists embrace the rigor of the scientific method and want desperately to do what is best for our patients. We have treatment after treatment that makes logical sense and shows early promise in case series and observational studies, but few data that support an evidence-based approach to practice. Using acute low back pain with sciatica as an example, several evidence-based reports have emerged to guide clinicians.[15] The only modalities that are rated as "beneficial" or "likely to be beneficial" are advice to stay active and the use of non-steroidal anti-inflammatory drugs, behavioral therapy, and multi-disciplinary treatment programs. Opioid analgesics, acupuncture, back schools, epidural steroid injections, and spinal manipulation were all judged to be of "unknown effectiveness." Nevertheless, in actual clinical practice in the United States, a short course of an opioid analgesic plus early intervention with epidural steroid injections is common. To complicate matters, the use of fluoroscopic guidance to direct injections to the affected level via an interlaminar or transforaminal approach has gained widespread acceptance, but with limited studies to guide us as clinicians. Those with persistent pain and contained disk herniations now have a dizzying array of treatment options, with only uncontrolled observational studies that suggest effectiveness.[16] The new devices are intellectually appealing and minimally invasive, yet only open surgical diskectomy has proved superior to conservative management in patients with persistent sciatica secondary to intervertebral disk prolapse.[17]

The evidence-based medicine movement gives little guidance to practitioners whose tools are still under development. They simply remind us that scant evidence regarding many of our techniques exists. Without declaring a moratorium on all interventional pain techniques, Merrill[9] offers the individual practitioner advice: monitor your own outcomes with valid measures, be more reflective and systematic in studying your own outcomes and patterns of care, and provide this information to your patients as part of the decision-making process. As pain practitioners, we have an expanding range of treatment options available to us, few with convincing evidence of efficacy superior to that of alternative treatments. We must evaluate each patient and use the limited evidence available to us today to guide compassionate and rational, if not evidence-based, use of therapy for our desperate patients.

The urgent need for expanded clinical research in pain medicine, coupled with recent efforts to improve multi-disciplinary training, is straining the ability of training programs to adequately provide the needed education and research experience for pain medicine fellows in the course of a one year fellowship. The ACGME and ABA are currently working to further restructure pain medicine training to accomplish these goals (for a review, see Rathmell[18]). The idea is to provide more comprehensive and multi-disciplinary training and require meaningful research experience during fellowship training. With this approach, we will create a more homogeneous group of pain medicine specialists who emerge with similar knowledge and skills, regardless of the parent discipline in which they trained. This will move us toward improving the consistency and quality of care of patients with acute, chronic, and cancer-related pain.

Key Points

- The first multi-disciplinary pain clinic was established by the late Dr. John Bonica. The International Association for the Study of Pain, founded in 1974, its United States chapter the (now dissolved) American Pain Society, and the journal *Pain* are his legacies.
- The initial accredited pain medicine fellowship programs were based on anesthesiology programs. The ACGME Residency Review Committees for Anesthesiology, Neurology, Physical Medicine, and Rehabilitation and Psychiatry agreed on standard multi-disciplinary requirements in late 2005, and the ACGME board approved their implementation for 2007. Several programs closed, and the more comprehensive programs continued the training of physician pain specialists. These programs have begun to produce more comprehensive and multi-disciplinary focused physicians from a wider range of primary disciplines.
- Detailed knowledge of the radiographic anatomy of the spine and the minor surgical expertise required to implant spinal cord stimulators and permanent spinal drug delivery systems are among the skills that a new graduate from a pain medicine fellowship program is expected to have.
- Together with the ACGME, the ABA developed a subspecialty certification examination in pain medicine, first named the "Certificate of Added Qualifications in Pain Management" and now titled "Subspecialty Certification in Pain Medicine." The first examination was given in 1993, and the number of candidates taking the examination has steadily grown.
- Many devices have been introduced to the market with approval through the Food and Drug Administration's 510K "substantially similar device" process with little or no data regarding efficacy. The means by which practitioners decide to adopt new technologies, the speed of progression of these new techniques, and the means by which practitioners gain enough expertise to introduce new techniques into their own practices are all highly variable. Rational steps in incorporating a new interventional technique into someone's practice are outlined in Box 7.1.
- Efforts to provide multi-disciplinary training and the need for clinical research are straining the ability of training programs to provide the education and research experience for pain medicine fellows in the course of a one year fellowship. The ACGME and ABA are currently working to further restructure pain medicine training to accomplish these goals.

Neurophysiology of Pain: Peripheral, Spinal, Ascending, and Descending Pathways

KARIN N. WESTLUND

Introduction

The neural circuits that are responsible for pain and the reactions to pain[1] can be termed the *pain* system,[2–4] or perhaps more appropriately, the *pain systems*. The pain systems include (1) peripheral neurons with a set of peripheral receptive elements, the nociceptors, (2) numerous central neuronal relay pathways, and (3) sets of integrative neurons that impose excitatory or inhibitory influences on nociceptive information at numerous levels of the neuraxis.

While functioning under normal conditions provides warning information vital to tissue protection, and if pain persists, maladaptive neuroplastic reconfiguration occurs at the synapse and in specific brain regions creating a chronic pain state. When expansion to other systems such as affective, aversive, learning, and memory occurs, chronic pain, anxiety, and depression can result.

The initial reception of inputs perceived by the brain to be painful occurs at the peripheral terminations of sensory axons, the nociceptors that transduce noxious mechanical, thermal, and chemical stimuli into action potentials. Sensory nerve axons transmit information about internal or external stimuli that are noxious, distressing, or damaging to the second order neurons located at the corresponding spinal cord or brainstem level (i.e. lumbar spinal cord for leg input, thoracic spinal cord for stomach lining input, and trigeminal spinal nucleus for face input). The spinal excitatory (glutamatergic) and inhibitory ([γ]-aminobutyric acid-ergic [GABAergic] and/or glycinergic) interneurons provide a complex integrative network circuitry influencing the incoming nociceptive input received by nociceptive spinal dorsal horn projection neurons. As examples, the projection neurons and the inhibitory neurons have excitatory drive from spinal interneurons and/or from primary afferent nerve fibers. Spinal inhibitory interneurons may mediate pre-synaptic inhibition at the terminals of primary afferent nerve fibers as well as pre- and post-synaptic inhibition of spinal excitatory interneurons. Nociceptive spinal dorsal horn projection neurons are modulated further by long, descending facilitatory and inhibitory pathways.

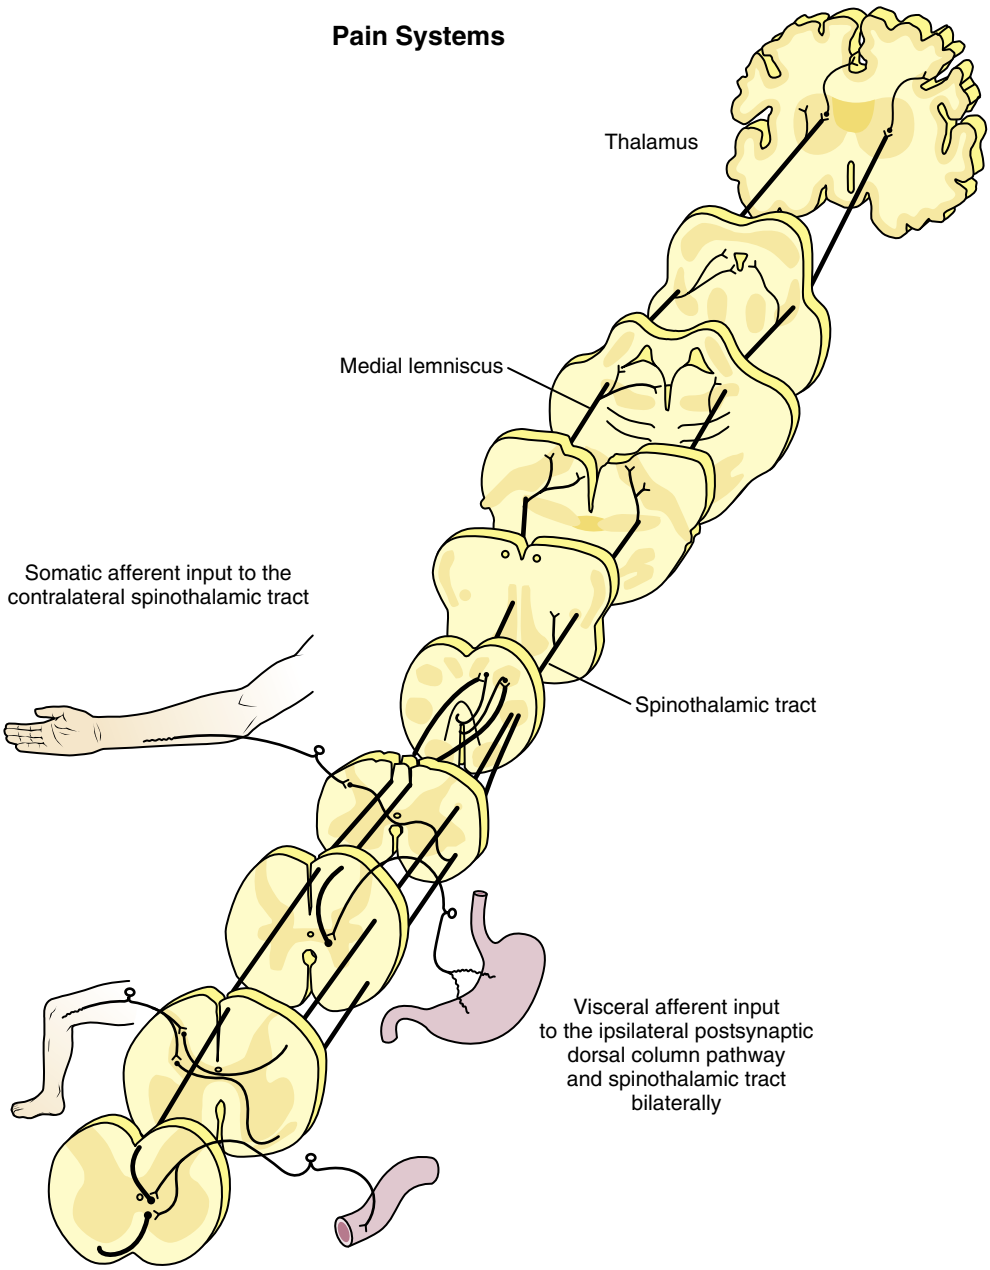
Nociceptive signals are then transmitted by the pain system projection neurons to other integration sites in the brainstem and higher brain via collateral input. The primary integration of site-specific sensory information in the brain occurs in the thalamus that then relays the information for cortical site perception. A variety of coordinated responses are generated in response to relay of nociceptive information to numerous other brain neuronal sites and circuitry activating integrative excitatory and inhibitory mechanisms. Beyond cortical awareness of pain, processing occurs to provide protective somatic and autonomic reflexes, endocrine actions, emotional responses, as well as learning and memory about the event.

In addition to pain and pain reactions, the brain centers that receive nociceptive information provide either negative or positive feedback that can reduce or accentuate pain and pain reactions. Negative feedback to the spinal cord circuitry is mediated by descending pathways that are often called the "endogenous analgesia system." The mechanism and pathways responsible for the accentuation of pain and pain reactions, referred to as *central sensitization,* can involve increased responsiveness at all levels of the pain systems, including the peripheral nociceptors, sensory neurons, the spinal cord, brainstem, and higher centers. The net effect of the positive and negative circuitry alterations leads to the perceptual experience of "pain," but over time the discomfort of continuing pathologic chronic pain can result in increased anxiety, depression, and disability.

Nociceptors

Peripheral Receptive Elements

The initial reception of noxious inputs perceived to be painful occurs at the specialized endings of primary afferent sensory neurons known as *nociceptors*. Reception of noxious input occurs at the functionally specialized free nerve endings of the skin, muscle,[5] joints,[6,7] viscera,[8,9] and dura (Fig. 8.1).[10] Nociceptive endings are also located in the fascia and adventitia of blood vessels.[11] Nociceptor subtypes respond best to mechanical (mechanical nociceptors); mechanical and thermal (mechano-thermal nociceptors); or mechanical, thermal, and chemical stimuli (polymodal nociceptors).[12,13] Common types of cutaneous nociceptors are Aδ mechanoreceptors and C polymodal nociceptors, which relay the transduced information about potentially harmful input via Aδ and C-fibers, respectively.[14,15] Glutamate receptors, as well as μ and δ-opiate, substance P (SP), somatostatin,



• **Figure 8.1** The pain systems convey input from somatic structures, as well as from viscera and other deep tissues, via peripheral nerves. Afferent nerve fibers carrying nociceptive information have free nerve endings in peripheral tissue and terminate in the superficial spinal cord dorsal horn. Information about pain is relayed through at least one synapse to cells in the spinal cord dorsal horn. Two parallel ascending pathways provide the information to integration centers in the thalamus, which provide the information to cortical regions. Input primarily from somatic structures is relayed to spinothalamic tract cells whose axons cross the midline and ascend in the lateral and ventrolateral spinal white matter as the spinothalamic tract. As the spinothalamic tract courses through the brainstem, collateral fibers innervate various brainstem centers involved in providing responses to nociceptive input on its path to the thalamus. Nociceptive input arising from visceral structures is relayed by post-synaptic dorsal column cells whose axons course in the dorsal columns. After a synaptic relay in the dorsal column nuclei and crossing to the opposite side of the brainstem, the medial lemniscus carries visceral nociceptive information to the thalamus. Both these routes are somatotopically arranged throughout their length.

and vanilloid receptors, have been identified immunohistochemically on the peripheral endings of cutaneous nerve fibers.[16–20] Neuroactivators released by tissue injury (ATP, bradykinin, nitric oxide, H+) and cytokines (tumor necrosis factor [TNF]α, interleukin [IL]-1β, IL-6) released by macrophages, neutrophils, and mast cells drawn to an injury site produce amplified peripheral nerve responses or peripheral sensitization (i.e. enhanced nociception).

Peripheral Nerves

The small axons that relay information about noxious input from the skin and other tissues to the central nervous system (CNS) fall characteristically into the range of unmyelinated fibers with conduction velocities less than 2.5 m/s in the case of C-fiber (or group IV) nociceptors (Fig. 8.2),[21] and small fibers wrapped in a

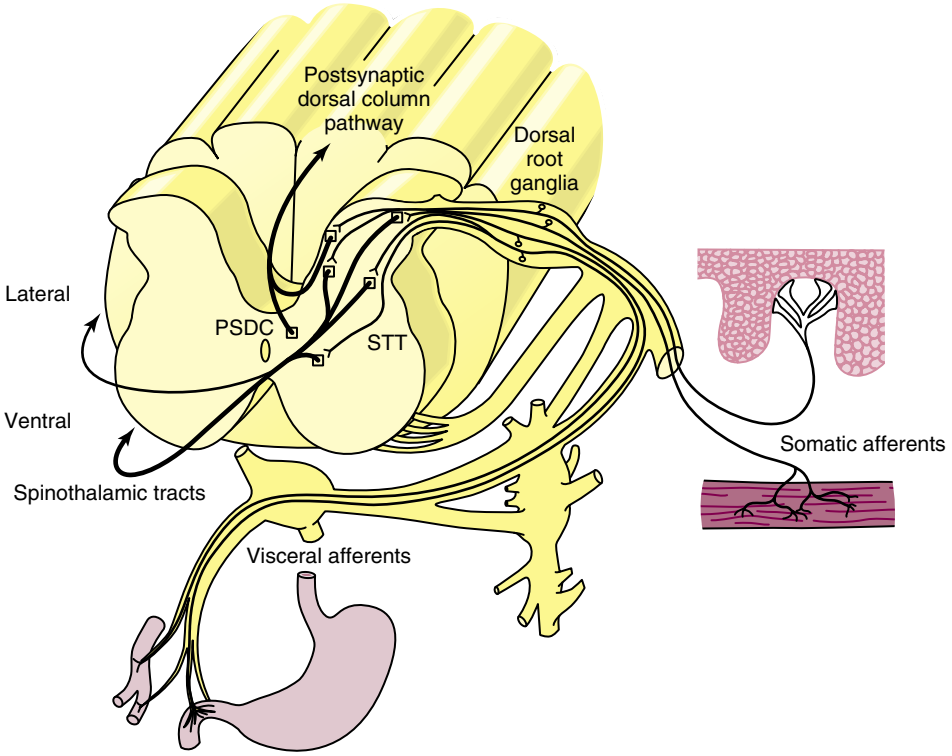
• **Figure 8.2** Peripheral nerves conveying information about pain are either small, slowly conducting fibers found unmyelinated in bundles or medium sized axons with thin myelin, which provides a higher conduction velocity.

thin layer of myelin produced by Schwann cells with a conduction velocity of 4–30 m/s in the case of the Aδ fibers (or group III).[22] Primary afferent C-fibers are more numerous than myelinated primary afferents in peripheral nerves. For example, in dorsal roots, the ratio of C-fibers to A fibers is about 2.5:1,[23] and in joint nerves (after sympathetic postganglionic axons are removed by sympathectomy), the ratio of C-fibers to A fibers is 2.3:1.[24]

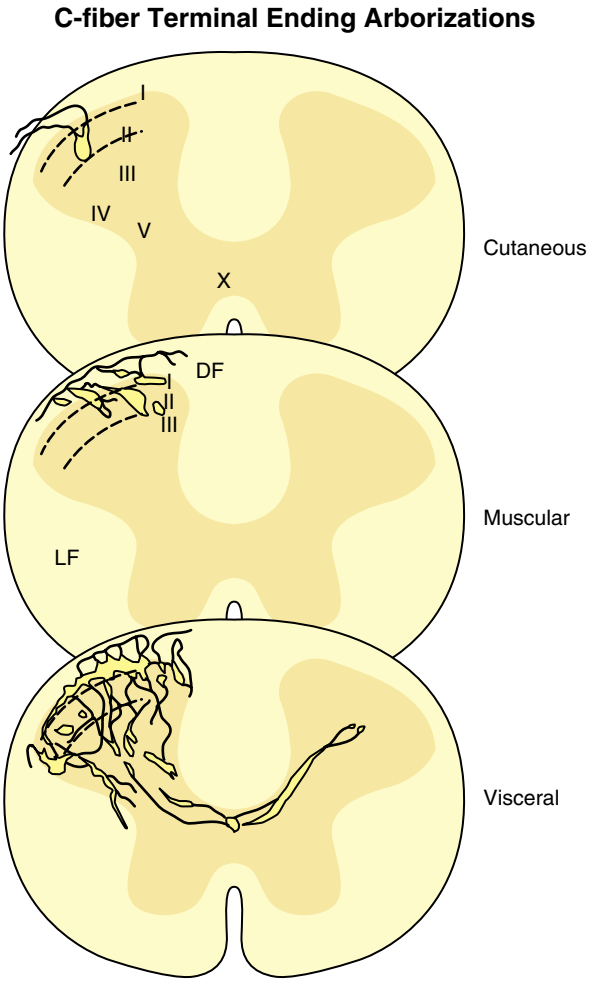
While peripheral nerves have both sensory and motor functions, all sensory afferent fibers, whether they innervate cutaneous, deep, vascular, or visceral tissue, separate from motor fibers near the spinal cord and join to form the dorsal root before entering the spinal cord on the dorsal surface (Fig. 8.3). Primary afferent fibers providing input from visceral structures and the vasculature travel along with the sympathetic efferent nerves. However, they pass directly through the sympathetic trunk to join other afferent fibers entering the dorsal horn of the spinal cord (Fig. 8.4). They remain silent unless provoked by inflammation or abnormal distension.

Cell Bodies in Dorsal Root Ganglia

The cell bodies of the nociceptive primary afferent nerve fibers lie just outside the spinal column clustered in the dorsal root ganglia (DRG). Nociceptive DRG neurons are small and medium sized but lie among the large dorsal root ganglion cells activated by touch, pressure, and vibration.[7,25,26] They extend their axons centrally to the spinal cord as dorsal roots. As in most central neuronal circuits, glutamate is the primary neurotransmitter substance in primary afferent nociceptors. Its action is modulated by neuropeptides co-released at their terminal endings and activation molecules. Calcitonin gene-related peptide (CGRP), SP, neurokinin A, galanin, and somatostatin are just a few examples of the many neuropeptides that provide



• **Figure 8.3** Nociceptive afferent nerve fibers have receptive free nerve endings in the dermal papillae of the skin and in the muscle, vasculature, and visceral structures. Nerves carrying nociceptive information travel with other somatic and autonomic motor axons, even passing through the autonomic ganglia, but have their cell bodies in the dorsal root ganglia located in the spinal vertebral column. The central axonal projection of afferent nerve fibers then passes through the dorsal root to innervate the spinal cord dorsal horn. Nociceptive information is relayed across at least one synapse in the dorsal horn to alert cells with projections to higher centers. The spinothalamic tract (*STT*) cells in the superficial dorsal horn send an axonal projection across the midline to travel in the lateral STT. STT cells in the deep dorsal horn send axons across the midline to ascend in the ventral white matter. STT cells bring information about both somatic and visceral pain to the thalamic levels. Post-synaptic dorsal column (*PSDC*) cells relay information about visceral pain through the ipsilateral dorsal column.



• **Figure 8.4** C-fiber terminal endings have been physiologically characterized and then filled with dye to reveal their terminal arborizations in the dorsal horn of the spinal cord. Examples of terminal arbors of axonal fibers with cutaneous, muscular, and visceral receptive fields are illustrated. The morphology of the cutaneous axonal ending would provide the anatomic substrate for precise point-to-point localization of a nociceptive insult on the cutaneous surface. Likewise, the diffuse widespread terminal arborization pattern of visceral afferent nerve fibers would account for the poor localization of visceral nociceptive sensation, which can be "referred" to other structures. Most visceral afferent nerve fibers innervate neurons that lie in the midline and some of the visceral fibers even cross the midline. The Roman numerals indicate Rexed's laminae. *DF*, Dorsal funiculus white mater; *LF*, lateral funiculus white matter.

neurogenic modulation and inflammation peripherally.[25,27] Modulatory neuropeptides produced in the DRG are transported quickly, both to the terminal endings in the periphery and to the spinal cord, and thus may not necessarily be evident in the cell body without experimental manipulations. The small satellite glia, the other primary component of the DRG, provide support but are capable of providing modulatory influences on the neurons that promote peripheral and central sensitization. The DRG, as well as afferent nerve endings both centrally and peripherally, are activated by pro-inflammatory mediators such as TNFα, IL-1, and IL-6.[28,29] Other activators include the small molecules adenosine, TRPV1, ATP, nitric oxide, and other reactive oxygen species.[30–34] All of these pro-inflammatory substances have been identified as being present at nerve terminal sites, in the DRG, and in the dorsal horn.

Transcriptomic profiling of single sensory ganglia neurons provides further functional classification diversity and molecular drug targets. As an example, ribonucleic acid (RNA) sequence data for visceral sensory neurons has been investigated.[35] Seven distinct subtypes of visceral sensory neurons of the splanchnic and pelvic sensory nerves retrogradely traced from their innervation of the colon have been distinguished using combined single-cell RNA sequencing, calcium imaging, qRT-PCR, and immunohistochemical validation as reviewed previously.[36] Five subtypes enter the thoracic level from the splanchnic nerve, and two almost exclusively from the pelvic nerve are located in the lumber five (L5) DRG. Like the distinct differences in somatic and visceral sensation, the molecular phenotype of visceral transient receptor potential channel (TRP)-sensitive mechanosensors differs from analogous somatosensory mechanosensors.[36] While both isolectin B4 positive (IB4+) and IB4- somatosensory neuron mechanoreceptor subtypes from naïve mice have similar broad tetrodotoxin (TTX)-resistant action potentials, proprioceptive neurons relaying position sense have TTX-sensitive, narrow action potentials.[37] Transcriptional profiling has revealed that these differences in firing characteristics can be attributed to the very different ion channel expression patterns of these neurons. Nociceptive neurons are highly enriched for Cacna2d1 (α2δ1) and Cacna2d2 (α2δ2), the pharmacologic targets of gabapentin and pregabalin.[38–40] Both IB4+ and IB4- somatosensory neurons express sodium ion channel Nav1.7, which, when congenitally absent in individuals, renders them without pain sensation and unprotected from injury.[41]

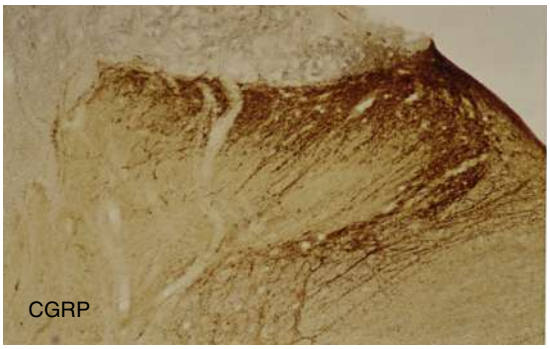
Spinal Cord and Spinal Trigeminal Nucleus

Nociceptor Terminations in the Spinal Cord Dorsal Horn

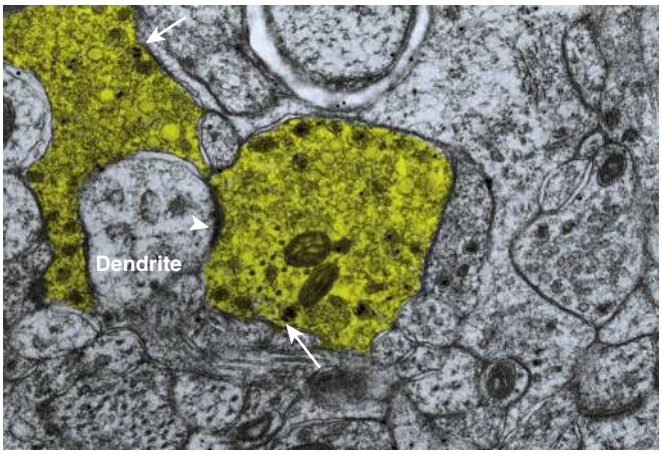
The afferent fibers enter the gray matter of the spinal cord through the dorsal root entry zone and primarily innervate regions of the spinal cord within the same or adjacent spinal segments matching that spinal nerve. The two major populations of small diameter primary afferent nerves carrying pain related information to the dorsal horn are classified as 1) peptidergic containing CGRP (Fig. 8.5)[42–44] and SP terminating in Lamina I-II_{outer}, and 2) nonpeptidergic neurons expressing P2X3 and binding IB4 terminating in Lamina II_{inner}.[45–47] Functional distinction between these nociceptors has been noted for their involvement in inflammatory and acute pain (IB4-), while the IB4+ neurons have more involvement in mechanical and chronic pain.[48–50] The IB4- neurons also express GDNF, TrkA, TRPV1, and other acid-sensing ion channels (ASIC) and have larger heat-evoked currents.[50–53] Neurons that are strongly IB4+ are C-nociceptor type with higher density of Nav1.9 voltage-gated TTX-resistant Na+ channel expression defining their longer action potential durations and rise times, slower conduction velocities, and negative membrane potentials.[47,51,54–57] A-δ low threshold mechanoreceptive neurons are weakly IB4+ or IB4-.[55]

Dorsal Horn Laminar Organization

The smaller myelinated and thinly unmyelinated axonal fibers carry information about temperature, and nociceptive input perceived as pain in humans enters the spinal cord segmentally through the dorsal roots. The fibers enter Lissauer's tract, then primarily innervate the superficial gray matter laminae I–II of the spinal cord where neuronal cell bodies and dendrites receive their



• **Figure 8.5** Calcitonin gene-related peptide (*CGRP*) is a good marker of the population of primary afferent nerve terminals innervating the dorsal horn.



• **Figure 8.6** Many afferent nerve terminals in the spinal cord dorsal horn terminate in irregular, scalloped endings filled with both clear and dense core vesicles containing neurotransmitter substances. The scalloped endings (*colored yellow*) are formed as the endings contact numerous small dendrites of spinal neurons, such as the one shown containing the arrowhead. The arrowhead is directed toward a synaptic contact. Several of the dense core vesicles illustrated (*arrows*) in the terminal endings contain dense gold particles indicating immunolocalization of calcitonin gene-related peptide.

arborized synaptic endings (Figs. 8.3 and 8.4).[58] The afferent fibers may also ascend rostrally or descend caudally through Lissauer's tract for a few spinal segments. For example, CGRP fibers extend extensive fiber terminations up and down the superficial spinal cord dorsal horn through as many as six spinal levels and can even cross the midline in small numbers.[42,59] Numerous other neuropeptides have been localized in the dorsal horn terminals and neurons.[27] Visceral afferents are rich in vasoactive intestinal polypeptide (VIP), bombesin, CGRP, and SP[8,25] and would account for some of the population of these peptides in the deep dorsal horn laminae. Other neurotransmitters and neuromodulators are discussed more thoroughly in Chapter 9.

The outer marginal layer or lamina I of the spinal cord contains nets of spiny dendrites of cells that are longitudinally arranged along the length of the cord. Somatic nociceptor C-fiber afferent endings are distributed mainly to laminae I and II in the same and adjacent segments. In contrast, visceral C-fiber afferents can extend for more than five segments before they terminate and are widely distributed in laminae I, II, V, and X ipsilaterally and in laminae V and X contralaterally (Fig. 8.4).[60,62] In addition to the afferent endings, fiber terminations of the descending pathways and the local interneurons also heavily innervate the superficial dorsal horn laminae I–II, adding to the dense crescent of terminal endings observed when stained immunocytochemically for many neurotransmitters and receptors. Cutaneous Aδ mechanical nociceptors terminate in the ipsilateral laminae I and V, and they may also have endings in lamina X and the contralateral dorsal horn.[61,62]

Primary Afferent Endings Contain Glutamate

Primary afferent endings in the spinal cord dorsal horn contain small, round, clear glutamate containing vesicles released upon nerve activation for synaptic transmission and relay of nociceptive information to spinal cord neurons.[44] The large, glomerular type afferent endings typically contain large, dense cored vesicles containing peptides[63] (Fig. 8.6). CGRP receptors on post-synaptic membranes of spinothalamic tract neurons are found opposite glomerular, elongated, and dome-shaped synaptic endings in the superficial dorsal horn.[42] In high activation states such as after tissue damage, increased release of glutamate further increases the activation of dorsal horn neurons as it does in other sites of neural integration. The increased release is accompanied by the release of small molecule modulatory peptides expressed by primary afferent neurons, including SP, CGRP, VIP, and cholecystokinin (CCK).[25–27,64] These modulators, along with cytokines (TNFα, IL-1β, IL-6) released from adjacent microglia and astrocytes in the spinal cord, generate central sensitization in the case of intense and/or prolonged nociceptive stimulation.[28,65]

Pre-synaptic Inhibition, Primary Afferent Depolarization, and Dorsal Root Reflexes

When afferent nerve endings are activated persistently after an injury, increased release of glutamate and other excitatory amino acids in the dorsal horn activates spinal cord interneurons.[66–68] The post-synaptic activation results in the increased firing of GABAergic inhibitory interneurons as well as the firing of excitatory interneurons. The gamma aminobutyric acid (GABA) hyperpolarizes the neuronal membrane that dampens incoming afferent firing. Pre-synaptic inhibition also occurs as the excessive glutamate activates autoreceptors on the afferent endings.[69] The depolarized membrane also causes the inactivation of voltage-gated calcium channels, preventing calcium influx at the synapse. The net result of pre-synaptic inhibition is reduced amplitude of the action potential as it invades pre-synaptic terminals. This results in less calcium influx and therefore less transmitter release. However, as the pre-synaptic inhibition continues, other changes in the inhibitory control process result in prolonged membrane hyperpolarization and chloride conductance that can actually depolarize the afferent nerve endings themselves. This occurs because of the activation of $GABA_A$ receptors that open Cl^- channels allowing chloride to enter the cell passively as it follows the chloride equilibrium gradient. Eventually, this will result in Cl^- efflux as the equilibrium potential is exceeded, resulting in depolarization of the afferent terminal. This process is referred to as primary afferent depolarization.[70] The depolarization can be blocked by antagonists of $GABA_A$ receptors. These findings and the initial work by John Eccles on pre-synaptic inhibition have since been extended in various ways. For example, it was later explained that with persisting afferent nerve activation, the potassium-chloride co-transporter (N^+-K^+-$2Cl^-$, NKCC1) becomes insufficient to remove the influx of chloride ions from the afferent terminals. When the intercellular

chloride ion concentration exceeds the equilibrium potential, a reversal occurs, and there is an efflux of chloride ions. After that, GABA has a depolarization effect.[71–73] Another contributor proposed is the increase in the extracellular concentration of K^+ following neural activity.[74]

Activation of nociceptive neurons resulting in primary afferent depolarization of the dorsal horn nerve ending initiates action potentials in the central afferent terminals. The action potentials generated travel back out the afferent nerve toward the periphery, where they have been recorded in A-β, A-δ, and C-fibers.[75–77] These "dorsal root reflexes" release neurotransmitters peripherally into the damaged tissue, such as glutamate and peptides, contributing to the increase in inflammation and peripheral blood flow, but it can be blocked centrally by $GABA_A$ and non-NMDA antagonists.[76–79] Likewise, the action potentials contribute further to the increased excitatory transmitter release in the dorsal horn. These events set up a reverberating positive feedback loop, amplifying nociceptive input and increasing both peripheral and central sensitization that can promote the establishment of chronic pain if it continues.

Spinal Interneurons

Most of the spinal cord neurons are interneurons (~90%).[80] The gray matter at the core of the spinal cord dorsal horn that receives sensory nerve terminations is comprised of excitatory and inhibitory integrative interneurons forming the first tier of sensory information processing, integration, and modulation of sensory inputs arising from the peripheral or internal environment. Spinal interneurons also receive input from other interneurons and descending pathways that together impact and integrate their responses.

Functional Somatotopy and Spinal Interneurons

Noxious input relayed by the primary afferent fibers is received by the dendritic arbors of neurons in the dorsal horn gray matter of the spinal cord. The gray matter is a matrix of synaptic terminations, neurons, and glial cells subdivided topographically as 10 laminae by Rexed based on histologic appearance (Figs. 8.4 and 8.7).[81,82] The site of afferent fiber type terminations centrally in spinal gray matter laminae is relevant to function. The importance of the laminar organization has been upheld by other phenotypic findings, including chemogenetic,[83] optigenetic,[84,85] and gene expression patterns.[86–89] Prominent among overrepresented genes in spinal neurons are transcription factors (30%–38%) and neuropeptides (24%–26%) relevant to a specific function.[90]

Excitatory neurons utilize glutamate neurotransmission (60%–70%) and inhibitory interneurons (30%–40%), GABA, and glycine.[58] Fifteen types of excitatory and 15 types of inhibitory interneurons have been identified using single-cell RNA sequencing in the mouse spinal cord.[88] Validated by spatial transcriptomics, this laminar distribution report classified heat and cold sensitive excitatory and inhibitory neuronal sets. In addition to glutamate, GABA, and glycine, interneurons contain many neuroactive substances that are presumably neurotransmitters or modulators involved in nociceptive processing by the local interneuronal circuits of the dorsal horn. These substances include adenosine, choline acetyltransferase, cholecystokinin, corticotropin releasing factor, dynorphin, enkephalin, galanin, neurokinin B, neuropeptide Y, neurotensin, protein kinase C γ, somatostatin, SP, and thyrotropin-releasing hormone.[8,87] Additional information on the molecular content is described in Chapter 9.

Excitatory interneurons predominate in the dorsal horn, although lamina II or the substantia gelatinosa contains both excitatory and inhibitory interneurons that modulate projection neurons. Two non-overlapping populations have been identified characterized by either their content of gastrin-releasing peptide (GRP) or SP (radial neurons with many dendrites).[88] The SP neurons generally show delayed firing and respond to noradrenaline and serotonin with an outward current under voltage clamp conditions, suggesting that they respond to descending monoamine modulatory input, but they have no response to A-δ opioid receptor agonist. The GRP interneurons do not respond to 5-HT, or NA, but respond with an inhibitory outward current to μ-opioid receptor agonist DAMGO under voltage clamp conditions. They do not respond to δ or κ agonists. The GRP interneurons have local intersegmental connectivity. Typical of lamina II are the large glomerular synaptic complexes sometimes referred to as scalloped primary afferent endings that contact multiple dendrites of dorsal horn cells simultaneously (Fig. 8.6).[7,92–95] The terminals contain large dense core vesicles, which are identified as neuropeptide-containing, with CGRP in particular. Dorsal horn protein kinase C gamma (PKCγ) containing excitatory interneurons (30%) with islet-like morphology and abundant spines have been characterized by delayed firing patterns and receive synaptic inputs from both Aδ and C low threshold mechanoreceptors.[87] Six other excitatory and four inhibitory interneurons receiving low threshold mechanoreceptor information were identified using genetic tools in that study.

The GABA inhibitory interneurons take the form of stalked (limiting) cells and the inhibitory containing islet (central cells) interneurons.[83,96] GABA interneurons contain parvalbumin (70%), and those found in laminae I and III can also contain another inhibitory amino acid, glycine,[87,97–99] with dendrites extending both dorsally into lamina I and ventrally into deeper laminae of the dorsal horn. The orientation of intralaminar connectivity among the excitatory dorsal horn interneurons in lamina II is extensive in the rostrocaudal plane compared to the inhibitory interneuronal connectivity, and both have limited dendritic spread in the mediolateral plane.[100] The central, radial, and islet cell populations receive extensive input almost entirely from within lamina II, including substantial input from both IIo and IIi. The vertical cell population receives additional input from the deep dorsal horn lamina III–IV and has been speculated to be highly modifiable in states of continued nociceptive activation.

Role of Spinal Interneurons in Gate Theory Spinal Inhibition

The many interneurons in the spinal cord circuitry are also highly involved in spinal modulation that decreases the impact of noxious input. Inhibition of spinal transmission by weak mechanical stimulation can occur either through activation of segmental or supraspinal circuitries. The events that can inhibit nociceptive transmission can occur by reducing neurotransmitter release from nociceptor terminals. While physiologists have conveniently explained "surround" type inhibition of dorsal horn synaptic transmission in terms of dorsal horn axo-axonic synaptic transmission, only a few anatomic figures of this type have been described for the dorsal horn.[98,101,102] Rather, the anatomic arrangement of synapses for the Gate Theory of Pain proposed by Melzack and Wall[103] is likely mediated through axodendritic arrangements of CGRP primary afferent terminals innervating the dendrites of GABA interneurons in lamina II and reciprocal interactions that

are difficult to image reliably. Fine myelinated and unmyelinated CGRP labeled afferent fibers have been observed synapsing with GABAergic dendritic profiles (islet cells),[102] which have also been shown to contain glycine.[98] GABA interneurons are uniquely qualified to provide the "pre-synaptic" inhibition of nociceptive input either through contacts provided by their dendrites back onto CGRP primary afferent endings or through axonal contacts back onto other dorsal horn neurons.[103] Other inhibitory neurons in the dorsal horn contain dynorphin and glycine. Similarly, an interposed excitatory interneuron, such as one containing glutamate, would provide an excitatory boost to spinal nociceptive processing. Interestingly, neurons in lamina II, the substantia gelatinosa, do not respond to the release of SP since they lack NK_1 (SP) receptors.[104] The SP terminal endings are located on nociceptive projection cells in both lamina I and the deep dorsal horn, including lamina I cells with NK1 receptors that rapidly internalize the receptors upon nociceptive stimulation.[105,106]

Role of Interneurons in Central Sensitization and Allodynia

The interneurons in the dorsal horn have been found to be highly involved in the activation of central sensitization when the nociceptive pathway is exposed to repeated noxious stimuli.[107–110] Dysregulation of the balance of excitatory and inhibitory interneurons results in sustained nociceptive transmission to higher brain levels.[107] Further discussion is provided below since glia are intimately involved in this process.

While signals from nociceptors are relayed across at least one synapse to activate spinal neurons prior to arriving at higher brain regions, input for non-noxious tactile discriminative sensory information (tactile, pressure, vibratory sense) is relayed directly to the dorsal column nuclei in the brainstem (Figs. 8.1 and 8.3). However, in states of intense or prolonged overactivation, the large myelinated primary afferent fiber collateral input to the dorsal horn becomes involved in nociceptive processing.[111] Their collateral input activates deep dorsal horn laminae III–IV neurons that then become sensitized in conditions of central disinhibition.[112] The percentage of superficial dorsal horn interneurons that receive polysynaptic A-β input is normally relatively low but can be increased by inhibitory transmitter blockade.[112] Increase in A-β input to the superficial dorsal horn in animal models of inflammatory or neuropathic pain hypersensitivity has also been reported.[113–116] This contributes to hypersensitivity, including thermal and mechanical allodynia.

Role of Glia in Central Sensitization, Allodynia, and Paradoxical GABAergic Excitation

Activation of spinal cord microglia (one to three days) and astrocytes (one to two weeks) after nerve injury plays an important role in the establishment and maintenance of neuropathic pain.[65,117–119] Microglia in the CNS have an innate immune function sensing damage, assuming a reactive morphology, and upregulating to secrete pro- and anti-inflammatory cytokines. After an injury, release of microglial BDNF and BDNF-TrkB signaling downregulates neuronal chloride transporter KCC2, resulting in a depolarizing shift in neuronal Cl- reversal potential. This increases the membrane potential such that inhibition is impaired and allodynia results.[73,120–123] Thus while chloride transporter KCC2 activity extrudes intracellular chloride to maintain Cl- membrane electrochemical gradient necessary for $GABA_A$ and glycine interneuronal inhibition, disruption of the inhibition and upregulation of facilitatory $GABA_B$ contributes to central sensitization.[71,72,123–126] Importantly, a second chloride transporter NKCC1 in lamina I–II peptidergic nerve terminals contacts astrocytes.[127] When activity in primary afferents is upregulated following an inflammatory insult, excessive GABA-ergic depolarization is produced in primary afferent terminals, leading to paradoxical excitation and cross excitation between low and high threshold afferents.[111]

The role of specific molecular targets upregulated in glia is also under investigation. For example, spinal cord astrocytes are activated by microglial-derived C1q in the late phase after somatic and trigeminal nerve injuries.[128] Upregulated TRAF6 has been shown to maintain neuropathic pain by integrating TNFα and IL-1β signaling and activating the JNK/CCL2 pathway in astrocytes.[129]

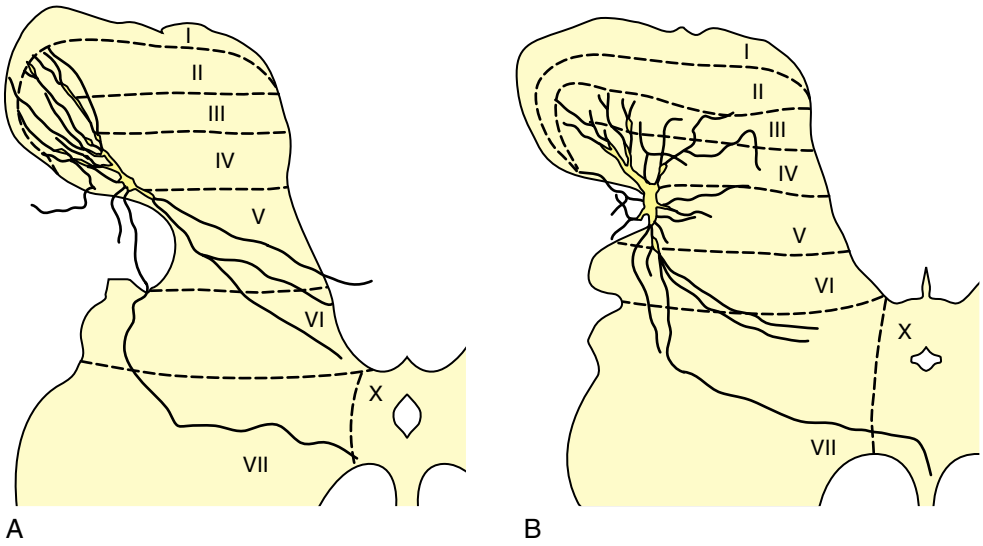
Thus nociceptive information entering the spinal cord dorsal horn is modulated by both excitatory and inhibitory neuronal and glial influences at the level of the spinal cord, prior to being relayed by projection neurons to higher centers. Modulation occurring after an injury or disease influences the local interneuronal circuitry and the circuitry activated by the projection neurons that influence brainstem modulatory input and higher brain pain circuitry.

Ascending Pain Pathways

Morphology of Projection Neurons

Several types of projection neurons in lamina I that send their axon rostrally to the brainstem have been described by Lima and Coimbra.[130–133] These cell types include fusiform (spindle-shaped), multipolar, flattened, and pyramidal neurons. Different subsets of these cells project their axons to the nucleus of the solitary tract, to the dorsal and lateral reticular nuclei in the medulla, pons and midbrain, and the thalamus. Neurons of the same morphologic type express SP, enkephalin, dynorphin, or GABA,[134] although some of the cells may have been interneurons. Three morphologic types of lamina I spinothalamic tract (STT) cells have been described in cats and monkeys: fusiform, pyramidal, and multipolar.[135,136] Evidence has been provided that the fusiform and multipolar STT cells are nociceptive, whereas the pyramidal STT cells are thermoreceptive.[137] Consistent with this, most fusiform and multipolar lamina I STT neurons express NK1 receptors, and most pyramidal STT cells do not.[104,138]

The projection cells found in the deeper laminae of the dorsal horn are typically located laterally in the dorsal horn. They are large, multipolar neurons with extensive dendritic arbors to receive numerous inputs and can thus convey highly integrated information to the thalamus. The dendrites of the deep projection cells tend to arborize radially in the spinal cord dorsal horn, in contrast to the lamina I projection cells whose dendrites are longitudinally distributed along the dorsal surface of the spinal cord gray matter so that they are barely visible in the coronal plane. A radial dendrite arrangement provides for the integration of the convergent input encoded by the STT cells in the deeper laminae instead of the superficial projection neurons situated to have ready access to specific incoming nociceptive and thermal input directly via the afferent nerve fibers. Some STT cells in deeper laminae do have dendrites that extend dorsally into lamina I and II (Fig. 8.7). These STT cells receive direct synaptic connections from the terminals of nociceptors ending in the superficial dorsal horn and are particularly responsive to high



• **Figure 8.7** Spinal cord cells that were physiologically characterized were filled with a stainable dye and reconstructed over many spinal cord slices to provide details of their dendritic arborization. The cell in A was characterized as a high threshold cell since it responded to intense stimulation in the digit of the hind limb. The cell body is situated in lamina IV, and its dendrites extend into all laminae. Dendrites extend almost a millimeter in the rostrocaudal direction. The axon bifurcates to cross the midline ventrally in lamina X, passing into the dorsal column. The cell in B was characterized as a "wide dynamic range cell" responding to a broader range of cutaneous input. The cell body is situated in lamina V, and its dendrites extend radially in all directions, including 1.2 mm in the rostrocaudal direction. The axon is seen crossing the midline in lamina X. The *dashed lines and Roman numerals* indicate Rexed's laminae.

threshold input.[7,139–141] Other STT cells identified as "wide dynamic range" cells respond to various mechanical, thermal, and nociceptive inputs. They have dendrites that extend chiefly in the ventral direction and receive convergent input from afferents supplying both deep somatic and visceral structures.

The spinothalamic tract and interneuronal cells in the dorsal horn express the early intermediate gene activation marker, c-Fos, with brief nociceptive stimulation in laminae I, IV, and V, whereas sustained nociceptive stimulation is needed to activate c-Fos in deeper laminae III, V, VII, and X, as in models of joint and visceral inflammation.[142,143] Some contacts on retrogradely labeled STT projection neurons contain peptides, such as SP, enkephalin, dynorphin, or VIP.[144,145] The dorsally directed dendrites of many deep dorsal horn neurons contain NK_1 (SP) receptors,[143] and these are internalized following presumably painful stimulation occurring during inflammation.[135] Lamina X STT cells have been shown to contain CCK, bombesin, and/or galanin.[146,147] Synapses found on the cell bodies of non-human primate and rat STT neurons of deep layers of the dorsal horn contain glutamate, GABA, glycine, SP, CGRP, vasopressin, norepinephrine, or serotonin.[102,105,141,148,154] Electrophysiologically characterized primate STT cell bodies with projections to the ventroposterolateral thalamus are glutamatergic. They are contacted by both excitatory (50%) and inhibitory (30%) terminals for direct impact integrative processing.[102,141] These ultrastructural studies have revealed post-synaptic localization of glutamate receptor subunits NMDA R1, AMPA GluR1, and GluR2/3, and metabotropic mGluR1.[153,154] The glutamate NMDA R1, mGluR2/3, and AMPA Glu R2/3 receptor subunits were localized pre-synaptically on the terminals contacting the identified STT neurons.

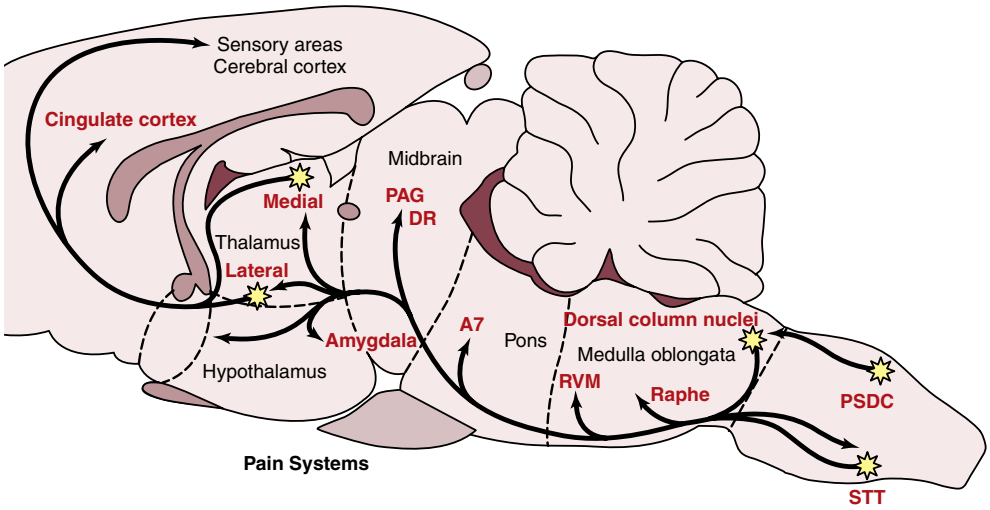
Ascending Pain Pathways

Medial Versus Lateral Pain Pathway Designation

The ascending pathways activated by noxious input are sometimes distinguished as medial and lateral pain pathways. An interesting hypothesis is that medial and lateral pain pathways provide affective and epicritic (discriminative) pain sensations, respectively. The ventrolateral spinothalamic tract clearly provides information for specific discrimination of pain and temperature, somatotopic localization, and quality and intensity coding of cutaneous pain. Some of the pathways in unique positions to assume a role in affective pain awareness include the spinoamygdalar pathway, the spinal pathways relaying visceral pain through the post-synaptic medial dorsal column route, and ventromedial projections to midline structures, including the rostral ventromedial medulla, periaqueductal gray, hypothalamus, and centrolateral and medial thalamus. Some of the non-overlapping but parallel medial and lateral ascending pathways carrying information to brain centers responsive to pain are described below.

Lateral Pain Pathways

Spinothalamic Tracts. The main lateral pain pathway is the well-known spinothalamic tract that transmits site-specific (discriminative) information about the location, quality, and intensity of the noxious input to the lateral thalamus. Thalamic neurons then relay the information to the SI, SII somatosensory cortex. The spinothalamic tract neurons send ascending axonal fiber projections across the spinal cord midline cord in the anterior white commissure ventral to the central canal. The STT axons in the deep dorsal horn (laminae IV–VII, X) ascend in the contralateral (opposite side) ventrolateral white matter of the spinal cord and brainstem (Figs. 8.1, 8.8 and 8.9).[155] The axons of STT cells terminate laterally in the posterior ventrobasal thalamic complex (ventral posterolateral, ventral posterior inferior) or medially in the medial and intralaminar thalamus (subparafascicular and central lateral). The thalamus is the main integration site of sensory information that is then provided to the somatosensory cortex. Noxious tactile information from the same body region converges upon the same thalamic neurons. The point-to-point reception of information in the lateral thalamus provides somatotopic encoding for specific localization of the input onto the cortical representation of the specific body region.[156] This provides the ability to precisely locate the origin of the nociceptive input.



• **Figure 8.8** Pain systems include the spinothalamic tract and the post-synaptic dorsal column pathways. These parallel pain systems ascending from the spinal cord converge to course through the brainstem as the spinothalamic tract and the medial lemniscus. Although the primary termination site for sensory integration is the thalamus, abundant collateral terminations are provided to integration sites throughout the brainstem. The ventral posterolateral nucleus of the thalamus is the principal somatosensory relay for information provided to the sensory areas of the cerebral cortex for localization of pain sensation. The medial and intermediate portions of the thalamus project to the anterior cingulate and frontal cortex, respectively, and provide input relevant to the affective responses to pain. Autonomic adjustments occur in response to the input provided to the hypothalamus. *A7*, Noradrenergic cell group; *DR*, dorsal raphe; *PAG*, periaqueductal gray; *PSDC*, post-synaptic dorsal column cell; *RVM*, rostral ventromedial medulla; *STT,* spinothalamic tract cell.

The STT cells receiving noxious temperature input are largely situated in lamina I.[157] Lamina I STT neurons send their axonal projections in the lateral white matter to terminate in the posterior part of the ventral medial nucleus of the thalamus and in the ventral posterior and medial dorsal nuclei. Early electrophysiologic studies reported parallel processing of nociceptive inputs in the cortex arising from the ventrobasal thalamus to the sensory (SI, II), cingulate, and insular cortex. This includes somatosensory and visceral sensory input from ventral posterolateral (VPL) and centrolateral (CL) thalamic nuclei, respectively, and oral/tooth pulp input from the ventral posteromedial nuclei (VPM) of the thalamus.[158–160]

Collateral branching of the spinothalamic tract innervates many sensory processing regions as it ascends, including the dorsal column nuclei, dorsal and ventral medullary reticular formation, dorsolateral pontine locus coeruleus/parabrachial region, midbrain periaqueductal gray, anterior pretectal nucleus, hypothalamus, and amygdala, as has been described and reviewed previously (Figs. 8.1, 8.8 and 8.9).[161–166] While much of the initial information about pain anatomy and function was derived from animal studies, clear visualization of activation in cortical sites is now available with functional magnetic resonance imaging (fMRI) imaging and is reviewed in a later chapter.[167,168]

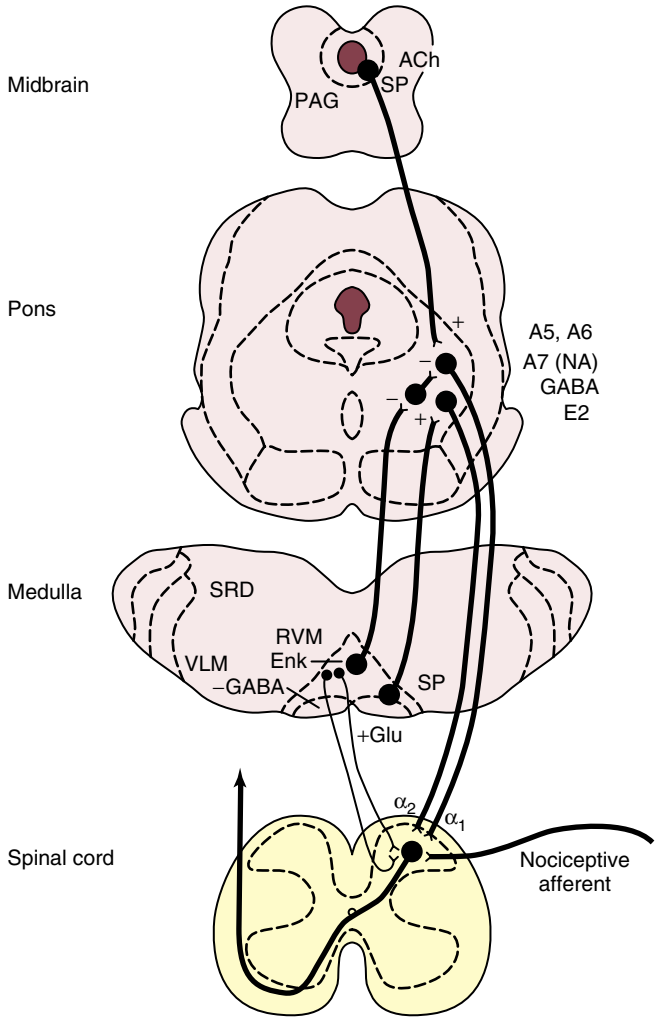
Spinoreticular pathways. Many projection axons from the spinal cord also provide direct and collateral innervation to the brainstem regions involved in pain related activities, including descending modulation of pain, autonomic responsiveness, alerting response, escape responses, and limbic and cortical activation. Collectively, these neurons are referred to as the spinoreticular system (Fig. 8.1, 8.8).[162,169–171] These integrative regions modulate and balance excitatory and inhibitory neuronal influences on nociception through reciprocal higher brain connectivity that ultimately determines the pain state.

A dorsal spinomedullary pathway arises from cells in laminae I, IV, and X to terminate bilaterally in the subnucleus reticularis dorsalis (SRD) of the dorsal medullary reticular formation, which is located just ventral to the cuneate and solitary nuclei of the dorsal medulla.[164,170] This nucleus is a brainstem site active in balancing descending inhibition and facilitation of nociceptive processes. The diffuse noxious inhibitory controls (DNIC) inhibiting wide dynamic range neurons in the spinal cord and competing with afferent input are dependent on a supraspinal loop through the SRD and a descending pathway.[170] Projections from this region innervate the contralateral somatosensory, motor, limbic, and insular cortex, and the periaqueductal gray (PAG), pons, cerebellum, trigeminal, and other brainstem nuclei.[172] Connections to the anterior cingulate gyrus participate in the descending facilitatory modulation of pain.[173]

Medial Pain Pathways

The medial pain system transmits nociceptive information to the midline brainstem, hypothalamus, amygdala, and the medial and intralaminar thalamus to regions organizing responses to pain.[174–178] Innervation of the hypothalamus and limbic structures, including the anterior cingulate cortex, activates affective, motivational, and autonomic responses to pain. Medial pain pathways include the spinoamygdalar, spinohypothalamic, medial spinothalamic, spinoreticular, and connections to the anterior cingulate, prefrontal, and insular limbic cortices.[171–174] Some of these axons include neurons in lamina X known to transmit visceral information.[175–178]

Anterograde and retrograde tract tracing studies demonstrate other first and second order pathways ascending on the same side or crossing to the opposite side white matter. Associated ascending spinal cord white matter projections described include the spinoreticular, spinoparabrachial, spinomesencephlic, spinohypothalamic, spinothalamic, spinoamygdalar, spinoinsular, and other spinolimbic tracts.[163–174] This includes innervation of the medullary subnucleus reticularis attributed to provide DNIC[164,170] and innervation of the medial thalamic nuclei, habenula, and insular cortex providing information about noxious visceral inputs.[175–178]



• **Figure 8.9** Multiple integration sites in the brainstem receive nociceptive input from the ascending pain systems. Complex brainstem circuitry provides both descending inhibitory and excitatory alterations of nociceptive responses at the level of the spinal cord. Cells are situated side by side in the rostral ventromedial medulla (*RVM*) that impose either excitatory or inhibitory influence. Cells in the RVM are both serotonergic (5-hydroxytryptamine) and nonserotonergic. They provide both a direct descending pathway to the spinal cord and a major input to the dorsolateral pons. The A5 to A7 noradrenergic (*NA*) cell groups in the dorsolateral pons provide major inhibitory feedback to the spinal cord. The PAG and the anterior pretectal nuclei provide inhibitory input to the spinal cord through connections with descending pathways from the dorsolateral pons. Specific neurotransmitters within brainstem regions are noted, as are specific receptors having an impact on nociception in the spinal cord dorsal horn. *ACh*, Acetylcholine; *E2*, estrogen receptor 2; *Enk*, enkephalin; *GABA*, γ-aminobutyric acid; *Glu*, glutamate; *SRD*, subnucleus reticularis dorsalis; *SP*, substance P; *VLM*, ventrolateral medulla.

Early electrophysiologic studies have reported that nociceptive inputs from the ventrobasal thalamus to the sensory (SI, II) cortex are paralleled by axonal projections to the limbic cingulate and insular cortices. This includes somatosensory and visceral sensory input from ventral posterolateral (VPL), medial, parafascicular, and centrolateral (CL) thalamic nuclei, and oral/ tooth pulp input from the ventral posteromedial nuclei (VPM) of the thalamus.[159,178–180] While much of the initial information about pain anatomy and function was derived from animal studies, clear visualization of activation and parallel processing in cortical sites is now available with fMRI imaging[168] and will be reviewed in a later chapter in this volume.

Post-synaptic dorsal column pathway. The spinal cord dorsal column midline contains less well studied ascending axons of the post-synaptic dorsal column neurons. These projection neurons are responsive to noxious visceral input. The axons are situated medial to the dorsal column ascending primary afferent neuronal axons relaying touch, pressure, and vibratory sensation. The cell bodies of many of these neurons are located in laminae III and IV[181] but are also described for lamina X.[176,177,181–183] Many excitatory interneurons near the post-synaptic dorsal column cells (30%) receive protein kinase C γ low threshold C-fiber mechanoreceptor synaptic input.[87] The neurons send a direct projection uncrossed to the caudal dorsal column nuclei in the dorsal medial medulla.[165,176,177,186] Sacral lamina X post-synaptic dorsal column neurons have axons traveling nearest to the dorsal column midline septum to terminate in the gracile nucleus. Axons arising from the thoracic spinal levels travel near the intermediate septum of the dorsal column and terminate in both the gracile and cuneate nuclei. The information is presumed to then travel with the crossed medial lemniscal fibers to the thalamus. Lamina X post-synaptic dorsal column neurons with axons transmitting visceral nociceptive information to the thalamus converge on some of the same thalamic cells receiving nociceptive information from the skin and other somatic structures (Fig. 8.1, 8.7).[175,180,183] Visceral only input can also be recorded in the centrolateral intralaminar nucleus of the thalamus.[177,186]

Spinohypothalamic, Limbic, and Cortical Connections. Pain is often accompanied by motivational-affective responses, including suffering, anxiety, increased attention and arousal, increased heart rate and blood pressure, as well as by changes in endocrine and autonomic responses. The neural structures and the pathways that relay these changes parallel those relaying information localizing the source of the noxious input on the body map but escape awareness in most instances.[178] Centrolateral and medial thalamic projections to the anterior cingulate and frontal cortices, respectively, have been described.[187,193] Their thalamic connections to the somatosensory (SI, SII) cortex and other cortical sites are less well studied.

Spinohypothalamic and spinoamygdalar pathways initially described are involved in autonomic and affective responses to pain.[172,188,189] Ascending axonal projections of these pathways arise primarily from the spinal cord laminae I and X), as well as from the lateral reticulated region of the spinal cord.[190–192] Synaptic contact is made in the lateral hypothalamus (LH) and the central nucleus of the amygdala (CA). Both of these regions are also involved in antinociceptive actions, as well as autonomic and affective responses to nociceptive input through connections with the medial thalamus and with other parts of the limbic system.

Spinal projections to the ventrolateral medulla are conveniently located to relay to the paraventricular nucleus of the hypothalamus,[166,189] amygdala,[167] and the medial preoptic region.[166,167,172,189,192] Ascending axonal projections of these pathways arise primarily from the spinal cord laminae I and deep spinal laminae (VII, VIII, and X).[160] The direct route to the medial thalamus, amygdala, and the spino-parabrachial-amygdala pathways are clearly involved.[187,188] A spino-reticulo-thalamo-cortical pathway was originally proposed as a projection to the forebrain relaying information about painful input, presumably for subjective interpretation based on known anatomical projections

of the reticular formation to higher brain centers.[195] Relays to the insular cortical structures have also been described as the "interoception" cortex receiving visceral input from all over the body.[196,197]

Evidence from imaging in patients with longitudinal back pain concludes that the plasticity of corticolimbic anatomic neuroanatomic features rather than the somatosensory pain circuitry contributes to the risk of chronic pain. Factors such as increased white matter connectivity and functional connections within the dorsal medial prefrontal cortex-amygdala-accumbens circuit, small amygdalar volume, and opioid gene polymorphisms contribute in these regions rich in opioid receptors.[198–200]

Trigeminal System. An important feature unique to trigeminal circuitry includes its close proximity to brain structures.[201,202] Information from the face pain travels via trigeminal primary afferents through the TG to synapse in the brainstem medullary dorsal horn as well as to directly innervate the parabrachial complex.[202] Thus the trigeminal innervation of the lateral parabrachial nucleus has more direct connectivity with the limbic system via one synapse while the spinal input crosses two synapses. Optogenetic activation of the trigeminal monosynaptic connectivity has been shown to induce escape and avoidance behavior.[202] Human study participants report increased fear after noxious facial stimulation compared to similar noxious stimulation of the hand.[203] Secondary axons ascend via the trigeminothalamic and parabrachio-amygdaloid tracts to the ventromedial thalamus and amygdala, respectively, then relay to several cortical and subcortical regions including primary and secondary somatosensory cortices, insula basal ganglia, anterior cingulate cortex (ACC), and limbic circuitry.[204,205] Nociceptive information relayed via the basal ganglia is transmitted to the prefrontal cortex and back to the amygdala.

Modulation of Pain

Ascending Modulation of Pain

Major ascending axonal projections relaying information about pain pass laterally through the brainstem but have collateral terminations in the reticular formation of the ventrolateral medulla (VLM), the rostral ventromedial medulla (nucleus gigantocellularus pars alpha and nucleus raphe magnus), and other sites known to modulate pain.[132,133,170,174] The collateral innervation of the monoamine cell groups are prominent in providing descending modulation. The midline raphe nuclei containing serotonergic and non-serotonergic neurons with descending projections to the spinal cord have been particularly well studied[124] and are reviewed in another chapter in this volume.

The spinal ascending pathways also traverse brainstem regions and have direct synaptic contact with catecholaminergic neurons, including the C1, A1, and A2 regions of the medulla and the A5, A6 (locus coeruleus), and A7 (subcoeruleus) neurons of the pons.[165] The catecholaminergic neurons of the brainstem are involved in diverse functions, including modulation of pain, stress responses, arousal, and learning. Connectivity is described among the ventromedial medulla and the catecholamine cells of the pons,[206,207] and the anterior cingulate gyrus,[173] as well as between brainstem catecholaminergic cells and the thalamus,[75] and ACC.[208] These interconnecting networks assist in the coordination of descending and facilitatory influences on pain perception and autonomic, affective, and stress responses.

Parabrachial Nuclei

Axonal collaterals of the ascending spinal projection neurons terminate in the parabrachial region. Small injections of retrograde tracer in the parabrachial nucleus confirm that the parabrachial nucleus receives projections primarily from lamina I nociceptive neurons.[208,209] The spino-parabrachial-amygdala pathways are clearly involved in descending inhibition, central pain, and emotional responses to chronic pain.[193–195]

Interestingly, high frequency stimulation inducing long term potentiation is described only for C-fiber synapses onto spinal lamina I neurons expressing neurokinin1 synapses with projections to the parabrachial nucleus.[209] The parabrachial nucleus projects directly to the PAG, amygdala, and ventrobasal thalamus.[210] Involvement in visceral nociceptive processing has also been reported for the parabrachial nucleus.[211] Direct trigeminal nerve innervation of the parabrachial nucleus is described as providing a route for direct access for orofacial nociceptive input to the amygdala.[202]

Periaqueductal Grey

Ascending pathways relaying nociceptive information are influential in the activation of the PAG, pontine noradrenergic cell groups, and midline midbrain reticular formation.[174,213–215] Direct neuronal projections from the central region of the spinal cord to midline brainstem nuclei, including the rostral ventromedial nucleus of the medulla and the midbrain PAG and raphe magnus, have been described as well.[177]

Anterior Pretectal Nucleus

Another termination site innervated directly by ascending pathways from the spinal cord and from the dorsal column nuclei is the anterior pretectal nucleus (APN).[216] The anterior pretectal nucleus is thought to be an important source of descending inhibition of nociceptive pathways. Evidence suggests that it sends axons to catecholaminergic neurons of the parabrachial region.[217–218]

Subnucleus Reticularis Dorsalis

The medullary SRD is active in balancing descending inhibition and facilitation of nociceptive processes. Projections from this region innervate contralateral somatosensory, motor, limbic, and insular cortex, and PAG, pons, cerebellum, trigeminal, and other brainstem nuclei.[172] Connections to the anterior cingulate gyrus participate in the descending facilitatory modulation of pain.[210] The DNIC inhibiting wide dynamic range neurons in the spinal cord competing with afferent input are dependent on a supraspinal loop through the SRD and a descending pathway.[164,174]

Descending Pathways Modulating Pain

Periaqueductal Grey

Descending inhibition of spinal nociceptive processes was initially described by Reynolds in 1969 in behavioral experiments in which electrical stimulation of the PAG resulted in antinociception.[225–227] The PAG in the midbrain makes descending connections with the rostral ventromedial medulla (RVM)[217] and the noradrenergic system of the dorsolateral pons.[218] A net inhibition of spinal nociceptive processing is initiated from the PAG through glutamate and SP inputs to these brainstem regions with major descending axonal projections. The cholinergic neuronal system that extends dendrites into the PAG is another major reticular system of the midbrain and other portions of the brainstem that

provides descending influences on nociception. The cholinergic mechanisms can reduce nociception and potentiate opiate analgesia.[219,220] These analgesic actions may be mediated through presynaptic terminations of laminae III–V cholinergic interneurons reported to synapse directly onto primary sensory endings.[221]

Raphe System

Anti-nociception because of descending modulation was proposed, based on behavioral, electrophysiologic, and morphologic studies, to occur through a PAG relay to the RVM and then to the spinal cord[222–232] (also see reviews[212,232–234]). Subsequent findings suggest that the process is mediated through more complicated brainstem circuitry (Fig. 8.9). It is now known that both inhibitory and excitatory influences on spinal cord nociceptive processing occur after activation of recurrent loops through the brainstem, activated by ascending pathways from the spinal cord. Extensive behavioral and electrophysiologic studies have found that bulbospinal facilitatory projections and, in particular, those descending from the RVM promote tactile and thermal hyperesthesias.[235–238] The RVM is responsible for the maintenance, although not the initiation, of neuropathic central[239–241] and visceral pain.[242,243] The RVM is composed of the midline raphe system and the adjacent ventral reticular formation. The raphe-spinal pathway is largely, but not entirely, serotonergic.[244–246] The component that originates from the nucleus raphe magnus (NRM) descending in the dorsolateral funiculus is primarily associated with inhibitory control, and a ventrolateral descending pathway is typically attributed with facilitatory control of nociceptive responses. Excitatory SP and inhibitory enkephalinergic connections between the NRM and the noradrenergic neurons of the dorsolateral pons are major components of the descending control system that promote both facilitatory and inhibitory influences modulating pain.[207,247] An additional supraspinal loop from the dorsal horn to the dorsal reticular nucleus and back to the dorsal horn also mediates both descending inhibition and facilitation.

Pontine Noradrenergic Neurons

Descending noradrenergic input to the spinal cord from the dorsolateral pons has been shown to limit responses to acute noxious stimulation.[211] However, elimination of the A6 locus coeruleus nucleus provides facilitation in the case of long term nociceptive activation.[248–250] The largest percentage of spinally projecting noradrenergic neurons has been identified in the locus coeruleus, subcoeruleus, and parabrachial and Kölliker-Fuse nuclei.[251–253] The noradrenergic A5 cell group in the ventrolateral pons/medulla and the adrenergic neurons of the ventrolateral medulla also send axonal projections to influence nociception in the spinal cord and thalamus.[208,253]

Anterior Pretectal Nucleus

The APN has also been associated with inhibition of nociceptive somatosensory function.[216] The anterior pretectal region evokes antinociceptive responses in the tail-flick, formalin, and paw pressure tests. However, this region has minor direct input from lamina I and X in the spinal cord, and direct innervation of the spinal cord by the APN has not been reported. Indications are that these effects are mediated through anatomic connectivity with the dorsolateral pontine pathways.

Hypothalamus

Many hypothalamic nuclei, including the LH, have descending connections to the PAG.[233,234,254] Hypothalamic axons form the largest input to the PAG.[254] The hypothalamic input to the PAG is topographic, linking particular hypothalamic nuclei with particular regions of the PAG.

Inhibition and Facilitation

While there are direct descending axons to the spinal cord, the PAG connections with the locus coeruleus and the raphe magnus are major sources of input driving descending inhibition and facilitation known to impact the perception of pain before and after the transition to chronic pain.[218–230,255,256]

Limbic Cortex

Several forebrain areas with descending projections impact nociception, including the central nucleus of the amygdala, the SI somatosensory cortex, and many parts of the limbic cortex.[178] Limbic regions include the anterior cingulate gyrus, the infra- and prelimbic cortex medially, the precentral medial cortex, and laterally the anterior and posterior insular cortex and perirhinal cortex.

The simplified schema of the supraspinal circuitry of the descending control systems imposing facilitative and inhibitory modulation of nociceptive processing is shown in Fig. 8.9. "Stress-induced analgesia" is a shift in the balance favoring descending inhibitory pathway activation. Nociceptive insults, such as nerve damage or tissue inflammation, increase the tone of both modulatory events shifting the balance toward inhibition.[230–232,255,256] While increased activation of the pain systems and increased descending inhibition predominate during pain states initially, descending inhibitory systems eventually become unable to damp the increasing nociceptive activation, ensuing in facilitation and central sensitization[250]. In truth, it is the summed effect of this complex polysynaptic inhibitory and excitatory circuitry that establishes the level of perceived pain intensity. Activation of higher brain limbic sites is evident in chronic brain states.

Centers for Higher Processing of Nociception

Perception of Pain

Early electrophysiologic studies reported parallel processing of nociceptive inputs from the thalamus to the sensory (SI, II), cingulate, and insular cortex.[178] Specific discriminative input in response to noxious somatic stimulation is received in the ventral posterolateral thalamus (VPL). The ventromedial nuclei of the thalamus receive face and tooth pulp input. This classic pain circuitry is responsible for site localization, intensity coding, and perception of pain. The midline and intralaminar thalamic centrolateral (CL) and parafascicular nuclei also receive less discriminative visceral nociceptive input when the typically silent visceroreceptors become activated by excessive stretch or inflammation.[8,9,165,180,257–259] Sensory interoception can then become a primary pain condition.[8,9,257–259]

Imaging of Pathologic Pain States

Confirmation of the activation of cortical and other brain sites became available with the advent of positron emission tomography (PET) and fMRI.[260–270] The activation indicated by an increased signal in the imaging studies on somatosensory processing regions of the ventral posterolateral thalamus, SI cortex, and SII cortex is consistent with a sensory-discriminative role of these structures.

Numerous studies have indicated that greater activation of the pain circuitry coincides with higher brain circuitry and neuroplasticity and is more easily observed in the trigeminal,

parabrachial, and amygdala circuitry.[272–275] Altered function of the brainstem pain modulation circuits, which is crucial for maintaining chronic pain, is supported by increased connectivity strength between the ventrolateral PAG and locus coeruleus with higher brain regions, including the hippocampus, nucleus accumbens, and ACC.[276]

However, improved resolution of MRI has even made it possible to confirm that pain activates many regions other than the thalamus and SI and SII somatosensory cortex observable using electrophysiology, particularly in the brains of patients with chronic pathologic pain. Imaging studies have found that the MRI signal increase indicating activation in limbic brain regions is imposed by chronic pain, and maladaptive cortical loss has also been reported.[199,200,277] In patients with pathologic pain and in persistent pain animal models, neuronal activation measured in the limbic cortex has been confirmed with imaging studies in the amygdala, medial prefrontal cortex/anterior cingulate gyrus (mPFC/ACC), and hippocampus (Fig. 8.8).[200,205,231,277,278] Altered connectivity with the amygdala, medial prefrontal cortex/anterior cingulate gyrus (mPFC/ACC), and hippocampus evident with MRI is correlated with the pain level and duration in patients with chronic pain.[198,278,279] After months of suffering, the limbic system eventually produces secondary dysfunctional affective/emotional responses symptoms, including anxiety and depression, via the mPFC/ACC and altered hippocampal cognitive function, even in research models.

Default mode circuitry activation affecting cognitive function in chronic pain patients is highlighted by increased fMRI signal intensity in the prefrontal cortex and hippocampus.[281] There is decreased coactivation in the caudate nucleus and nucleus accumbens bilaterally in multiple sclerosis patients with chronic pain.[282] The ventral striatum, including the nucleus accumbens and the caudate nucleus, is connectionally associated with the limbic structures and the prefrontal cortex and is involved in motivational and emotional aspects of behavior, including reward, which is important for planning and decision making.[284,285]

Most of the limbic regions significantly activated by pain are components of the anxiety and aversion/reward circuitry.[285,286] Intense stimulation such as noxious thermal stimuli in healthy, pain-free study participants or pathologic pain in patients activates limbic brain regions, including the ACC, prefrontal cortex, amygdala, medial dorsal thalamus, and ventral tegmental area in the base of the midbrain. The ACC and the amygdala are highly involved in the interpretation of the emotional significance of the painful input, alerting, and determining the affective response to pain.[283,285,287,288] These brain regions are responsible for affective and contextual associations of pain and pain related aversion.[285–292] Activation occurring particularly in these brain areas is involved in planning the motivational and emotional response to pain and, as such, probably reflects the maladaptive physiology of chronic pain. Optogenetic stimulation studies indicate that the excitatory projection from the parabrachial nucleus to the central nucleus of the amygdala (CeA) drives negative emotions, including anxiety, depression, and aversion, in rats.[291] In contrast, activation of excitatory projections from the basolateral amygdala to CeA counteracts each of these negative emotion behaviors. The histone deacetylase SIRT1-CaMKIIaα pathway in the central amygdala is a key epigenetic mechanism guarding against the development of comorbid emotional disorders under chronic pain, but its dysfunction causes increased vulnerability to the development of chronic pain.[293]

Chronic pain causes dysfunction of the prefrontal-hippocampal circuitry, leading to working memory deficits. The hippocampus, insula, cerebellum, ACC, and frontal cortex all contribute to memory and learning of events related to painful stimuli, such as avoidance behavior based on previous pain experience.[294,295] Chronic inflammatory pain affected the patterns of the medial prefrontal cortex-mediodorsal thalamus (mPFC-MD) activity while rats performed spatial alternation working memory.[294] In rats with spared nerve injury induced neuropathic pain, this disruption was reversed by the selective optogenetic inhibition of the prelimbic area of the mPFC CaMKIIα-expressing neurons during the last portion of the delay-period, but without any significant effect on pain responses.[293] The basal ganglia (caudate, putamen, globus pallidus) and cerebellum may have a role in the learning of reflexive motor responsiveness to painful input necessary to protect the individual.[204,296] Multiple brain networks processing sensation, affect, and cognition interact to create the pain experience and pain related decision making: for example, the nucleus accumbens is important in planning and decision.[295] Patients with subacute back pain who are at risk for becoming chronic back pain patients exhibit limbic system structural alterations, including loss of low frequency fluctuations in nucleus accumbens activity during the time that patients transition to the chronic phase, affecting its connectivity with the rostral ACC.[296]

Together with the habenula, the ACC is involved in negative outcome learning and, as such, contributes to chronic pain associated anxiety.[297–300] The habenula is considered an evaluator of numerous inputs converging on it and has connections with regions with descending input.[299] An excitatory projection from the basal ganglia to the lateral habenula (LHb) described explains how LHb-projecting basal ganglia neurons have encoding properties similar to those of LHb neurons themselves and provide a link between "anti-reward" excitatory synapses and serotonin, a neuromodulator implicated in depression.[300] Patients with ACC lesions have decreased affective responses to pain.[205] Human study participants can control experimental pain sensation by reducing the neuronal activity within the ACC.[298]

A review of these many brain regions involved in pathologic pain, their neurotransmitters, anatomic structure, and connectivity circuitry is available.[303] A more detailed discussion of the clinical correlation of these topics is available in other chapters in this volume.

Reward/Aversion Circuitry

While morphine provides relief from pain through activation of the reward circuitry, dysfunction in the parallel aversion circuitry is activated in chronic pain patients. It is well known that alterations in the reward/aversion circuitry are ongoing in the development and persistence of chronic pain and chronic pain associated anxiety and depression.[286,287] The "salience network" includes the anterior insula, amygdala, ACC, and ventral striatum and is involved in the interoception of the feelings associated with reward. The salience network is said to be functionally damaged in chronic pain patients as a consequence of a barrage of repeated painful input and positively correlated with drug craving and withdrawal.[286,287]

The posterior cingulate cortex, precuneus, medial prefrontal, and inferior parietal cortices are thought of as the "default mode network" (DMN).[300] Studies suggest that DMN activation is positively correlated with drug craving and withdrawal, while substance consumption suppresses the activity of DMN.[286,287]

The increased cross-network functional connectivity between the default mode network and the salience network is proposed as a metric of functional brain abnormality in chronic pain.[304]

Neuroplasticity and Alterations in the Pain Circuitry During Chronic Pain

The process of pain "chronification" involves stress, age, genetics, environment, and immune responsivity of individuals but is based on molecular, physiologic, neuroplastic, and even anatomic alterations,[305,306] resulting in brain remodeling that includes recruitment of limbic and aversion circuitries.[200,307–309] fMRI scans of patients with chronic back pain identified altered brain circuitry in the amygdala, medial prefrontal cortex/anterior cingulate gyrus (mPFC/ACC), and hippocampus within three to 12 months that correlated with pain level and duration.[198,199] Chronic pain can cause functional reorganization of the brain as well as reduction of gray matter volume in distinct cortical regions because of central plasticity but only at chronic time points. It can recover once the pain is alleviated.[198,310,311] Chronic pain causing concurrent activation of emotional brain circuits can produce secondary dysfunctional affective/emotional symptoms such as anxiety, depression, and altered cognitive function that alter the quality of life.[199,273,280,286–288,291,310,311] The powerful extent to which the widespread brain endogenous opioid system, with its endomorphin 1 and 2 (μ-opioid) receptors potentiated by dynorphin (δ-opioid) receptors, plays a role in these dysfunctional pain related symptoms and therapy related addiction has long been under study and is discussed in subsequent chapters.[312,313]

Conclusion

This chapter has reviewed information about the pain system circuitry from peripheral nociceptors, spinal interneurons, and projection neurons that provide the nociceptive information to higher centers. The functional and content differences of nociceptive afferents are discussed. The laminar phenotypes of excitatory and inhibitory spinal interneurons forming the basis of spinal modulation are differentiated. While primary afferent depolarization, dorsal root reflexes, gate theory, neuroglia, and neurotransmitters utilized are discussed, detailed information about how the modulation actually occurs and transitions to central sensitization is still unknown. The organization of several ascending nociceptive pathways, including the well-known lateral spinothalamic, spinomesencephalic, spinoreticular, and spinocervical tracts, is described. The lesser known medial spinolimbic, spinohypothalamic, and post-synaptic dorsal column pathways are also discussed in some detail. Description of nociceptive processing in the thalamus and cerebral cortex is left to other chapters, but brainstem regions receiving ascending nociceptive information that provide descending modulation are detailed. The analgesic/facilitatory descending systems discussed that modulate and augment the neuroplastic events leading to central sensitization include the PAG, locus coeruleus, parabrachial area, NRM, reticular formation, and APN. Several components of the limbic system are described, revealed primarily in MRI and clinical studies. With overactivation, the limbic circuitry components become dysfunctional players in the pain circuitry, often permanently altering the perception of pain. Their functions and their importance in chronic pain overshadow the basic ongoing reliable functioning of the somatosensory system. While the descriptions of the pain circuitry have been accumulating over the past four decades, the current knowledge about the basic, static physiology pales compared to the advances in our knowledge potentially available in the future. The tools available to reveal the molecular, epigenetic, and genomic events occurring in the pain systems driven under the pathologic stress of chronic pain can now be determined and will add significant knowledge at an ever-increasing pace. New findings are defining fruitful lines of research that will certainly lead to improvements in therapy for pain management.

Key Points

- Nociceptive nerve endings transduce information about internal and external mechanical, thermal, and chemical stimuli that are noxious, distressing, or damaging. Sensory nerves transmit the information centrally.
- Pain is communicated from nerve endings to the spinal cord, relayed across a synapse in the spinal cord, and then transmitted to brainstem integration sites.
- Spinal cord and spinal trigeminal dorsal horn interneurons provide state dependent signal modification, either amplifying or inhibiting the pain signal prior to the relay of information to brainstem integration sites.
- Central ascending spinothalamic pathways carry discriminative pain related information coded for location, intensity, and quality of the noxious input. Axons of lamina I spinothalamic tract neurons cross the midline and ascend in the lateral spinal cord white matter on the opposite side. Spinothalamic tract neurons in deeper laminae send their axons through the ventrolateral spinal white matter on the opposite side, through the ventrolateral brainstem, to the primary integrative site for discriminatory sensory information in the ventral posterolateral (VPL) nucleus of the thalamus.
- Discriminative information about pain is relayed by neurons of the VPL thalamus primarily to the somatosensory cortex (SI, SII) with connectivity to the motor cortex to plan and execute appropriate escape responses.
- Collateral axons of the ascending spinothalamic tract directly innervate integrative brainstem sites, including the lateral medullary and pontine reticular formation, parabrachial nuclei, PAG, hypothalamus, and amygdala. Termination sites suggest that the lateral pain related pathways impact limbic activation, emotional response, and autonomic regulation along with direct connections of the spinoparabrachial and spinoamygdalar pathways.
- Along with the spinoamygdalar and spinoparabrachial pathways, other phylogenetically older axonal pathways carry visceral pain and mechanotactile information from deep tissues arising from neurons in lamina III, VII, VIII, and X in the deep dorsal horn. These axons ascend in the dorsal column to innervate the caudal dorsal column nuclei in the midline of the caudal medulla or travel in the ventral midline and lateral white matter to innervate ventral and medial brainstem sites, pontine parabrachial nuclei, PAG, hypothalamus, amygdala,

substantia innominata, nucleus basalis of Meynardt, globus pallidus, insular cortex, and the medial and intralaminar thalamus. The termination sites of these pathways suggest they impact limbic activation, fear motivated avoidance, emotional response to pain, and autonomic responses.

- Descending input to the spinal cord modulates the primary sensory information to either facilitate or inhibit the sensory signal.
- Descending pathways to the spinal cord that modulate pain include axons originating in the PAG, raphe system, pontine locus coeruleus, and medullary reticular formation. These centers are impacted by input from higher brain centers and by incoming spinal sensory transmission.
- Complex integrative connectivity among centers for higher processing of pain, including medial and lateral thalamic, cortical, limbic, and hypothalamic sites, impact the awareness and chronification of pain, motivational responses to pain, and regulation of autonomic, emotional, and motor responses to pain. PET and MRI imaging provide better information about altered pain processing in higher brain centers and the effect of pharmacologics.

Neurochemistry of Nociception

TONY L. YAKSH, GILSON GONÇALVES DOS SANTOS, LAURIANE DELAY, ELAYNE VIERA

Origins of the Pain Phenotype

For heuristic purposes, we can distinguish the three mechanistically distinct sources of a pain state: (1) high intensity stimulation, (2) local tissue injury and products released secondary to injury and inflammation, and (3) injury to the peripheral nerve. These conditions may achieve further distinction by being characterized as acute or chronic, where chronic pain is defined as persistent or recurrent pain lasting longer than three months. Exposure of the organism to these conditions will typically lead to escape from the stimulus condition, emphasizing a hallmark of pain, which is that the stimulus condition is aversive and fraught with negative re-enforcing properties. This endows a painful state with two properties: (1) it supports avoidance behavior and (2) it can provide negative connotations to otherwise innocuous stimuli with which it is paired.

Acute Nociception

In the early 1900s, Sir Charles Sherrington designated high intensity stimuli that signaled a potential injury to the body as being *nociceptive* in character. The application of such stimuli to the body produces a syndrome that includes the withdrawal of the affected body part, signs of autonomic activation, and a complex set of behavioral responses that in intact animals include agitation and vocalization. In humans, an unconditioned high intensity stimulus evokes discrete sensations that have the assigned attribute of being *painful* (e.g. the sensation initiated by picking up a very hot cup of coffee). The reported sensation refers to the site of stimulation, and the magnitude of the report or response varies with the intensity of the stimulus. Termination of the stimulus before injury results in the cessation of sensation. Accordingly, *nociception* is a descriptor that refers to the physiologic response generated by high intensity, potentially tissue-injuring stimuli, whereas *pain* represents the interpretation of that event as a sensation with highly aversive properties. Such stimuli have powerful motivating effects that can support the generation of escape behavior when cued by innocuous stimuli that have previously been paired with a nociceptive stimulus. Thus a strong shock evokes a nociceptive state from which the animal will seek to escape. A light paired with that shock will become conditionally associated with the shock, such that in a short time, the light alone can initiate the same profile of nociception.

Tissue Injury and Inflammation

Suppose the stimulus is of sufficient magnitude to result in local injury (tissue disruption, plasma extravasation). In that case, a pain sensation will persist after removal of the stimulus, and the injury will be accompanied by increased sensitivity to subsequent stimuli applied to the injury site (primary hyperalgesia) and enhanced sensitivity to stimuli applied at sites adjacent to the injury site (e.g. secondary hyperalgesia or allodynia). Again, these states of enhanced sensation indicate that the non-tissue-injuring stimulus now acquires an aversive property (e.g. warm water on a sunburn). As will be considered below, the injury yields the release of chemical products that can, through eponymous receptors, directly increase activity in afferent systems that are typically activated by high intensity, nociceptive stimuli.

As an overview, the effects of a high intensity, tissue-injuring stimulus reflect an initial activation of the primary afferents that project to the dorsal horn of the spinal cord, from which transmitters are released that activate a complex dorsal horn circuitry. Under normal circumstances, these spinal neurons respond maximally to input arising from the root projecting to the spinal segments in which the cell lies. However, even though these afferents primarily activate these homosegmental neurons, they also send collaterals rostrally and caudally up to several spinal segments away, where they make synaptic contact with neurons in adjacent segments (heterosegmental). These distal neurons are less efficiently activated than the homosegmental cells (and may not be activated sufficiently to generate an action potential). However, these homosegmental and heterosegmental cells form the real or potential dimension of the dermatome of the spinal segment. As will be shown later, if the *excitability* of these higher-order spinal heterosegmental neurons is increased, cells that were not activated by a given input become depolarized, and the size of the dermatome of a given segment will be increased. These dorsal horn neurons then project by long tracts in the ventrolateral quadrant either (1) directly to diencephalic sites (e.g. thalamus, hypothalamus) or (2) indirectly through an intermediate synapse on neurons in the medulla, pons, or mesencephalon, which then project to a variety of diencephalic and limbic forebrain sites. The anatomic details of these pathways have been discussed previously (see Chapter 8).

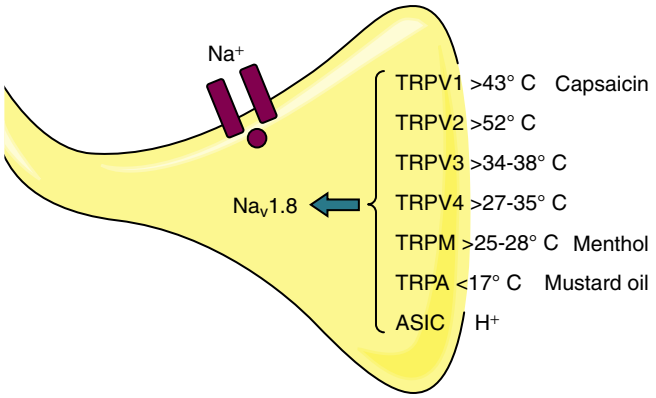
In general, the processes leading to a pain state secondary to a high intensity peripheral stimulus reflect the frequency of traffic that appears in these spinofugal pathways. Activity in the spinofugal systems is primarily dependent on the intensity of the afferent

stimulus, but as will be made evident, a variety of systems serve to increase the gain of the spinal input-output function and depress this gain. In the first case, we anticipated that there would be an increased pain sensation associated with any given stimulus, whereas in the second case, the pain sensation produced by a given stimulus would be diminished. This dynamic property of the input-output systems represents an important characteristic of systems that process nociceptive stimuli. In the following sections, we consider the transmitter pharmacology that defines these synaptic linkages.

Nerve Injury

Peripheral nerve injury may arise secondary to a variety of conditions, including physical injury (section, compression), changes in trophic functionality (ischemia, metabolic poisons), or immune interactions (as with autoantibodies). The functional phenotype of these changes is often an ongoing pain state, referring to the distribution of the injured nerve and an enhanced response to low-intensity mechanical or cold stimuli.

In the following sections, we provide an overview of the mechanisms underlying these pain states.



• **Figure 9.1** Transducer channels on a small afferent terminal. Optimal stimulus intensities for activating channels and various chemicals that also activate these channels are indicated. Different terminals express different combinations of channels, which would define the response properties of that afferent. Channel activation leads to the activation of voltage-sensitive sodium (Na_v) channels. The $Na_v1.8$ subtype of channels is frequently present only in unmyelinated axons (C-fibers).*ASIC*, Acid-sensing ion channel; *TRP*, transient receptor potential.

Primary Afferent Signaling

Acute Stimulation

The systems underlying this acute psychophysical experience begin with the primary sensory neuron, the afferent fiber. The afferents possess several intrinsic attributes.

1. In the absence of a stimulus, most primary afferents show little or no ongoing activity.
2. Activity in these afferents is initiated by various mechanical, thermal, or chemical stimuli, which activate specific populations of primary afferents.
3. The nature of the sensory information encoded by a given primary afferent is dependent on the properties of the transduction channels or receptors that are expressed on the terminals of that sensory axon.
4. The frequency of firing in these afferents generated by a particular stimulus varies monotonically with the intensity of the stimulus (e.g. temperature for a thermal-sensitive afferent). Thus the specific population of primary afferents is activated, and the frequency of discharge encode the intensity of the stimulus.
5. Sensory afferents are morphologically categorized by diameter, state of myelination, conduction velocity, and stimulus properties that lead to their activation.

Aβ axons. These are large, myelinated, fast-conducting axons and exhibit specialized transducer elements (such as the Pacinian corpuscle). These afferents are typically activated by low-intensity mechanical stimuli.

Aδ axons. These are smaller, myelinated, fast-conducting afferents with subpopulations that preferentially respond to thermal or mechanical stimuli that may be preferentially activated by low-intensity or high intensity stimuli. Those responding only to high intensity thermal or mechanical stimuli are referred to as Aϑ nociceptors. As larger myelinated axons, these Aϑ often display specialized nerve endings.

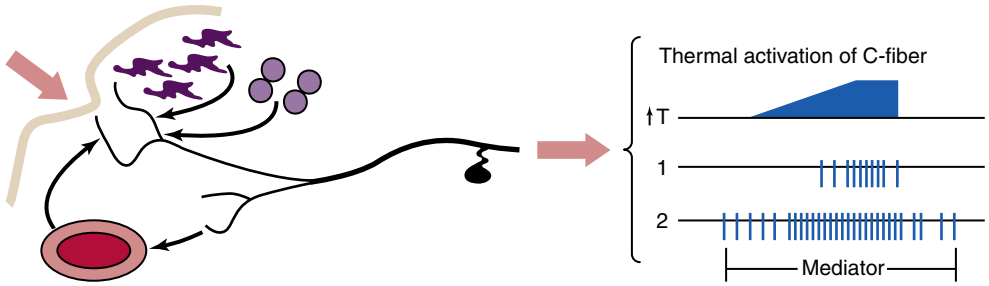
C axon. These are small, unmyelinated, very slowly conducting afferents that are activated by high intensity thermal, mechanical, or chemical stimuli. As a given C-fiber may be activated by high thermal, mechanical, and chemical stimuli, they are called *polymodal nociceptors*. In contrast to myelinated afferents, unmyelinated afferent axons typically show "free nerve endings." That is, they display no evident morphologic specialization. However, these terminals express a myriad of specific transducer channels that are sensitive to specific physical and chemical stimuli and increasingly depolarize the afferent terminal as the stimulus intensity increases. When activated by an appropriate stimulus, these channels in turn activate voltage-sensitive sodium channels that pass Na^+ and initiate action potentials. As indicated in Figure 9.1, some of these channels that transduce a physical stimulus may also be activated by various chemicals. In this case, these chemicals produce a sensation that reflects the physical stimulus that is transduced by that channel (e.g. the transient receptor potential vanilloid-1 [TRPV1] receptor is activated by capsaicin, which produces a painful burning sensation, whereas menthol activates the TRPM8 cold receptor and initiates the sensation that would be generated by low temperature).

During development, the soma of the afferent neuron starts as a bipolar neuron. However, during development, the soma buds off from the axon, remaining attached by a long sinuous glomerulus. The primary afferent axons in the periphery typically display arborization in the target tissue. Importantly, action potentials traveling from the periphery continue to the spinal dorsal horn but also travel up the glomerulus to the dorsal root ganglion cell body. Thus the dorsal root ganglion (DRG) displays depolarization. As action potential can travel down the glomerulus, the DRG can be a source of action potential generation, as can occur when an avulsed disc fragment is compressed in the DRG in the vertebral foramen.

Tissue-Injuring Stimuli

High intensity stimuli may result in local tissue injury. Such injury leads to cellular disruption, injury to local vascular integrity, and subsequent plasma extravasation, and migration of inflammatory cells such as macrophages and neutrophils. These events give rise to the release of various *active factors* from injured cells and the migration of inflammatory cells such as mast cells, macrophages, lymphocytes, and neutrophils (Box 9.1). The contents of this local milieu of an injury, often referred to as the *inflammatory soup,* acts upon eponymous receptors that are present on the terminals of many unmyelinated axons. Activation of these receptors typically

• BOX 9.1 Agents Released by Tissue Injury That Depolarize and Sensitize Small Primary Afferent Terminals



The mediators listed below are released by injury from macrophages, mast cells, and blood vessels. These mediators evoke spontaneous activity in otherwise silent C-fibers and lower the threshold for activation in response to a ramped thermal stimulus (right: one vs.).

1. **Amines.** Histamine (mast cells, basophils, and platelets) and serotonin (mast cells and platelets) are released by various stimuli, including mechanical trauma, heat, radiation, and certain products of tissue damage.
2. **Kinin.** Bradykinin is synthesized by a cascade triggered by the activation of factor XII by agents such as kallikrein and trypsin and physical trauma. It acts through specific bradykinin receptors (B1/B2).
3. **Lipidic acids.** Tissue injury activates a variety of widely distributed phospholipases that are free of AA. AA is a substrate for a large family of enzymes, such as cyclooxygenase, to synthesize lipid mediators, including prostaglandin E_2, prostacyclin, and thromboxane A_2, all of which can facilitate the excitability of C-fibers through specific membrane receptors (EP-r, IPR, and Tx-R, respectively).
4. **Cytokines.** Cytokines such as tumor necrosis factor-α and interleukin such as IL-1β are released by inflammatory cells (macrophages) and sensitize C-fibers through eponymous binding sites.
5. **Proteinases.** Thrombin or trypsin is released from inflammatory cells and activates specific receptors (proteinase-activated receptors).
6. **Neurotrophic factors.** Nerve growth factor (NGF) activates primary afferent terminals by binding to TrkA tyrosine kinase. NGF is released from fibroblasts and mast cells via injury and inflammation.
7. [H]/[K], Elevated H^+ (low pH), and high K^+ levels are found in the injured tissue. A variety of channels present on C-fibers (e.g. transient receptor potential vanilloid-1 [TRPV1]/acid-sensing ion channels [ASICs]) are activated by H^+. Acid pH potentiates terminal activation by noxious heat and other chemical mediators.
8. **Primary afferent peptides.** CGRP and substance P are found in and released from the peripheral terminals of C-fibers. These peptides produce vasodilation, plasma extravasation, and degranulation of mast cells through their respective receptors. This leads to local reddening and swelling of the skin innervated by the stimulated sensory nerve.

initiates two events: (1) an increase in intracellular calcium leading to depolarization of the terminal, leading to the discharge of the afferent, with the frequency of activation being dependent on factor concentration, and (2) activation of intra-terminal processes (phosphorylation of local membrane receptors and channels), which sensitizes the terminal such that the degree of depolarization for a given stimulus is enhanced. Such effects yield "spontaneous afferent activity," and an enhanced response to a subsequent stimulus applied to the site of injury.

The changes in the milieu of the peripheral terminal secondary to tissue damage and the accompanying extravasation of plasma occur because of increased permeability of the capillary wall (see Box 9.1). These events are responsible for the "triple response": reddening at the site of the stimulus (reflecting local arterial dilation), local edema (increased capillary permeability), and a regional reduction in the magnitude of the stimulus required to elicit a pain response (i.e. hyperalgesia).

Nerve Injury as a Stimulus

Following nerve injury arising from various insults, the organism will frequently display the development of a variety of highly aversive "spontaneous" sensations over time. This aversive component arises from aberrant ongoing afferent traffic. Sensory axons typically display little spontaneous activity in the absence of a stimulus. This is particularly true for small, high threshold afferents. However, after a chemical, immune, or mechanical injury to the nerve, afferent axons exhibit (1) an initial burst of afferent firing, (2) electrical silence for an interval of hours to days, and (3) the appearance over hours to days of "spontaneous" bursting activity in both myelinated and unmyelinated axons. This aberrant traffic may arise from several sources. This ongoing activity reflects the initial dying back of the injured axon (retrograde chromatolysis) and the initiation of sprouting. Collections of these sprouts form neuromas. Recording from the afferent axon indicates that the ongoing activity originates after an interval of days to weeks from the lesioned site (neuroma) and from the DRG of the injured nerve.

Several lines of evidence support the assertion that the ectopic activity in the afferent arising from the neuroma or the DRG of the injured axon is in part responsible for the observed pain behavior: (1) the onset of ectopic activity in the neuroma or DRG and the onset of pain behavior have parallel time courses, (2) pain behavior can be blocked by the application of tetrodotoxin (TTX) or local anesthetic to the neuroma or DRG, (3) dorsal rhizotomy transiently reverses the pain behavior, and (4) irritants applied to the DRG will initiate activity and yield pain behavior. Several changes can lead to prominent alterations in ongoing afferent activity.

Altered Channel Expression

A variety of channels in the sensory afferents can modulate excitability. Two major classes are the sodium channel, which carries the primary current for axonal depolarization, and several potassium channels. The activation of these potassium channels can reduce axon excitability. Upregulation of sodium channels or downregulation of potassium channels would have a net effect of increasing axon excitability.

Sodium Channels

A large increase in the expression of sodium channels in the neuromas and DRGs occurs after nerve injury. Several sodium channel variants exist in primary afferent neurons, including subtypes designated as $Na_v1.6$, $Na_v1.7$, $Na_v1.8$, and $Na_v1.9$. Those designated as resistant to the sodium channel blocker TTX, $Na_v1.8$ and $Na_v1.9$, are found primarily in small DRG cells (C-fibers). These channels mediate slow activation and slow inactivation of sodium currents. The importance of some of these variants in nerve injury pain states is suggested by "knock-down" studies wherein reduction of, for example, $Na_v1.8$ has no effect on baseline pain thresholds but reverses nerve injury evoked pain states in animal models. In humans and animal models, systemic lidocaine at plasma concentrations that block ectopic activity can attenuate the hyperpathic state observed after nerve injury, thus confirming the importance of sodium channels in the post–nerve injury pain state. In humans, mutations in one sodium channel ($Na_v1.7$) can cause *extremely painful conditions*. Conversely, loss-of-function mutations lead to *prominent insensitivity* to pain generated by tissue-injuring stimuli. Conversely, other mutations can result in a "gain of function," which Additionally correlates with syndromes such as erythromelalgia, characterized by severe episodic pain.

Potassium Channels

Following nerve injury, potassium currents (e.g. K2P, TWIK-related K^+ channels) have been shown to be reduced, thus suggesting downregulation of these channels. Potassium channel blockers increase ectopic firing after peripheral nerve injury.

Changes in the Chemical Sensitivity of Neuromas and Dorsal Root Ganglia

Sprouted terminals of an injured axon display sensitivity to several humoral factors, including prostanoids, catecholamines, and chemokines or cytokines such as tumor necrosis factor (TNF). Several examples of how this sensitivity is related to the appearance of ongoing activities are noted.

Cytokines/Chemokines

After nerve injury, the release of various cytokines, including TNF, interleukins (IL), interferons (IFN), colony-stimulating factors, transforming growth factors, and *chemo*attractant cytokines, also called chemokines, have been noted in various local inflammatory cells. These cytokines directly activate the nerve and neuroma through eponymous receptors expressed in the membrane after nerve injury. For example, the mechanisms of TNF interactions are multiple and complicated. TNF decreases potassium conductance in neurons, whereas long-term effects may be initiated through activation of a variety of kinases (mitogen-activated protein kinases [MAPKs]). Behaviorally, the application of TNF to the nerve results in hyperalgesia, and systemic delivery of TNF-binding protein reduces free TNF and decreases pain behavior in animals with neuropathic pain.

Catecholamines

Following nerve injury, post-ganglionic *sympathetic efferents* (cell bodies in the sympathetic ganglion) and sympathetic afferents (afferents that travel with the sympathetics but the cell body for which is located in the DRG) sprouts into the peripheral injury site and the DRG of the injured axons. In response to the release of nerve growth factors from local Schwann and inflammatory cells, these post-ganglionic terminals locally release catecholamines. Physiologic studies have shown that following nerve injury, stimulation of post-ganglionic axons will excite the injured axon and the DRG of the injured axon and that such activation is blocked by α-adrenergic antagonism. After nerve injury, upregulation of sympathetic fibers and α_1-adrenergic receptors in the DRG and skin has been demonstrated. Accordingly, increased catecholamine concentrations in the vicinity of the DRG or injured neuroma can translate into enhanced activity.

Dorsal Root Ganglion

Neuronal soma, post-ganglionic sympathetic axons, satellite glial cells, macrophages, and blood vessels in the DRG are densely packed into this small niche environment. In addition to neuronal somata (small, medium, and large fibers), macrophages and satellite glial cells have been shown to play a key role in pain processing. Macrophages produce a variety of chemokines and cytokines (e.g. IL-6) that can trigger neuronal sensitization. Satellite glial cells have been shown to enhance afferent signals by increasing interneuronal communication through *gap junctions*, and satellite glial cells are involved in IL-1B and prostanoid production.

Prostaglandin Receptors

Prostanoids are released by inflammatory cells secondary to tissue injury. Activation of prostanoid receptors leads to sensitization of the primary afferent nociceptors by phosphorylation of ion channels such as TRPA1 and TRPV1. Moreover, they can enhance the opening of TTX-insensitive sodium channels by acting through eponymous receptors on the afferent terminal. TTX-insensitive channels are typically found on small unmyelinated axons, which emphasizes the association of these observations with axons carrying information having "nociceptive" content.

First-order Synapse

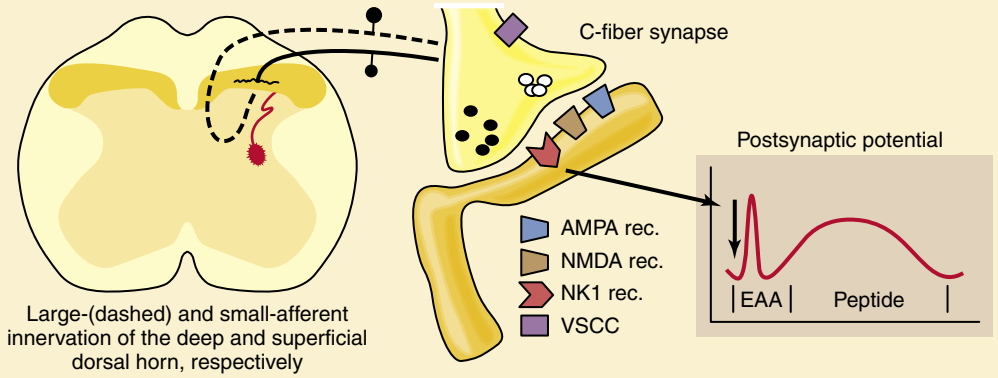
Primary afferents enter the spinal dorsal horn. Large afferents (Aβ) terminate deep to the Rexed lamina III of the dorsal horn. Aδ afferent fibers terminate superficially and in deeper laminae, whereas C-fibers generally terminate superficially in laminae I and II (marginal layer and substantia gelatinosa).

Primary Afferent Transmitters

It has classically been appreciated that primary afferent input results in a postsynaptic excitatory event, thus emphasizing that primary afferent transmitters are uniformly excitatory. In general, it appears that the principal primary afferent neurotransmitter evoking acute excitation is glutamate. It is present in the synaptic vesicles of most spinal afferent terminals, and its synthetic enzymes have been identified in virtually every primary afferent DRG cell body, regardless of the size or state of myelination. These acute effects are mediated by α-amino-3-hydroxy-5-methyl-4-isoxazolepropionate (AMPA)-type glutamate ionophores present on second-order neurons. This receptor produces a robust but short-lasting depolarization of the postsynaptic membrane by increasing sodium conductance (Table 9.1).

In addition to glutamate, populations of primary afferents may contain and release several neuropeptides, notably substance P (SP) and calcitonin gene-related peptide (CGRP), as well as certain growth factors such as brain-derived neurotrophic

TABLE 9.1 Summary of Primary Afferent Transmitter Organization



Primary Afferent Transmitter	Receptor	Postsynaptic Action
	Peptides	
Substance P **CGRP**	**Neurokinin 1 (NK1)** **CGRP1**	**G Protein Coupled; Slow, Long-lasting Depolarization**

factor (BDNF). Given the complexity of coding, it is likely that a variety of transmitters processes nociceptive information. The transmitters in these small high threshold afferents display several general properties.

1. Consistent with their location in small afferent terminals, high levels of peptides are present in laminae I and II, and these levels are reduced by rhizotomy or ganglionectomy or by treatment with the small afferent neurotoxin capsaicin. The sensitivity of these afferents to capsaicin indicates that one important characteristic of many (but not all C-fibers) is the expression of the TRPV1 (capsaicin) receptor. A second population of C-fibers that do not express TRPV1 typically expresses a second marker (isolectin B4 [IB4]). These IB4-positive afferents characteristically project to the deeper layers of the dorsal horn and do not express neuropeptides.
2. Glutamate and many peptides are co-contained and co-released (e.g. glutamate, SP, and CGRP in the same C-fiber terminal).
3. Release is dependent on the opening of voltage-sensitive calcium channels, and the magnitude of release is proportional to the stimulus frequency.
4. Iontophoretic application of glutamate and the peptides found in primary afferents onto the dorsal horn will produce postsynaptic excitation. Amino acids produce a rapid, short-lasting depolarization, whereas peptides produce a delayed and long-lasting discharge (see Table 9.1).

Regulation of Dorsal Horn Excitability

As noted in the introduction, the intensity of the painful stimulus is encoded in the projection to higher centers by the frequency of the output function. Accordingly, factors that enhance the excitability of spinal afferent terminals (leading to increased release of the transmitter) or the excitability of the dorsal horn projection neuron will increase the apparent magnitude of a given stimulus. In contrast, factors that diminish the excitability of the primary afferent or the projection neuron will lead to a reduction in the apparent stimulus intensity. In the following section, we will consider substrates that enhance and diminish the response of the dorsal horn to a given stimulus.

Facilitation of Dorsal Horn Excitability

Persistent small (C-fiber), but not large (A-fiber) afferent activation of lamina I (marginal cell) and lamina V (wide dynamic range [WDR]), as occurs with tissue injury and inflammation, has been shown to (1) enhance the response to subsequent dorsal horn input and (2) increase the receptive field of the activated neurons. Thus, the conditioning afferent input increases the receptive field

size of the neurons such that afferent input from dermatomal areas that previously did not activate the given neuron evokes a prominent response. Moreover, low threshold tactile stimulation has also become increasingly effective in driving these neurons. This phenomenon, first described by Lorne Mendell and Patrick Wall in the mid-1960s, is broadly referred to as "wind-up" These physiologic effects reflect events that are referred to as *central* or, more specifically, *spinal sensitization* and are believed to underlie the psychophysical correlates of tissue injury, wherein tissue injury leads to hyperalgesia and secondary hyperpathia (e.g. increased sensitivity to stimuli applied outside the area of injury). The relevance of this small afferent evoked facilitation in humans has been emphasized in psychophysical studies in humans. Here, local activation of C-fibers by the intradermal injection of capsaicin leads to an initial pain report followed by a surrounding region that shows enhanced mechanical and thermal sensitivity for an extended period. This effect is blocked by a transient local anesthetic block of the nerves innervating the capsaicin-injected area. These observations emphasize that ongoing small afferent inputs can initiate the central sensitization of pain processing.

Based on the above commentary, a decrease in C-fiber evoked excitation in the dorsal horn produced by a reduction in the release of a small afferent transmitter or block of the postsynaptic receptor (e.g. AMPA for glutamate) will diminish the magnitude of the afferent drive and, accordingly, diminish the facilitated processing evoked by protracted small afferent input. However, the facilitated state reflects more than the repetitive activation of a simple excitatory system.

Glutamate Receptors and Spinal Facilitation

The first real demonstration of the unique pharmacology of the facilitated state was achieved by showing that spinal wind-up was prevented by the spinal delivery of antagonists of the *N*-methyl-D-aspartate (NMDA) receptor, a glutamate ionophore composed of several subunits that are potently excitatory. When activated, it passes a large amount of Ca^{2+} and Na^{+} currents. It is important to note that NMDA antagonists do not affect acute evoked activity but reduce the wind-up induced by repetitive C-fiber stimulation. Correspondingly, behavioral studies have revealed that such drugs have no effect on behavior evoked by acute noxious stimuli (e.g. acute thermal escape) but do reduce the hyperalgesia observed after tissue injury and inflammation.

The absence of an effect of NMDA antagonism on acute afferent evoked activation, or the pain state reflects an important property of this receptor. At the resting membrane potential, the NMDA receptor displays a blocking of the channel by Mg^{2+}. Occupancy of the NMDA receptor by glutamate does not activate ionophores in the presence of Mg^{2+}. With ongoing depolarization of the membrane (as produced during repetitive stimulation) secondary to the activation of AMPA and SP receptors, the Mg^{2+} block is removed. If several allosteric binding sites on the NMDA ionophore are occupied (glycine/polyamine sites), glutamate may activate the NMDA channel and permit the passage of Ca^{2+} and Na^{+} currents. This opening thus serves to further depolarize the membrane and, importantly, increase intracellular Ca2+, which initiates downstream components of the excitatory and facilitatory cascade (see below).

It has become increasingly apparent that although AMPA mediates acute depolarization, reflecting an increase in Na^{+} influx in the presence of repetitive stimulation, Ca^{2+} permeability develops in the AMPA channels (e.g. calcium-permeable AMPA channels with a distinct antagonist pharmacology). Importantly, nerve injury increases the prevalence of calcium-permeable AMPA channels in spinal dorsal horn neurons.

Downstream Cascades

Primary afferent C-fibers release peptides (e.g. SP and CGRP), purines (adenosine triphosphate [ATP]), and excitatory amino acid (glutamate) products. These peptides and excitatory amino acids induce excitation in the second-order neurons. As noted for glutamate, direct monosynaptic excitation is mediated by AMPA receptors (i.e. acute primary afferent excitation of WDR neurons is not mediated by NMDA or neurokinin 1 [NK1] receptors). This initial activation leads to the enablement of the NMDA ionophore (and the generation of Ca^{2+}-permeable AMPA channels), which in turn initiates several complex cascades that reflect processes that serve to "sensitize" the postsynaptic dorsal horn neurons. Several primary examples of such facilitatory cascades initiated by repetitive small afferent inputs are presented below.

Local Neuronal Circuits

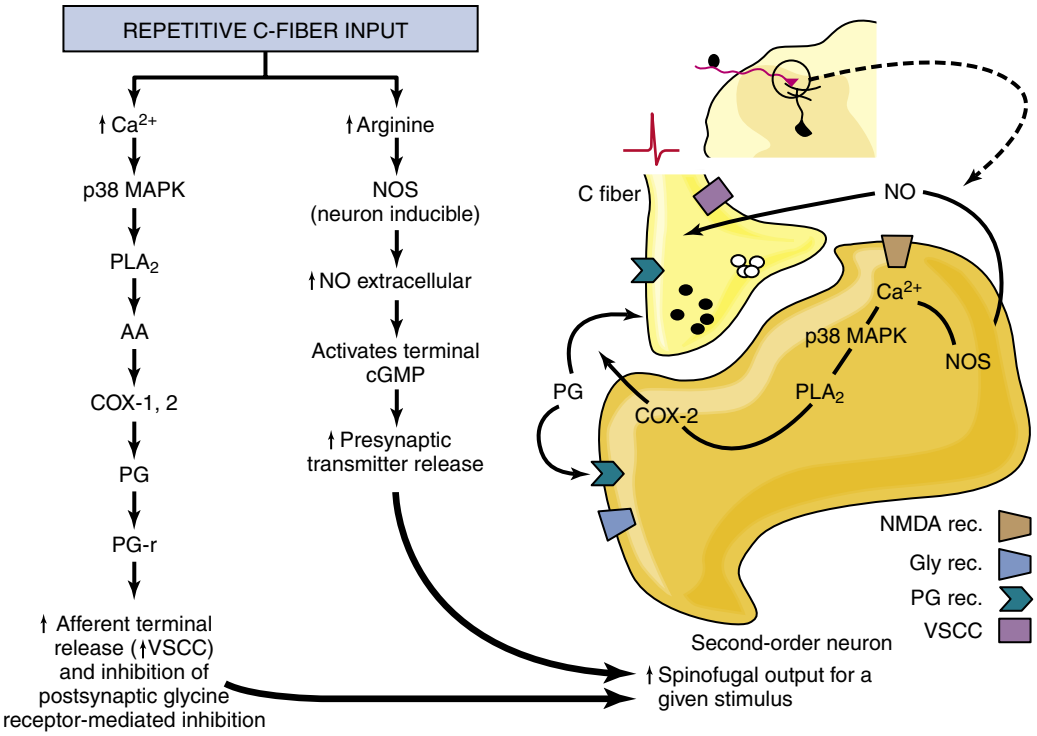
NMDA Receptors. The best example of a cascade initiated by a small afferent input is the activation of the NMDA receptor. As noted above, with ongoing membrane depolarization, the NMDA ionophore loses its Mg^{2+} block, which allows a large increase in intracellular Ca^{2+}.

AMPA Receptors. Although the AMPA receptor is largely considered an acutely activated ionophore that allows the primary passage of sodium, structural variants on the AMPA receptor allow it to pass calcium. This Ca^{2+} permeability is determined by the absence of a specific AMPA receptor subunit, GluA2. GluA2-lacking AMPA receptors are believed to participate along with the NMDA receptor in various aspects of spinal facilitation.

Neurokinin 1 Receptors. NK1 receptors are G protein coupled receptors that are activated by SP released from small primary afferents. Activation of this receptor leads to prolonged depolarization and mobilization of intracellular calcium. Spinal delivery of agents that block the NK1 site for SP can diminish the wind-up and significantly reduce the second-phase response to intradermal formalin injection.

Prostaglandin Cascade. The increase in intracellular calcium promotes the transmigration of various phospholipases to the membrane, where they then serve to cleave arachidonic acid. Arachidonic acid serves as a substrate for cyclooxygenase (COX) to produce several prostanoids. All these enzymes have been found to be constitutively expressed in spinal neurons and non-neuronal cells. This cascade leads to the release of several prostaglandins that act on a number of eponymous receptors that are presynaptically located on the primary afferent terminal and *postsynaptically* on second-order neurons. The presynaptic effect has been shown to enhance the opening of voltage-sensitive calcium channels, which mediate vesicular mobilization and release of the transmitter. A postsynaptic action that attenuates the activation of *inhibitory* glycine receptors has been demonstrated. This leads to a loss of regulatory inhibition that otherwise limits postsynaptic activation. This results in an enhanced response of the second-order (projection) neuron to a given afferent input (Fig. 9.2).

Nitric Oxide Synthase. Small afferent inputs also lead to the activation of nitric oxide synthase (NOS). Neuronal NOS and inducible NOS are both present in neurons and other cells. In the presence of arginine, nitric oxide forms and diffuses to act presynaptically (retrograde transmission) through cyclic guanosine monophosphate to enhance the release of transmitters



• **Figure 9.2** Small afferent input activates second-order neurons, leading to increased intracellular calcium, which initiates several intracellular cascades. (1) Activation of phospholipase A_2 (PLA_2) increases free arachidonic acid (AA). This serves as a substrate for cyclooxygenase (COX-1 and COX-2), which leads to the release of a number of prostaglandins (PG) that act on a variety of eponymous prostanoid receptors that are located presynaptically on the primary afferent terminal and postsynaptically on the higher-order neurons. See text for further comment. (2) Activation of nitric oxide synthase (NOS) in the presence of arginine leads to the release of nitric oxide (NO), which diffuses to enhance the release of a transmitter (e.g. glutamate). These events can serve to increase terminal release and increase postsynaptic excitability. *cGMP*, Cyclic guanine monophosphate; *Gly*, glycine; *NMDA*, *N*-methyl-D-aspartate; *p38 MAPK*, p38 mitogen-activated protein kinase; *rec.*, receptor; *VSCC*, voltage-sensitive calcium channel.

(e.g. glutamate). These events can serve to increase the terminal release and postsynaptic excitation (Fig. 9.2).

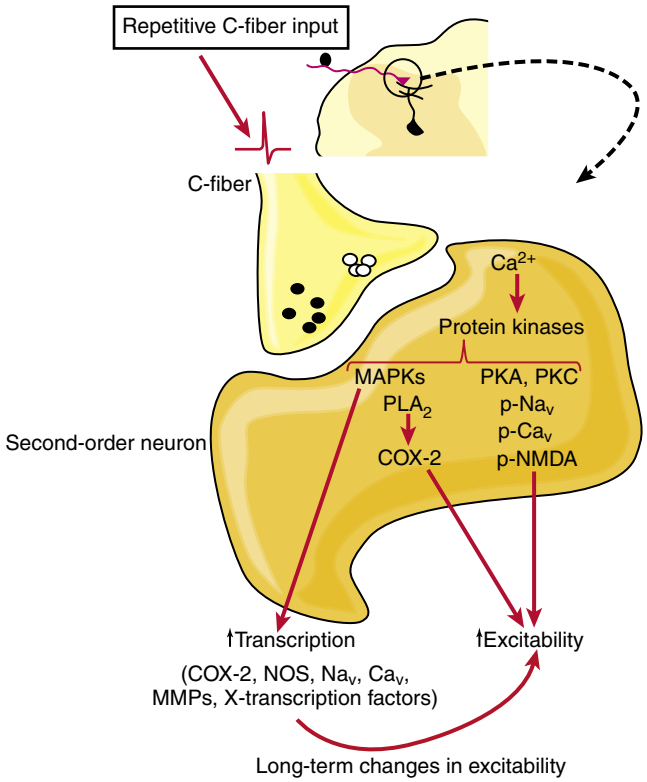
Phosphorylation. As noted, small afferent input serves to increase intracellular Ca^{2+} in second-order neurons. This leads to the activation of several protein kinases, such as protein kinase C (PKC), protein kinase A, and mitogen-activated protein kinase (MAPK) (Fig. 9.3). There are many isoforms of these kinases. All serve to phosphorylate consensus sites on various proteins. PKC has been shown to phosphorylate amino acid sites on the NMDA and AMPA receptors. This phosphorylation tends to lower the threshold for activation, which leads to greater membrane permeability. The NMDA ionophore serves to lower the threshold for removal of the Mg^{2+} block, which otherwise prevents channel activation. p38 MAPK, when activated, phosphorylates phospholipase A_2, thereby leading to its activation (see Fig. 9.2), which activates various transcription factors, such as the nuclear factor NF-κB, which serves to increase the synthesis of various proteins, such as COX, and a variety of channels (Na_v, Ca_v), receptors (TRPV1), and transcription factors (activation transcription factor 3 [ATF-3]).

Bulbospinal Pathways. Of particular interest is the growing appreciation that small afferent inputs can initiate facilitated activation through spinobulbospinal linkages (Fig. 9.4). Thus it has been shown that C-fibers make synaptic contact with superficial dorsal horn neurons (lamina I neurons). These neurons project into the brainstem and make synaptic contact with the medullary midline raphe spinal neurons that are serotonergic. These cells, in turn, project into the spinal dorsal horn and make synaptic contact with several neuronal populations but, importantly, those with cell bodies in the deep dorsal horn (lamina V). The serotonergic projections act through excitatory 5-HT_3 receptors to enhance the firing of these lamina V neurons. As stated, these cells are noted for their ability to display a facilitated state called "wind-up." Blocks of this bulbospinal linkage or the use of 5-HT_3 inhibitors have been reported to reduce this facilitated state.

Non-neuronal Cells

The central nervous system contains a wide variety of non-neuronal cells. Astrocytes and microglia are among these proteins. These astrocytes, microglia, and neurons form a complex network in which each can influence the excitability of others (Fig. 9.5).

Transmitter Mediators of Non-neuronal Cell Activation. Primary afferents and intrinsic neuron transmitters (glutamate, ATP, and SP) can overflow from the synaptic cleft to these adjacent non-neuronal cells, leading to their activation. Activation of neurons can result in the release of chemokines such as fractalkine. Astrocytes may communicate with microglia by releasing several products, including glutamate/cytokines and "S-100" protein. These products have eponymous receptors, which can lead to changes in the biology of astrocytes and microglia, resulting in the extracellular movement of a variety of neuroactive products, such as free radicals, cytokines (such as interleukin-1β [IL-1β] and TNF), BDNF, and a host of lipid mediators, including arachidonic acid, platelet-activating factor, prostaglandins, and leukotrienes. Notably, many glial cytokines, chemokines, and growth factors can modulate synaptic activity at nM concentrations,



• **Figure 9.3** Small afferent input serves to increase intracellular calcium in second-order neurons, which activates several protein kinases such as PKC and PKA or MAPKs, which serve to phosphorylate various proteins. Specifically, in this schema, PKC and the NMDA and AMPA receptors are phosphorylated, which leads to lower activation thresholds. When activated, p38 MAPK phosphorylates PLA_2, which results in its activation (Fig. 9.2) and serves to activate various transcription factors (e.g. nuclear factor κB) that increase the synthesis of various proteins (e.g. COX) and a variety of channels (Na_v, Ca_v), receptors (transient receptor potential vanilloid 1 [TRPV1]), and transcription factors (activation transcription factor 3 [ATF-3]). *AMPA*, DL-α-amino-3-hydroxyl-5-methyl-4-isoxazole propionic acid; *COX*, cyclooxygenase; *MMP*, matrix metalloproteinase; *NMDA*, *N*-methyl-D-aspartate; *NOS*, nitric oxide synthase; *PLA_2*, phospholipase A_2; *rec.*, receptor; *VSCC*, voltage-sensitive calcium channel.

while μM concentrations of neurotransmitters such as glutamate, gamma-aminobutyric acid (GABA), and glycine are necessary to produce synaptic effects. Astrocytes have the well-known ability to regulate extracellular glutamate through an active uptake system. Conversely, these intracellular glutamate stores can be released during certain activation or stress, resulting in significant increases in extracellular glutamate concentration.

Gap Junctions. Astrocytes may communicate over a distance by the spread of excitation through local non-synaptic contacts, referred to as "gap" junctions. These junctions represent specialized proteins (hexagonal multimers made up of connexin macromolecules) that serve to link the adjacent membranes of two cells. Through such linkages, local excitation in one astrocyte can lead to increased Ca^{2+} reversal of a glutamate transporter and increased extracellular ATP, which can depolarize local neuronal processes and produce local cerebrovascular constriction. Although classically limited to astrocytes, it is currently evident that such linkages may also occur between astrocytes, neurons, and microglia. Thus the gap junction represents a mechanism whereby a syncytium of excitability can be created.

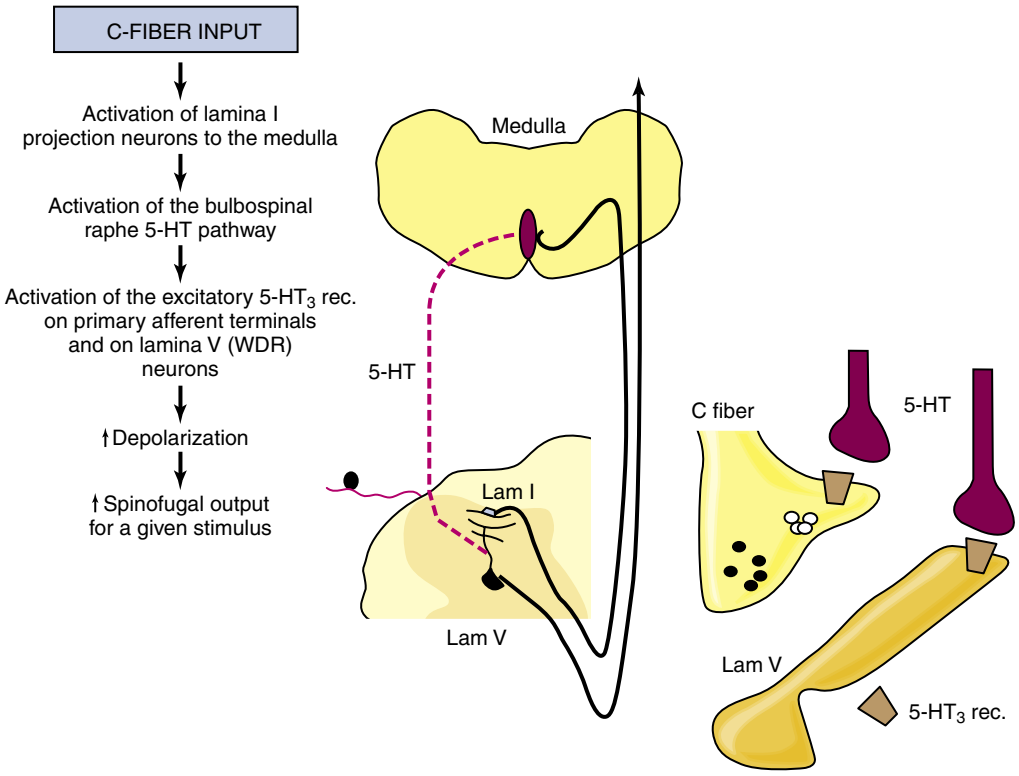
Circulating Factors. Finally, circulating cytokines (such as IL-1β and TNF) can activate perivascular astrocytes and microglia after tissue injury and inflammation. As noted, microglia are, in fact, brain-resident macrophages. Such mechanisms provide an important linkage for the somatic sensations associated with systemic infection (e.g. in the course of a common cold or the "flu").

The relevance of the non-neuronal cell population to the facilitation process in pain processing after peripheral injury is supported by a variety of observations. First, peripheral injury and inflammation lead to acute and chronic activation of microglia and astrocytes. Thus p38 MAPK-β is present in microglia and is activated in minutes after a peripheral injuring stimulus. Over longer periods, other markers of microglia (OX42) and astrocytes (glial fibrillary acidic protein [GFAP]) showed a significant increase in expression. Drugs such as minocycline (a second-generation tetracycline) and pentoxifylline have been reported to block microglial activation and diminish hyperalgesic states. Similar metabolic inhibitors that block astrocyte activation (fluorocitrate) can also diminish hyperalgesia after nerve and tissue injury. These agents, though not clinically implemented, suggest important directions for drug therapy development.

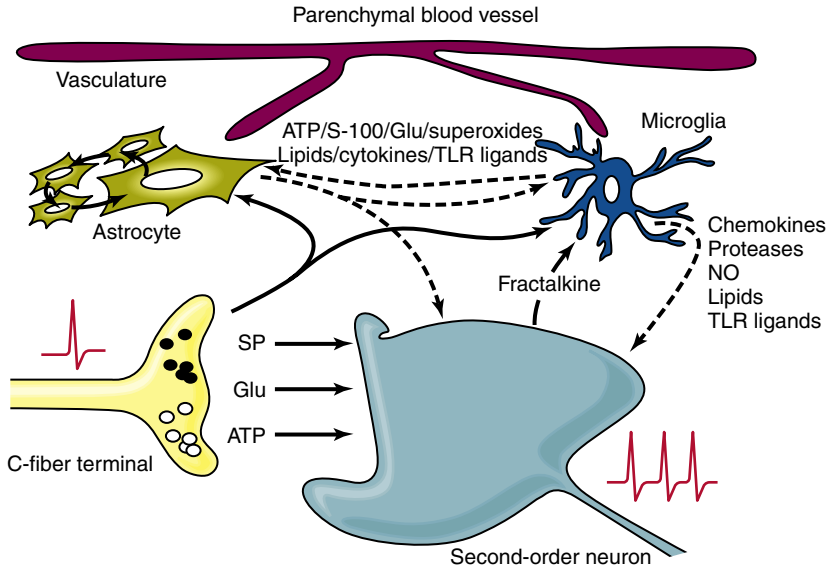
Innate Immune Systems. It has become increasingly appreciated that components of the innate immune response system may also play a role in the development of ongoing pain after an injury. One component is toll-like receptors (TLRs). TLRs recognize molecules derived from damage and infectious products and are expressed in cells involved in immune function (e.g. macrophages and neutrophils). They are also found in the spinal cord neurons, glial cells, and DRGs. Several TLRs have been implicated in pain processing through the use of mutant mice. These receptors signal via a complex series of downstream cascades that can lead to signaling mediated by a wide variety of cytokines. For example, in DRG neurons, consistent with the expression of TLR messages, TLR4 agonists increase intracellular calcium levels, thereby leading to the release of neurotransmitters. It is important to note that many ligands, such as tenascin C, which can activate various TLRs, are generated in neuraxial tissue after peripheral injury and inflammation.

Adaptive Immunity

It is appreciated that in the face of tissue injury and inflammation, autoantibodies are formed that enter the circulation. These antibodies can have two types of interactions. Some may recognize specific epitopes, such as membrane-expressed proteins, such as for a potassium channel. Binding to this channel may lead to its disablement. In this case, the loss of a potassium channel function would lead to increased excitability of the membrane. Similarly, the antibody may recognize an inhibitory receptor such as glycine, which would lead to a loss of inhibition and increased excitability. In addition, autoantibodies can form immune complexes and may interact with traditional adaptive immune signaling receptors, such as Fcgamma receptors expressed on inflammatory cells as well as afferent neurons. In this case, the binding might lead to activation of the membrane through Fcgamma signaling to the generation of a complement reaction leading to the activation of inflammatory cells. Importantly, it has been shown that antibodies from certain states, such as fibromyalgia, may express autoantibodies, which lead to a hyperpathic state when injected into a normal mouse. Such autoantibodies have also been identified in nerve injury (see below).



• **Figure 9.4** Small afferent evoked activation of lamina I neurons that project into the medullary raphe nuclei and serve to excite bulbospinal serotonin (5-hydroxytryptamine [5-HT]) pathways that activate excitatory 5-HT_3 receptors on lamina V neurons. This projection serves to facilitate the firing of these lamina V projection neurons and may underlie the phenomenon of "wind-up." *rec.*, receptor; *WDR*, wide dynamic range.



• **Figure 9.5** Schematic showing the complex assemblage in the dorsal horn with respect to astrocytes, microglia, and neurons. Products released from neurons can activate the release of a variety of active products from astrocytes and microglia. Astrocytes can activate other astrocytes through gap junctions, activate microglia, and induce the excitability of neurons by releasing a variety of active factors. As indicated, postsynaptic neuronal activation can lead to the release of chemokines such as fractalkine, which can act on eponymous receptors on microglia. See text for further details. *ATP*, Adenosine triphosphate; *Glu*, glutamate; *NO*, nitric oxide; *SP*, substance P; *TLR*, toll-like receptor.

Spinal Facilitatory Systems

The preceding section reviewed several systems that serve to increase the gain of the spinal transmission system. This facilitation serves two interrelated functions. First, it explains in part the mechanisms whereby a peripheral injury that leads to repetitive small afferent input can result in a potent hyperalgesic state (i.e. the response to any subsequent afferent stimulus is enhanced). Second, following local injury, there is frequently the development of enlarged receptive fields that extend beyond the territory of the original injury. As discussed earlier, the dermatome for any given root is represented in part by spinal collaterals of afferents that project to neurons in adjacent segments. When these cells undergo facilitation, the input from distal dermatomes becomes sufficient to drive activity in these cells. Accordingly, the receptive field of that cell now incorporates this distal body surface. Given this perspective, it is not surprising that agents targeted at these facilitatory mechanisms can profoundly affect injury-induced pain states. Agents such as COX inhibitors are an important example for emphasizing the role of the facilitated state in the pain experience. COX inhibitors diminish hyperesthesia secondary to tissue injury. This reaction reflects the important role of prostaglandins released in the periphery and in the spinal cord, where they can facilitate the release of C-fiber transmitters such as

SP. Current evidence suggests that both COX-1 and COX-2 are important constitutive enzymes in the spinal system. However, spinal COX-2 inhibitors appear to be particularly important in regulating injury-induced spinal facilitation. Nonetheless, work also points to other facilitatory mechanisms that may likewise be useful targets in the development of future agents. The potency of NOS inhibitors on behavior suggests the importance of the spinal release of nitric oxide in facilitatory processes leading to hyperalgesia. Agents that inhibit microglial and astrocyte activation can also diminish hyperalgesia. Though not clinically useful or defined as safe after spinal delivery, these agents suggest important directions for drug therapy development.

As a final *caveat* to this discussion of neuraxial facilitation, it is important to note that central facilitation studies examining the effects of repetitive C-fiber stimulation on dorsal horn neurons (described earlier) are conducted in animals that are under minimum alveolar concentration anesthesia (1 MAC, typically isoflurane or halothane). Indeed, behavioral models of facilitation wherein the injury are induced under the effect of a systemic anesthetic (e.g. barbiturate, volatile agent) show that the hyperalgesic state may be initiated although the injury is produced under anesthesia. The relevance of this observation to the performance of surgery on patients "anesthetized" with volatile anesthetics or with barbiturates alone is clear. Though preventing the ascending pain message, these anesthetics surprisingly do not appear to block the facilitatory processes that are initiated by small afferent input, probably at the level of transmitter release at the first spinal synapse. This lack of anesthetic effect on primary afferent release is believed to represent the basis of the consideration for the concept of "preemptive analgesics" via such therapeutic approaches as regional anesthesia.

Spinal Inhibitory Systems

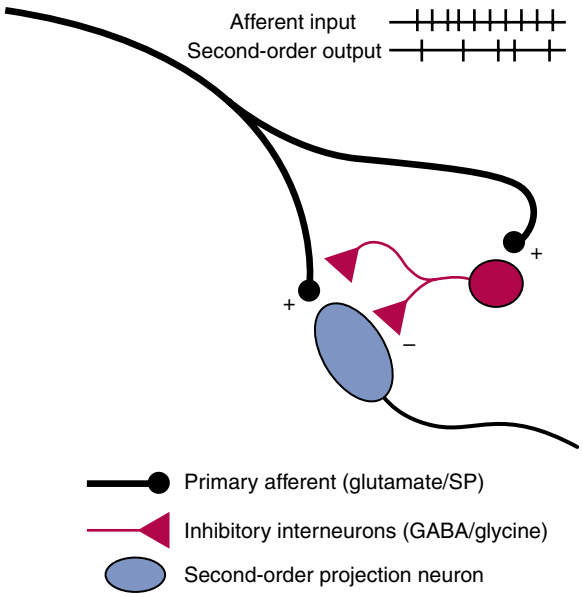
Second-order dorsal horn neurons (WDR neurons) receive excitatory input from large afferents, as well as from excitatory interneurons. This input is typically mediated by glutamate. The output from the spinal dorsal horn evoked by such excitation is subject to upregulation of excitability, but it has long been appreciated that these cells are also subject to mechanisms that downregulate local excitability. In the following sections, we will consider the pharmacology of these processes.

Local Inhibitory Circuits

This section considers systems that are local to the dorsal horn and regulate the local excitability.

Inhibitory Amino Acids

Based on the effects of various inhibitory amino acid antagonists, it appears that the excitatory effect of primary afferents, both small and large but particularly large (Aβ) ones, are subject to potent inhibition that is expressed by inhibitory γ-aminobutyric acid (GABA) and glycine receptors, which are both presynaptic on the primary afferent and postsynaptic on the second-order neuron. This relationship is shown in Figure 9.6. The release of GABA and glycine from local interneurons act on $GABA_A$/$GABA_B$ receptors and glycine receptors, respectively. The $GABA_A$ receptor and glycine receptors are ionophores that, when activated, serve to increase Cl– conductance. Based on resting transmembrane Cl– gradients, such an increase in permeability leads to modest membrane hyperpolarization and an increase in the shunting current.



• **Figure 9.6** Schematic showing presynaptic and postsynaptic regulation by glycine/γ-aminobutyric acid (GABA) interneurons of Aβ afferents input onto a second-order dorsal horn neuron. As indicated, the afferent input activated the second-order projection neurons and inhibitory interneurons. The delay in GABA/glycine release results in delayed inhibition of the second-order neurons. This results in a sculpting of second-order neuron output. In the absence of such inhibition, the afferent input yields a pronounced increase in second-order neuron outflow: *SP*, substance P.

These effects reduce the ability of excitatory input to depolarize cells. $GABA_B$ receptors are G protein coupled receptors that are also inhibitory. The relevance of this ongoing inhibitory organization to ongoing sensation is substantiated by the fact that local application of $GABA_A$ (bicuculline) or glycine (strychnine) receptor inhibitors will lead to powerful augmentation of the discharge of dorsal horn neurons evoked by large (Aβ)-afferent input.

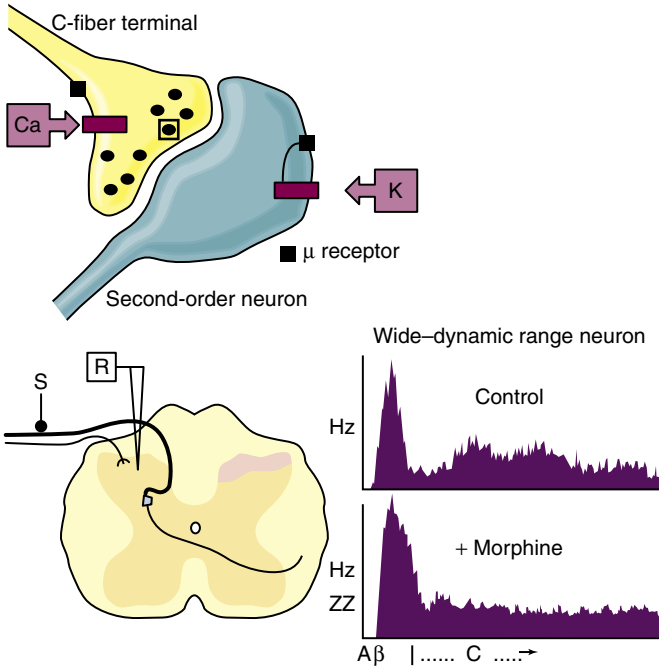
Opioids

The potent analgesic effect of opiates reveals the efficient role played by opiate receptors in regulating pain transmission. A systematic study has shown that opiate receptors that regulate the pain response are located at the spinal level and in several brain loci.

Spinal Opiate Action

Intrathecal delivery of opiate agonists will potently inhibit the injury evoked discharge of superficial and deep dorsal horn neurons induced by small high threshold afferents (C-fiber). The deep dorsal horn neurons also receive input from low threshold large (Aβ) afferents, but this evoked component is not typically blocked by opiates. These effects are mediated by an action on opioid receptors (typically characterized as μ-opioid based on agonist and antagonist pharmacology). Localization of these μ receptors has revealed that they are largely on C-fiber primary afferents that terminate in the superficial dorsal horn and on the dendrites and cell bodies of deeper dorsal horn neurons (Fig. 9.7).

Intrathecal administration will reliably attenuate the response of the animal to a variety of unconditioned somatic and visceral stimuli that would otherwise evoke organized escape behavior in all species. Confirmation of the presynaptic action is provided by the observation that opiates reduce the release of primary afferent



• **Figure 9.7** Opiate receptors are located presynaptically and postsynaptically on small primary afferents terminating in the substantia gelatinosa. A local action of opiates in the spinal cord will selectively depress the discharge of spinal dorsal horn neurons activated by small (high threshold, delayed) but not large (low threshold, short latency) afferents. C, C-fiber; R, recording electrode; S, stimulating electrode.

peptide transmitters, such as the SP contained in small afferents. The presynaptic action corresponds to the ability of opiates to prevent the opening of voltage-sensitive Ca^{2+} channels, thereby preventing mobilization and release of the transmitter. Postsynaptic action is demonstrated by the ability of opiates to block the excitation of dorsal horn neurons evoked by glutamate, a process reflecting direct activation of the dorsal horn. The activation of potassium channels leading to membrane hyperpolarization is consistent with direct postsynaptic inhibition.

Supraspinal Opiate Action

Direct injection of opiates into the brain has shown that opioid receptors that modulate pain behavior are found in several restricted brain regions, including the amygdala and the midline medulla. However, the best characterized supraspinal sites identified in this study are the mesencephalic periaqueductal gray (PAG). Microinjection of opiates into this region blocks the nociceptive response in a naloxone-reversible fashion. Several mechanisms exist whereby opiates acting in the PAG may alter nociceptive transmission.

1. Activation of bulbospinal projection. In the PAG, opiate receptors are presynaptic on GABAergic terminals that inhibit projection to the medulla. Morphine acts to block the release of GABA, which terminates inhibitory control over PAG outflow. The PAG has excitatory projections into the medulla, which then activates the bulbospinal noradrenergic and serotonergic pathways. Noradrenergic projections act through spinal α_2-receptors to reduce dorsal horn excitation.
2. Opiate binding within PAG. Such binding may be preterminal to the ascending spinofugal projection. This preterminal action inhibits input into the medullary and mesencephalic cores.
3. Outflow from the PAG. PAG outflow can increase the excitability of the dorsal raphe and locus coeruleus/lateral tegmental nuclei from which ascending serotonergic and noradrenergic projections, respectively, originate and project to the limbic forebrain. These projections were thought to modulate emotionality (see later).

These three mechanisms are summarized in Figure 9.8.

Endogenous Opiates

Opiate receptors are presumed to be targeted by endogenous compounds released from local interneurons. Several such functionally qualified families of agents have been identified according to the family of prohormones from which they are derived: proenkephalin (enkephalins), prodynorphins (dynorphins), and pro-opiomelanocortins (β-endorphin). Other endogenous opioids, such as endomorphins, have also been described. These peptides have been shown to have a significant affinity for one or more of the several identified opioid receptors. Enkephalins have been found in the dorsal horn interneurons and bulbospinal pathways. Such interneuronal systems are present throughout the brain. β-Endorphin is present in long projection pathways that largely originate in the hypothalamus. Although opiate receptors can regulate spinal nociceptive processing, surprisingly limited data suggest that endogenous systems have a robust effect on pain processing. Naloxone, an opioid antagonist, has a modest effect on ongoing pain processing. Enkephalins are rapidly metabolized by various peptidases, and changes in the pain threshold in animal models have been shown to alter pain thresholds in several experimental pain states.

Bulbospinal Projection Systems

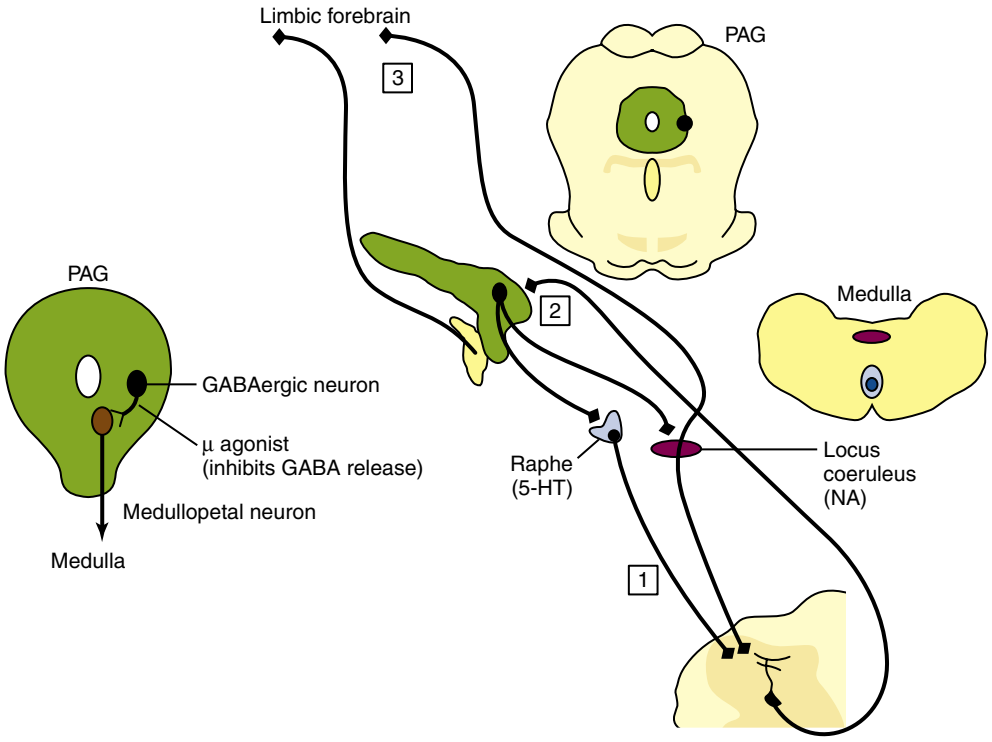
Several transmitters are known to be contained in and released from bulbospinal projecting pathways. However, the best characterized are the monoamines, norepinephrine, and serotonin.

Bulbospinal Norepinephrine

Norepinephrine projections to the spinal cord arise from lateral medullary sites and the locus coeruleus, whereas norepinephrine projections to the forebrain arise from the locus coeruleus (Fig. 9.8). Rostral projections are believed to play a primary role in altering the affective components of behavior. The caudal adrenergic projections play a principal role in regulating spinal nociceptive processing through action on spinal dorsal horn α_2-adrenergic receptors that are located presynaptic and postsynaptic to the primary afferent. Spinal delivery of α_2-adrenoceptor agonists, such as clonidine and dexmedetomidine, produces significant analgesia. The spinal action of an α_2-agonist is mediated by a mechanism similar to that used by spinal opiates. However, the receptor is distinct: (1) α_2 binding is presynaptic on C-fibers and postsynaptic on dorsal horn neurons, (2) α_2-receptors can depress the release of C-fiber transmitters, and (3) α_2-agonists can hyperpolarize dorsal horn neurons through a G_i-coupled potassium channel.

Bulbospinal Serotonin

Serotonin (5-hydroxytryptamine [5-HT]) arises from the nucleus raphe magnus, which projects spinally, and from the raphe dorsalis, which provides the principal source of 5-HT in the forebrain. As reviewed earlier, spinipetal 5-HT projections can have multiple effects, including excitation and inhibition. These complex effects



• **Figure 9.8** Schematic of organization of opiate action within the periaqueductal gray (PAG) whereby μ-opiate actions block the release of γ-aminobutyric acid (GABA) from tonically active systems that otherwise regulate projections to the medulla and lead to activation of PAG outflow. (1) Excitatory outflow from the PAG activates bulbospinal projections that release serotonin (5-hydroxytryptamine [5-HT]) or noradrenaline (NA), or both, at the spinal level. (2). Preterminal opiate binding within the PAG on the ascending spinofugal projection. (3) Outflow from the PAG increases excitability of the dorsal raphe and locus coeruleus, from which ascending serotonergic and noradrenergic projections originate and project to the limbic forebrain.

suggest that under certain conditions, increasing the spinal 5-HT tone may *facilitate* nociceptive processing.

Altering Terminal Monoamine Concentrations

Notably, agents that regulate the extracellular concentrations of these monoamines can have pronounced effects on emotional tone and nociceptive transmission. Because extracellular levels depend not only on release but also on their reuptake, agents that block the reuptake transporter, such as tricyclic anti-depressants, can have analgesic properties. Current evidence suggests that analgesic actions are largely mediated through an effect on norepinephrine and not serotonin. This difference in their relative contributions to analgesic efficacy may reflect several opposing effects associated with the action of serotonin.

Nerve Injury Initiated Signaling and Pain

From the preceding sections, it was evident that the events that occur following peripheral tissue injury can lead to potent facilitation of neuraxial processing, which results in a large part of the persistent small afferent traffic that occurs with injury and inflammation. These changes reflect events that occur in the injured nerve (as reviewed in the preceding section): alteration of protein expression leading to upregulation of some proteins and downregulation of others. The increased spontaneous activity arising from neuromas and DRGs provides a tentative explanation for the ongoing dysesthesias associated with various nerve injury conditions. The prominent finding is that low threshold tactile stimulation acquires an aversive component that appears to present a more complex set of events. Current thinking is that it is mediated by low threshold mechanosensitive (Aβ) afferents. The precise mechanism of this involvement of low threshold afferents in the initiation of pain is not known, although several possibilities have been considered credible.

Crosstalk Between Large and Small Afferents

Following nerve injury, "crosstalk" mediated by ephaptic contacts may develop between afferents in the DRGs and neuromas. Here, depolarizing currents in one axon would generate a depolarizing voltage in an adjacent quiescent axon. In this manner, a large low threshold afferent drives the activity in an adjacent high threshold afferent.

Large-afferent Sprouting

As reviewed previously, large myelinated (Aβ) afferents project into the spinal Rexed lamina III and deeper. Small afferents (C-fibers) tend to project into spinal laminae I and II, a region populated by neurons responding to this high threshold input. It has been argued that following peripheral nerve injury, the central terminals of myelinated afferents (A-fibers) sprout into lamina II of the spinal cord. With this synaptic reorganization, stimulation of low threshold mechanoreceptors (Aβ-fibers) could produce excitation of these neurons and be perceived as painful. The degree to which this sprouting occurs is a point of the current discussion, and even though it does appear to occur, it is considerably less prominent than initially reported.

Loss of Intrinsic Inhibitory Control

A large number of small interneurons lie in the superficial dorsal horn; these interneurons contain and release GABA and glycine. As reviewed earlier, these terminals are presynaptic to the large central afferent terminal complexes and form reciprocal synapses, and GABAergic axosomatic connections have been identified in second-order and projection neurons (Fig. 9.6). Accordingly, these transmitters exert powerful inhibitory control over the activity of Aβ primary afferent terminals and second-order neurons in

the spinal dorsal horn. As discussed earlier, the importance of this local inhibitory circuitry is indicated by the observation that intrathecal delivery of a $GABA_A$ receptor or glycine receptor antagonist evokes a powerful tactile allodynia. Such observations led to the hypothesis that nerve injury may induce a loss of GABAergic and glycinergic neurons. Although some data support the loss of such neurons, this loss appears to be minimal. Recent observations suggest a second alternative. After nerve injury, spinal neurons are altered so that GABAA and glycine receptor activation become excitatory. As noted previously, these receptors are chloride ionophores. When these ionophores are activated, chloride moves according to the transmembrane gradient. The transmembrane gradient is maintained by transporters that export chlorides. After nerve injury, the activity of the chloride transporter is reduced, which leads to an increase in intracellular chloride and an increase in membrane Cl– conductance, as occurs with $GABA_A$ receptor activation, resulting in membrane depolarization. Thus paradoxically, afferent inputs that activate $GABA_A$/glycine channels may facilitate membrane depolarization and lead to a significantly enhanced response to the Aβ drive.

Enhanced Excitatory Drive

Glutamate Release

Spinal glutamate release plays an important role in post–nerve injury pain states. There is a significant enhancement in resting spinal glutamate secretion after nerve injury. This release is in accordance with (1) increased spontaneous activity in the primary afferent and (2) loss of the intrinsic inhibition that may serve to modulate resting glutamate secretion (see below). Several observations emphasize the significance of this release: (1) intrathecally delivered glutamate evokes powerful tactile allodynia and thermal hyperalgesia through the activation of spinal NMDA and non-NMDA receptors. (2) Spinal delivery of NMDA antagonists has been shown to attenuate hyperpathic states arising in animal models of nerve injury. NMDA receptor activation mediates the facilitation of neuronal excitability. In addition, the NMDA receptor is a calcium ionophore, which, when activated, leads to prominent increases in intracellular calcium levels. The increase in intracellular Ca^{2+} initiates a cascade of events, including the activation of a variety of enzymes (kinases), some of which phosphorylate membrane proteins (e.g. calcium channels and NMDA receptors) and others, such as the MAPKs, which mediate intracellular signaling, thereby leading to the altered expression of a variety of proteins and peptides (e.g. COX and dynorphin). Several factors have been shown to enhance glutamate release. Two examples are discussed below.

Spinal Dynorphin

Nerve injury leads to a prominent increase in spinal dynorphin expression. Intrathecal delivery of dynorphin can initiate the concurrent release of spinal glutamate and potent tactile allodynia; NMDA antagonists reverse this effect. Although dynorphin is an endogenous opioid peptide, these effects appear to be independent of any action on an opiate receptor.

Altered Channel Expression

As reviewed previously, nerve injury leads to the upregulation of various sodium channels and downregulation of potassium channels. This altered expression is referred to as the *neonatal phenotype.* This assertion belies the enormous changes in channel expression associated with nerve injury. For example, it has been shown that after nerve injury, there is a significant increase in the expression of the $\alpha_2\delta$ subunit. This subunit is found in the structures of several members of the voltage-sensitive calcium channel family. This binding site is densely present in the substantia gelatinosa of the superficial dorsal horn and DRG at the spinal level. The relevance of this increased expression is suggested by the potent anti-allodynic effects associated with the action of gabapentin. This molecule appears to exert its effects by highly selective binding to the $\alpha_2\delta$ subunit. N-type voltage-sensitive calcium channels also show increased expression, and spinal delivery of N-type calcium channel blockers such as ziconotide also produces potent anti-allodynic effects.

Non-neuronal Cells and Nerve Injury

As reviewed in the preceding sections, astrocytes and microglia have been shown to play a powerful constitutive role in increasing synaptic excitability through the release of a variety of active factors (Fig. 9.5). After nerve injury, significant activation of spinal microglia and astrocytes occurs in the spinal segments that receive input from the injured nerves. Work with TLRs suggests that products released centrally by nerve injury can activate these cells through constitutively expressed TLRs. This activation is manifested by morphologic changes in these cells and increased expression of cellular markers for microglia (e.g. OX42/p-p38 MAPK) and astrocytes (GFAP). Of particular interest is that in the presence of pathologies such as bone cancer, extravagant activation of these non-neuronal cells has been shown to occur. Although the origin of this activation is not clear, increased afferent traffic and release of excitatory transmitters and products that appear to be increased secondary to nerve injury, such as growth factors, appear to be involved. This activation of intracellular transcription factors serves to increase the spinal expression of COX, NOS, glutamate transporters, and proteinases and to downregulate other systems such as the chloride transporters discussed in the preceding section. Such biochemical components have been previously shown to play an important role in the facilitated state.

In addition to the role played by glia, there is also the appreciation that after injury, a variety of cell surface markers are expressed in the DRG that promote the migration of macrophages and neutrophils into the DRG. These cells are thought to contribute to the inflammatory milieu.

Adaptive immune signaling

As reviewed above, there is increasing evidence that autoimmune signaling may contribute to the appearance of facilitated states after nerve injury. Studies have shown that antibodies from patients displaying causalgic phenotypes (e.g. hyperpathia after nerve or tissue injury) given to mice can initiate a hyperpathic state in the animal and that patients where immune complexes have been removed may show improvements.

Supraspinal outflow

While the majority of this review has focused on the organization of the input/output function of spinal systems, it is evident that the manifestations of the pain experience occur because of the input into a higher-order system. Dorsal horn projection neurons (second-order neurons) relevant to the pain experience typically cross to ascend in the contralateral–ventrolateral quadrants of the spinal cord following two trajectories: (1) into the somatosensory thalamus, while the third-order neurons project to the somatosensory cortex (the classical somatosensory pathway),

and (2) to regions such as the parabrachial, medial, and ventromedial thalamus. Here, the third-order neurons project to various limbic forebrain (e.g. hippocampus, amygdala, anterior cingulate, and inferior insula). The first trajectory has properties that suggest encoding both the stimulus location and intensity. The second trajectory serves to innervate systems robustly associated with emotionality, affect, and the integration of memory and other sensory components (e.g. smell, hearing, vision). These systems provide the substrate for encoding the *sensory-discriminative* aspects of the pain phenotype, while the latter serves to integrate the emotionality and experiential components of the pain phenotype, which we refer to as the *affective motivational component*. Such circuitry would be considered to underlie the strong emotional component that a pain stimulus can evoke.

Overview

In summary, the post–tissue injury pain state reflects sensitization of the peripheral terminal in response to the local release of a variety of factors that initiate spontaneous activity and sensitization of the peripheral terminal. There is also a potent central (spinal) sensitization that leads to enhanced responsiveness of dorsal horn neurons that receive ongoing small afferent traffic. This condition results in an enhanced response to input from the injured receptive field and enlargement of the peripheral fields, which can activate these neurons through originally ineffective subliminal input. The augmentation reflects the local synaptic circuitry (glutamate/SP) and the spinobulbospinal linkages (5-HT) and by-products released from local non-neuronal cells. Afferent activation and sensitization are subject to regulation by various systems, including those that regulate the release of transmitters from the primary afferent and activation of second-order or projection neurons.

Regarding the events that occur after nerve injury, it is evident that there are two principal elements: those that account for spontaneous pain and those that lead to an alteration in the encoding of normally innocuous low threshold mechanical stimuli. Spontaneous activity is probably a reflection of the complex events that arise from channel expression and the inflammatory factors that appear after nerve injury and lead to ectopic activity. The alterations related to the facilitated response represented evident changes in the dorsal horn function. The net effect appears to be enhanced excitability secondary to the increased expression of excitatory elements and reduced inhibitory contribution. The increased excitation probably arises from several sources, including the activation of non-neuronal cells.

Finally, peripheral nerve injury, such as that caused by compression or trauma and chemotherapy, leads to a persistent pain state. In contrast, local tissue injury or inflammation results in hyperpathic states, with a time course parallel to the onset and resolution of the injury state. However, as reported in humans, the pain state originating from prolonged inflammation may persist even when the inflammatory state resolves (loss of neutrophils/macrophages and cytokines). Comparable pain states have been identified in pre-clinical models. Recognition of this propensity of an acute injury to transition to a persistent or chronic pain condition raises important issues regarding the convergence of mechanisms that underlie inflammatory and nerve injury conditions. For example, it is noteworthy that trophic and persistent changes in the DRG have been identified after long intervals (days to weeks) in animal models. In this case, transcription factors (e.g. ATF-3) are activated and show little tendency to reverse even over extended intervals. This suggests the possibility that in populations of patients and certain pre-clinical models, peripheral inflammation may lead to persistent changes in afferent neuraxial coupling. In studies involving TLR mutants, these changes in persistent pain and upregulation of transcription factors have been prevented. Other persistent changes were also identified. Importantly, this spinal encoding serves to encode the content of the message that is relayed to higher centers in the brain that serve to integrate the content with complex issues of emotion, affect, and learned experiences.

Key Points

- Aβ afferents, which are large, myelinated, fast-conducting axons, are typically activated by low-intensity mechanical stimuli. Aδ-fibers, which are smaller, myelinated, intermediate-conducting afferents, have subpopulations that preferentially respond to thermal or mechanical, low or high threshold stimuli. C-fibers, small unmyelinated, very slowly conducting afferents, are activated by high intensity thermal or mechanical stimuli (or both).
- With tissue injury, ongoing activity is initiated by changes in the local milieu that evoke activity and sensitize the peripheral terminal. With ongoing small afferent input, there is a spinal sensitization that reflects acute increases in neuronal responsiveness mediated by NMDA receptors and longer-term events reflecting activation of kinases, generation of pro-inflammatory intermediaries, and more persistent events mediated by transcriptional activation.
- After a chemical, immune, or mechanical injury to the nerve, afferent axons display (1) an initial burst of afferent firing, (2) electrical silence for an interval of hours to days, and (3) the appearance of "spontaneous" bursting activity in both myelinated and unmyelinated axons over hours to days. This ongoing activity reflects the initial dying back of the injured axon (retrograde chromatolysis) and the initiation of sprouting.
- Bulbospinal serotonergic projections act through excitatory 5-HT_3 receptors to enhance the firing of these lamina V neurons. These cells are noted for their ability to display a facilitated state called "wind-up." Blockade of this bulbospinal linkage or the use of 5-HT_3 inhibitors has been reported to reduce this facilitated state.
- It has been demonstrated that behavioral models of facilitation wherein the injury is conducted under a systemic anesthetic (e.g. barbiturate, volatile agent) show that the hyperalgesic state may be initiated. However, the injury is inflicted under the influence of an anesthetic.
- Though preventing the ascending pain message, anesthetics surprisingly do not appear to block the facilitatory processes that are initiated by small afferent input, probably at the level of transmitter release at the first spinal synapse.
- Prostaglandins act on a number of eponymous receptors located *presynaptically* on the primary afferent terminal and *postsynaptically* on second-order neurons.
- Following peripheral nerve injury, ongoing pain appears to represent ectopic activity in the neuroma and the DRG, a phenomenon reflecting upregulation of sodium channels and the expression of receptors activated by changes in the local milieu. The enhanced response to low threshold stimulation

may reflect the loss of intrinsic GABA and glycinergic inhibition and activation of non-neuronal cells.
- Current work increasingly points to the role of circulating autoantibodies that can interact with membrane channels and receptors, leading to their disablement and creation of a facilitated state or to classical Fcgamma receptors that can initiate signaling of afferents.
- The content of the ascending information arising from tissue and nerve injury is provided to supraspinal systems that integrate that information arising from the somatic and visceral body with the rich tapestry of learned experience, emotion, and other sensory inputs.

The contents of this chapter on the pharmacology of the substrates activated after tissue injury and nerve injury must be considered a broad overview. More detailed considerations and citations can be found in the detailed reviews listed below.

10 Neuroimaging Techniques

MATHIEU ROY, ÉTIENNE VACHON-PRESSEAU, MARKUS PLONER, ARIANA M. NELSON

Introduction

Pain, defined as the conscious subjective experience associated with real or potential tissue damage,[1] is a product of coordinated activity across large portions of the brain.[2] In contrast, the concept of nociception refers to the objective neural processes triggered by nociceptive stimuli and does not imply consciousness. Therefore one important goal of neuroimaging is to understand how nociception leads to pain and explain what happens when pain appears to be dissociated from nociception, as observed in many chronic pain syndromes. This chapter discusses the non-invasive imaging modalities that can depict the structural and functional central nervous system (CNS) features associated with experimentally induced and chronic pain. The main objective of this chapter is to survey the brain imaging literature on these highly prevalent functional chronic pain syndromes, for which it is difficult to identify a clearly defined pathology. A more in-depth treatment of radiologic imaging techniques routinely used to identify CNS damage can be found in Chapter 20.

An overview of the most commonly used neuroimaging modalities can also be found in Box 10.1, where we briefly survey the techniques routinely used to identify damage to the CNS, as well as functional techniques that can assess CNS activity as a function of experimentally induced or chronic pain, which will be the focus of this chapter. We will begin with a brief historical overview of functional magnetic resonance imaging (fMRI) studies of acute experimentally induced pain before examining how chronic pain differs from pain evoked by nociceptive stimuli. We will then turn to positron emission tomography (PET) studies of endogenous opioidergic and dopaminergic systems in chronic pain syndromes. Finally, we will review recent electroencephalographic (EEG) studies of acute and chronic pain. Overall, this chapter should provide the reader with a good overview of the cerebral underpinnings of pain, as well as how this knowledge may have contributed to change our conception of pain and how it could be harnessed to guide certain clinical decisions.

Brain Imaging of Acute Experimental Pain

Brain Mapping

The study of the cerebral correlates of pain began with the investigation of patients with brain lesions causing abnormal pain perception.[3,4] The main conclusion from these studies was that pain was principally perceived in the thalamus, with a limited role in the cortex. However, as neurophysiologists began to follow the projections of nociceptive pathways up to the brain, the role of cortical structures in pain perception has gradually become more important.[5–8] With the advent of functional neuroimaging techniques in the late 1980s—first PET and then fMRI—researchers became endowed with a means to non-invasively probe the human brain in search for areas responding to noxious stimuli. Using these techniques, several studies found that high-intensity noxious stimuli (thermal, electrical, mechanical, or chemical) systematically produced more activity than low-intensity innocuous stimuli in a set of regions comprising the thalamus, anterior cingulate cortex (ACC), insula (Ins), primary and secondary somatosensory cortices (S1 and S2), and prefrontal cortex (PFC) (Fig. 10.1).[9,10]

Inspired by Ronald Melzack's terminology,[11] researchers soon started to refer to this collection of brain regions as the "pain matrix."[12,13] Melzack's original "Neuromatrix" theory of pain proposed that the conscious experience of pain was generated by the flow of activity within a widespread network of convergent/divergent loops between the thalamus, cortex, and limbic system. He thought that the general function of this network, which he called the "body-self neuromatrix," was to produce a unified representation of the body and self. Moreover, he suggested that the various bodily states generated by the neuromatrix each had a particular "neurosignature" (i.e. a characteristic pattern of neuronal activity stemming from the interaction between environmental inputs and the pre-existing state of the neuromatrix). Therefore according to Melzack, there is no "pain center" in the brain, but rather a general-purpose "body-self neuromatrix" capable of representing a wide array of bodily states, of which pain is just one particular example. Eventually, Melzack's idea of a "body-self neuromatrix" was simplified, and the term "pain matrix" began to be used to refer to the brain regions generally activated by pain.

Discussions in the field revolved around how different regions of the "pain matrix" contributed to the unified pain experience. An important distinction was made between the sensory dimension of pain, reflecting the location, intensity, and sensory quality of the experience, and the affective dimension reflecting the intrinsic unpleasantness of pain.[14] The sensory dimension of pain is thought to result from activity in the cerebral targets of the lateral spinothalamic system: ventral posterior (VPI) and ventral posterior lateral thalamic nuclei, S1, S2, and posterior insula (pINS). Studies of patients with brain lesions confirmed that damage

• BOX 10.1 Overview of Neuroimaging Modalities

Neuroimaging techniques are defined by the obligatory processing of the data after acquisition to be interpreted visually as an image by a human clinician. The amount of processing required for the following imaging modalities is listed in approximately ascending order, starting with plain radiographs, which is the only modality that does not absolutely require processing.

Radiographs (XR): Penetrating ionizing radiation is used to distinguish radiopaque tissues from those that are radiolucent in a two dimensional view. Although simple radiographs of the cerebrum and spinal column can be used clinically to evaluate structural abnormalities in the osseous structures that house neural pathways, they do not reveal disruption of the neural soft tissues. These are most often used clinically to evaluate injury following trauma or to assess prior surgical interventions for hardware integrity and osseous fusion.[175]

Computed Tomography (CT): Tomography is defined as an image produced by a penetrating wave, and in medicine, CT scans are a fast and relatively inexpensive method of imaging the brain and spinal cord. Although CT can visualize solid or aqueous structures with much higher resolution than a plain radiograph, it is still difficult to discern the characteristics of the soft tissues, and the amount of post-processing that can be conducted is limited. Resolution can be improved by the addition of intravenous or intrathecal contrast. The use of CT with intrathecal contrast is most commonly used when patients have spinal hardware *in situ*, which obscures the relevant anatomy under MRI.[176]

Positron electron tomography (PET): This 3D imaging modality uses intravenous radionuclide tracing to assess tracer uptake in different organs or estimate neurotransmitter activity or receptor availability for ligands (e.g. opioids).[177] Once taken up by tissues, the tracer decays into positrons that react with electrons in the body and emit photons. This is detected by sensors, and the processed images are often coupled with CT to form clinically relevant images and have recently been paired with magnetic resonance for improved resolution.[178]

Magnetic resonance imaging (MRI): Structural MRI evaluates the white matter, gray matter, and cerebrospinal fluid of the cerebrum and spinal cord. In the presence of the magnet, the random motion of atoms within the body is brought into alignment. The radiofrequency coils of the MR machine produce a pulse of energy that slightly tilts the atoms away from their original alignment with the magnetic field. As they recess back to their original orientation, they emit a pulse of energy, which is captured by sensors and processed into an image.[179] MRI can be used to form images with or without the use of paramagnetic contrast dye, and indications for contrast include suspicion for metastasis or hardware *in situ* that will cause non-contrast MRI to obscure relevant anatomy.[180] Most MR machines in clinical use are those with a 1.5 Tesla or 3 Tesla magnetic field, with a higher Tesla strength correlating to higher image resolution.[179]

T1 sequence: The spin-echo (T1) sequence is clinically preferred for MR studies with contrast in evaluation of perfusion of spinal tissues, most commonly to assess primary tumors for vascularization, indicative of high tumor grade, or to evaluate metastases for vascularity that would be amenable to endovascular ablation. It is also used for cerebral imaging in the evaluation of neurologic disorders and supratentorial lesions.

T2 Sequence: Fast spin-echo (T2) is the most common MRI sequence examined by pain physicians evaluating spinal anatomy. In this sequence, the tissues with high water content (e.g. the cerebrospinal fluid) are white/bright on the image, making areas of spinal stenosis or disc herniation highly visible.

STIR: Short tau inversion recovery has higher sensitivity but lower specificity than other conventional sequences in assessing spinal abnormalities because of infectious or neoplastic etiology in the spinal column. Clinically, this is most useful in the evaluation of the spinal cord for multiple sclerosis lesions,[181] and in the vertebral bodies for compression fractures.[182]

FLAIR sequence: The fluid attenuated inversion recovery (FLAIR) sequence is a further modification of the traditional spin-echo (T2) technique that suppresses the CSF signal and minimizes the contrast between gray and white matter. This improves the detectability and visibility of pathologic lesions adjacent to the CSF. This sequence is considered more sensitive in the evaluation of ischemia, neoplastic disease, and multiple sclerosis in the neuraxis.[183]

Angiography: Both CT and MR angiography can be used to assess spinal blood supply for surgical planning or in the diagnosis of vascular pathologies, such as spinal dural arteriovenous fistulas.[181]

Advanced MRI Techniques

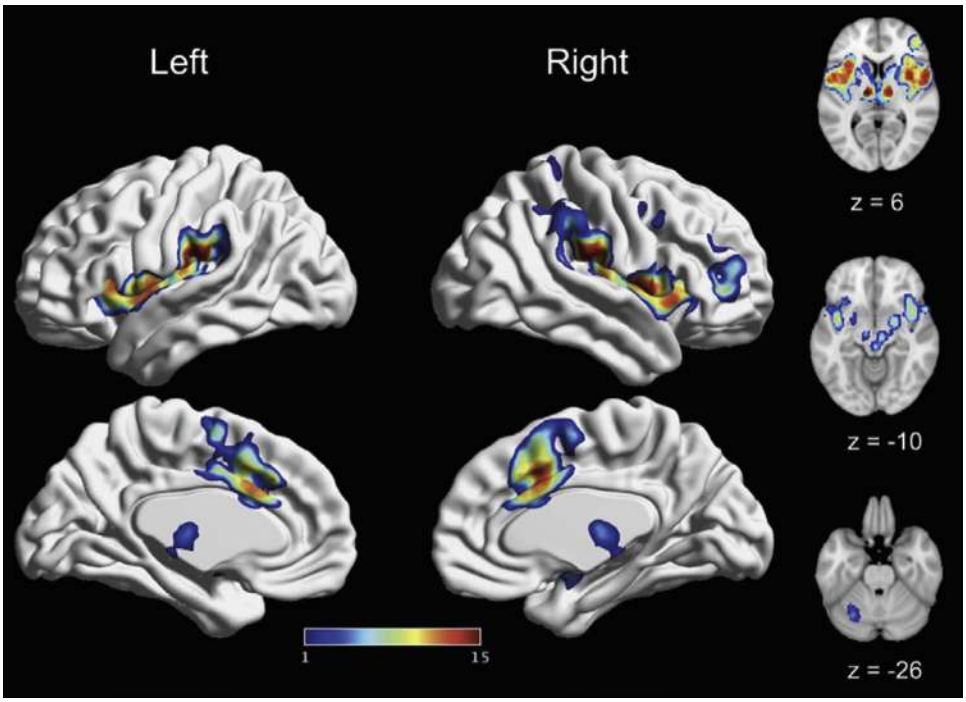
Functional MRI (fMRI) and diffusion MRI (dMRI) have been increasingly used in research studies targeting acute and chronic pain populations. These methods represent the only objective method of measuring the subjective experience of pain, as it changes the mentation of the individual. Although these techniques show great promise in future clinical applications, at the time, they are purely used in investigational pursuits.

fMRI: fMRI involves the acquisition of T2*-weighted images of the brain that are sensitive to the proportion of oxygenated and deoxygenated hemoglobin (also called BOLD signal), which is related to brain activity. In *task-based fMRI*, experimental pain stimuli (thermal, mechanical, electrical, or chemical) can be repeatedly administered to participants for several tens of minutes. The general linear model is then used to estimate the amplitude of the hemodynamic response function, which is the influx of oxygen that follows neuronal activity in small parcels of the brain called voxels. Each voxel had a volume of approximately 8-64 mm^3. A typical $3 \times 3 \times 3$ mm voxel (27 mm^3) contains about 5.5 million neurons.[184] In *resting state fMRI* (rs-fMRI), participants are scanned while still lying in the scanner for periods of 5–30 min or more. Then, correlations in the time series of functional images can be computed for one or several pairs of brain regions to assess their functional connectivity. Finally, in *ASL*, brain perfusion is measured by "tagging" water molecules with a radiofrequency pulse in certain slices of the brain and then tracking them as they release their energy in other regions of the brain. Therefore ASL can track metabolic activity related to more diffuse states such as chronic pain, but one current problem is its relatively low signal-to-noise ratio.[185]

Diffusion-weighted imaging (DWI): DWI measures the diffusion of water molecules in the brain. Diffusion tensor imaging (DTI), a special type of DWI, has been used extensively to map white matter tracts in the brain. Metrics derived from DTI include mean diffusivity (MD), which is the degree to which water diffuses at each location, and fractional anisotropy (FA), which is the coherence of this diffusion in a particular direction.[186]

to S1/S2 produces impairments in perceiving the intensity and location of pain.[15] Moreover, the parieto-opercular region, which encompasses S2 and pINS, seems to be particularly important for pain. Not only is activity in that region relatively specific to pain,[16] but it is also the only region of the brain where brain stimulation can occasionally provoke painful sensations.[17] However, without further activation of other brain regions associated with affective feelings, activity in these sensory regions does not appear sufficient to produce a full-blown pain experience.

Indeed, nociceptive sensations must also be perceived as unpleasant to really be considered as pain. The affective dimension of pain is thought to depend on activity in the cerebral targets of the medial spinothalamic pathway: the medio-dorsal thalamic nucleus, ACC, and anterior Ins (aINS). Lesions in the ACC, or of the white matter tracts connecting it to the operculo-insular cortex, can produce a condition called pain asymbolia, whereby nociceptive sensations seem to be devoid of negative affect.[18] Finally, activity in the aINS is generally ascribed to interoception, that is, the constant monitoring of the internal state of the body in the service of homeostasis,[19] which includes pain but also other imperative sensations such as hunger or thirst.[20] In addition to activity in core "pain matrix" regions (thalamus, S1, S2, ACC, insula), brain imaging studies of acute experimental pain have often reported activation in several other regions of the brain such as



• **Figure 10.1** Brain regions consistently associated with experimentally induced pain. Results of a 2020 meta-analysis of 200 fMRI studies. The value assigned to each voxel reflects the number of main effects analyses, in which it was reported to be significant. The most consistently activated areas included the bilateral thalamus, bilateral insula, bilateral SII, and bilateral MCC. Adapted from Xu et al.[9]

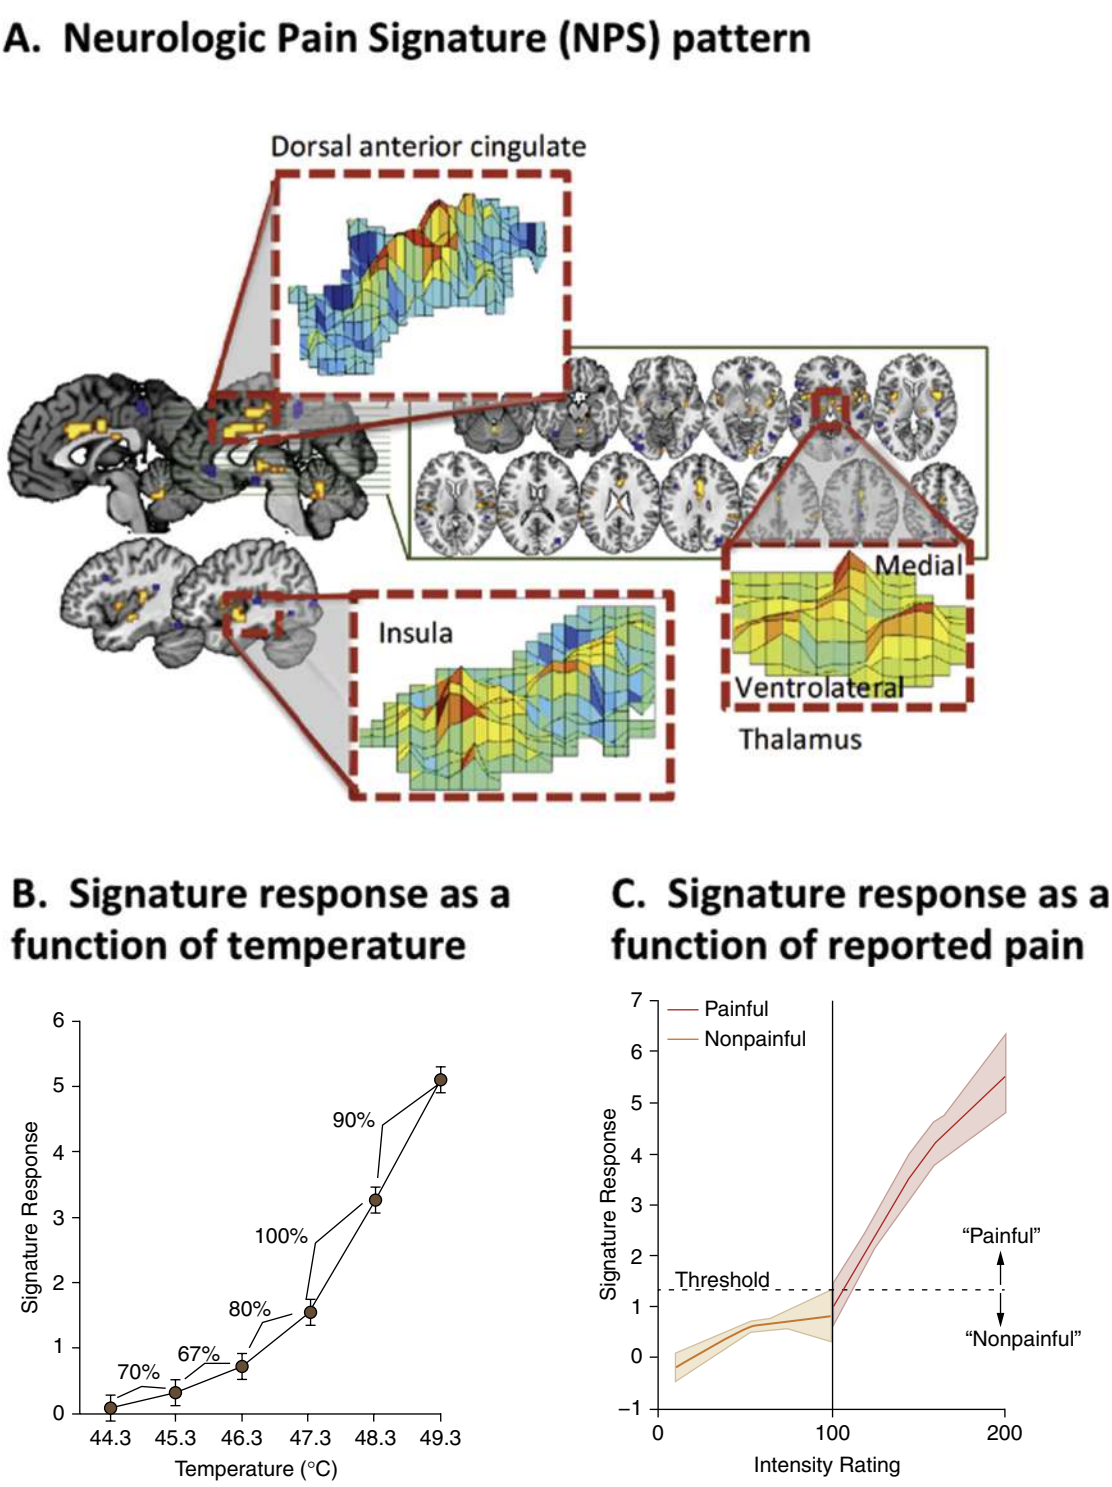
the brainstem (BS), amygdala, hippocampus, and prefrontal cortex (PFC).[9] Activity within these regions tends to be interpreted as either reflecting non-experiential aspects of pain, such as learning or autonomic regulation, or post-experiential processes not specific to pain, such as secondary appraisals and action selection. Therefore an important distinction in the field was between a primary pain effect that would be specific and intrinsic to the pain experience, and a secondary pain effect that would be more optional and the result of secondary appraisals about the significance of pain for oneself.[14]

Problem of Specificity and Multivariate Approaches

The concept of the "pain matrix" soon became criticized based on its lack of specificity. Because of its nature, pain results from excessive somatosensory stimulation. Accordingly, brain imaging studies of acute experimental pain have capitalized on the difference between high- and low-intensity stimulation to track regions responding to pain. However, this means that activity in these regions can also be interpreted as reflecting the perceptual salience of high-intensity stimulations, which may or may not be specific to pain. By comparing the patterns of activity elicited by visual, auditory, and tactile non-painful and painful heat stimulations, Mouraux et al.[21] concluded that most regions of the "pain matrix," such as the Ins and ACC, responded to the salience of external stimulation and were not specific to pain.

It is only with recent advances in machine learning that more accurate and fine-grained multivariate pain-predictive patterns could be devised.[22] Machine learning departs from traditional statistics by assessing the prediction accuracy on a different subpartition of the data than that used for developing the predictive model. From this perspective, predictive models can be said to be "trained" to minimize their out-of-sample error, thereby maximizing the prediction accuracy for new unseen data points.[23] This makes machine learning an ideal technique for optimizing the predictions of individual patients. Before being applied to pain, machine learning has already been used in cognitive neuroscience to make different types of predictions based on patterns of brain activity, such as identifying which letters participants are seeing[24,25] or the content of their dreams.[26] Using a similar approach, Wager et al.[27] developed an fMRI-based brain signature to predict the pain produced by thermal stimuli of different intensities (Fig. 10.2). This signature pattern, called the neurologic pain signature (NPS), also proved to be highly sensitive to the presence of diverse types of pain in new individuals tested on different scanners. The NPS also distinguished pain from other salient and unpleasant events, such as social rejection,[28] or vicarious pain.[29] Finally, although the NPS was shown to be highly sensitive to pain caused by the intensity of noxious inputs, it appeared to be insensitive to the impact of psychological interventions, such as cognitive self-regulation.[30]

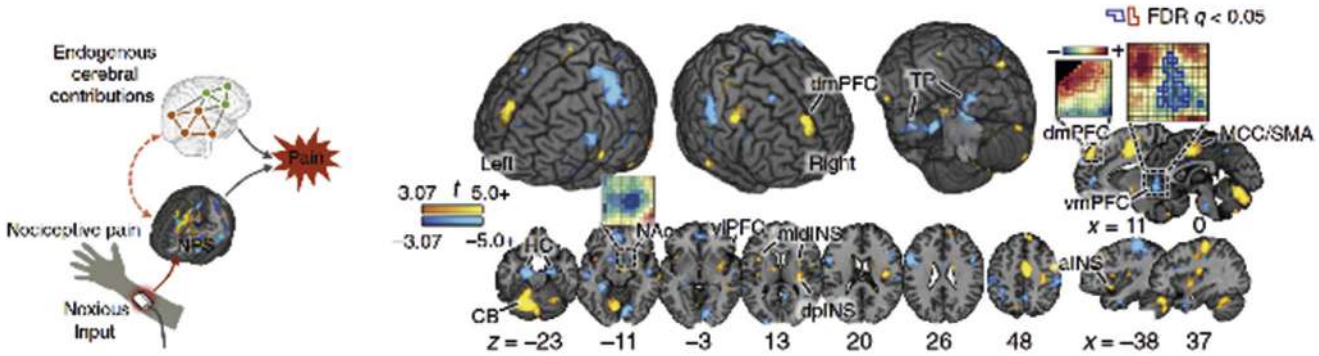
To capture the additional, non-nociceptive source of variation in pain ratings, a second signature was trained to predict pain after controlling for stimulus intensity and NPS pattern expression. The resulting signature, called the stimulus intensity independent pain signature (SIIPS; Fig. 10.3), was shown to explain approximately 16% of the variation in pain ratings for single pain trials, which is comparable to the variance explained by the NPS. When combining both signatures, predictions account for 25% of the explained variance for single trials and over 80% of the explained variance when averaging over several trials. Eventually, other signatures were also trained to predict social rejection,[28] vicarious pain,[29] negative affect,[31] and various other subjective experiences related to pain.[32]



• **Figure 10.2** Neurologic Pain Signature (NPS). A, The NPS pattern. The map shows weights that exceed a threshold (false discovery rate of q<0.05) for the display. Insets stress the importance of multivariate patterns in the three key regions. Adapted from Zaki et al. (2016).[172] B and C, In a separate study, the NPS signature response score tracked the temperature of the stimulation (percentages represent discrimination accuracies between pairs of adjacent temperature levels), as well as subjectively reported pain (100 = pain threshold). Adapted from Wager et al.[27]

Therefore it seems possible to use measures of brain activity to predict the presence of pain or other phenomena closely related to pain.

This new multivariate approach also marks a departure from traditional brain mapping grounded in systems neuroscience. Indeed, instead of tracking pathways that convey nociceptive information from the periphery to the brain, the goal is to identify the patterns of brain activity that may give rise to our subjective experiences of pain. One interesting avenue for understanding mind-brain relationships comes from the field of emotion research, where more recent theories of emotional feelings have stressed the concept of



• **Figure 10.3** Stimulus Intensity Independent Pain Signature (SIIPS). The SIIPS was developed to model endogenous cerebral contributions to pain beyond nociception. Some of the cerebral contributions may interact with nociceptive brain systems (red nodes), whereas others contribute to pain independent of nociceptive processing (green nodes). *Right*, the SIIPS pattern, which is predictive of residual pain ratings after removing the effects of stimulus intensity and NPS response. The map shows thresholded voxel weights (at q<0.05, false discovery rate [FDR]). "degeneracy."[33] Degeneracy refers to the idea that there may be a many-to-one mapping between brain activity and subjective experiences. This suggests that the same subjective experience, such as pain, may be caused by different patterns of brain activity on different occasions.[34] However, this not mean that *any* pattern of brain activity could produce pain, but rather that there can be substantial variation within a restricted set of possibilities. This is what Melzack had initially proposed, and recent research on pain neurosignatures supports this. We may need to abandon our search for a one-to-one mapping between pain and a specific pattern of brain activity, as this concept is likely fundamentally flawed.

Brain Imaging of Chronic Pain

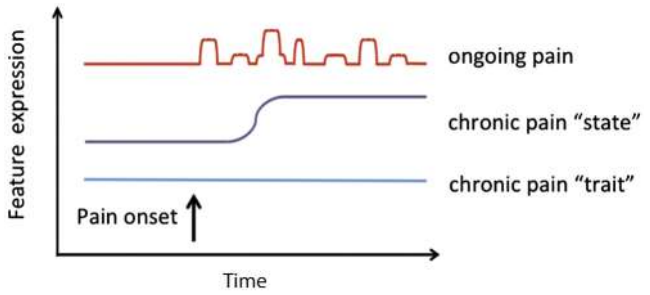
Chronic pain is usually defined as pain lasting for more than six months.[35] It comprises many clinical conditions that can differ on several dimensions: etiology, location, temporal characteristics, intensity, quality, and whether the pain is spontaneous or evoked by certain activities. One important puzzle for clinicians and researchers is that peripheral markers of disease often do not predict subjectively reported pain and associated disability, as observed in osteoarthritis (OA), chronic low back pain (CLBP), or fibromyalgia (FM).[36] Therefore researchers have focused on brain imaging to examine the role of the CNS in the maintenance of chronic pain.

Evoked Pain and Hyperalgesia

The first brain studies of chronic pain were set out to examine the brain activity of patients with chronic pain in response to noxious stimuli. While some studies seem to confirm the idea that certain chronic pain syndromes may be associated with a hyperalgesic state, it is difficult to draw a firm conclusion from these studies.[37–49] One problem is that flexibility in the list of regions comprising the "pain matrix" may have rendered the hypothesis of increased activity in the pain matrix difficult to falsify.[50] Still, it is fair to assume that the cerebral processing of nociceptive stimuli can be influenced by the state of the brain that receives these noxious inputs.[51] In a pioneering study, Baliki et al.[52] found that patients with CLBP have reduced nucleus accumbens (NAc) responses to painful stimulus offset. More recently, Callan et al.[53] used machine learning techniques to classify CLBP versus healthy controls with 92.3% accuracy based on their brain responses to painful electric shocks. Interestingly, brain responses to nonpainful stimuli can sometimes differentiate patients from controls. For instance, it has been proposed that patients with FM also experience multisensory hypersensitivity. Consequently, brain responses to stimuli from other sensory modalities, such as visual stimuli, can be used to distinguish patients with FM from healthy controls with 82% accuracy.[54] Moreover, combining responses to visual and mechanical stimuli increases classification accuracy up to 93%, suggesting that there may be virtue in combining responses to different kinds of tasks or stimuli.[55] Altogether, this suggests that stimulation paradigms can potentially provide a way to classify patients based on their brain's response to external stimuli.

Chronic Pain "State" vs. "Trait"

Structural MRI. Several studies have observed various structural alterations in the brains of patients with chronic pain compared to healthy controls. In a meta-analysis of 23 early volumetric studies conducted prior to 2011 and covering over 15 different pain disorders, Smallwood et al. found that chronic pain was associated with decreased gray matter volume in more than 30 different brain regions, suggesting that chronic pain may be associated with a widespread decrease in gray matter volume.[56] However, one important recurring question is whether structural differences between patients and controls reflect premorbid traits associated with an increased risk of chronicity (chronic pain "trait"), or if they reflect relatively stable consequences of being subjected to constant uncontrollable pain (chronic pain "state").[57] One way of distinguishing between the two has been to track patients as they transition from acute/subacute (<three to six months) to chronic (>six months) pain. Any brain feature remaining stable throughout the transition likely represents a predisposition, whereas features changing as a function of the transition toward chronic pain might be more reflective of a chronic pain "state" (Fig. 10.4). Using this approach, Vachon-Presseau et al. found that small



• **Figure 10.4** Brain imaging can track different aspects of chronic pain. Different brain features (e.g. volume of a certain region or certain connectivity patterns) can track different aspects of chronic pain. Certain features can track the ongoing subjective feeling of pain, which typically fluctuates over time (red line). Other types of features can track the more diffuse state (purple line) associated with the prolonged presence of recurrent pain episodes. The chronic pain "state" reflects the consequences of pain and may take a certain amount of time to develop. Finally, certain features may reflect more stable "traits" that precede the onset of pain and may confer vulnerability to chronic pain.

hippocampus and amygdala volumes predicted the risk of transitioning from subacute to CLBP, suggesting that it may constitute a predisposition rather than a consequence of the pain.[58]

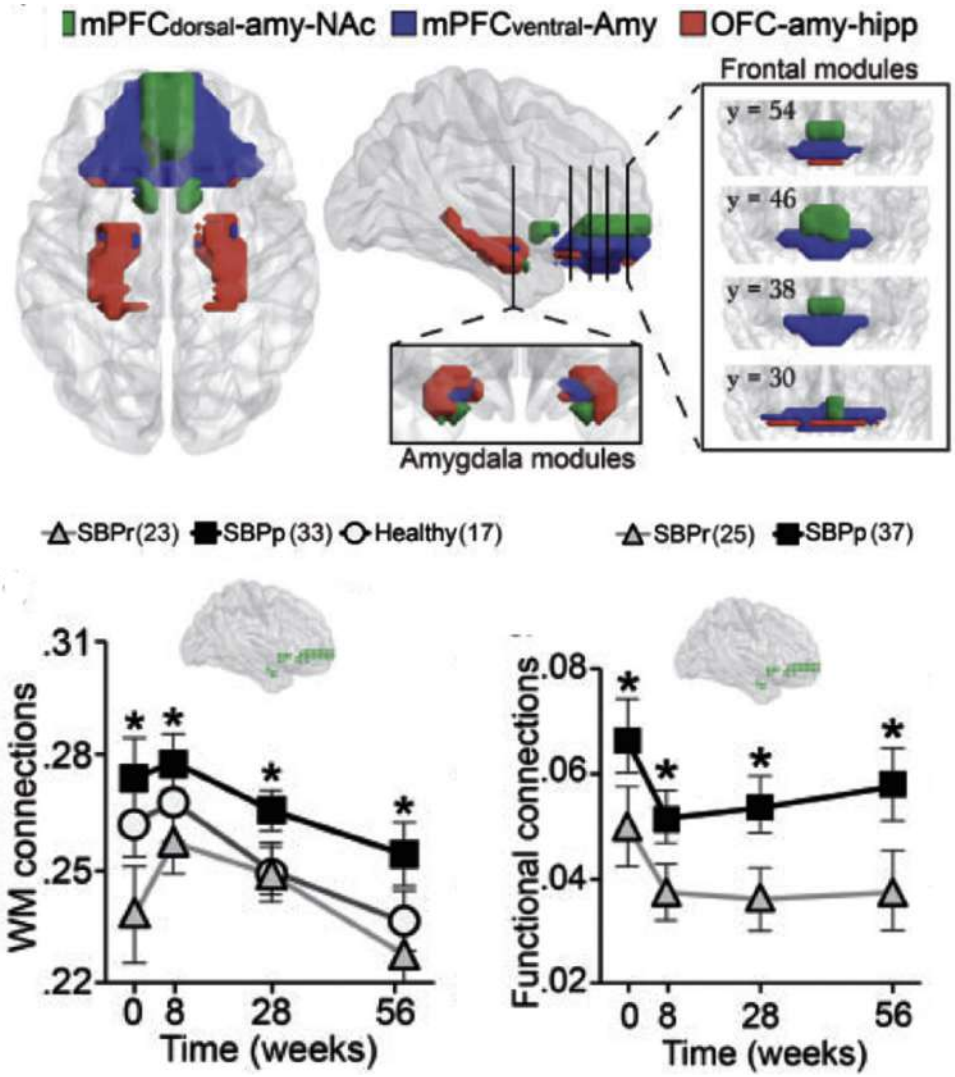
Another strategy used to disentangle chronic pain "trait" vs. "state" has been to track the impact of pain-relieving interventions on the brain: brain features associated with chronic pain "state" should come back to normal following successful pain treatments, whereas brain features associated with chronic pain "trait" should remain unchanged. Using this approach, Seminowicz et al. found that successful treatment with CLBP (surgery or facet joint injections) reversed thinning of the dorsolateral prefrontal cortex (DLPFC).[59] These findings were in part replicated in a study examining the effects of cognitive behavior therapy for CLBP, which also observed increases in DLPFC volume as well as in the volume of the hippocampus and several parietal and frontal areas.[60] Finally, the last approach to disentangle chronic pain state vs. trait could be to experimentally induce chronic pain, a procedure that can only be performed in animal models of chronic pain. Using this approach, Seminowicz et al.[61] found that a spared nerve injury (SNI) rat model of chronic pain was associated with thinning of the prefrontal, entorhinal, and retrosplenial cortices, corroborating the results obtained in patients. Altogether, these findings suggest that reductions in prefrontal brain volume associated with chronic pain could largely be a consequence rather than a cause of pain chronicity.

When using machine learning to devise structural brain signatures of chronic pain, prediction accuracies tend to remain relatively modest (i.e. between 70% and 76%). Moreover, predictive patterns differ widely between studies examining various chronic pain syndromes such as CLBP,[62] chronic pelvic pain,[63] FMS,[64] irritable bowel syndrome,[65] dysmenorrhea,[66] and migraine.[67] Alterations in the medial prefrontal and somatosensory cortices seemed to predominate in most predictive patterns. These findings are similar to those of the previously mentioned volumetric meta-analysis, which also reported a widespread reduction in gray matter in patients with different types of chronic pain.[56] A more parsimonious explanation of these findings could be that these diffuse alterations in gray matter reflect accelerated brain aging. This hypothesis was recently confirmed by applying a validated brain signature of aging to a sample of patients with chronic pain.[68,69] An important avenue for future research is to try to understand what drives these structural changes. As mentioned previously, rodent models of chronic pain could provide useful information for understanding structural brain changes resulting from chronic pain.[61]

Resting state connectivity While there has traditionally been sustained interest in the structural brain features associated with chronic pain,[56] the field has recently witnessed an important shift toward functional connectivity-based markers of chronic pain. This reflects a more general tendency in brain imaging studies of neuropsychiatric conditions, which have found that resting state connectivity data contain useful information for classifying various conditions such as Alzheimer's disease or schizophrenia.[22] During a resting state scan, blood-oxygen level dependent (BOLD) activity is measured while participants rest in the scanner, typically for durations of 5–30 min. Brain activity is then extracted from a hundred or so functional sub-regions of the brain, which are called parcels. Finally, the temporal time-course of BOLD activity in each parcel is correlated with all other parcels to produce connectivity maps or connectomes, which can be diagnostic of certain brain conditions. This approach has demonstrated that patients with chronic pain display increased connectivity between limbic structures (striatum, amygdala, hippocampus) and orbito- and medial prefrontal cortices (Fig. 10.5).[70,71] Moreover, these patterns of altered connectivity have been shown to be stable in time and to predict the transition from subacute to chronic pain, suggesting that they may reflect stable "traits" conferring a higher risk of developing chronic pain. One possibility could be that limbic-prefrontal connectivity predisposes individuals to various kinds of stress-related disorders, of which chronic pain is one instance.[50]

Similar connectivity-based signatures have also been developed for the diagnosis and prognosis of other painful conditions, such as functional dyspepsia,[72,73] rheumatoid arthritis, FM,[74] migraines,[75] neuropathic pain,[76] or chronic pelvic pain.[77] However, because these different studies employed different analytical techniques or tried to make slightly different predictions, it is difficult to draw any general conclusions regarding commonalities and differences between their findings. To identify predictive patterns that are common across pain conditions, Baliki et al. used the same analysis pipeline to directly compare predictive signatures for CLBP, OA, and complex regional pain syndrome (CRPS).[78] Altered connectivity between the mPFC, ACC, and insula was common to all conditions, consistent with the idea that it might reflect a more general vulnerability trait. In contrast, each condition was associated with a unique profile of altered connections with cortical areas that could reflect the disease-specific consequences of persistent pain. In support of this hypothesis, Mansour et al.[79] observed that CLBP, OA, CRPS, and a rodent SNI model of chronic pain all displayed a global disruption in brain connectivity patterns, which seems to follow the onset of chronic pain.

Finally, one of the most promising applications of brain imaging could be its use in precision medicine, that is, the customization of treatment as a function of the patient's individual characteristics. For instance, in the case of depression, Drysdale et al. used resting state fMRI (rsfMRI) to cluster depressed patients into four biotypes, one of which was associated with higher chances of successful treatment by transcranial magnetic stimulation.[80] In the case of pain, an early study by Wanigasekera and colleagues tried to predict opioid analgesia in a sample of healthy individuals subjected to painful thermal stimulation.[81] They found that trait reward responsiveness and brain responses to noxious stimuli in the rostral ACC, orbitofrontal cortex (OFC), amygdala, hippocampus, caudate, NAc, and ventral tegmental area predicted the effect of remifentanil



• **Figure 10.5** Functional and structural connections predicting transition from acute to chronic pain. *Top.* Modularity analysis performed on prefrontal-subcortical networks identified three sub-systems: (i) dorsal medial PFC-amygdala-nucleus accumbens (mPFCdorsal-amy-NAc); (ii) ventral medial PFC-amygdala (mPFCventral-Amy); and (iii) orbitofrontal cortex-amygdala-hippocampus (OFC-amy-hipp). *Bottom.* Functional and white matter connections in the mPFC-dorsal-amy-NAc sub-system differentiate subacute back pain patients who will remit (SBPr) from those who will persist (SBPp). Differences between SBPr and SBPp patients were present at time zero (duration of pain < six months) and remained stable over time. Adapted from Vachon-Presseau et al.[58]

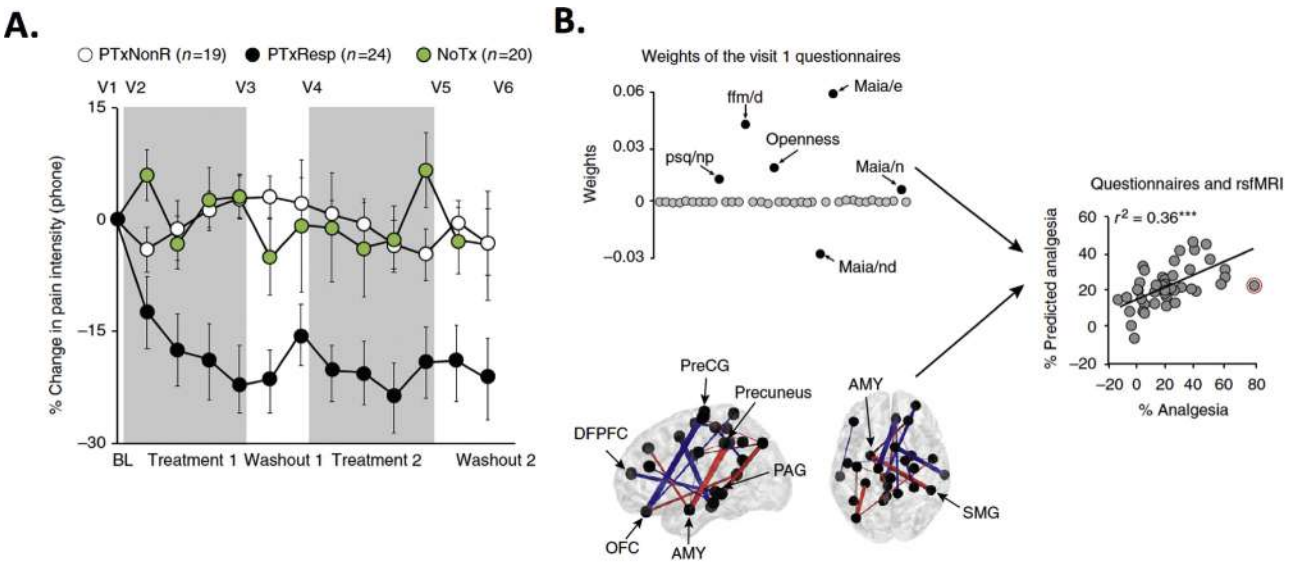
on thermal pain. More recently, Vachon-Presseau et al. combined questionnaire data and structural and resting state fMRI to predict placebo analgesia in a sample of patients with CLBP. They found that subcortical limbic volume asymmetry, sensorimotor cortical thickness, functional coupling of prefrontal regions, ACC, and periaqueductal gray (PAG), as well as psychological traits related to interoceptive awareness and openness, could predict the presence of a placebo effect with an accuracy of 0.72 (Fig. 10.6).[82] Importantly, brain imaging contributed predictive information that was not present in the questionnaire data and could therefore have an added value in precision medicine for chronic pain.

Ongoing Pain

The last important aspect of chronic pain that has proven particularly difficult to capture is the pain itself, that is, the ongoing feeling of pain that patients may experience at any given moment. In a recent study, Wasan et al. employed arterial spin labeling (ASL) to measure brain perfusion before and after CLBP patients engaged in "clinical maneuvers" (such as straight leg raises or pelvic tilts) designed to exacerbate patients' pain.[83] The pain produced by the maneuvers was associated with increased perfusion in the S1, S2, anterior insula, and medial and dorsolateral PFC. A relatively similar approach was recently used with resting state fMRI by Lee and colleagues.[84] They began by devising a connectivity-based signature that predicted the tonic pain state induced by the oral administration of capsaicin. Then, in the second step, they applied this tonic pain signature, or ToPS, to two other data sets of patients with CLBP and found that the ToPS could reliably distinguish patients from controls and predict subjectively reported low back pain (Fig. 10.7). This suggests that the ToPS was in part capturing the patient's ongoing back pain. The most reliable positive weights of the signature (i.e. higher pain with increasing connectivity) were found in the connections between the somatomotor network (SMN), the frontoparietal network (FPN), the visual network, and the dorsal attention network, which seems to suggest the importance of multisensory integration,[85] and top-down attention processes in tonic pain.[86] The most reliable negative weights (i.e. lower pain with increasing connectivity) were found in the limbic and paralimbic cortical regions (limbic network, LN) and BS, indicating the importance of context processing,[87] and the involvement of descending pain modulation.[88]

Positron Emission Tomography

PET is a brain imaging technique that uses radiolabeled tracers to measure brain metabolism or receptor availability. As mentioned above, the first brain imaging studies of pain used PET



• **Figure 10.6** Brain predictors of placebo analgesia. *Left.* Participants were administered a placebo pill for two periods of 14 days (treatment one and two in *gray*), each followed by a washout period of seven days (washout one and two in white). Placebo responders (*black circles)* displayed reduced pain over the course of the study compared with non-responders (*white circles*) or controls receiving no treatment (*green circles*). *Right.* Questionnaire data (top) and functional connectivity data (*bottom*) combined can predict 36% of the variance in placebo analgesia. In the top figure, *black dots* on the top represent questionnaires that significantly contributed to the prediction. *Maia*, Multidimensional assessment of interoceptive awareness; e, emotional awareness subscale; n, noticing subscale; nd, not distracting subscale; ffm/d, five-facet mindfulness/description; psq/hp, pain sensitivity questionnaire/high pain; openness, openness subscale from the NEO Five Factor Inventory. with radiolabeled water molecules (H_2O)[15] to measure changes in regional blood flow (rCBF) in response to pain.[89–91] However, PET was soon replaced by fMRI, which had better spatial and temporal resolution and did not require the injection of radioactive tracers. Subsequent PET studies capitalized on PET's unique ability to measure various neurochemical processes, notably opioid and dopamine receptor availability. Because the production of most of these tracers requires a cyclotron facility near the PET scanner, only a few sites in the world can conduct this type of research. Moreover, because the costs of PET imaging are high (approximately $1000–$3000 per scan depending on the tracer), sample sizes tend to be relatively low (often <20 participants). Consequently, PET appears to be a promising yet underutilized brain imaging technique.

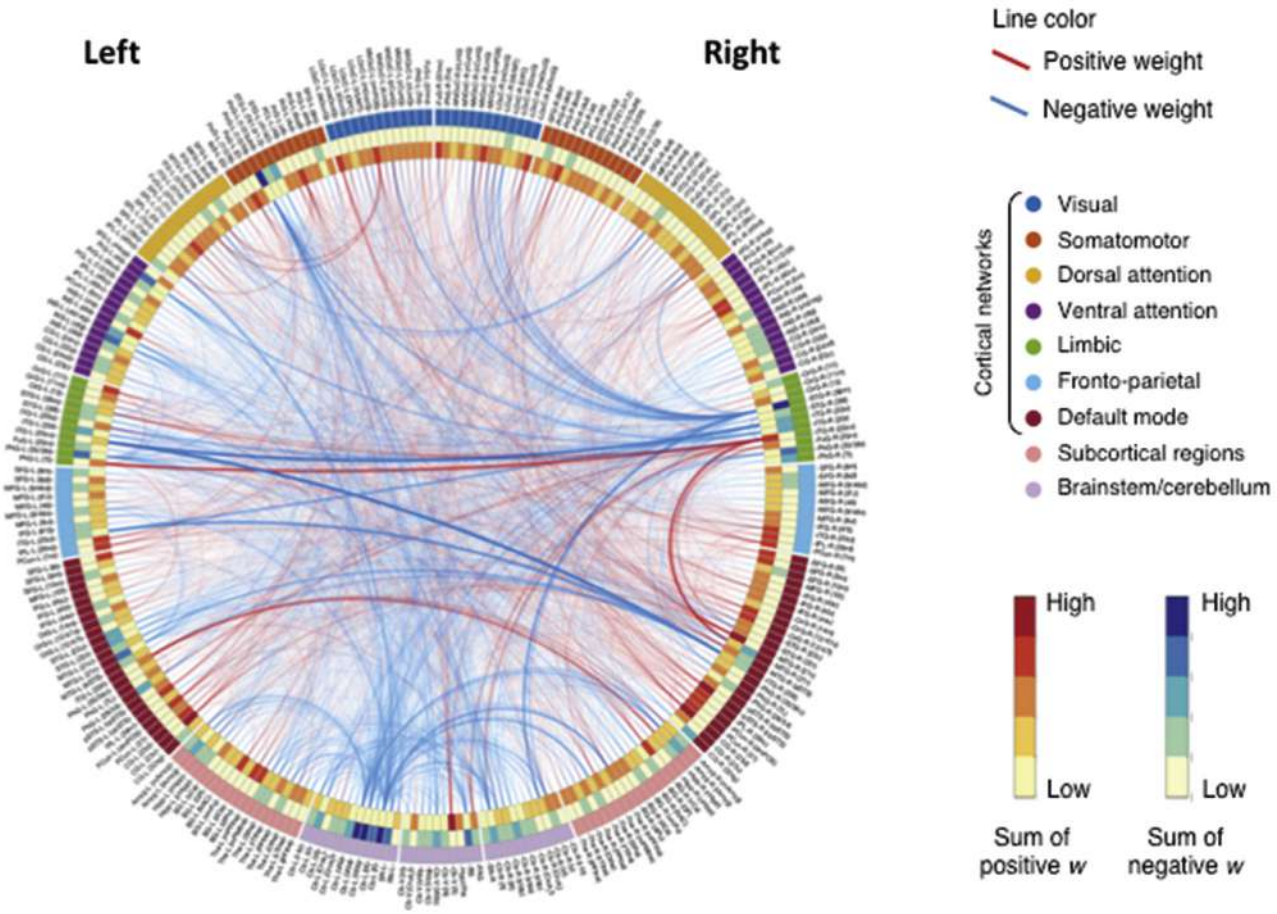
The earliest PET studies of the opioidergic system employed selective μ-opioid radioligand [11C]carfentanil to measure changes in μ-receptor availability in response to tonic pain induced by the administration of topical capsaicin,[92] or injection of 5% hypertonic saline in the masseter muscle.[93] Both studies showed that pain induces the release of endogenous opioids in several brain regions, including the contralateral thalamus, amygdala, hypothalamus, Ins, ACC, and DLPFC. Interestingly, it seems that the degree of release of endogenous opioids by pain is inversely correlated with experienced pain,[93] suggesting that acute pain triggers the release of endogenous opioids, which in turn inhibits pain. Supporting evidence for this hypothesis came from a more recent PET-fMRI study showing that the release of endogenous opioids in the thalamus was associated with reduced BOLD activity in the same region.[94]

Early on, researchers also observed substantial interindividual variability in both μ-opioid receptor availability and in the activation of the μ-opioid system, which could in part be linked to different catechol-O-methyltransferase (COMT) gene polymorphisms.[95] COMT is an enzyme that metabolizes catecholamines and may indirectly affect opioid neurotransmission. Met/met carriers, who have lower COMT activity and higher pain sensitivity, display lower pain evoked μ-opioid activation in the thalamus, NAc, and pallidum, suggesting a lack of endogenous pain inhibition. PET could therefore help identify the cerebral mechanisms associated with genetic predispositions toward chronic pain in a way that may inform future therapeutic interventions.

A few studies have examined the state of the opioid system in various chronic pain disorders, such as arthritis,[96] central post-stroke pain,[97] and FM.[98] These studies have shown that chronic pain is associated with a decreased availability of opioid receptors in several brain regions involved in the perception and regulation of pain, such as the thalamus, amygdala, PAG, cingulate cortex, Ins, PFC, and parietal cortex (Fig. 10.8b). Moreover, in the study by Harris et al. on FM,[98] decreased receptor availability in the NAc was associated with increased pain ratings, a result that was replicated in a sample of patients with neuropathic pain.[99]

However, one recurring question with PET concerns the interpretability of binding potential: decreased receptor availability can either be because of a reduced number of receptors or to an increased level of endogenous neurotransmitters. To address this issue, Thompson et al. combined PET imaging with immunochemistry in a rat model of neuropathic pain and showed that decreased receptor availability is because of a reduced expression



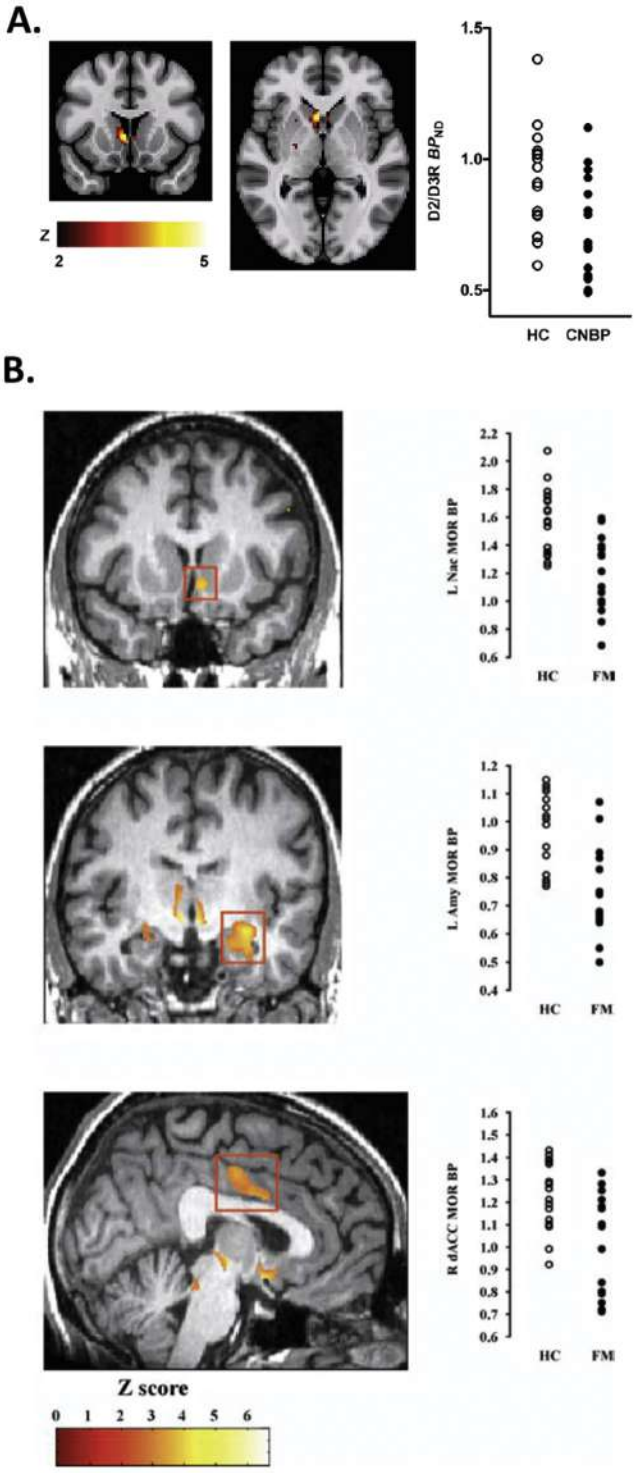
• **Figure 10.7** Tonic pain signature (ToPS). The pattern of functional connections that make the ToPS. The ToPS was trained to predict the pain produced by the oral administration of capsaicin and was found to be generalized to CLBP. The *outer circle* represents the different brain parcels used for the development of the ToPS as a function of the functional networks to which they belong (see the color code in the legend on the right). *Inner circles and lines* represent positive (warm colors) and negative (cold colors) connections, which significantly contribute to the ToPS. Lee JJ, Kim HJ, Čeko M. et al. A neuroimaging biomarker for sustained experimental and clinical pain. *Nat Med*. 2021;27:174–182. https://doi.org/10.1038/s41591-020-1142-7.[173]

of μ-opioid receptors.[100] Altogether, these results indicate that chronic pain is associated with reduced μ-receptor availability, which may compromise the brain's ability to regulate pain, and could explain the reduced efficacy of opioid therapy in many patients with chronic pain.

Several lines of evidence also suggest that dopaminergic system dysfunction may be associated with chronic pain. As mentioned above, genes involved in dopaminergic regulation seem to be predisposed to greater pain sensitivity.[101] Moreover, functional connectivity within the mesolimbic dopamine system (NAc-MPFC) has been repeatedly shown to be altered in patients with chronic pain.[58,51] PET studies using [11C]raclopride in healthy individuals have repeatedly shown that striatal D2/D3 receptor availability tends to be negatively correlated with pain sensitivity, suggesting that high synaptic endogenous dopamine tone might contribute to pain inhibition (but see [108] for contradictory findings).[102–105,106,107]

However, the relationship between dopamine receptor availability and chronic pain is more complex. Pain conditions that are primarily of neural origin, such as restless leg syndrome,[109] Parkinson's disease,[110] burning mouth syndrome,[111] and migraines in the ictal phase,[112] seem to be associated with an increased baseline availability of striatal dopamine D2/D3 receptors. In contrast, non-neurologic pain conditions, such as FM[107,108] and chronic back pain,[113] seem to be associated with a decreased baseline availability of striatal dopamine D2/D3 receptors, as well as a decreased pain induced dopamine response (Fig. 10.8a).[107,113] However, as for endogenous opioids, it is unknown whether decreased receptor availability in those conditions is related to increased dopamine release or reduced receptor density.

As mentioned previously, another important question concerns whether differences between patients and controls reflect stable traits predisposing people toward chronic pain or consequences of being in pain. While increased receptor availability in neurological disorders such as burning mouth or restless leg syndrome seems to contribute to the etiology of the condition, it is probable that reduced receptor availability in musculoskeletal disorders such as CLBP reflects the consequences of prolonged pain. One interesting possibility could be that dopaminergic dysfunction in these chronic pain syndromes is related to a general "illness response" whereby sustained pain causes systemic inflammation, which in turn reduces dopaminergic signaling to promote rest and recovery.[115] This could explain the gradual appearance of the different comorbidities that often accompany chronic pain: widespread pain, fatigue, cognitive deficits, anhedonia, and depression.[114]



• **Figure 10.8** Positron emission tomography (PET) studies of chronic pain. A, Levels of striatal D2/D3 receptor binding potential (BP_{ND}) in chronic non-neuropathic (CNBP) patients and healthy controls (HC). Significant reductions in D2/D3 receptor BP_{ND} compared with HC samples were observed in the right ventral striatum. Adapted from Martikainen, et al. (2015).[113] B, Levels of the μ-opioid receptor (MOR) binding potential (BP) in chronic non-neuropathic (CNBP) patients and HC. Significant reductions in MOR BP compared with HC sample were observed in the left ventral striatum (*top*), left amygdala (*middle*), and right dorsal anterior cingulate cortex (dACC; *bottom*). Note that images are displayed in radiological convention where the left hemisphere is shown on the right side of the image. Adapted from Harris et al.

While the exact sequence of events remains to be determined, the recent development of certain markers of glial activation, which bind to the translocator protein (TSPO), has allowed to observe increased glial activation in the thalamus and somatosensory cortex of patients with CLBP.[115] Moreover, TSPO expression in the ACC/PFC and Ins has been shown to correlate with depressive symptoms associated with chronic pain.[116,117] Finally, a recent multi-site study of patients with FM fibromyalgia also showed increased TSPO expression in the parietal, somatosensory, and motor cortices. Despite the several caveats associated with TSPO imaging,[119] these results indicate that neuroinflammation may be associated with certain pain states such as CLBP or FM.

Electroencephalography

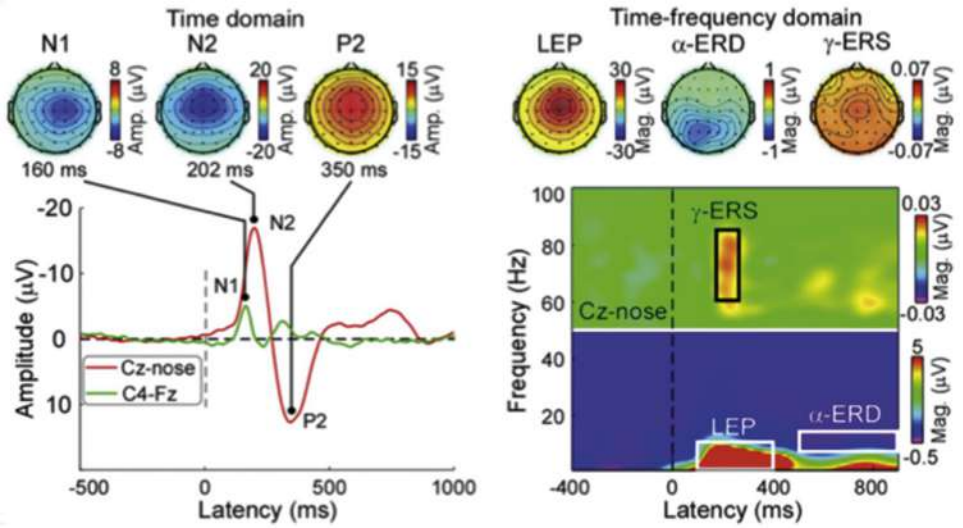
Electroencephalography (EEG)[119] and magnetoencephalography (MEG)[120] are direct and non-invasive measures of brain function. While EEG measures the small electrical currents resulting from postsynaptic potentials, MEG measures the magnetic fields induced by these currents. The major strength of both methods is their high temporal resolution in the range of milliseconds. Thus EEG and MEG perfectly complement fMRI, which has an excellent spatial but lower temporal resolution. A particular strength of EEG is that it is cost-effective, broadly available, and mobile. Thus EEG lends itself to broad clinical use. The limitations of EEG are its low spatial resolution and insensitivity to processes in deep brain areas. As magnetic fields are not distorted by the scalp and skull, MEG has a higher spatial resolution than EEG. The downside of MEG is that it is technically more demanding, more expensive, rarely available, and stationary. However, novel sensor types of MEG might render it more cost effective and mobile in the future.[121] In the following sections, we will use the term "EEG" for convenience, but most parts apply similarly to MEG.

EEG Measures of Acute Experimental Pain

The most popular EEG approach to pain is the assessment of evoked potentials in response to brief noxious stimuli, such as thermal laser stimuli of milliseconds duration.[122] This approach yields a typical sequence of responses that are termed N1, N2, and P2,[122] based on their sequence and polarity (Fig. 10.9). Source localization of EEG recordings and intracranial recordings have shown that these responses originate from core areas of the brain network associated with pain processing, that is, from S1, the operculo-insular region, the aINS, and the cingulate cortex.[123,124] The analysis of evoked potentials yields two main readouts: the latencies and amplitudes of the different responses.

The amplitudes of evoked potentials have been shown to vary with objective stimulus intensity and subjective perception of pain under many different experimental conditions.[125] However, innovative paradigms have revealed that the relationship between evoked potential amplitudes and pain is not one-to-one.[126] Instead, evoked potentials are currently thought to reflect the importance[127] of noxious stimuli and defensive actions rather than pain.[128] Thus the initial hope that evoked potentials represent a reliable biomarker of pain has not been answered. Evoked potentials are sensitive to damage to nociceptive pathways. Thus they have been established as a clinically useful measure of the integrity of nociceptive pathways in the brain.[129,130]

Time-frequency analyses complemented and extended the evoked potential approach. These analyses have revealed that brief noxious stimuli modulate neuronal oscillations at α (8-13 Hz), β (13-30 Hz), and γ (40-100 Hz) frequencies (Fig. 10.9) that partially



• **Figure 10.9** EEG Measures of acute experimental pain. *Left*, Time-domain analyses of EEG data show the temporal sequence of evoked potentials in response to painful stimuli, including N1, N2, and P2. *Right*, time-frequency analyses of M/EEG data show induced responses at α (a-ERD) and γ (g-ERS) frequencies in response to painful stimuli. Adapted from Hu & Iannetti.[174]

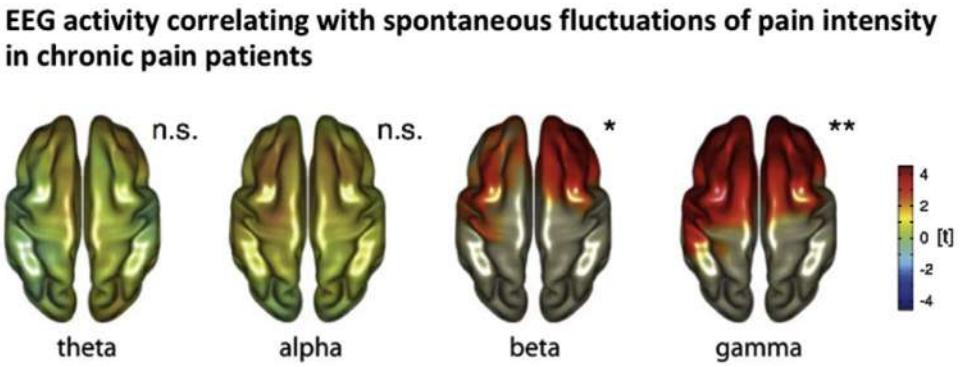
overlap in time and space with the evoked potentials.[131–133] In particular, γ oscillations originating from S1 are closely related to the subjective experience of pain.[134] This close relationship has been observed during spontaneous variations of pain as well as during experimental manipulation of pain in animals and humans.[133,135,136] Recent optogenetic inductions of γ oscillations in mice have demonstrated that they are indeed casually related to pain.[137] It has been shown that γ oscillations in the S1 yield network effects in the PFC and subcortical brain areas. Thus γ oscillations are the EEG responses most closely related to pain. However, this relationship is not one-to-one. For instance, during placebo manipulations, the dissociation of γ oscillations and pain has been found.[138] This dissociation might reflect that γ oscillations could be more closely related to behavioral responses to noxious stimuli than their perception.[139] Thus similar to the lack of a certain brain area encoding pain, no single brain response determines pain at a certain latency or frequency. Instead, pain is most likely encoded by complex patterns of brain activity, which include not only neuronal activity in different brain areas but also brain activity at different latencies and frequencies.

Finally, novel paradigms of experimental pain have extended the EEG-based assessment of pain from brief noxious stimuli to longer-lasting tonic stimuli as a first step toward the main clinical problem of ongoing pain.[140–144] The results showed that tonic pain is associated with decreases and increases in brain activity at α and γ frequencies, encoding objective stimulus intensity and subjective pain intensity, respectively. Moreover, the patterns of brain activity during tonic noxious stimulation fundamentally differ from those of brief noxious stimuli, with a shift from the encoding of pain intensity by activity in multiple frequency bands in somatosensory cortices to an encoding by γ oscillations in the PFC.[140,141,143] This again highlights the important role of γ oscillations in the brain processing of pain. Moreover, it shows that insights into the brain mechanisms of brief experimental pain cannot easily be transferred to longer-lasting pain, including chronic pain states.

EEG Measures of Chronic Pain

Although EEG is available in nearly every neurology office and department, evidence on the EEG correlates of chronic pain is surprisingly limited.[145,146] To date, two different EEG approaches have been investigated. The first uses the evoked potential approach to investigate whether the processing of painful or non-painful stimuli is abnormal in chronic pain. The results show that damage to nociceptive pathways in neuropathic pain is associated with a reduction in evoked potentials.[130,146] Other abnormalities such as a disinhibition or lack of habituation of evoked potentials in some chronic pain conditions such as migraine or FM are not consistently found.[146] Moreover, it remains unclear how these findings relate to the basic pathology of chronic pain and phenomena such as central sensitization.[147]

The second approach quantifies ongoing EEG activity during the resting state in patients with chronic pain. The earliest finding was a slowing of α activity and a widespread increase in brain activity at θ frequencies (3-8 Hz).[148,149] Together with evidence from thalamic recordings,[150,151] these observations have motivated the thalamocortical dysrhythmia model of chronic pain.[152] In this model, abnormal nociceptive input yields abnormal thalamic bursts at θ frequencies. These θ oscillations are transmitted to the cerebral cortex, which results in disinhibition of neighboring areas, which in turn results in abnormal oscillations at γ frequencies and eventually in ongoing pain. This model is highly appealing, but the evidence is inconsistent. While some studies in animals provided further support for the model,[153,154] other EEG studies in larger cohorts of patients did not find abnormal θ activity.[155,156] However, a recent resting state EEG study in a large cohort of patients indicated that patients with chronic pain had higher prefrontal γ oscillations and global network reorganization at γ frequencies.[156] Other EEG studies have shown further changes in brain oscillations and connectivity within and across intrinsic brain networks at θ, α, β, and γ frequencies in patients suffering from different types of chronic pain.[157,158] Thus accumulating evidence implicates complex changes in brain network function, particularly oscillations and connectivity at γ frequencies in the brain mechanisms of chronic pain. This is further supported by the recent observation that the momentary intensity of chronic pain was positively related to γ oscillations in the PFC (Fig. 10.10).[159] However, owing to their low signal-to-noise ratio and sensitivity to artifacts from muscles, the assessment of pain-related gamma oscillations using EEG remains challenging.



• **Figure 10.10** EEG Measures of chronic pain. Topographies of the correlation of neural oscillations with spontaneous fluctuations of pain intensity in patients with chronic back pain. Neural oscillations over the prefrontal cortex at β and γ frequencies are significantly related to pain intensity. (May et al.)[160]

Other recent studies did not directly address the EEG correlates of chronic pain, but investigated whether EEG signals can predict an individual's response to analgesic treatment and/or sensitivity to pain. First, results have revealed that some EEG features, such as the amplitude of delta (1-3 Hz) activity during tonic pain, can predict treatment success (e.g. the responsivity to post-surgical opioid treatment).[160–162] Other studies have indicated that the individual peak frequency of sensorimotor α oscillations relates to an individual's sensitivity to experimental pain.[163,164] In particular, the lower the peak α frequency, the higher is the sensitivity to pain. As sensitivity to pain represents an important predictor of chronic pain, the analysis of α oscillations and their peak frequency represents an appealing and clinically useful direction for future studies.

EEG for Clinicians: Current State and Future Perspectives

EEG using the evoked potential approach is the first clinically useful measure of pain-related brain activity. The approach objectifies damage to nociceptive pathways, thereby helping to establish a diagnosis of neuropathic pain. Consequently, it has been included in the guidelines for the assessment of neuropathic pain.[130] While other EEG measures are not yet ready for clinical use, the first steps have been made toward the development of clinically useful biomarkers of pain.[165] Such biomarkers could be diagnostically useful when verbal reports are not available or reliable. Moreover, they could help predict and classify chronic pain and tailor individual treatment. In addition, EEG-based biomarkers of chronic pain could represent direct targets of pain therapy. For instance, abnormal EEG patterns might be modulated by neurofeedback,[166] non-invasive brain stimulation,[167] or sensory entrainment approaches,[168] which can selectively alter neuronal oscillations at certain frequencies. As EEG is broadly available, potentially portable, and can easily be used in medical offices or at home, an EEG-based biomarker of pain is particularly appealing. The integration of EEG-based information with other measures resulting in multimodal composite biomarkers of pain might further enhance the clinical usefulness of such biomarkers.[169]

Conclusion and Future Directions

The subjective experience of pain is a product of brain activity. Therefore any biologic explanation of pain will have to ultimately explain how it is generated by the brain. Intuitively, it seems that nociceptive signals coming from the periphery should ultimately reach a "pain center" in the brain where the subjective experience of pain is generated. However, decades of brain imaging research suggest that there is no one-to-one relationship between pain and any pattern of brain activity. Unlike other senses, there does not seem to be a brain region or set of brain regions specifically dedicated to pain processing.[34] Rather, pain seems to be encoded by distributed fine-grained patterns of brain activity spanning several brain areas. In that respect, the cerebral representation of pain might be more similar to that of emotions.[33] Indeed, the concept of pain appears to regroup various sensations designed to have a protective function. Recent advances in machine learning have allowed the development of multivariate pain neurosignatures,[27,170] that can reliably predict pain based on brain activity. However, these neurosignatures should not be interpreted as unique and inflexible pain-predictive patterns. They are quite the contrary: neurosignatures represent vast multivariate patterns within which various, and sometimes even quite distinct, patterns of brain activity can equally represent pain. Altogether, recent advances in fMRI research indicate that there is degeneracy in the relationship between brain activity and pain perception, whereby a diversity of brain activity patterns can equally represent pain within the soft constraints of a few neurosignature patterns, the number of which remains to be determined.

Moreover, several studies have demonstrated that the development of MRI-based biomarkers for various chronic pain conditions is now feasible.[23] Biomarkers can be used for diagnosis, prognosis, prediction of treatment outcomes, and precision medicine as surrogate endpoints to monitor the evolution of the condition or to track treatment efficacy.[23] However, prediction accuracies are still insufficient for practical purposes, and their specificity and generalizability remain uncertain. The main obstacle for the development of chronic pain biomarkers is the current lack of large datasets of patients. For instance, the UK biobank currently comprises close to 15 000 participants reporting chronic pain with brain scans (https://www.ukbiobank.ac.uk/). However, phenotyping is minimal. Researchers can also access existing datasets on openpain.org, an open registry of brain imaging studies. Collectively, these different resources should greatly improve our capacity to develop brain-based biomarkers for chronic pain.

Therefore brain imaging of chronic pain will likely follow the path laid out by other neuropsychiatric disorders, such as Alzheimer's disease, schizophrenia, or depression, in identifying brain markers of disease.[22] However, it is still unclear whether chronic pain constitutes a brain disease in the same sense as these other neuropsychiatric disorders, which could lead the field to face challenges unique to chronic pain. Pain is a subjective experience

generated by the brain. Therefore any biologic explanation for it will inevitably stumble upon the complexities associated with the question of mind-body relationships. Moreover, chronic pain syndromes constitute a heterogeneous category of multisymptomatic disorders, for which pain might not always be the most important or central feature. Therefore it is unclear whether brain imaging can differentiate between different clinical phenotypes or whether it should be attempted to accomplish this. There may be more value in identifying different brain imaging phenotypes rather than simply confirming clinical phenotypes. Indeed, if the principle of degeneracy also applies to chronic pain conditions, then this would mean that different brain phenotypes could underlie the same clinical phenotype, and consequently, different subgroups of patients may benefit from different types of treatment.

Different brain imaging techniques are highly complementary and may serve different purposes. For instance, EEG might prove quite sensitive and easy to administer, but its specificity might be an issue. Therefore it could be well suited to serve as a first screening tool.[171] RsfMRI may be more specific, but the neurophysiologic mechanisms underlying functional networks remain opaque, making it difficult to use rsfMRI to identify new targets for treatment. Multimodal MRI techniques examining different aspects of brain structure (e.g. gray matter density, cortical thickness, subcortical structure volume, diffusion, tractography, perfusion, magnetization transfer, MR spectroscopy) appear to convey information that could eventually be used for developing new therapeutic targets. However, there is a large gap between the indirect indices of brain macrostructure obtained with MRI and the underlying cytoarchitectural processes that could potentially be used as targets for treatments. One potentially promising and currently underexplored avenue for future research could be to combine human and rodent brain imaging to identify the cytoarchitectural changes associated with pain-related plasticity in homologous brain regions. PET may provide more direct information about potential treatments, but high costs and reduced access to facilities capable of producing specific radioligands remain an important limitation. Finally, one exciting recent development has been the creation of pain-predictive neurosignatures, which currently do not have the sensitivity or specificity to be used as clinical tools but could be improved to potentially make clinically relevant predictions.

Overall, the practical contribution of brain imaging to clinical practice remains difficult to assess beyond basic investigations of CNS damage. However, brain imaging techniques have clearly contributed to changing our concept of pain from a symptom of objective tissue damage to that of a subjective experience generated by the brain. In this sense, brain imaging has broadened the historical focus of pain research and treatment of peripheral and spinal mechanisms toward a concept that now embraces peripheral, spinal, and cerebral mechanisms equally.

Key Points

- Early brain imaging research identified a collection of brain regions associated with evoked pain, often referred to as the "pain matrix" (thalamus, ACC, Ins, S1, S2). However, the activity of these structures appears to be relatively unspecific to pain.
- Recent developments in machine learning have allowed the development of more specific multivariate pain-predictive neurosignatures that use fine-grained patterns of brain activity to predict evoked pain.
- The relationship between brain activity and experience pain appears to be characterized by degeneracy, meaning that there is a many-to-one relationship between patterns of brain activity and pain.
- The patterns of activity associated with chronic pain appear to be qualitatively different from those associated with evoked pain.
- Findings from brain imaging research could potentially explain the dissociation between nociception and self-reported pain observed in certain chronic pain syndromes.
- Brain imaging findings of patients with chronic pain can reflect at least three different aspects of chronic pain: (1) stable traits that precede the onset of the painful condition and that confer vulnerability toward pain chronicity, (2) the chronic pain "state," which gradually develops as pain becomes chronic and remains prolonged in time, and (3) ongoing pain, which can fluctuate more rapidly in the range of minutes or hours.
- Provided sufficient data, pain-predictive biomarkers could be developed to make clinically relevant predictions.
- Using EEG for the development of a biomarker of pain is appealing as it is broadly available, cost effective, and potentially mobile. This approach is under development but is not yet ready for clinical use.

Individual Differences in Experience and Treatment of Pain: Race, Ethnicity, and Sex

SAMANTHA M. MEINTS, DIKACHI OSAJI, KYLIE STEINHILBER, ROBERT R. EDWARDS

Though the experience of pain is nearly universal, the experience and burden of pain vary across race, ethnicity, sex, and gender. This chapter will discuss the disparities in the experience and burden of pain and variability in responses to treatment across these groups.

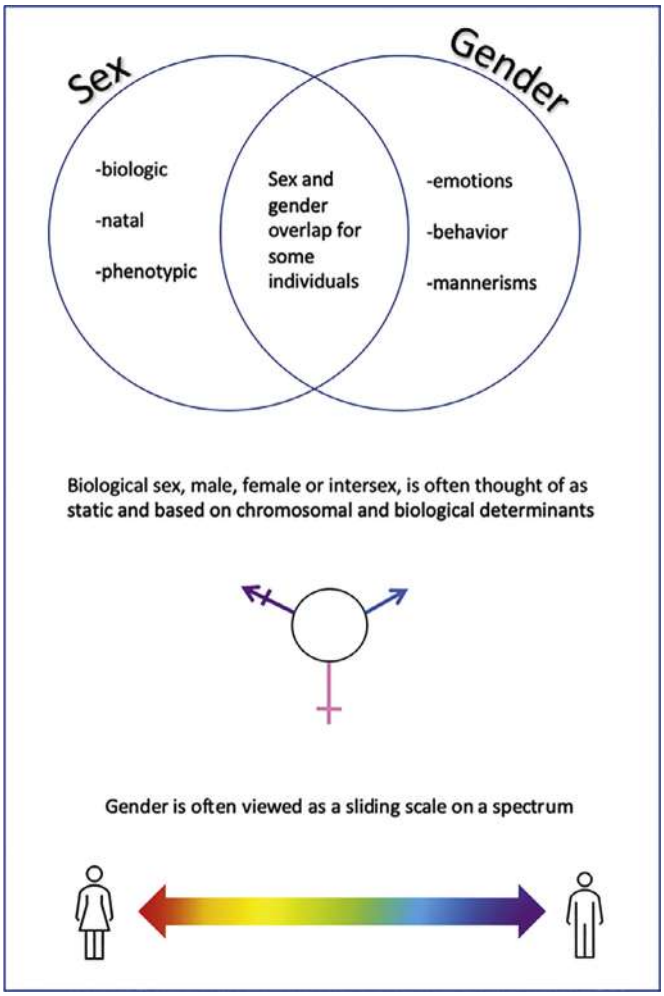
Clarification of Terminology

Race and ethnicity are often used interchangeably in both colloquial language and research. However, these represent two different constructs. Race refers to groups with common descent or heredity, shared physical characteristics, culture, and self-identity [e.g. non-Hispanic White/Caucasian, Black/African American, Asian, Native American/Native Canadian], whereas ethnicity indicates cultural groupings with a common language, religion, nationality, or heritage (e.g. Hispanic/Latinx).[1,2] In this chapter, we will use the term non-Hispanic White (NHW) to refer to anyone of White or Caucasian descent, African American (AA) to refer to anyone of Black or African descent, and Hispanic to refer to anyone of Hispanic descent or who identifies as Latinx. Similarly, sex and gender are not interchangeable. Sex is defined as the biologic phenotype an individual is born with that can be categorized as either male, female, or intersex, while gender is an individual's expression of internal identification that may fall into preexisting social, behavioral norms. Gender consists of a set of cultural behaviors that society has assigned to a specific sex (e.g. cooking is considered a task for women while plumbing is a task for men); thus gender is a social construct. Gender is also viewed on a spectrum between male and female and can evolve throughout one's lifetime. An individual's sex and gender are not always synchronous; therefore an individual may have a natal sex that does not correspond with their expressed gender (see Fig. 11.1). In the current chapter, we will be addressing the influence of race, ethnicity, and sex on the experience, burden, and treatment of pain.

Racial and Ethnic Differences in Pain

Racial and ethnic differences in the pain experience are consistently demonstrated across experimental and laboratory-based studies. In the United States, much of this literature has focused on AA/NHW differences, and the results are not always consistent. In general, research has demonstrated that, compared to NHW individuals, AA individuals are more sensitive to nociceptive stimulation (i.e. lower thresholds) and less tolerant of pain overall,[3] though these results have some variability based on the modalities and outcomes assessed. Groups of NHW individuals demonstrate, on average, a higher cold pain tolerance and provide lower pain ratings (i.e. thresholds) for cold-induced pain than do groups of AA individuals.[3] Although there are not AA-NHW differences in heat-induced pain thresholds, NHW people show a higher heat-induced pain tolerance and provide lower suprathreshold heat pain ratings than AA people.[3] Regarding pressure pain, AAs have lower pressure pain thresholds than NHWs.[4] AAs also have a lower tolerance to ischemic pain than NHWs, though there are no differences in ischemic pain threshold.[2,5] AA participants in experimental pain studies also rate mechanical pricking pain as more intense than do NHW participants in such studies.[6] In addition to these pain sensitivity measures, there are also AA-NHW differences in experimental measures of centralized pain facilitation and inhibitory pain modulation (i.e. temporal summation and conditioned pain modulation [CPM]). AA individuals demonstrate consistently higher temporal summation of pain than NHWs.[6] However, the CPM literature is small and inconclusive; one study found that AAs showed less CPM than NHWs,[5] but other studies found no racial/ethnic differences in CPM.[6]

Although much of the disparities literature has focused on differences between AA and NHW individuals, there is some recent evidence of disparities in experimental pain sensitivity among Hispanics, Native Americans (NAs), and Asians. Asians consistently demonstrate a lower tolerance and higher suprathreshold cold pain ratings relative to comparison groups such as NHW.[7] Hispanics also demonstrate lower pain tolerance and provide greater suprathreshold pain ratings relative to NHWs.[8] Asian and Hispanic people also report lower threshold and tolerance for heat pain.[8,9] However, Asians have a higher pressure pain threshold than AAs.[10] Few studies have compared experimental pain processing between NAs and other groups. Such studies have indicated that AAs reported higher electric pain thresholds and lower pain ratings than NHWs.[11] There were no differences in temporal summation between NA and NHWs.[11] Collectively, the literature on laboratory-based pain assessment suggests that individuals from racial and ethnic minority backgrounds (many of whom have likely experienced substantial discrimination and mistreatment) appears to suggest an overall



• **Figure 11.1** Sex and Gender Infographic. Sex is viewed as a fixed biological trait while gender is an individual's expression.

increase in pain sensitivity among individuals from these minority groups relative to individuals reporting their ethnic/racial background as "White."

Besides racial and ethnic disparities in experimental and laboratory-based pain, there are also considerable differences in the experience of clinical pain conditions. For example, osteoarthritis (OA) is an increasingly common painful musculoskeletal condition. While AAs show a greater likelihood to have both radiographically confirmed and symptomatic OA,[12] NHWs have a higher age-adjusted prevalence of chronic pain overall than do AAs.[13] This difference was negated when the researchers only considered high impact chronic pain (i.e. chronic pain that frequently limits life or work activities).[13] Other studies show quite a different pattern. Numerous studies demonstrated that AAs and other minority groups report more severe acute and chronic pain.[2,6] Compared to NHWs, AAs report more pain from chronic conditions such as AIDS[14] and glaucoma,[15] greater postoperative pain,[16] more pain sites and greater pain severity, depression, and disability, and have poorer outcomes on performance testing that is sensitive to the functional impact of chronic pain (e.g. timed-up-and-go task, 6 min walking test).[2,17,18] Disparities in clinical pain exist between NHW and other minority groups as well. For example, minority patients report more severe low back pain than do NHWs.[19] While Hispanic individuals report fewer pain conditions and experience less pain interference than NHWs, they have more severe clinical pain,[20] Hispanic individuals also report greater postoperative pain.[16] Although studied to a lesser degree, Asians also report greater pain intensity than do NHWs, particularly for knee OA.[21] NAs are also more likely to experience pain complaints than the general United States population.[22,23] Overall, the literature on acute and chronic clinical pain indicates that the experience and adverse impact of pain may be more frequent and severe in groups of individuals from non-White racial and ethnic backgrounds.

Sex and Gender Differences in Pain

Beyond race and ethnicity, the perception and experience of pain also vary as a function of sex. In laboratory settings, women demonstrate lower pain thresholds and tolerance and provide higher pain ratings for mechanical-, electrical-, thermal- (both heat and cold), and chemical-induced nociceptive stimulation than men.[24,25] In addition to these measures of general pain sensitivity, women also exhibit greater central pain facilitation (e.g. temporal summation of pain) and less effective endogenous inhibitory control of pain (e.g. CPM).[26,27] Moreover, women demonstrate a lower threshold for eliciting the nociceptive reflex, an involuntary spinal reflex resulting from electrical nerve stimulation.[28]

Similar sex differences are found for clinical pain. Indeed, large epidemiologic studies across geographic regions indicate that pain is more frequently reported by women than men,[25] women are more likely to seek treatment for pain, and that women consistently report higher pain ratings than men across diagnostic groups.[29] There is a higher prevalence of numerous painful diseases among women. Women are nearly twice as likely to experience neuropathic pain than men.[30] They are also more likely to experience musculoskeletal (MSK) pain and report greater pain severity among MSK conditions[31], across 17 countries and six continents, women had a higher prevalence of MSK pain (45%) than men (31%).[32] This is specifically true for fibromyalgia, back pain, and osteoarthritis-related pain.[33,34] Women are also more likely to report pain across ten different anatomical regions and chronic widespread pain.[35] They are also at higher risk of experiencing abdominal pain such as interstitial cystitis.[36] In fact, there is a 3:1 female-to-male ratio of irritable bowel syndrome (IBS) prevalence.[37] Regarding headaches, women are more likely to experience tension-type headaches and migraines.[36,38] These sex disparities are also prominent in post-procedural pain. Women not only experience greater acute pain following various procedures, including cholecystectomy, hernia repair, colonoscopy, general outpatient surgery, and orthopedic surgeries,[39] but also greater chronic postsurgical pain following total knee arthroplasty (TKA).[40] However, there are no sex differences in chronic postsurgical pain following total hip arthroplasty, gallbladder surgery, or hernia repair.[41–43] There is also no consistent evidence for sex differences in cancer pain.[25] Thus there appear to be discrepancies in sex differences depending on the nature of the pain and treatments received.

Racial and Ethnic Differences in Pain Treatments Provided

It is well documented that racial and ethnic minorities have disproportionately more unrelieved pain than NHWs. This is because of racial and ethnic differences in both the assessment administered

and treatments prescribed for pain across various conditions and settings.

Traditionally, racial and ethnic minorities and other vulnerable groups (e.g. homeless) are more likely to seek and receive care in the emergency department (ED).[44] However, the care they receive in the ED is not equivalent to that received by NHWs. The ED care delivered to individuals from racial and ethnic minority backgrounds is of consistently lower quality, as outlined below. For example, minority groups have longer wait times and are less likely to be admitted as inpatients than NHWs.[45] Minority patients also wait longer to receive pain medications in the ED than do NHWs.[46] Results of a recent meta-analysis including 13 studies of racial disparities in pain care in United States EDs found that AAs were 36% less likely, Hispanics 30% less likely, and Asians 42% less likely to receive analgesics than NHW patients with similar injuries and complaints. Similarly, AAs were 35% less likely and Hispanics 23% less likely than NHWs to receive opioids for acute pain.[47] Moreover, NHWs are 82% more likely than AAs to be discharged with a prescription for analgesics and 98% more likely to be discharged with an opioid prescription.[48] In fact, AAs are less likely to receive opioid prescriptions in the ED than any other group racial or ethnic group.[49] Perhaps this is because providers are more likely to view AA patients as drug-seeking. Indeed, although ED staff perceive only 7%-9% of the general patient population to be opioid dependent, they believe that opioid dependence affects a substantially higher percentage, 13%-17%, of patients with sickle cell disease, a disease that primarily affects AA individuals.[50] Moreover, 22% of ED physicians believe that more than half of patients with sickle cell disease are addicted to opioids despite only 2%-4% actually meeting the criteria for a substance use disorder.[51,52]

Across other treatment settings, AA individuals are twice as likely as other racial and ethnic groups to have their pain underestimated by the physicians.[53] Minority patients are also less likely to be treated in pain clinics and receive comprehensive diagnostic and treatment for pain than NHWs.[54] When minority patients are treated, they receive lower doses of analgesic medications,[55] are less likely to receive opioids, and are less likely to undergo surgical procedures (e.g. joint replacement)[49,56,57] despite having a higher prevalence of painful conditions and reporting higher pain scores.[58]

Sex Differences in Pain Treatment

Much like racial and ethnic minorities, women are at greater risk for the undertreatment of pain. They often receive less treatment, and the treatment they receive is less effective at providing pain relief.[25] In one study in the ED, women were less likely to be prescribed opioid medication than men.[58] Likewise, Hamberg and colleagues found that women with neck pain were more likely to receive non-specific somatic diagnoses and analgesic and psychoactive medication prescriptions, regardless of the sex of the provider.[59] Other studies have found that pain treatment differs because of the interaction between patient and provider sex. In one study, female providers prescribed higher opioid doses for women than men with low back pain, whereas male providers prescribed higher doses for male patients.[60] Another found that female providers were more likely to recommend psychosocial treatments (i.e. anti-depressants and mental health referrals) for female than male pain patients.[25,61] This is consistent with evidence suggesting that women may be more likely to be mistrusted and "psychologized" by their providers, regardless of the sex of the provider.[62] Unfortunately, this only increases distress among female patients that then may contribute to a cycle of chronic pain. While relatively little research has examined the intersectionality of race and sex related to chronic pain, it appears likely that AA women may be at particular risk for undertreatment and for having their pain reports underestimated or dismissed.[63]

Racial and Ethnic Differences in Pain Treatment Outcomes

Beyond disparities in how pain is treated, there are also disparities in treatment outcomes when treatments are provided. Pain interventions (both pharmacologic and nonpharmacologic) may cause disparate analgesic effects based on race, ethnicity, and sex. For example, compared to NHW individuals, AA individuals are not only less likely to opt for surgical treatment options such as a total joint replacement,[64] but when AA individuals do receive treatment (e.g. hip and knee arthroplasty, spinal surgery), they also report greater pain intensity, pain-related disability, and pain frequency than NHW individuals.[65] A retrospective study using data from the Spine Patient Outcomes Research Trial found that of patients with spine disorders those that underwent spinal surgery had an improved outcome compared to those in the nonoperative treatment group.[66] However, of those in the surgical group, the NHW patients reported significantly greater improvement in pain outcomes than the AA patients.

The effect of race and ethnicity on surgical treatment outcomes are subject to the intersectionality of socioeconomic factors. Indeed, Goodman et al.[65] used self-reported and census data to investigate the interaction between race and socioeconomic variables on the outcomes of TKA. They found that worse pain outcomes were associated with race and socioeconomic factors and that AA patients from poorer communities showed evidence of suffering from a double disparity.

The research on racial disparities in nonsurgical pain treatment outcomes is scant and shows mixed results. In a laboratory study of opioid analgesia, researchers found that AA participants showed a greater analgesic response to morphine and butorphanol than NHWs.[67] Concerning multi-disciplinary pain treatment outcomes, evidence suggests no racial or ethnic differences in treatment efficacy, including a reduction in pain severity. For example, Cano et al. demonstrated that controlling for age, sex, and other social determinants of health still resulted in a lack of racial and ethnic differences.[68] In contrast, Merry and colleagues[69] found that NHW and AA patients experienced improvements in pain-related interference following multi-disciplinary pain treatment, but only NHW participants reported reduced pain severity. A study of a cognitive-behavioral self-management program for chronic back pain showed yet a different pattern of results. While NHW, AA, and Hispanic participants all showed improvements in disability, only Hispanic participants improved in pain intensity.[70] Taken together, it is clear that racial and ethnic minority patients experience different outcomes from treatment than NHWs. However, the evidence does not provide a consistent pattern of disparities.

Sex Differences in Pain Treatment Outcomes

The literature, including several meta-analyses, describes sex differences in pain treatment outcomes, especially for opioid analgesia. One such review found that women have a lower opioid

consumption post-surgically than do men.[71] A meta-analytic review of 11 studies found that women not only self-administer lower daily doses of opioids via patient-controlled analgesia pump (PCA) but also receive lower daily doses of opioids for chronic non-cancer pain.[72] Moreover, women experience greater morphine-induced analgesia than do men across experimental and clinical studies.[73] Together, this suggests that women respond better to opioids and require lower amounts than men for both acute and chronic pain. However, it is important to note that women are also more likely to experience opioid-induced side effects and mortality than men,[74,75] which may result from their increased sensitivity to the effects of opioids.

Sex differences in response to surgical pain treatment are consistent. Overall, women fare worse than men across surgical types and outcomes. Among patients undergoing orthopedic surgery, women reported a greater "worse pain" intensity since surgery and more time spent in severe pain than did men.[76] Similarly, women are more likely than men to have persistent post-surgical pain three months following orthopedic trauma surgery.[77] Women also report higher pain than men following rotator cuff repair. However, these differences dissolve after one year.[78] It is important to note that while others have also acknowledged sex differences in pain, disability, and quality of life following orthopedic surgery, with women experiencing worse outcomes than men, women consistently had greater pain, disability, and poorer quality of life pre-surgically. After controlling for baseline differences, there were no sex differences in symptom improvement.[79] Thus it is important to identify presurgical factors that may differ between men and women that may be contributing to sex differences in post-surgical pain.

There is also evidence of sex differences in outcomes for non-pharmacologic pain interventions, although these results are more inconsistent. For example, response to inter-disciplinary pain management programs may differ by sex. Keogh and colleagues found that although inter-disciplinary pain management was effective at reducing pain for both men and women, men reported ongoing relief after three months, whereas women's pain had returned.[80] In other studies, however, women showed greater improvement than men in pain and pain-related disability following a multimodal pain management program.[81] Thus sex differences in outcomes of multimodal treatment may depend on the specific outcome (pain severity vs. disability) and the timing of follow-up. However, it is important to note that across studies of these inter-disciplinary, multimodal pain treatment programs, most patients are female. Thus more research may be needed to better understand the effectiveness of such programs among men. Regarding other non-pharmacologic treatments such as physical therapy, conventional physical therapy (e.g. heat, cold, massage, stretching, electrotherapy, and exercise) has shown to be more effective for men while intensive dynamic exercises are more effective for women.[82] There is also some evidence that women are more responsive to psychological pain interventions. For example, women undergoing cognitive-behavioral therapy showed improved quality of life, whereas men did not.[83] Likewise, there is evidence that acceptance-based interventions for pain may be more helpful in reducing pain for women than men.[80] Sex differences in the pain experience (e.g. coping, catastrophizing, negative affect) may explain some of these treatment differences. Specifically, psychological interventions often target pain mechanisms such as catastrophizing. Perhaps the changes in these constructs as a result of treatment vary by sex, thus resulting in more broad sex differences in treatment outcomes.

Contributing Factors to Racial, Ethnic, and Sex Disparities

Coping

Pain coping refers to the thoughts and behaviors people use to manage their pain or their emotional reactions to their pain.[84] Coping strategies are differentially associated with pain-related outcomes. Active coping, an attempt to control pain or function despite pain, includes strategies such as coping self-statements, diverting attention, exercise, and ignoring the pain. In contrast, passive coping is an attempt to relinquish control of their pain to others and includes catastrophizing, hoping/praying, retreating, using medications, and worrying. Active coping has been linked to less pain, depression, and better physical and psychological wellbeing. Passive coping, however, is associated with increased pain and depression.[85]

Coping is differentially associated with pain. Nevertheless, there are racial, ethnic, and sex differences in pain coping. In a meta-analysis of 19 studies, Meints and colleagues found that AA individuals engage in more coping overall than NHW individuals.[86] More specifically, AAs report greater use of passive coping strategies (e.g. hoping and praying and catastrophizing), whereas NHW individuals are more likely to use active strategies such as ignoring pain. Indeed, AA and Hispanic Americans pray more in response to pain than do NHWs,[86,87] whereas there are no differences between AA and Hispanic Americans for prayer.[88] Moreover, praying has been associated with greater pain severity, interference, and disability[89] and at least partially contributes to race differences in experimental pain.[87] A more granular look at the literature on prayer in response to pain has found that passive prayer (e.g. "God, take away the pain)" is associated with poorer pain tolerance than active ("God help me endure the pain") or no prayer.[90] Despite consistent race differences in ignoring pain,[86] this strategy has not been found to mediate AA-NHW differences in pain.[87] Furthermore, Mexican Americans, NA, and Asians are more likely to cope stoically.[91–93] Although the relationship between stoicism and pain has not been examined, it serves to reason that stoicism may be related to underassessment and undertreatment of pain.

There are also sex differences in pain coping that may play a role in sex-related differences in pain. For example, men are more likely to engage in distraction while women seek social support, use positive self-statements, cognitive reinterpretation, and increase physical activity.[94] There are mixed results related to problem- versus emotion-focused coping. In one study, women were more likely to engage in problem-focused coping or direct action.[95] In contrast, another study suggested women are more likely to engage in emotion-focused coping (e.g. venting or reinterpreting emotions, seeking emotional support), and men are more likely to engage in problem-focused coping.[96] Overall, it is clear that women use more coping strategies than men (e.g. more tools in their coping toolbox). However, some of the strategies more likely to be used by women may be associated with increased pain and dysfunction, which may help to explain sex differences in the perception of pain.

Catastrophizing

Catastrophizing is a cognitive and emotional response to pain characterized by rumination, magnification, and helplessness. Catastrophizing, sometimes considered a coping strategy[97] and

others a pain appraisal,[98] is associated with greater pain intensity, interference, and disability.[99] There is not only consistent evidence that women, AA, and Hispanic individuals catastrophize more in response to pain than men and NHWs,[100,101] but that catastrophizing mediates race and sex differences in pain sensitivity. Women and AA individuals catastrophize more in response to pain, which is associated with poorer pain tolerance. It is important to note, however, that catastrophizing may not be "all bad." According to the communal coping model of catastrophizing, catastrophizing may serve to maximize social proximity and support.[102] Women and members of racial and ethnic minority groups are often more social and, as a result, more likely to seek social support. This social inclination may explain the racial, ethnic, and sex differences in catastrophizing. Unfortunately, the increased pain behavior exhibited by those more likely to catastrophize is associated with poorer outcomes, including increased pain and disability, less solicitousness and more punishing responses from partners, and a poorer relationship with pain care providers.[103,104] Thus attempts to increase social support via catastrophizing may create a "double disparity," increasing pain sensitivity, social isolation, and resulting in poorer pain treatment.

Negative Affect

Negative affect, including depression and anxiety, are associated with increased experimental and clinical pain, disability, and a poorer quality of life.[105] The comorbidity between pain and depression has been well documented.[106] There is consistent evidence that depression is more prevalent among women than men,[106] and among people with depression, women are more likely to report pain.[107] Similarly to depression, women report greater levels of anxiety and more frequently experience anxiety disorders.[108] However, anxiety may be more strongly related to pain among men. In one study, anxiety was associated with pain sensitivity among men but not women.[109] Greater pretreatment anxiety predicted greater reductions in pain after interventional therapy for men, but not for women.[110] Similarly, negative affect also seems to explain some of the racial and ethnic differences in the pain experience. In a study of individuals with OA, AA individuals experienced greater negative effects than NHW individuals, which accounted for greater pain severity.[111] There are also consistent findings indicating that the link between emotions and pain is greater among AA than NHW individuals.[2,6] Perhaps the greater levels of negative affect experienced by ethnic and racial minorities alters their central pain processing, thus resulting in pain disparities. Indeed, Bulls and colleagues found that AA participants experienced greater depressive symptoms than NHW participants and that this was associated with greater temporal summation of pain, a measure of pain facilitation.[112]

Treatment Expectations

Patient expectations are an increasingly relevant topic because of the shift toward patient-centered health care and are positively associated with pain treatment outcomes.[113] That is, better treatment expectations are associated with better treatment outcomes. There is evidence, particularly in the context of joint replacement, that minority patients generally have poorer pain expectations[114] and that these expectations are associated with less willingness to undergo such procedures. However, there is a paucity of research assessing other racial, ethnic, or sex differences in treatment expectations and how those potential differences may influence outcomes.

Gender Roles

Gender roles of pain, the normative sociocultural response to pain that differs by gender, may also influence sex differences in pain. Masculine gender norms are associated with increased tolerance to pain among men, while feminine gender norms suggest pain is a normal part of life and, therefore, are more permissive of pain expression.[39] Studies have shown that these norms are associated with threshold and tolerance for noxious stimulation. Indeed, higher masculinity is associated with greater threshold and tolerance and lower pain ratings for noxious stimuli, while higher femininity is associated with lower tolerance.[115] Using the Gender Roles Expectations of Pain questionnaire (GREP), researchers found that both men and women considered women to be more pain sensitive, less enduring of pain, and more willing to report pain than the typical man.[116] There is also evidence that women view overt expressions of pain as more acceptable than men, explaining sex differences in cold pain.[117] It is important to note that gender roles of pain are malleable. When participants are given gender-based expectations for pain, sex differences in cold pain tolerance are no longer significant.[118]

Epigenetic Differences

Because of race differences in early life conditions, AA may likely experience epigenetic changes that influence racial differences in chronic pain.[119] Epigenetics, heritable changes in gene expression that do not alter the underlying genetic sequence,[120] result from several mechanisms including DNA methylation. DNA methylation, a chemical modification of DNA that regulates genetic phenotypes, is sensitive to environmental input. For example, environmental stressors such as adverse childhood experiences (ACEs), chronic stress, and low socioeconomic status are all more common among AA[121] and contribute to epigenetic changes via higher DNA methylation levels.[122] There is growing evidence that these epigenetic changes are associated with the development of chronic pain.[123] Indeed, greater DNA methylation is associated with chronic low back pain and fibromyalgia.[124] Thus environmental adversity, more common among racial minorities, leads to epigenetic changes that are but another mechanism of developing and maintaining ethnic and racial pain disparities.

Allostatic Load

Racial, ethnic, and sex differences in allostatic load may also contribute to pain disparities. Allostatic load, or the systemic stress on the body to maintain balance,[125] are associated with exposure to chronic stressors, including ACEs, trauma, discrimination, poverty, and chronic illness.[126] Although few studies have examined the relationship between allostatic load and pain, there is evidence that greater allostatic load is associated with greater headache prevalence, more reports of pain lasting more than 24 h, and greater widespread body pain, and greater chronic pain severity.[127,128] Because women and members of racial and ethnic minorities are more likely to experience significant life stressors, it is reasonable to presume that the resulting allostatic load may be contributing to pain disparities.

Hormones

In addition to gynecologic syndromes that lead to pain as well as greater female longevity, several other biologic factors contribute to sex differences in pain. Gonadal hormones can affect both the

peripheral and central nervous systems and influence the perception of pain. This is evidenced by age-related changes in pain prevalence that coincide with age-related changes in gonadal hormones and differences in pain perception across the menstrual cycle. For example, migraine and temporomandibular disorders (TMD) prevalence are similar between prepubescent boys and girls but then rises in women after puberty.[129,130] Similarly, migraine frequency and TMD pain are reduced during pregnancy while the severity of IBS-, TMD-, headache-, and fibromyalgia-related pain all vary across the menstrual cycle.[131] Postmenopausal women on hormone replacement therapy and women using oral contraceptives are at increased risk for various chronic pain conditions.[132,133] Further highlighting the association between estrogen and increased pain are results from a study indicating that approximately one-third of male-to-female transsexuals undergoing hormone replacement therapy develop chronic pain. In contrast, half of female-to-male transsexuals report improvement in chronic pain.[134] On the other hand, as estrogen rises during pregnancy, migraine and TMD pain decreases. Similarly, the sudden decrease in estrogen after pregnancy is associated with greater pain, stiffness, and the precipitation of migraine pain.[135]

Endogenous Opioid System

There are also sex and racial differences in multiple levels of the endogenous opioid system. Differences in the distribution, expression, and sensitivity of opioid receptors across race, ethnicity, and sex indicate this may be another biologic mechanism underpinning disparities in pain perception and response to treatment. For example, at rest, women show higher μ-opioid receptor binding than do men.[136] Moreover, women with high estradiol show higher brain μ-opioid receptor binding than women in low estradiol states.[137] In contrast, men show higher μ-opioid receptor binding in response to experimentally-induced muscle pain.[136] There are also sex differences in the metabolization of opioids.[138] Women have greater expression of the CYP3A4 enzyme and thus metabolize opioids such as fentanyl more quickly, resulting in less effectiveness. Men have greater expression of the CYP2D6 enzyme resulting in faster metabolism of and poorer response to codeine.[139] Differences in body composition may also affect blood concentrations of opioids. Because opioids are lipophilic and women have more body fat than men, women may have greater blood concentrations of opioids.[138]

Although less studied, there is also evidence there may be racial and ethnic differences in the endogenous opioid system, and these may contribute to the greater burden of pain experienced by racial and ethnic minorities. In a recent study examining race differences in μ-opioid receptor binding, Letzen and colleagues found that AA participants demonstrated greater opioid binding potential in cortical areas associated with pain processing (e.g. ventral striatum, insula, dorsolateral prefrontal cortex) than did NHW participants.[140] These results suggest that AA individuals' greater unoccupied μ-opioid receptor density may be related to less endogenous opioid binding, resulting in greater pain sensitivity. Furthermore, there is evidence that AA individuals demonstrate less endogenous opioid pain inhibition than NHWs, providing further support for endogenous opioid system functioning as another mechanism of racial and ethnic pain disparities.[141]

Central Nervous System Functioning

Functional imaging has provided evidence for sex differences in the central nervous system functioning in response to pain. For example, women show greater contralateral thalamus and interior insula response to heat pain than men.[142] They also show greater deactivation in the somatosensory cortex, insular cortex, and dorsolateral prefrontal cortex. In response to a laser heat stimulus, men show greater activation of the parietal cortex, secondary somatosensory cortex, prefrontal cortex, and insula, while women show greater activation in the perigenual and cingulate cortices.[143] Similar results have also been shown in patients with IBS. In response to visceral pressure created via a balloon catheter in the rectal colon, women show more activation of the ventromedial prefrontal cortex, the right anterior cingulate cortex, and the left amygdala.[144] In contrast, men show more activation of the right dorsolateral prefrontal cortex, insula, dorsal pons, and periaqueductal gray matter. While the nuances of individual and group differences in central nervous system responses to pain are still being examined, there is evidence to suggest that sex hormones influence the processing of pain-related stimuli. Indeed, a study of women using oral contraceptives with low testosterone levels showed reduced pain-related activation in pain inhibitory regions of the brain, including the rostral ventromedial medulla.[145] However, more research is needed to further elucidate the relationships between sex, gender, gonadal hormones, and cortical pain processing.

Discrimination & Bias

Perceived bias and discrimination may also contribute to racial disparities in the pain experience. The majority of AA and Hispanic people in the United States report that they have been discriminated against because of their race or ethnicity.[146] Such discrimination is a chronic stressor that may be associated with the development and maintenance of chronic pain.[147] Indeed, experimental studies demonstrate higher levels of perceived racial discrimination associated with greater pain sensitivity among AA with chronic pain.[148] Likewise, perceived discrimination is also associated with elevations in clinical pain severity among patients with chronic pain.[149] Thus it is important for providers to consider the role of their own biases and decades of structural racism in the experience of pain among minority patients.

Although overt discrimination is rare, Hoffman and colleagues found that medical students and residents held false beliefs about biologic differences between AA and NHW patients and that these were associated with racial bias in pain perception and treatment recommendations.[150] Moreover, Hispanic Americans and African Americans (HAs) and AAs with chronic pain report fear of discrimination based on their race/ethnicity when seeking pain care[52] and indicate that ethnicity and culture have affected their access to pain management.[151] Results of vignette-based studies have confirmed this. For example, patient race has been shown to influence providers' judgments of pain and their recommendation for pain relief.[152] While the specific mechanisms driving such bias remain unclear, there is evidence to suggests that racial biases in pain perception and treatment are due, at least in part, to implicit rather than explicit bias and are specific to pain rather than general bias.[153]

Patient Preference

Cultural differences across racial and ethnic groups may influence patients' treatment preferences. For example, 38% of HAs and 9% of AAs are concerned about taking too many analgesics, while 27% of HAs and 12% of AAs are concerned about side effects.[55] These concerns may be related to addiction. Indeed, AAs and HAs have a greater fear of addiction to pain relievers than do NHWs.[154] Even in terminally ill patients, minorities are more likely than

NHWs to refuse additional pain medications because of fear of addiction.[155] Additionally, minority patients may not believe in the efficacy of analgesics. Compared to NHWs, AAs believe pain medications cannot control pain[156] and instead rely more on other nonpharmacologic coping strategies. Similar to AA patients, Hispanic individuals are more hesitant to take pain medication.[20] This may lie in cultural norms of pain perception, in which Hispanic Americans are found to be more stoic and tend to bear more pain than NHWs.[20] Hispanic culture is family centric and holds a belief in overcoming pain unless completely unbearable. Culturally, Hispanics report that taking pain medication could be seen as a form of weakness. Additionally, Hispanics feel a stronger sense of responsibility toward caring for their family members and may inhibit seeking pain care out of fear that treatment may leave them unable to care for their family.

Communication

The experience of chronic pain involves frequent engagement with healthcare services and providers to treat or manage one's pain. Interactions with healthcare providers influence the degree to which patients feel empowered in managing their pain. While more frequent visits to the doctor's office are associated with greater pain, support from doctors in managing one's pain is associated with less pain overall.[157] Yet, many patients with chronic pain feel unsatisfied in their relationships with their providers. A meta-ethnography of qualitative literature on patient-provider relationships in pain-related care conducted by MacNeela et al. indicates that across studies, both patients and providers are dissatisfied with their relationships in pain management care.[158]

Patient-provider relationship dissatisfaction in pain management care may stem from poor communication, especially patient-centered communication. There are several ways patient-provider relationships demonstrate sub-optimal communication. In a review of communication problems, Ovretveit highlighted the consistent finding that providers might fail to create an optimal care environment which contributes to a breakdown in communication.[159] Problems in communication then reflect both provider and patient ineffectiveness.

Patients identify issues in communication, such as providers failing to take enough time with patients to fully listen to them and understand their experience and preferences for treatment.[160] Patient and providers can disagree on many areas of treatment, including the seriousness of the condition, barriers to care, the approach to illness management, treatment goals, and the importance of a definitive diagnosis. Additionally, providers may not communicate effectively in collaborative treatment planning. Breakdowns in communication can contribute to dissatisfaction among both patients and providers.[161]

When examining sex differences in patient-provider communication among samples of patients with chronic pain, women report more negative communication from their providers, which impacts their overall satisfaction with care. Women are more likely to experience comorbid pain conditions and, as a result, face more barriers in communication regarding the nature of their pain and treatment approach, leaving them feeling misunderstood by their providers.[162] In particular female veterans with chronic pain have identified that they feel their providers, especially ones who primarily treat men, display a worse understanding of their pain.[162] Additionally, women with fibromyalgia report encountering negative gender-based stereotypes related to being labeled as hypochondriacs when discussing disability claims with their providers.[63] Whereas NHW women may only rely on medical documentation for such purposes, women of color report having to engage in more moral-boundary work to legitimize their pain complaints and have them recognized as worthy of assistance.[63] In this way, providers require women of minority ethnic backgrounds to communicate in different ways to obtain the same resources as NHW women.

There are also racial and ethnic disparities in patient-provider communication. Racial and ethnic minority patients report more difficulty than NHW patients in communicating in ways that health providers understand and believe.[163] This may be particularly true in EDs where there are not established relationships and minimal time.[1] Indeed, when under time constraints, providers may be more reliant on stereotypes and heuristics, which in turn may impact communication with minority patients. Providers display less patient-centered orientation in their communication with AA patients and demonstrate greater verbal dominance[164] when compared to NHWs. Physician verbal dominance in conversations with AA patients is more likely to occur when providers endorse greater racial bias.[165] When providers perceive AA patients consistent with common AA stereotypes, they also demonstrate slower speech, less patient centeredness, and poorer quality interpersonal care. In contrast, providers who perceive White patients consistent with White stereotypes demonstrate less verbal dominance, faster speech, and person-centered care.[165]

Researchers have posited that differences in preferred language may be a barrier to effective communication,[166] particularly among Hispanic patients. Indeed, Hispanic patients are more likely than NHW patients to report that providers do not believe their pain.[163] Spanish-speaking Hispanic patients report believing that seeking care is more difficult because they speak Spanish and tend to seek care less often than Hispanic individuals who speak English. One reason for such difficulties may be the lack of Spanish-proficient providers in pain care and a lack of interpreter services.[167] Language barriers can also have a negative impact on the care of Hispanic patients during care. For example, Hispanic patients may experience difficulties describing their pain to providers or understanding treatment decisions and recommendations.[168] Overall, disparities in provider-to-patient communication strongly affect how patients engage with care. Providers unaware or unresponsive to cultural variation in the pain experience are more likely to interpret pain in terms of their own culture, which can adversely impact pain management.[169] Given these communication difficulties, it is not surprising that racial/ethnic minority patients prefer providers of the same race/ethnicity and report greater satisfaction with care when racially matched with their providers.[170]

Underreporting

The Institute of Medicine has documented that chronic pain is typically underreported, and this under reporting may be magnified among groups of individuals from minority backgrounds.[171] Pain may be underreported for a wide variety of reasons, including patient non-disclosure or because providers may not question patients about pain. Among racial and ethnic minority patients, non-disclosure may be indicative of cultural beliefs about reporting pain and distress. For example, 21% of AAs report difficulty talking to their provider about cancer pain. Moreover, 57% of AAs and 38% of Hispanic Americans report that providers did not ask about their pain.[172] Hispanic and NA specifically hold culturally-bound beliefs regarding disclosure of pain. For example, NAs do not like to talk about themselves, complain about pain, or ask for

help. Moreover, when they ask for help and their needs have not been met, they will often not voice this until the pain is severe.[93] Among Hispanic individuals, pain is often faced with stoicism, although there seems to be an influence of sex.[92] While Hispanic men and women both report pressure to withhold disclosing pain, men endorse "machismo" or a sense of masculinity while women forgo their own needs to prioritize their family. Hispanic individuals may also refrain from reporting pain to their health care providers because they view pain as a natural consequence of their condition or a punishment from God. Together, such under reporting of pain may play a critical role in the undertreatment of pain among minorities.

Access to Care

Limitation in access to care remains a great public health issue that plagues the healthcare community. However, in this section, we will discuss access to care in relation to racial and ethnic disparities in pain relief. Systemic factors affecting patient access to care are inextricable from race and ethnicity. Minority groups are more likely to be of lower economic standing and thus live in areas in which there are fewer hospitals or pharmacies.[173] Even when minorities have access to pharmacies, they may not be able to get their prescriptions locally. Studies have shown that pharmacies in White neighborhoods are better stocked with opioids than minority non-White neighborhood pharmacies that tend to stock fewer medications.[174] In fact, 50% of randomly selected New York City pharmacies did not have adequate opioid analgesics in stock.[175] The study further showed that pharmacies in predominately Hispanic and AA neighborhoods were less likely to stock opioid analgesics than NHW neighborhoods.

Minority groups also have a more difficult time accessing specialty providers such as tertiary pain clinics. Thus AAs are more likely to present with pain in emergency rooms than their NHW counterparts.[174] Access to high quality pain care is also related to disparities in access to health insurance. AAs and Hispanics are more likely to be on a government funded healthcare insurance provision than NHWs. They are also more likely to be underinsured, making access to pain relief more difficult.[176] In addition, nearly half of Hispanics and one-third of AAs with chronic pain report financial concerns prevent them from getting their pain treated.[52] Taken together, it is clear that access to quality and appropriate pain treatment is disparate across racial and ethnic groups, an issue that significantly contributes to the unequal burden of pain.

Conclusion

Although pain is a pervasive problem, the burden of pain differs by race, ethnicity, and sex. Various biologic, psychological, and social factors have been identified as contributing to disparities in pain experience, report, treatment, and outcome. At this point, it seems insufficient to merely continue conducting research that identifies and quantifies these disparities. Instead, future work encompassing clinical research, service delivery, and healthcare practice should focus on mitigating the above-described contributing factors to diminish disparities in the experience and treatment of pain, improving the experience of pain care, and optimizing the diagnosis and management of pain for all sufferers. While some factors may not be modifiable (e.g. hormones, endogenous opioid system), providers must understand their role and adopt an individualized approach to pain management that considers them.

Key Points

- Despite the universality of pain, the burden of pain varies across race, ethnicity, and sex.
- Racial and ethnic minorities and women have greater pain prevalence and severity and are more likely to have their pain underestimated and undertreated.
- While there are some biologic determinants of pain disparities (i.e. hormones, endogenous opioid system, and central nervous system functioning), psychosocial factors seem to play an important role.
- Although disparities are examined on a group level, providers must use an individualized medicine approach to be aware of and reduce disparities whenever possible.

Communication and Clinician Relationships to Improve Care for Patients With Chronic Pain

DAVID J. TAUBEN, MARK D. SULLIVAN

Introduction

In March 1927, Dr. Francis Peabody, Harvard Medical School educator and Boston surgeon, published a seminal article in the Journal of the American Medical Association with the oft-quoted maxim, "One of the essential qualities of the clinician is interest in humanity, for the secret of the care of the patient is in caring for the patient."[1] Caring, by optimizing therapeutic relationships between clinicians and patients, has since been characterized as the practice of "patient-centered" medical care.[2] In 2001, patient-centered care was described by the National Academy of Medicine's (formerly Institute of Medicine) *Crossing the Quality Chiasm: A New Health System for the 21st Century* as "respectful of and responsive to individual patient preferences, needs and values, and ensuring that patients' values guide all clinical decisions."[3] Patient-centered care consists of two essential components: 1) taking the patients' perspective on their illness and their life and 2) activating the patient for self-care.[4] Both of these components are essential in the care of patients with chronic pain.

All clinically directed health care involves interpersonal interactions of patients with their treatment providing clinicians. So, why is this therapeutic relationship especially important in the context of caring for patients with chronic pain? Chronic pain, a biopsychosocial condition, by its very nature, includes more than just a straightforward communication of biomedical objective information. Unlike some other medical conditions, pain is not itself visible. Therefore individuals with chronic pain often struggle to have their condition recognized and legitimated. The comprehensive assessment and effective treatment of chronic pain also entails an understanding of its impact, so we must also understand our patients within the broader context of their pain experience and how they see themselves managing, or more likely struggling, with their persistent and intrusive painful sensations. This includes relationships with families and communities. It also includes managing home and work responsibilities and striving for life goals that offer meaning and purpose in their lives.

Hearing the patient identify personal goals of pain care and providing a space and an opportunity to comfortably disclose their beliefs and expectations and how it is that they *really feel* means that the management of patients with chronic pain requires a trusting relationship with a clinician. This type of relationship requires communicating with patients in their own words and recognizing their behaviors from their unique perspectives, and also by acknowledging that their pain is "real." Treatment relationships begin with therapeutically effective communication. This chapter will describe why empathic communication is especially important for chronic pain management, how a strong therapeutic alliance can improve chronic pain care outcomes, and what specific clinical competencies have been demonstrated to improve patient engagement in their treatment.

Listening and Narrative Medicine

In 2010, Eloise Carr, RN PhD, a researcher studying patient experiences of chronic pain, recalled a patient's statement: "Stop trying to cure me and start listening."[5] Clearly, this individual's prior experience of pain treatment did not include "being heard." Being heard means being acknowledged. Being heard means being understood. Listening to the patient is fundamental to establishing the clinician-patient relationship.

However, *demonstrating* that you have listened and that you understand is another essential part. Check with your patient if you have understood their predicament with their pain. Restate what you have heard and ask the patient if you have it right. Acknowledge the pain and its impact on their life. When pain becomes chronic and therefore complex, objective physical exam findings, imaging, and laboratory studies are insufficient to capture the nature and effects of the illness for the patient. Patient self-reported pain intensity has long been a component of chronic pain evaluation.[6] But it is a gross oversimplification of a chronic illness and leaves many questions unanswered. In 2014, an undergraduate journalism major enrolled in an elective course titled "Pain" was asked, "What does 12/10 pain intensity mean?" He replied, "Maybe the patient is shouting."[7] So, with a maximum score of "10" to rate an unimaginably severe pain experience, this "unheard" patient felt there was no other option than to increase the numeric volume to "12/10." A patient who feels understood will be more likely to trust their provider, be more likely to follow suggested treatment recommendations, and be more satisfied with their care.

Communication begins with an *action*, such as a patient sending a message of distress, followed by an *interaction* whereby the

physician responds with a message of understanding, and a *transaction*, such as commitments to a future course of action.[8] The style and techniques for effective listening will vary based on the differences of personality, temperament, and cultural and racial experiences of clinicians and their patients. Communication is also much like a dance since each partner strives to follow the other's cues. Although conversations with patients struggling with chronic pain do follow a classical choreography, it often requires a jazz-like improvisation.

Published recommendations now call for a wider range of questions beyond quantification of pain intensity, including interference with function, enjoyment of life, sleep, mood, treatment expectations, and goals.[9] Above all, patients want to tell the story of their pain, and they want to know that their clinicians have understood it. Chronic pain is experienced within an individual's unique life events, preformed and yet changeable social context, and subjective cognitive and emotional states.[10] Pain neuroscience researchers describe a so-called "dynamic pain connectome" based on fMRI evidence of "brain-wide network communication on multiple timescales," and that "attentional states are in constant fluctuation."[11] According to pain neuroimaging researcher Irene Tracey, "Pain is not a unitary thing, and no two pains are the same, even in the same individual."[12] Scientific medicine relies upon measurement to both diagnose and track treatment outcomes. Without specific biomarkers that can describe, record, measure, and track the variable and dynamic human experience of pain, validated patient reported outcome questionnaires are necessary.[13] So too is listening.

The biopsychosocial evaluation and treatment of chronic pain also depend upon an in-depth exploration of the patient's own beliefs and attributions, what *it is* they understand to be causing their pain and why it persists even after extensive biomedical evaluations and many treatments have been tried and failed. What does the patient believe to be the cause for their persistent pain? It may be that the cause for their pain has so far simply been missed. Why do they believe prior treatments have failed? It may be a conviction that their prior doctors just do not know, or worse, do not care. What are their worries? Often it is being told "*there is nothing left to be done*" or thinking, "*it's all in my head.*" What might other family members and friends be thinking? Maybe "*I'm just making it up*," *"I'm a burden on everyone,"* or "*I'm not someone they want to be with anymore.*" What expectations will define a successful outcome? Maybe the doctor "*could do the correct surgery*," the "*right procedure*," or prescribe the "*best medication*" and everything would be how it was before their pain began. What else is going on in the patient's life? Might it be: "*All my time is spent finding a way to get better," or "Since nothing else matters but my pain, there's no point in planning ahead*"? What are the patient's own goals? It is important to know whether it is to become pain-free or if it is to be able to return to improved function and begin to recover their life. Since many pain treatments will require an effortful and patient-directed commitment to a range of behavior changes and self-management approaches, treatment will need to be tailored to the patient's perceived needs and hopes. Interpreting pain, function, and mood numeric ratings are, of course, important. For many complex chronic pain presentations, such as those more complex patients referred to pain specialists, much depends upon the patient's own story. Pain, a biopsychosocial condition, requires more than just the "medical story." Knowing how patients experience their pain requires effective patient-centered communication. The mystery is in the history.

Clinician-Patient Relationships: Empathy and Therapeutic Alliance

Empathic listening to the patient's story using the techniques of "narrative medicine" is a long established approach to advance care and improve chronic illness treatment outcomes.[14] "Not only is diagnosis encoded in the narratives patients tell of symptoms but deep and therapeutically consequential understandings of the persons who bear symptoms are made possible in the course of hearing the narratives told of illness."[15] Intentional and directed attention to what our patients say, *active listening* is not merely kind and courteous but will increase the likelihood of a more effective treatment outcome. Effective communication explicitly acknowledges patients as persons: "The clinician must know the patient well enough to be able to answer the patient's question 'What would you do, if you were me?'"[16] Empathy is commonly described as the ability to understand the inner experiences of patients, to communicate this understanding, and to respond therapeutically.[17] Empathy is distinct from sympathy. Sympathy names the ability to feel someone else's emotions, especially by feeling sad about their misfortune. Empathy names the ability to understand other people's feelings as if we were having them ourselves.

Empathic listening and compassionate clinical care date to antiquity, long before medicine had developed as a scientific profession (e.g. Hippocrates, 5th century BCE: "Cure sometimes, treat often, comfort always"; Ovid, 1st century: "When the mind is ill at ease, the body is affected.") More recently, Abraham Verghese, physician and author of the widely acclaimed 2009 novel *Cutting for Stone,* wrote, "'Tell us please, what treatment in an emergency is administered by ear?'…I met his gaze and I did not blink. 'Words of comfort'…."[18] The same unblinking response applies to clinicians caring for patients with chronic pain, which for many patients represents an unrelenting emergency.

Modern scientific medicine has since elevated the role of clinical objectivity and technical competency. However, technical access to objective disease can displace empathic concern for what our patients tell us about their individual illness experience. This competing tension has reportedly led to an overall decline in empathy as trainees progress through medical school and residency training.[19] Efforts are underway in medical school curricula to improve medical student empathy and narrative competency,[20,21] but these efforts encounter competition for space in the crowded time to cover other crucial biomedical topics, technical competencies,[22] and other recommended pain topics.[23]

Empathy, in its most basic form, is described as "emotional contagion," characterized by unconscious state-matching (the contagious yawn!). Neuroimaging studies in humans,[24] and even electrophysiologic[25] and behavioral findings in rodents,[26] suggest that empathy for pain is evolutionarily conserved. Therefore we are hard-wired for empathic behavior; we need only harness this natural capacity to show that we understand *our patients' feelings* as if *we were having them ourselves.* The significance of empathy is even more striking in pain medicine since chronic pain is a complex social phenomenon that often leaves individuals with chronic pain socially isolated from family and friends and feeling misconceived and misunderstood by their doctors.[27] Neuroscience research has shown that social exclusion and physical pain also share neuroanatomic structures and functions.[28] The clinician has a unique opportunity to provide a "social buffer" that, even in the absence of any other intervention, may positively impact the patient's pain experience.

In a busy clinic setting, it is challenging to take adequate time to listen, sit down, look directly at our patients rather than their electronic health record, and not interrupt patients who may be attempting to understand our questions. However, it is possible to allow more time by scheduling longer or more frequent visits or by dedicating periodic visits to pain exclusively so as not to be distracted by the many other general health and preventative medicine concerns also needing attention. If such measures are not feasible, we can introduce even very brief breaks from our intensive data-gathering agenda to practice active listening. Look our patients in the eye; patients notice these actions, particularly those who have had a long history of feeling ignored. Listen without judgment and pay attention to nonverbal cues. Take a few moments to paraphrase what we have heard and demonstrate to our patient that they have been heard. If we fail to listen, patients may register negative feelings of clinicians' disinterest and disdain rather than empathic concern, in other words, "They don't want anything to do with you."[29] Hurried and tightly scheduled primary care and pain specialty practices are challenged by system-related (e.g. too little time[30,31]), patient-related (e.g. difficult communication,[32] particularly when opioid management is involved[33]), and physician-related barriers (e.g. compassion fatigue[27]) that may lead to reduced empathic behaviors. Empathic failure can reduce patient satisfaction and compliance with treatment guidelines, worsen clinical outcomes, reduce ratings of clinical competence, and increase burnout, medical-legal risk, and overall healthcare costs from excess diagnostic test expenditures.[34] Demonstrating empathy may also improve the accuracy of clinical decisions since pain related medical decision making is so often based on personal features and values of the patient that extend beyond objective medical evidence.[35]

Expectations Influence Pain

The patient expectation of pain relief is among the leading causes of placebo analgesia and associated with many of the described psychological and neurophysiologic mechanisms of placebo response. Placebo analgesia response has been proposed to be a form of "top-down" conditioned modulation, an "evolutionary imperative to optimize the selection of future actions" in response to "bottom-up" peripheral pain sensations that may or may not represent potential bodily injury.[36] There is extensive literature on neurophysiologic and behavioral mechanisms of placebo analgesia studies, including several recent excellent reviews.[37,38] Nocebo response, the experience of a *negative* response to an otherwise inactive treatment, is also conditioned by expectations. Nocebo response can be predicted by prior lack of response, adverse events, or even negative outcomes following prior ineffective medication, behavioral health, physical therapy, or surgical treatments. Any time spent is well invested when patients better understand their condition, share expectations of their treatment, are provided clear instructions, and shared goals are communicated in advance of treatment delivery, whether it be medication, behavioral health interventions, physical therapy, or procedural management.[39,40]

Taking a step further, setting realistic expectations in advance of initiation of pain treatment "*-any treatment-*" would then be likely to predict more favorable treatment outcomes. Cheerfulness and unfounded optimism can lead to patient and clinician frustration and further disappointment when new or different treatment approaches are not met with immediate positive results. How can we determine what our patients expect? Since patient and physician expectations of pain treatments are frequently not aligned (e.g. just temporary relief from local anesthetics, only modest response to a gabapentinoid or serotonin-norepinephrine reuptake inhibitor, or delayed benefit from cognitive behavior or physical therapies), it is important to understand what the patient expects treatment to accomplish and how long it may take to perceive benefits.[41,42] Favorable treatment outcomes can result as much from the pharmacologic activity of a drug, the technical precision of an interventional procedure, or the specific physical therapy modalities as from the clinicians' method of communication delivery. The nocebo response is also relevant. An otherwise potentially effective treatment that had been previously tried and "failed" because of minor initial side effects may have become unacceptable and indefinitely rejected by the patient. By establishing trust using empathic communication and acknowledging prior side effects, resetting expectations with a very gradual upward titration may find a prior unsuccessful treatment to be well tolerated and effective. Similarly, reframing "failed" behavioral health or physical therapy by explaining a clear rationale and establishing patient-centered goals may overcome prior objections. Being heard and being understood matters across all domains of chronic pain management. So, pain treatment outcomes—positively or negatively—will be significantly affected by what we say to our patients, how we say it, how it is understood, the confidence we have earned, and the overall quality of a shared therapeutic alliance.

Patient-Centered, Shared Decision Making

Patient-centered, shared decision making is a widely advocated clinical practice intended to improve patient adherence, satisfaction, and clinical outcomes across many disciplines.[43–45] Based on the assumption that patients are experts in their own experience of disease, patient-centered care is especially relevant for the uniquely personal experience of chronic pain that is often biomedically invisible. Patient-centered means that the care has solicited and included the patient's personal goals of treatment. However, shared decision making in chronic pain treatment presents unique challenges since pain science remains poorly understood by both patients and many care providers and much depends upon self-motivated patient self-management activities (e.g. behavioral and physical therapies). This is, in contrast, to passively delivered drug administration and surgical treatments effective for many other common chronic medical conditions. In addition, non-opioid treatments and procedural interventions often provide less than hoped for pain relief and remain highly dependent on concurrent long-term patient commitment to behavioral, fitness, and lifestyle modifications. Furthermore, while opioids unquestionably provide significant relief for acute and perioperative pain, their effectiveness in chronic non-cancer pain is not proven for many commonly occurring pain conditions, and their side effects and management risks are significant.[46] Opioid prescribing for chronic pain does represent a challenge to patient-centered, shared decision making since it is the clinician, NOT the patient, who ultimately controls prescribing. Notably, published United States opioid guidelines for chronic pain recommend clinicians should "collaborate" and "*empathically* review benefits and risks…" and should *offer to work with the patient.*[47] Regardless, patient-centered shared decision in chronic pain remains important and possible.

An individual who understands why chronic pain persists despite normal tissue healing and who is knowledgeable about treatment risks and benefits is more capable of active participation in informed patient decision making. This will require time and

effort dedicated to straightforward patient-level education about basic neurobiology and neurophysiology of pain processing by the nervous system that is both accessible and understandable to be truly patient-centered. There have been increasing numbers of popular self-help books and online resources that can be recommended and may be helpful to support in-clinic pain education for patients and families.[48–52] Neuroscience education for patients with chronic musculoskeletal pain disorders has been demonstrated by physical therapists with a positive effect on pain, disability, catastrophizing, and physical performance.[53] Evidence also supports the benefits of neuroscience education in chronic low back[54] and spinal pain.[55] Even very brief in-clinic physician and/or nurse or social worker directed education followed by recommended online, in-print reading or audiobooks improves adherence to drug and non-drug treatments, engagement in self-motivated pain-relieving behaviors (e.g. exercise initiation, pacing, relaxation techniques), and compliance with referrals for behavioral counseling can be beneficial.

Motivational Interviewing

Motivational interviewing (MI) is a well-established interview technique, initially developed as a systematic approach to engage patients in substance abuse treatment.[56] MI explores the gap between the patient's own aspirations for health behavior change and their current health behaviors. MI is intended to identify and develop patients' own motivations to change self-defeating behaviors. By exploring internal conflicts about the patient's values and behaviors, MI aims to uncover ambivalence about behavior change (e.g. physical exercise, sleep hygiene, medication, and healthcare seeking) and discover the patient's own motivations for change.[57] MI depends upon an active listening technique and a systematic and responsive approach to questioning intended to promote patient recognition of self-identified specific obstacles to achieving their own stated goals using their own words. MI is more applicable in difficult opioid prescribing situations than shared medical decision making since solicitation of the patient perspective is crucial, specifically the life goals and health aspirations that are part of an MI conversation. Although MI techniques have been most widely used in substance abuse care, they can be readily deployed in other aspects of pain medicine because engagement in self-management is essential if patients are to improve sleep, fitness, and diet. MI is directly linked to narrative pain management:

> *Intrinsic motivation for change arises in an accepting, empowering atmosphere that makes it safe for the person to explore the possibly painful present in relation to what is wanted and valued. People often get stuck, not because they fail to appreciate the downside of their situation, but because they feel at least two ways about it. The way out of that forest has to do with exploring and following what the person is experiencing and what, from his or her perspective, truly matters.*[58]

DiClemente and Velasquez frame the link between MI and the *stages of change* "through which people pass as they change a behavior."[59] They also provide a very useful verbal script for pain clinicians: "How has your pain changed you as a person, or stopped you from growing, from moving forward?" Since chronic pain cannot be separated from the person who has it, the clinician's task is to engage the patient to become the agent of their own change.

MI may be particularly useful when introducing the option of tapering and discontinuing opioids and other controlled substances because many patients are ambivalent about continuing on long-term opioid therapy and may benefit from MI techniques for patients to self-identify opioid related problems.[60] At times, MI can be effective in de-escalating difficult conversations, a well-recognized challenge in clinician-patient communication,[32] since the mere mention of de-prescribing medications can generate negative and confrontational interactions.

The use of a multidimensional tool at initial clinical assessment and then tracking change at every visit provides consistent opportunities to identify patient-reported outcomes (PRO) that are well suited to introduce specific domains for motivational change are especially valuable.[13] Though there are many ways to introduce MI into chronic pain conversations, eight PRO items measured by zero to ten numeric rating scales that are easily understood and have been very well accepted by patients can be used to facilitate the process. These include the three item PEG tool (i.e. pain intensity, pain interference with the enjoyment of life, pain interference with general activity),[61] two items about pain interference with sleep initiation and sleep maintenance, and the four item Patient Health Questionnaire (PHQ-4),[62] which assesses symptoms of anxiety and depression. At the initial visit, the clinician can review these items with patients asking them to identify which of these eight areas of their life they could possibly change. When pain intensity exceeds seven out of ten, a shared agreement can be developed when the status quo is not working. Other items can be viewed, and the clinician can seek shared agreement on which area they prefer to tackle first (e.g. poor quality of life, poor function, poor sleep, poor mood). Sleep disturbance is exceptionally common in chronic pain; nonpharmacologic options can be offered (e.g. sleep hygiene), and consider other potentially effective non-sedative hypnotic sleep medications (e.g. melatonin, low-dose tricyclic when appropriate). If patients choose to tackle general activity, possible ways to accomplish that (e.g. short walk, aquatic therapy, slow-paced targeted physical therapy) can be shared. Asking patients for their own interpretation of their outcomes by acknowledging that their time and effort are valued and that the information they shared will guide your shared treatment decisions. Table 12.1 delineates a four step approach, modified from Lussier and Richard's step-wise "communication tips" for nonpain-related topics applicable for motivating patients with chronic pain to behavior change.[57] Reducing pain intensity is the least likely to change, a trailing indicator of success, and so clinicians should do their best to steer patients away from expecting a reduction in pain intensity as their first step goal.

TABLE 12.1 Sample "Tips" for Motivating Patients to Change Behaviors to Improve Management of Chronic Pain

1. Is the status quo working?
Examples: "How does poor sleep/fitness /anxiety/depression/sedating or opioids medications affect your life?"
2. Is change possible?
"How do you think you might be able to get better sleep/become fitter/feel less depressed/take fewer pills?"
3. Can change happen?
"I see that you are now sleeping better/exercising more/seeing your therapist/taking fewer pills."
4. Coach to sustain change
"How can you keep going with your sleep/fitness/therapy/medication taper plan?"

Enhancing Clinician-Patient Relationships With a Collaborative Pain Care Model

Both pain experts and primary care providers often find it difficult to "be with" patients demonstrably suffering from chronic pain. Making this a satisfying line of work and avoiding burnout by working as a pain management *team* is very helpful. Incorporating a collaborative care model within multi-disciplinary pain management practice promotes improved communication by deploying a team of interprofessionals, who can then share the challenges and reduce the requirements for a medically trained pain expert to singlehandedly deliver emotional and social communication. A coordinated team of experts from multiple disciplines (e.g. medicine, psychology, physical therapy, social work, nursing, pharmacy), who share the same understanding of the interacting biopsychosocial dimensions of chronic pain, communicate effectively across their interprofessional competencies and keep *caring* for the patient as a common goal, will indeed have a positive impact on pain treatment outcomes.

Summary: Putting It Into Practice

The long history of the healing arts is founded on communication, caring, and compassionate listening. Acknowledging patients by empathically listening to their stories, narratives, and medical history is key to effective communication. Being with and sitting alongside patients as conversation partners and lead with open-ended questions since a therapeutic alliance arises from two-way conversations. Affirmation of patient progress toward their goals is key to motivating patients to continue to engage in changes necessary to improve their lives in the face of pain. At times fear, anger, and tears may be unavoidable, yet consolation may require just your silent presence and behaviorally communicated empathy. A few words of comfort may be all that is necessary, an acknowledgment that they are not alone and that their pain and suffering are not misunderstood. Remember that empathy is the ability to *understand* other people's feelings *as if* we were having them ourselves. However, they are not our feelings; they are theirs. A senior colleague from decades ago, recovering from protracted cancer treatment, once said, "It's always better to be the doctor than the patient." We are reminded of this when encountering a quagmire of anger and tears and then redirect this flood of emotions to deliberative clinically proven approaches that can offer some hope of relief and promote healing.

Ideally, a clinician's practice setting is already set up as a collaborative care model and includes a team of interprofessional pain care providers so that a nurse care coordinator, clinical psychologist, or clinical social worker can step in to help, so you would have no need to run away from an upset patient, and instead to redirect care temporarily to another qualified member of your pain care team. Although it is ideal to have an interprofessional pain care team embedded within one's practice setting, when such a team is not available, an effective alternative is to maintain a readily available, vetted, updated, and shared list of other appropriate community-based clinicians knowledgeable, skilled, and interested in the collaborative chronic pain care of your patients. A physical therapist focused on sports medicine and postoperative orthopedic rehabilitation may be unhelpful or may even frighten patients away from exercise of any kind.[53] Similarly, a psychologist focused on insight alone or supportive counseling approaches may omit important cognitive and behavioral skills addressing negative thoughts about pain, goal-setting strategies for structured behavioral activation routines, and communication strategies around pain related difficulties, which have been shown to be particularly important.[50]

To successfully care for those who present after months to years of chronic pain, exhaustively evaluated, seen by many other clinicians over many years without alleviation of symptoms, with the stigma of "a chronic pain patient," and without hope is no small challenge. To help to make a change in the lives of patients with chronic pain and to hear "thank you for giving me back my life" is a remarkably satisfying experience for patients, their families, and, of course, for clinicians. Improved communication skills that emphasize the patient perspective and leverage our natural empathic abilities can and do improve the care and outcomes for patients with chronic pain. Moreover, for successful pain clinicians, nothing is better than that.

Key Points

- Management of chronic pain, a biopsychosocial condition, by its very nature, includes more than just a straightforward communication of biomedical objective information.
- Patient-centered chronic pain care consists of taking the patients' perspective on their pain and activating the patient for self-care.
- Shared medical decision making aims to align therapeutic goals, improve patient treatment engagement, and support an agreed upon self-management plan.
- Narrative medicine communication skills such as empathic, reflective listening, and use of nonjudgmental language endeavor to strengthen clinician-patient therapeutic alliance, improve treatment acceptability and compliance, and increase patient and clinician satisfaction with pain care.
- Motivational interviewing (MI) challenges patient behaviors by contrasting these with patient aspirations. It can be used to change interfering behaviors such as poor sleep hygiene, insufficient exercise, inconsistent treatment adherence; and is particularly useful when tapering and discontinuing opioids and other controlled substances.
- A collaborative care model can improve communication by deploying an inter-disciplinary team who share the same understanding of the interacting biopsychosocial dimensions of chronic pain. This can reduce requirements for a medically trained pain expert to singlehandedly communicate and deliver all aspects of complex chronic pain care.

Pharmacogenetics in Pain Management

ERICA L. WEGRZYN, HIMAYAPSILL BATISTA QUEVEDO, JEFFREY FUDIN, CHARLES E. ARGOFF

CASE 13.1

A 58-year-old Asian-American male with no other significant past medical history presents to the clinic with acute herpes zoster in the left T4 dermatome. The patient endorsed severe localized pain and tactile allodynia associated with a vesicular eruption. After three months, the rash resolves, but he complains of severe burning pain, allodynia, and hyperalgesia in the left T4 dermatomal region, suggesting that he has developed post-herpetic neuralgia (PHN). Nortriptyline 10 mg was prescribed, but shortly after starting the medication, he developed severe sedation, orthostatic hypotension, and xerostomia. Nortriptyline was then discontinued, and tramadol was initiated. However, the patient did not tolerate tramadol either. A third medication was then trialed hydrocodone/acetaminophen, but yet again, the patient responded poorly. Lastly, gabapentin 300 mg nightly was prescribed and titrated over several weeks to a target dose of 1800 mg/day in three divided doses. This medication slightly alleviated the neuropathic pain, but it was still not well-controlled, and the patient return for further assessment and treatment. It took over six weeks to select and titrate a medication that achieved any notable pain reduction in this specific patient.

This patient was treated according to available evidence-based guidelines,[1–3] yet he did not obtain adequate analgesia from the prescribed medications. Clinicians recognize that each individual patient responds differently to pain itself, and in the same fashion, response to medications varies from person to person. Advances in pharmacogenomics can help providers understand how genetic variations affect drug metabolism and response, thus offering clinicians the opportunity to identify the most appropriate pharmacotherapy before prescribed and improve patient-specific outcomes. Appropriate knowledge and utilization of pharmacogenomics can allow for the individualization of medication selection.

In the case described, the patient's inadequate pain relief requires a careful evaluation of the potential reasons rendering the medication ineffective. For example, nonadherence, drug interactions, pain mechanism, or a combination of these could be factors limiting medication efficacy. It is also important to consider the patient's genetic makeup affecting medication metabolism, thus impacting efficacy and toxicity. This is where pharmacogenomics can play a crucial role in pain management. The case illustrates the variable response and adverse event profile that might be observed when analgesics are prescribed. As noted, clinicians are keenly aware of how often individuals may not obtain the expected therapeutic benefit from analgesic medications across several pharmacologic medication classes.[4]

The response rates in well-designed studies of various analgesic therapies are approximately 55%. This "treatment success" rate is muddled by favorable analgesia to placebo.[5] A large number of patients will not respond to initial therapy. Many key areas of medicine are similarly affected by poor responder rates in clinical trials of diverse drug types. A clear understanding of how pharmacogenomic factors influence the effect of a prescribed analgesic could allow clinicians enhanced analgesic treatment outcomes.

The Impact of Pharmacogenomic Research on Clinical Medicine

Pharmacogenomics is the study of the impact of genetics on pharmacotherapeutic responses and tolerability. It is used to improve drug safety and efficacy through genetically guided, individualized treatments.[4] As previously noted, the same drug can be associated with different clinical responses among various populations. This is because each individual's unique genetic composition (i.e. genotype) provides the blueprint for the generation of singular protein expression profiles (i.e. phenotype), which subsequently leads to functional variations observed as clinical responses. Considering such genetic predisposition and receptor subtype expression can result in improved outcomes or resolution of disease. This approach is undoubtedly at the core of personalized medicine. When the clinician is aware of a patient's genetic predisposition and receptor subtype expression, this knowledge may lead to more individually focused prescribing with improved efficacy and safety for the patient.[4] Key terms used in pharmacogenomics can be viewed in Table 13.1.

The utilization of genetic information in clinical practice has far-reaching implications. The benefit of utilizing information derived from pharmacogenomics in the future of clinical medicine may lead to improved success rates, decreased side effect burdens, and reduced healthcare costs.[6] For example, the clinical integration of genetic information is routinely used in oncology to guide treatment.[7,8] Other areas of medicine are also beginning to tailor pharmacotherapies based on an individual's genetic information, and certain biomarkers are now known that can help guide treatment in many areas of medicine, including pain

management and rheumatologic diseases.[9] Pharmacogenomic testing has benefited patients and clinical medicine in general by improving the ability to stratify the risks of various treatments for individual patients by identifying groups of patients with a higher potential for poor efficacy or for adverse treatment effects (Table 13.1).[6]

The most commonly observed DNA sequences of a gene are termed "wild-type," and the less common alleles are "variants" if they occur in more than 1% of the population. The even less prevalent alleles have another name; DNA sequences in genes found in less than 1% of the population are called "mutations."[10]

Pharmacogenetics can allow clinicians to predict medication's pharmacokinetics and pharmacodynamics and can also help identify patients who are more prone to certain genetically associated diseases. For example, within pain management, an autosomal dominantly inherited peripheral neuropathy, hereditary sensory, and autonomic neuropathy type I confers insensitivity to pain mediated through the progressive degeneration of the dorsal root ganglia and motor neurons as the result of mutations within a specific location in chromosome 9.[11,12] Individuals with this genetic background cannot perceive pain, making them particularly prone to painless but potentially severe injuries, with detrimental complications, such as chronic skin ulcers and distal amputations. Kirsh and colleagues studied the polymorphism of a population in Louisiana by administering pharmacogenomic testing to all new patients. Based on 388 tests conducted, 42.3% of individual tests were extensive metabolizers (normal), 25.5% were intermediate metabolizers, 7.2% were ultra-rapid metabolizers, and 7.0% were poor metabolizers; 18% exhibited indeterminate results from inadequate DNA samples or unknown polymorphism. The authors noted that the study yield abnormal pharmacogenetic testing in nearly 40% of patients. In contrast, some studies have found that 83% of patients have abnormal CYP450 defects compared to 20% to 30% of the general population and that other sources found results consistent with the population of Louisiana studied. The growing body of evidence indicates that polymorphism can vary even among subpopulations, thus limiting the generalizability to other pain clinic samples.[13]

TABLE 13.1 Key Pharmacogenetic Terminology

Genome	The entire collection of genetic information (or genes) that an organism possesses
Genotype	The genetic constitution of an individual, either overall or at a specific gene
Heterozygous	The presence of two different alleles (one on the maternal chromosome and one on the paternal chromosome) at a gene location
Homozygous	The presence of two identical alleles at a gene location
Isoform	A variant in the amino acid sequence of a protein
Messenger RNA	An RNA-containing single-strand copy of a gene that migrates out of the cell nucleus to the ribosome, where it is translated into a protein
Mutation	A rare variant in a gene, occurring in less than 1% of a population
Pedigree	A diagram depicting heritable traits across two or more generations of a family
Phenotype	The observable characteristics of a cell or organism, usually resulting from the product coded by a gene (genotype)
Polymorphism	The existence of two or more variants of a gene in a population, with at least 1% frequency of the less common variant
Prodrug	A medication that is inactive until it is converted enzymatically to its active metabolite
Single nucleotide polymorphism (SNP)	A single base-pair change in a DNA sequence compared with the "common" or "wild-type" sequence
Variant allele	The allele at a particular SNP that is the least frequent in a population
Wild-type allele	The allele at a particular SNP that is most frequent in a population also called the "common" allele

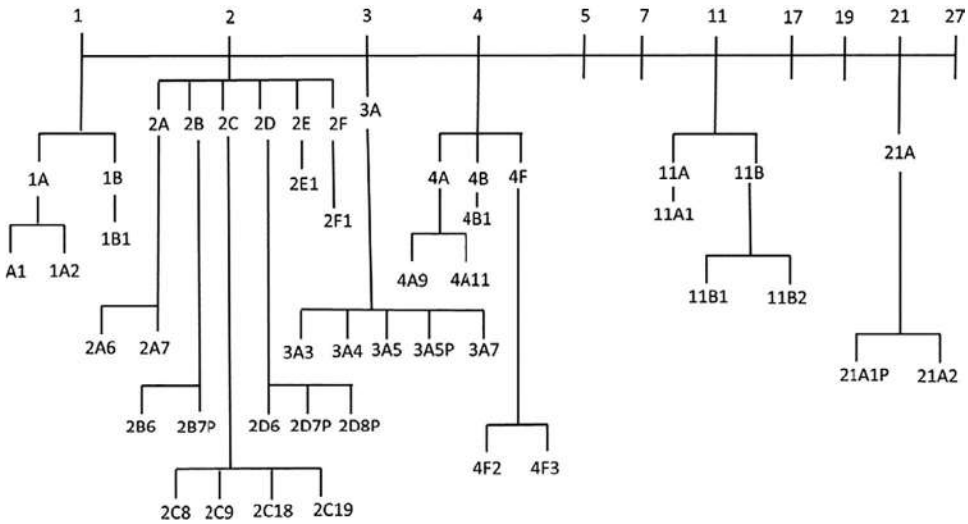
The Impact of Pharmacogenomics on Pain Medicine

In terms of efficacy, toxicity, pharmacokinetics, metabolism, and drug transport, differences in clinical response to pain medications have been linked in part to genetic variations.[4] To understand how pharmacogenomics can guide medication selection, it is important first to review how drugs are metabolized. Most medications are primarily metabolized in the liver. Hepatic metabolism occurs through phase I reactions, phase II reactions, or both. Phase I reactions are most commonly catalyzed by the cytochrome P450 (CYP450) system, whereas phase II conjugation enhances water solubility for excretion. The CYP450 genes encode enzymes responsible for the metabolism of approximately 75% of commonly prescribed medications.[14] CYP450 is classified by gene sequencing, assigned a family number, a subfamily letter, and then a number for the individual enzyme based upon the order in which it was discovered and is outlined in Figure 13.1.[15,16] Individual variations of CYP gene expression results in altered metabolism, impacting drug concentration and response. These CYP variations are dependent on the metabolizer phenotype.[17] Pharmacogenetic testing for variant and wild-type alleles of CYP450 enzyme groups patients by their phenotype. Poor metabolizers who have two nonfunctional enzyme alleles resulting in an inability to metabolize; intermediate metabolizers, who have at least one reduced functional allele of an enzyme; extensive metabolizers, who have at least one functional allele; and ultra-rapid metabolizers, who have multiple copies of a functional allele or an allele with a promoter mutation that confers increased transcription of that gene.[17,18] Extensive metabolizers, the typical phenotype, obtain the expected therapeutic benefit and adverse effect profile from standard doses of a drug. In contrast, individuals who are poor metabolizers are at risk of poor efficacy or adverse effects if given a prodrug that is incompletely metabolized because of genetic



• **Figure 13.1** Cytochrome P450 enzyme Tree. Adapted from Riddick DS, Drug biotransformation. In: Kalant H and Roschlau W (Eds.). *Principles of Medical Pharmacology.* 6th ed. New York: Oxford University Press: 1997. and reprinted with permission from paindr.com.

differences in their liver enzyme systems. For example, a patient who is a poor metabolizer may not be able to convert the parent drug of an opioid into the active metabolite needed for analgesia (i.e. codeine to morphine, tramadol to o-desmethyltramadol). In contrast, ultra-rapid metabolizers can be prone to adverse effects because of higher than expected drug concentrations from enhanced metabolism (i.e. morphine toxicity from rapid metabolism from codeine).[19]

Non-CYP Polymorphisms

Genetic determinants beyond metabolic enzymes (such as the CYP450 family) also affect an individual's response to opioid analgesics. These include drug transporters and drug targets such as the μ-opioid receptor gene OPRM1. A common polymorphism of OPRM1 is the substitution of a single nucleotide at position 118 with an adenine substitution by guanine. The reported allelic frequencies for this are estimated at 10% to 30% among Caucasians, lower among African Americans, and higher among Asians.

Polymorphism of the OPRM1 gene can result in reduced expression of μ-opioid receptors. There is great interest in this polymorphism because it has been associated with pharmacologic and physiologic consequences affecting not only experimental pain models but also neuraxial opioid use for labor analgesia, postoperative analgesia, and cancer-related pain.[20] Studies have suggested that patients presenting with this genetic polymorphism may require higher doses of opioids for analgesic benefit.[21] The different combinations of these single nucleotide polymorphisms (SNPs) within genes that code for the targets of opioid analgesics (e.g. OPRM1) may result in different clinical effects, and thus knowledge of these for a specific patient could one day allow for improved outcomes for opioid prescribing. In addition to the CYP450 family of enzymes, the μ-receptor gene (OPRM1, p.118A/G), and the catechol-O-methyltransferase (COMT Val158MET), several types of the adenosine triphosphate (ATP)-binding cassette, and subfamily B member one gene (ABCB1) have been extensively studied.[20]

Methylenetetrahydrofolate reductase (MTHFR) and COMT are crucial in opioid and anti-depressant response. Patients with chronic pain often present with comorbid mental health disorders. COMT enzyme regulates the breakdown of serotonin, dopamine, norepinephrine, and putative neurotransmitters, while MTHFR is responsible for converting 5,10-Methylenetetrahydrofolate to 5-Methyltetrahydrofolate to its active, usable form of folate. The COMT Val158MET polymorphism is associated with low COMT activity, resulting in increased concentrations of dopamine and norepinephrine.[22] High concentrations of dopamine are associated with upregulation of opioid receptor expression. Ultimately, patients with the Val158MET variant may require fewer opioids for pain relief. [20] MTHFR polymorphism is associated with folate bioavailability impairment.[22]

It has been determined that the interaction of several polymorphisms likely influences the pharmacokinetics and pharmacodynamics of medications—for example, inherited differences—in drug targets (receptors) and drug metabolism and drug transport.[20] Recognizing that morphine and most clinically used opioids act via the μ-opioid receptor, the concept of μ-receptor multiplicity has been studied with the recognition that different splice variants of the MOR-1 gene exist with the potential to clinically affect the benefits or lack thereof of morphine and other opioid analgesics.[23] This kind of information will likely affect the manner in which clinicians prescribe opioids in the future.

Research continues to demonstrate the necessity of genomic testing, as it can optimize medication efficacy, reduce adverse events, decrease hospitalizations, and even prevent deaths in select cases.[24] Additionally, studies have also concluded cost effectiveness on clinical outcomes when genotyping is performed.[25]

Tricyclic Anti-depressants

Consider the patient example described above, in which the tricyclic anti-depressant (TCA) administered to the patient presenting with PHN led to intolerable adverse effects. As previously mentioned, TCAs are one of the many medications metabolized in the liver by the CYP450 system, and polymorphisms within this class of enzymes can lead to reduced or accelerated metabolism of their substrates.[26] As such, two individuals having the same weight and given the same drug dosage can have more than a 1000-fold difference in their plasma drug levels.[4] This can be extremely important to recognize from a clinical viewpoint as the plasma drug concentrations in individuals given the same dose of anti-depressants have been found to vary—primarily based on the polymorphisms present in the CYP2D6 enzyme (and CYP1A2, CYP2C19, and CYP3A4/5).[27,28] Relevant to the patient presented at the beginning of this chapter, individuals who are poor metabolizers of TCAs (approximately 7% of the Caucasian population) tend to accumulate drug concentrations outside of the narrow therapeutic range of the drug classes, leading to adverse TCA effects at lower than expected doses.[18,26] In contrast, patients who are CYP2D6 ultra-rapid metabolizers may require higher doses to achieve analgesia.[18,27,28] Potentially, the patient presented is a CYP2D6 poor metabolizer.

The value of genotyping before prescribing anti-depressants was considered in a large population-based study of 1198 elderly Dutch patients. Perhaps not surprisingly, poor metabolizers of TCAs more than extensive metabolizers required either lower maintenance doses or discontinuation of TCAs altogether.[25] Although research does not provide clear evidence to support the routine clinical use of liver enzyme genotyping before analgesic treatment, an increasing number of commercial entities have developed the capabilities to perform these assays. Thus they are now available for the clinician to consider using.[4] Clinically, the recognition that an individual patient could be a poor metabolizer, with or without confirmatory testing, can assist the prescriber to consider medication changes (dose adjustment or frank discontinuation) when poor efficacy or adverse events are observed.

Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

Pharmacogenomic research in pain management has identified wide interindividual variation in the analgesic efficacy of both nonspecific NSAIDs and selective inhibitors of cyclooxygenase-2 (COX-2) because of SNPs within the COX genes.[29,30] A SNP in the promoter for the gene encoding COX-2 (the -1195G to A change) has a prevalence of greater than 10% and has been associated with mild asthmatic reactions.[31] Indeed, another functional effect of the increased expression of COX-2 potentially mediated by several SNPs is the enhanced susceptibility to hypersensitivity in response to standard doses of aspirin and other NSAIDs that inhibit COX-2, otherwise known as aspirin-intolerant asthma.[32] Additionally, a large genotyping study has determined that individuals with specific variants of the COX-1 and COX-2 genes have an increased risk of cardiovascular disease when taking aspirin.[29] Other studies have investigated an association between genotypes of the cytochrome P450 enzyme CYP2C9 and taking NSAIDs metabolized by that enzyme. An increased risk of developing gastroduodenal bleeding was noted in patients with this co-occurrence.[33–35]

Opioid Analgesics

Single Nucleotide Polymorphisms

In properly selected patients, opioids can be effective treatments for acute and chronic moderate to severe pain.[36] Similar to tricyclic anti-depressants, most opioids are metabolized by the CYP450 enzyme class (Table 13.2).[18] Hence, SNPs in CYP450s can have an impact on clinical analgesia and adverse effect responses. In particular, codeine has been associated with variable individual clinical responses. Codeine itself does not have analgesic activity as it is a prodrug: a medication that is inactive until it is enzymatically converted to its active metabolite. Approximately 10% of codeine is converted to its active metabolite, morphine, via CYP2D6 to provide analgesia.[20] Therefore patients with an ultra-rapid phenotype are at increased risk of respiratory depression because of extensive conversion of morphine.[37] The rest of codeine is converted to inactive metabolites via CYP3A4 and glucuronidation.[20,37,38] In contrast, CYP2D6 poor metabolizers may experience suboptimal analgesic efficacy when prescribed "routine" doses of codeine. This is also true for tramadol, another prodrug that undergoes extensive metabolism to the active metabolite via 2D6, and utilization of 3A4 and 2B6 to inactive metabolites produce opioid receptor mediated analgesia.[37] Figure 13.2 outlines the metabolism of common opioids and substrates. Tramadol is metabolized to O, N-desmethyltramadol by CYP3A4 and the primary active metabolite o-desmethyltramadol (M1) by CYP2D6. Notably, tramadol provides analgesia not only through opioid meditated receptors but also through inhibition of norepinephrine reuptake, similar to anti-depressant's mechanism of action. However, the reuptake inhibition of serotonin by tramadol does not provide analgesia, although abrupt discontinuation could result in serotonin withdrawal, which is often misinterpreted as opioid withdrawal. This is particularly important when selecting an agent as the risk of serotonin toxicity is increased with concomitant use of serotonergic medications such as serotonin reuptake inhibitors (SSRIs) (i.e. fluoxetine, paroxetine, sertraline).[20,38,39]

The extensive metabolism of tramadol (Fig. 13.3) also presents the opportunity for significant drug interactions, as when paired with an inhibitor of the CYP2D6 pathway, the expected response is similar to those with reduced CYP2D6 phenotype expression. An alternative option to consider in this case is the structurally similar tapentadol, which conversely, tapentadol avoids the CYP450 system, metabolized by phase II with no active metabolites. This makes tapentadol a lower risk medication for drug-drug CYP450 drug interactions and avoids the potential for genetic polymorphisms to impact metabolism. Unlike tramadol, tapentadol has a significant binding affinity for the μ-opioid receptor, and it has norepinephrine reuptake inhibiting properties only, with no effect on serotonin reuptake.[39]

The metabolism of many currently available opioids can be affected by SNPs with the CYP450 system; however, five opioid analgesic medications are not metabolized through this system at prescribed doses: hydromorphone, levorphanol, morphine, oxymorphone, and tapentadol.[37,40] Therefore if it has been identified, perhaps by noting poor analgesic efficacy or intolerable adverse effects (or even possibly actual pharmacogenetic testing) that an individual has an SNP that alters the enzymatic activity of one or more of the CYP450 isoenzymes; an opioid analgesic (if otherwise appropriate for that patient) might be considered that is not

TABLE 13.2 Metabolizer Status by Racial/Ethnic Group

Gene or Enzyme	Examples of Drugs Metabolized by This Enzyme	Phenotype and Frequency by Groups	Clinical Effect
CYP1A2	Anti-convulsants: phenytoin, carbamazepine substrates Anti-depressants: clomipramine, fluoxetine, fluvoxamine, imipramine, maprotiline, nortriptyline Muscle relaxant: cyclobenzaprine NSAIDs: acetaminophen, naproxen	PM: Caucasian, 12%	Weak metabolism of enzyme
CYP2C9	Warfarin substrates Phenytoin Angiotensin II blockers: irbesartan, losartan NSAIDs: celecoxib, diclofenac, ibuprofen, meloxicam, naproxen Oral antidiabetics: glipizide, tolbutamide	PM: Caucasian, 2%-6%	Weak metabolism of enzyme
CYP2C19	Anti-convulsants: diazepam, phenytoin substrates Proton pump inhibitors: omeprazole, pantoprazole	PM: Caucasian, 2%-6%; Chinese,15%-17%; Japanese, 18%-23%	Weak metabolism of enzyme
CYP2D6	Analgesics: codeine, dextromethorphan, oxycodone, tramadol substrates Antiarrhythmic drugs: ajmaline, flecainide, mexiletine, propafenone Antiemetics: metoclopramide Antipsychotics + SSRIs: fluoxetine, haloperidol, paroxetine β-Blockers: metoprolol, propranolol, timolol 5-HT3 antagonists: ondansetron, tropisetron TCAs: amitriptyline, clomipramine, desipramine, imipramine	PM: Caucasian, 3%-10%; Chinese/Japanese/African American, <2% UR: Ethiopian, 20%; Hispanic, 7%; Scandinavian, 1.5%	Weak metabolism of enzyme Enhanced metabolism of enzyme substrates

5-HT3, serotonin; *NSAIDs*, nonsteroidal anti-inflammatory drugs; *PM*, poor metabolizer; *SSRIs*, selective serotonin reuptake inhibitors; *TCAs*, tricyclic anti-depressants; *UR*, ultra-rapid.

metabolized through this mechanism to increase the likelihood of a successful treatment outcome.

The current clinical value of pharmacogenomic research illustrates that pharmacogenomic data may play a role in risk stratification and may help guide prescribers in their decision making. Relevant to the patient presented previously, 41% to 51% of individuals of Asian origin express an unstable CYP2D6 enzyme, whereas 12% to 21% of Caucasian people express an inactive CYP2D6 enzyme.[41] However, in clear contrast, 10% to 29% of people of Ethiopian or Saudi Arabian descent have heightened CYP2D6 activity.[41] When considered for the purposes of clinical decision making, this pharmacogenomic information can provide clues about how a specific patient may respond to codeine, and other opioids metabolized by CYP2D6 and, thereby, offer prescribing guidance (Table 13.3). The patient presented may be genetically predisposed to low CYP2D6 activity. His inherent enzymatic capacity may not be sufficient to obtain analgesia from the prodrug codeine and other opioids such as hydrocodone (hydrocodone is metabolized to hydromorphone through a CYP450-dependent process).[42] Pharmacogenomic information may provide the connection between the opioid prescribed and the lack of expected clinical response or the presence of unexpected adverse effects. Opioid responsiveness is widely recognized as a highly individualized phenomenon that depends on many factors, including pain etiology, prior exposure to opioids and opioid tolerance level, and other psychophysiological determinants. Consequently, pharmacogenomics can have a significant impact on the clinical response to opioid therapy.[43]

Alternative Splicing

Although most studies concerning opioid-response variability have focused on SNPs, other investigators are examining cellular mechanisms that may contribute to the interindividual variable response to opioid analgesics.[44] Evidence has identified multiple μ-opioid receptor subtypes, often referred to as "splice variants," with distinct properties that influence the pharmacodynamics of individual opioids.[44] To understand this source of diversity, consider a brief review of the central tenets of molecular biology.[10]

Genetic material (DNA) is transcribed into ribonucleic acid (RNA) and then translated into proteins, with cellular structural, enzymatic, and receptor functions. SNPs are sources of variation in the DNA, while diversity is also introduced during the transcription of RNA, during which alternative splice variants are produced. This idea was proposed in the 1980s by Nobel Prize winner Walter Gilbert and has since been well characterized and is recognized as the major source of proteome diversity enabling the complexity of human traits.[26]

Alternative splice variants of the μ-opioid receptor have been identified and correlated with the clinical phenomenon of incomplete cross-tolerance by which tolerance to one opioid does not translate to tolerance to other opioids.[23] In addition, although most clinically used opioids are selective for the μ-opioid receptor, their ability to activate the receptor can vary, leading to widely different efficacies and side effect profiles between individual patients. The minimal effective analgesic concentration for morphine can vary among patients by as much as 10-fold.[45] Further response variation within an individual is related to gene expression patterns changing over time and even diverging across organ systems and tissues, based on an individual's state of health and the degree or type of physiologic or emotional stress present.

As previously mentioned, clinically significant response variation in both the efficacy and adverse events of opioids and other analgesics has been noted for many years.[46a,46b] Chronic opioid therapy treatment guidelines developed by the American Pain Society and the American Academy of Pain Medicine recommended considering "opioid rotation" (e.g. switching from one opioid to another) if the initially prescribed opioid is neither well tolerated nor clinically effective after a reasonable trial.[36] Grilo and colleagues completed a study of patients with difficult-to-treat rheumatologic pain, in which most patients rotated from morphine to either transdermal fentanyl or hydromorphone.[46a,46b] Those patients who underwent opioid rotation experienced a mean reduction of 30 mm on a visual analog scale, indicating a clinically meaningful reduction in pain intensity.[46a,46b,47] In a study of opioids for the treatment of chronic non-cancer pain, Quang-Cantagrel and colleagues reported that the first long-acting opioid

TABLE 13.3 Enzymes Involved in Opioid Metabolism

Class	Drug	Metabolism
Phenanthrenes	Codeine	10% CYP3A4 (to norcodeine); 5% CYP2D6 (to morphine); 80% UGT2B7
	Hydrocodone	CYP2D6 (to hydromorphone) and CYP3A4 (to norhydrocodone); other minor non-CYP oxidative enzymes
	Morphine	UGTs (GYP-metabolized products)
	Oxycodone	Hepatic glucuronide by UGT1A3 and UGT2B7
		CYP2D6 (to oxymorphone) and CYP3A4 (to noroxycodone); GYP-metabolized product(s) by UGTs
	Dihydrocodeine	5%-10% CYP2D6 (to dihydromorphine) and CYP3A4 (to nordihydrocodeine); 85% UGT2B7
	Hydromorphone	Hepatic glucuronide conjugation via UGT1A3, UGT2B7; dihydromorphinone ketone reductase
	Oxymorphone	UGT1A3 and UGT2B7, with UGT2B7 being the predominant enzyme
	Buprenorphine	CYP3A4 (65%), CYP2C8 (30%), CYP3A5, CYP3A7,CYP2C9, CYP2C19, and CYP2C18; GYP-metabolized product(s) further cleared by UGTs
	Naloxone	Conjugation with glucuronic acid via UGTs, mainly UGT2B7
	Naltrexone	Aldo-keto reductase (dihydrodiol dehydrogenase); glucuronidation via UGTs
Diphenylheptylamine	Methadone	N-demethylation by CYP3A4
	Propoxyphene	N-demethylation by CYP3A4
Phenylpiperidines	Fentanyl	N-dealkylation by CYP3A4
	Meperidine	CYP3A4, CYP286, and CYP2C19
	Remifentanil	Nonspecific blood and tissue esterases to remifentanil acid
	Sufentanil	N-dealkylation by CYP3A4
Phenylpiperidine derivatives	Loperamide	N-demethylation by CYP2B6, CYP2C8, CYP2D6, and CYP3A4
Phenylpropylamine	Tramadol	O-demethylation by CYP2D6; N-demethylation by CYP286 and CYP3A4
	Tapentadol	N-demethylation (13%) by CYP2C9 and CYP2C19; Hydroxylation (2%) by CYP2D6; Hepatic glucuronide (55%) by UGT1A9 and UGT2B7

prescribed was effective for 36% of patients.[48] However, the initially prescribed opioid had to be discontinued because of adverse effects in 30% or ineffectiveness in 34% of those studied. Eventually, a clinical response was obtained by changing to a second (31% responded), third (40% of the remainder responded), fourth (56% of the remainder responded), and fifth (14% of the remainder responded) opioid.[48] These data, however, do not indicate that eventually, a patient will respond to a particular opioid, and thus it is important to note that the failure of one opioid does not predict the patient's response to another opioid analgesic.[49]

The concept of opioid rotation is based not only on empirical clinical observations but also on the pharmacogenetic considerations discussed earlier. Safe and effective opioid rotation requires specific clinical knowledge; if opioid rotation is believed to be an appropriate approach to managing the care of an individual patient, guidelines are available for the calculation of equianalgesic dosing and other important steps in this process.[43]

Future Outlook and Conclusions

Advances in pharmacogenomics continue to grow and allow clinicians to more precisely individualize optimal pharmacologic care for their patients with acute and chronic pain. Commercial pharmacogenomic testing is currently available. However, cost and provider education and result interpretations are still an obstacle to implementing its use as a standard of care. It is critical for prescribing clinicians to be trained and proficient in understanding the influence of genetic and genomic variations on drug responses or consider collaborating with a pharmacist with specialized training. The potential benefits of such testing are attractive enough, given the potential for more effective and safer management of patients with acute and chronic pain to warrant further study to improve their clinical applicability.

Key Points

- Pharmacogenomics is the study of the impact of genetics on pharmacotherapeutic responses and tolerability to improve drug safety and efficacy through genetically guided, individually tailored treatments.
- Advances in pharmacogenomics allow for a better understanding as to why patients may have variable responses to various analgesic therapies and may soon allow an opportunity for clinicians to identify the most appropriate pharmacotherapies for a patient *before* prescribing.
- SNPs in the CYP450 system can lead to drug response variability impacting drug efficacy and safety.
- Genetic variance can impact the therapeutic response of specific pain medications or predispose an individual to adverse effects.
- Extensive metabolizers obtain the expected therapeutic benefit from standard doses of a drug. In contrast, individuals who are poor metabolizers are at risk of poor efficacy and/or adverse effects if given a prodrug that is incompletely metabolized because of genetic differences in their liver enzyme systems.
- It is important to consider metabolite activity when determining the impact of genetic polymorphism on medication selection. A prodrug will have the opposite effect compared to a medication without active metabolites.

Psychosocial and Psychiatric Aspects of Chronic Pain

DENNIS C. TURK, TASHA B. MURPHY

Introduction

When a patient presents to a healthcare provider with a symptom of pain, the initial focus is on the patient's medical history and the underlying pathology—a search to identify the "broken body part" that once identified is treated to eliminate the symptom. When pain is not easily alleviated and becomes chronic, it can cause a patient (provider and significant others) significant distress with many other ongoing difficulties that compromise all aspects of their lives. Living with chronic pain requires considerable emotional resilience as it depletes people's emotional reserves; the continuing quest for relief often remains elusive, leading to feelings of demoralization, helplessness, and hopelessness.

Historically, the amount of pain a person reported was expected to be related to the amount of tissue damage—"somatogenic." When the presence and extent of pain report was not adequately explained by any identifiable pathology, pain was considered "functional" or "psychogenic." Psychological factors were then considered to be playing a causal role. However, over the past four decades, research has consistently demonstrated that pain is not unidimensional; it is instead a complex biopsychosocial phenomenon. A range of cognitive, affective, behavioral, and sociocultural factors, in addition to physical and other biomedical factors, all contribute to the chronic pain experience. Treating individuals with chronic pain requires a comprehensive approach customized to each patient's unique characteristics and needs.

Advances in the knowledge of the neurophysiology of pain have resulted in the development and evolution of pharmacologic agents, surgical interventions, innovative technologies (e.g. spinal cord stimulation, implantable drug delivery systems), and nonpharmacologic treatments (e.g. neurofeedback, cognitive-behavioral therapy) for the treatment of patients with chronic pain.[1–3] However, despite these developments, the amount of pain reduction averages only about 35%, and fewer than 50% achieved this result.[4] Therefore many people with persistent pain shuttle from healthcare provider to healthcare provider, diagnostic test to diagnostic test, in a frustrating and prolonged quest to achieve relief. This experience of "medical limbo"—the presence of a painful condition that, in the absence of acceptable pathology, is either attributed to psychiatric causation or malingering on the one hand, or an undiagnosed but potentially progressive and untreatable disease on the other—is itself a source of significant and ongoing stress that can initiate high levels of emotional distress or aggravate a premorbid psychiatric condition.[5]

The person who has chronic pain resides in a complex world populated not only by them but also by their significant others, including family healthcare providers, employers, and third-party payers. Family members feel increasingly hopeless and distressed as medical costs, disability, and emotional suffering mount while available treatment options and income decline. Healthcare providers grow increasingly frustrated and ineffective and defeated as available treatment options are exhausted, while the pain condition remains a mystery and with no end in sight. Providers may come to question the veracity of their patients and their complaints. Employers, who are already resentful of growing worker's compensation benefits, pay higher costs while productivity declines because the employee frequently calls out sick or cannot perform at his or her usual level ("presenteeism"), often with coworkers having to pick up the slack. Third-party payers watch as healthcare expenditures soar with repeated diagnostic testing, often with inconclusive results. In time, the legitimacy of the individual's report of pain may be questioned since often a physical etiology fails to substantiate the cause of the symptoms.

People with chronic pain may feel that their healthcare providers, employers, and even family members are skeptical, blaming them when their condition fails to respond to treatment as expected. Some may suggest that the individual is complaining excessively in an attempt to obtain prescriptions for centrally acting and reinforcing medications (e.g. opioids, mood altering), receive attention, benefit financially (i.e. obtain disability compensation), avoid undesirable activities, or be relieved from onerous obligations (e.g. gainful employment, household chores). Others may suggest that the pain reported is not real, that they are feigning or exaggerating their symptoms, and it is "all in their head." Often, the ensuring result is an unfortunate, inappropriate, and detrimental adversarial relationship between patients, their healthcare providers and employees.

As a result of these attitudes, and in the absence of a cure or even substantial pain relief, individuals experiencing chronic pain may withdraw from contacts, lose their sources of income, alienate family, friends, and coworkers, and become more and more isolated, despondent, and depressed. They may become angry and frustrated as their bodies, the healthcare system, legal system, and their significant other have all let them down; they may feel they have even let themselves down as they relinquish their usual activities and responsibilities because of symptoms that are intractable,

yet often inscrutable when not directly observable or validated by objective pathologic findings. This emotional distress can be exacerbated by a variety of other factors, including fear of disease progression and their vulnerability to escalating sets of symptoms and disabilities, insufficient or maladaptive support systems, inadequate personal and material coping resources, treatment-induced (iatrogenic) complications, including overuse of potent drugs with significant adverse effects, disruption of usual activities and sleep disturbance, inability to work, financial difficulties, and prolonged litigation. Living with persistent pain conditions requires considerable emotional resilience and tends to deplete people's emotional reserves, taxing not only the individual sufferer but also the capacity of family, friends, coworkers, employers, and society to provide support.

Based on what we describe above about the plight of the person with chronic pain, two conclusions are obvious: (1) psychosocial and behavioral factors play a significant role in the experience, maintenance, and exacerbation of pain and potentially even the cause,[6] and (2) since some level of pain persists in the majority of people with chronic pain regardless of treatment, self-management is an important complement to biomedical approaches.[7] In this chapter, we will emphasize a set of important psychological constructs, including dispositional, cognitive, affective, behavioral, and contextual factors. We discuss them individually for ease of explication. However, it is important to note that although we will describe these separately, there is considerable overlap and interaction among them. We will conclude with a discussion of integrative models and treatments for people with chronic pain.

Historical Models

Biomedical Model of Chronic Pain

The traditional biomedical model of pain—which dates back to the ancient Greeks and was inculcated into medical thinking and practice by Descartes in the 17th century—assumes that people's symptoms result from a specific disease state represented by disordered anatomy and pathophysiology. The diagnosis is confirmed by data from objective tests of physical pathology and impairments, and medical interventions are specifically directed toward correcting the organic dysfunction and organic source of pathology.

Healthcare providers often undertake Herculean efforts (often at great expense to the patient or third-party payer) attempting to establish the specific link between objective indications of tissue pathology and the reported presence and severity of pain. The expectation is that once *the* physical cause has been identified, appropriate treatment will follow. Treatment will then focus on eliminating or blocking the putative cause(s) of the pain, chemically (e.g. oral medication, regional anesthesia, implantable drug delivery systems), surgically (e.g. laminectomy, spinal fusion), or physically (e.g. spinal cord stimulation, transcutaneous electrical nerve stimulation [TENS]) on the pain pathways.

Several perplexing features of chronic pain do not fit neatly within the traditional biomedical model, suggesting an isomorphic relationship between pathology and symptoms. For example, pain may be reported even in the absence of identified pathologic process. It is estimated that one-third to one-half of all visits to primary care physicians are prompted by symptoms for which no biomedical causes can be detected.[8] In up to 86% of the cases, the cause of back pain is unknown despite the performance of sophisticated imaging.[9] Conversely, imaging studies using computed tomography scans and magnetic resonance imaging (MRIs) have noted the presence of significant pathology in up to 35% of *asymptomatic* people.[10,11] Yet, they do not appear to experience any pain. Thus those who report severe pain with *no* identifiable pathology and those with demonstrable pathology may *not complain* of or even experience any pain. Moreover, the nature of patients' responses to treatment often has little to do with their objective physical condition.[12]

Several different psychological perspectives on chronic pain have evolved because of the multiple psychosocial factors involved in the onset and maintenance of chronic pain. Many of the psychological treatments for chronic pain are based on different psychological principles, which differ and complete from one another. Thus it is important to consider the varying perspectives.

Psychogenic Perspective of Chronic Pain

As often happens in medicine, when a biologic explanation for symptoms seems inadequate or is disproportionate to objective physical pathology, the pain reports are attributed to a psychological etiology and thus are "psychogenic." The psychogenic perspective is the opposite of the biomedical model. When a patient's report of pain occurs in the absence of demonstrable pathology, it may be viewed as a psychiatric diagnosis within the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual* (DSM-V):[13] Pain disorder associated with psychological factors or even a pain disorder associated with psychological factors *and* a general medical condition.

A psychodynamic perspective on chronic pain was first described systematically in the 1960s. During this time, people with pain were viewed as having compulsive and masochistic tendencies, inhibited aggressive needs, and feelings of guilt—"pain-prone personalities."[14] It was commonly held that people with pain had childhood histories fraught with emotional abuse, family dysfunction (e.g. parental quarrels, separation, divorce), illness or death of a parent, early responsibilities, and high orientation toward achievement.[15] Some current research has reported associations between chronic pain and childhood trauma, although the research is not consistent.[16] Based on the psychogenic perspective, assessment of persons with chronic pain is directed toward identifying the psychopathologic tendencies that instigate and maintain pain. It is assumed that reports of pain will cease once the psychogenic mechanisms are resolved. Treatment is geared toward helping patients gain "insight" into the underlying maladaptive psychological contributors.[16,17]

Although the psychogenic pain notion is ubiquitous, empirical evidence supporting it is scarce. A substantial number of chronic pain patients do not exhibit significant psychopathology. Moreover, studies suggest that in most cases, the emotional distress observed in these patients occurs in response to the persistence of pain and not as a causal agent[18,19] and may resolve once the pain is adequately treated.[20] Furthermore, insight-oriented psychotherapy has not been shown to be effective in reducing symptoms for the majority of patients with chronic pain.[21] Studies suggest that the emotional distress observed in patients with chronic pain more typically occurs in *response to* the persistence of pain and not as a causal agent,[22,23] and may resolve once the pain is adequately treated.[20] The psychogenic model has thus come under critical scrutiny and may be flawed in its view of chronic pain.[24]

Secondary Gain Perspective on Chronic Pain

The secondary gain (motivational) perspective is a variant of the psychogenic model frequently invoked within the legal system. From this perspective, reports of pain in the absence of or in excess

of physical pathology are attributed to the desire of the patient to obtain some benefit such as time off from undesirable activities, financial compensation, or acquisition of mood altering drugs—*secondary gains.* In contrast to the psychogenic model, in the secondary gain view, the assumption is that the patient is *consciously* attempting to acquire a desirable outcome. The complaint of pain in the absence of pathologic process, thus, is regarded as fraudulent.[25]

Behavioral Formulations

Pain is an unavoidable part of human life. No learning is required to activate nociceptive receptors. However, pain is a potent and salient experience. Beyond mere reflexive actions, people must learn to avoid, escape, modify, or cope with noxious sensations. Three major behavioral learning principles can help us understand the acquisition of adaptive versus dysfunctional responses associated with pain: classical (respondent) conditioning, operant conditioning, and observational (social) learning.

Classical (Pavlovian, Respondent) Conditioning

According to the classical (Pavlovian, respondent) conditioning model, if a painful stimulus is repeatedly paired with a neutral stimulus, the neutral stimulus will elicit a pain response. The influence of classical conditioning (i.e. the result of a stimulus followed by a response) can be observed in pain patients. Consider physical therapy, a mainstay of treatments for chronic pain patients, where treatment may evoke a conditioned fear response in patients. A patient who experienced pain after performing a treadmill exercise, based on the frequent pairing of exercise followed by pain, may become "conditioned" to experience a negative emotional response to the presence of the treadmill and any stimulus and any contextual cues associated with the nociceptive stimulus (e.g. physical therapist, gym). The negative emotional reaction may instigate muscle tensing, thereby exacerbating pain and further reinforcing and thereby strengthening the association between the stimulus and response (pain). People with chronic pain may avoid and attempt to escape from activities previously associated with pain onset or exacerbation.

Once a pain problem persists, fear of motor activities may become increasingly connected (i.e. conditioned), resulting in avoidance of activity in anticipation of avoidance of pain. Avoidance of pain is a powerful rationale for the reduction of activity, where muscle soreness associated with exercise functions as a justification for further avoidance. Thus although it may be useful to reduce movement in the acute pain stage, limitation of activities can be maintained not only by pain but also by *anticipatory* fear that has been acquired through the mechanism of classical conditioning. Thus cognitive processes may intervene with pure conditioning. The anticipation motivates a conscious decision to avoid or seek to escape from specific behaviors or stimuli.

In chronic pain, many activities that were initially neutral or even pleasurable may come to elicit or exacerbate pain. So they are experienced as aversive and actively avoided. Over time, a greater number of stimuli (e.g. activities) may be expected to elicit or exacerbate pain and will be avoided. This process is called *stimulus generalization.* Thus the anticipatory fear of pain and restriction of activity, and not just the actual nociception, may contribute to disability. Anticipatory fear also can elicit physiologic reactivity (e.g. increased muscle tension) that may aggravate pain. As a consequence, conditioning may directly increase nociceptive stimulation and, subsequently, the perception of pain.

The conviction that patients hold that they should remain inactive is challenging to modify, as long as activity-avoidance succeeds in preventing aggravation of pain. By contrast, repeatedly engaging in behavior—*exposure*—that produces progressively less pain than was predicted (corrective feedback) will be followed by reductions in anticipatory fear and anxiety associated with the activity.[26] Such transformations add support to the importance of a quota-based physical exercise program, with patients gradually and progressively increasing their activity levels despite fear of injury and discomfort associated with the use of deconditioned muscles.[27] This exposure, in the absence of anticipated pain, provides the *corrective feedback* that should be positively reinforcing and increase the likelihood of continuation of previously avoided activities.

Operant Conditioning

The effect of environmental factors in shaping the experience of people with pain was acknowledged long ago.[28] However, a new era in thinking about pain began with Fordyce's extension of *operant conditioning* to chronic pain.[29] The fundamental principle is that if the *consequence* of a given behavior is rewarding, its occurrence increases, whereas if the consequence is aversive, the likelihood of its occurrence decreases. The key in this model is the role of consequences. The main focus of operant learning is modification in the frequency of a given behavior—increasing desirable behaviors and extinction of maladaptive behaviors. When a person is exposed to a stimulus that causes tissue damage, the immediate behavioral response is withdrawal in an attempt to escape from noxious sensations. Such reflexive behaviors are adaptive and appropriate. However, in chronic pain, avoidance may be maladaptive as it may lead to reductions in strength, flexibility, and endurance, all of which contribute to increasing disability. The principles of learning suggest that through a process of learning, responses that receive positive consequences (positive reinforcement), especially repeated desirable consequences, will more likely be maintained; behaviors that fail to activate positive consequences, or that receive negative consequences (punishment), will be less likely to occur and thus reduced (i.e. extinguished) or avoided. Behaviors may also be maintained by the escape from undesirable events, in the case of pain, by the use of analgesic drugs, rest, or the avoidance of undesirable activities.

Fordyce underscored the fact that since there is no objective way to measure pain—no pain thermometer that can accurately measure the amount of pain a person feels or should be experiencing—the only way we can know of anyone's pain is by their behavior, whether verbal or nonverbal expressions labeled *pain behaviors.* The pain behavior originally elicited by organic factors caused by injury or disease may later occur, totally or in part, in response to reinforcing environmental events.

Although pain behaviors include verbal reports, paralinguistic vocalizations (sighs, moans), motor activity, facial expressions, body postures and gesturing (limping, rubbing a painful body part, grimacing), functional limitations (reclining for extensive periods, inactivity), and behaviors designed to reduce pain (taking medication, use of the healthcare system).

The central features of pain behaviors are that they are (1) sources of communication and (2) observable. Observable behaviors are capable of eliciting a response, and the consequences of behavior will influence subsequent behavior. According to Fordyce,[29] these pain behaviors can become subjected to the principles of operant conditioning. That is, since these behaviors are observable, they are capable of evoking responses, and it is the consequences following the behavior that are particularly important as they can serve to maintain or diminish the likelihood of the behavior recurring.

Pain behaviors may be positively reinforced directly (e.g. attention from a spouse or healthcare provider, monetary compensation, avoidance of undesirable activity). Pain behaviors may also

TABLE 14.1 Operant Schedules of Reinforcement

Schedule	Consequences	Probability of the Behavior Recurring
Positive Reinforcement	Reward the behavior	More likely
Negative Reinforcement	Prevent or withdraw aversive results	More likely
Punishment	Punish the behavior	Less likely
Neglect	Prevent or withdraw positive results	Less likely

be maintained by the escape from noxious stimulation through the use of drugs or rest or the avoidance of undesirable activities such as work. In addition, "well behaviors" (e.g. activity, working) may not be positively reinforcing, and the more rewarding pain behaviors may be maintained.

Table 14.1 summarizes basic operant principles of conditioning. The operant learning paradigm does not explain the etiology of pain or initiation of the behavior but rather focuses primarily on the maintenance of pain behaviors and deficiency in well behaviors. Adjustment of reinforcement schedules will likely modify the probability of recurrence of pain behaviors and well behaviors.

It is important not to make the mistake of viewing pain behaviors as being synonymous with *malingering*. Malingering involves the patient *consciously* and *purposely* faking a symptom such as pain for some gain, often financial (secondary gain). There is no suggestion of conscious deception in the case of pain behaviors but rather the unintended performance of pain behaviors resulting from environmental reinforcement contingencies. Contrary to the beliefs of many third-party payers, there is little support for the contention that outright faking of pain for financial gain is prevalent.[30]

There is some support for the operant model.[31–33] For example, Romano et al.[33] videotaped patients and spouses in a series of cooperative household activities and recorded patients' pain behaviors. Sequential analyses showed that spouses' solicitous responses were more to precede and follow pain behaviors in patients than pain-free controls. At least a subset of patients demonstrate high levels of pain behaviors and benefit from treatment targeting these behaviors.[34]

Observational (Social) Learning Processes

The *social (observational) learning perspective* emphasizes the point that behavior can be learned not only by actual reinforcement of an individual's behavior but also by observation of how others respond and the consequences following responses—*observational learning* and *modeling* processes. That is, people can acquire behavioral responses that were not previously in their repertoire by the observation of others, particularly others whom they view as similar to themselves. For example, a middle-aged man might learn what to expect by observing how other middle-aged men with similar medical problems are treated. This is a powerful way of learning, especially when the others being observed are judged to be similar to the observer.

Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior social learning history. The culturally acquired perception and interpretation of symptoms determine how people deal with disease states. The observation of others in pain is an event that captivates attention. This attention may have survival value, may help to avoid experiencing more pain, and may help to learn what to do about acute pain.

Observed *models* can influence the expression, localization, and methods of coping with pain.[35] Physiologic responses may even be conditioned during observation of others in pain.[36] Expectancies and actual behavioral responses to nociceptive stimulation are based, at least partially, on prior experience, either direct or from observation of others. This may contribute to the marked variability in response to objectively similar degrees of physical pathology observed.

Families and Family Systems Perspective

In *family systems* (and this could be expanded to significant others and not only traditional conceptualizations of nuclear families), the family is viewed as an interactional unit, and family members profoundly impact each other's emotions, thoughts, and behaviors. Thus the functioning of family members is interdependent, and family relationships are an important factor not only in psychological but also physical health.[37]

Recent studies have pointed to the insecure parental attachment as a risk factor for the development of chronic pain.[38] Individuals who grew up with an insecure parental attachment have been shown to experience more pain and disability than individuals with secure parental attachment.[39] It has been suggested that biologic factors (e.g. hypothalamic-pituitary-adrenal axis, sympathetic and central nervous system, immune statue) mediate the association between insecure parental attachment and chronic pain. The experience of chronic stress within the family has also been hypothesized to contribute to the development of chronic illness.[40] Specifically, chronic stress within the family may play an important role in the sympathetic nervous system and endocrine dysregulation often found in chronic pain patients.

A major tenet of the family systems perspective is that families influence the development and maintenance of chronic pain.[41] One important mechanism is based on operant theory.[33, 34] Expressions of acute pain (reporting pain, grimacing, avoidance of activity, and use of pain medication) because they are overt and observable may be reinforced through expressions of concern from family members. In support of this idea, investigators[34] have found that spousal attentiveness to expressions of pain was positively correlated with higher levels of reported pain, pain behavior frequency, and disability. However, social interaction may not always be viewed negatively and may be important in building intimacy, serving as positive support for a person with pain who is distressed.[42] Marital satisfaction has also been identified as an important mediator of disability associated with chronic pain.[43] Recent research has noted that partners rarely acknowledged patients' motive for seeking validation and were more likely to attribute negative motives (e.g. expressing anger) to a patient's pain behaviors, which may lead to their hostility toward patients.[44]

Pain does not take place in isolation but in a social context. Pain does not occur solely in people's bodies, nor does it occur solely in their brains, but, instead, it occurs in their lives. The emphasis on the role of significant others is important, as it reminds us that to successfully treat chronic pain patients requires that we not only assess and treat the patient but must also target significant others that can either impede or facilitate rehabilitation.[45]

Gate Control Model

Although not a psychological formulation itself, the *gate control model (GCM)*[46] was the first to popularize the importance of central, psychological factors in pain perception. Perhaps the most important contribution of the GCM is the way it changed thinking about pain perception. Melzack and Casey[47] differentiated three systems related to the processing of nociceptive stimulation—sensory-discriminative, motivational-affective, and cognitive-evaluative—all thought to contribute to the subjective experience of pain. Thus the GCM specifically includes psychological factors as an integral aspect of the pain experience. It emphasizes the central nervous system mechanisms and provides a physiologic basis for the role of psychological factors in chronic pain.

The GCM contradicts the notion that pain is *either* somatic *or* psychogenic. Instead, it postulates that both factors have potentiating and moderating effects. According to this model, both the central and peripheral nervous systems interact to contribute to the experience of pain. It is not only these physical factors that guide the brain's interpretation of painful stimuli that is at the center of this model; psychological factors (e.g. thoughts, beliefs, emotions) are also painful stimuli.

Prior to the Melzack and Wall[46] formulation of the GCM, psychological processes were largely dismissed as reactions to pain. Although the physiologic details of the GCM have been challenged,[48] it has had a substantial impact on basic research. It can be credited as a source of inspiration for diverse clinical applications to control or manage pain, including neurophysiologically based procedures (e.g. neural stimulation techniques from peripheral nerves and collateral processes in the dorsal columns of the spinal cord, pharmacologic advances, behavioral treatments, and those interventions that target modification of attentional and perceptual processes involved in the pain experience).

Cognitive-Behavioral Perspective

The *cognitive-behavioral perspective (CB)*, perhaps the most commonly accepted model for the psychological treatment of individuals with chronic pain,[49,50] incorporates many features of the classical conditioning, operant conditioning, and social learning models and a range of psychological variables described below. However, this perspective suggests that cognitive factors rather than conditioning factors alone play an important role. The model suggests that conditioned reactions are largely self-activated based on *learned expectations* rather than automatically evoked. It suggests that behaviors and emotions are influenced by interpretations of events, emphasizing how peoples' beliefs and attitudes interact with physical, affective, and behavioral factors. It proposes that conditioned reactions are largely activated by learned expectations rather than automatically evoked. In other words, it is the person's information processing that results in anticipatory anxiety and avoidance. Therefore the critical factor is that people learn to anticipate and predict events and to express appropriate reactions.[51]

From the CB perspective, people with pain are viewed as having negative expectations about their ability to control certain motor skills without pain. They tend to believe they have limited ability to exert any control over their pain. Such negative, maladaptive appraisals about the situation and personal efficacy may reinforce the experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals and expectations are postulated as having an effect on behavior, leading to reduced efforts and activity, contributing to increased psychological distress (helplessness) and subsequent physical limitations. If one accepts that pain is a complex, subjective phenomenon uniquely experienced by each person, then knowledge about idiosyncratic beliefs, appraisals, and coping repertoires becomes critical for optimal treatment planning and accurately evaluating treatment outcomes.

People with chronic pain's beliefs, appraisals, and expectations about pain, their ability to cope, social supports, their disorder, the medicolegal system, the healthcare system, and their employers are all important because they may facilitate or disrupt the sense of control. These factors also influence patients' investment in treatment, acceptance of responsibility, perceptions of disability, adherence to treatment recommendations, support from significant others, expectancies for treatment, and acceptance of treatment rationale. Research has consistently demonstrated that patients' attitudes, beliefs, and expectancies about their plight, themselves, their coping resources, and the healthcare system affect reports of pain, activity, disability, and response to treatment.

Cognitive interpretations also affect how patients present symptoms to others, including healthcare providers. Overt communication of pain, suffering, and distress (pain behaviors) will enlist responses that may reinforce maladaptive behaviors and impressions about the seriousness, severity, and uncontrollability of pain. That is, complaining of pain may induce physicians to prescribe more potent medications, order additional diagnostic tests, and, in some cases, perform surgery. Significant others may express sympathy, excuse the person with chronic pain from responsibilities, and encourage passivity, fostering further physical deconditioning. It should be obvious that the CB perspective integrates the operant conditioning emphasis on external reinforcement and respondent view of conditioned avoidance within the framework of information processing.

People with persistent pain often have negative expectations about their ability and responsibility to exert any control over their pain. They often view themselves as helpless. Such negative, maladaptive appraisals about their condition, situation, and their personal efficacy in controlling their pain and problems associated with pain reinforce their experience of demoralization, inactivity, and overreaction to nociceptive stimulation. These cognitive appraisals are posited as having an effect on behavior, leading to reduced effort, reduced perseverance in the face of difficulty, reduced activity, and increased psychological distress.

The CB perspective on pain management focuses on making patients aware of the the effects of their thinking (beliefs, expectations) and providing the patient with techniques to gain a sense of control over the effects of pain on his or her life and modifying the affective, behavioral, cognitive, and sensory facets of the experience. Behavioral experiences help show individuals with chronic pain that they can, more than they assumed, increase their sense of personal competence. Cognitive techniques (e.g. self-monitoring to identify relationships among thoughts, mood, and behavior, distraction using imagery, and problem solving) help place affective, behavioral, cognitive, and sensory responses under the person's control.

The assumption is that long-term maintenance of behavioral changes will occur only if the person with pain has learned to attribute success to his or her own efforts. There are suggestions that these treatments can result in changes of beliefs about pain, coping style, reported pain severity, and direct behavior changes. Treatment that results in increases in perceived control over pain and decreased catastrophizing also results in decreases in pain severity and functional disability. When successful rehabilitation occurs, there is a major shift from beliefs about helplessness and passivity

to resourcefulness and ability to function regardless of pain and from an illness conviction to a rehabilitation conviction.

Several studies have attempted to identify specific cognitive factors that contribute to pain and disability.[51–53] These studies have consistently demonstrated that a person's attitudes, beliefs, and expectancies about their plight, themselves, their coping resources, and the healthcare system affect reports of pain, activity, disability, and response to treatment. For example, people respond to medical conditions in part based on their subjective ideas about illness and their symptoms. When pain is interpreted as signifying ongoing tissue damage or a progressive disease, it is likely to produce considerably more suffering and behavioral dysfunction than if it is viewed as being the result of a stable problem that is expected to improve.

Healthcare providers working with chronic pain patients are aware that patients having similar pain histories and reports of pain may differ greatly in their beliefs about their pain. Behavior and emotions are influenced by interpretations of events and expectations rather than solely by objective characteristics of the event itself.

People develop fairly elaborate views of their physical states, and these views or representations provide the basis for action plans and coping. Beliefs about the meaning of pain and their ability to function despite discomfort are important aspects of expectations about pain. A good example of this is how chronic pain patients often demonstrate poor behavioral persistence in exercise tasks. Their performance on these tasks may be independent of physical exertion or actual self-reports of pain but rather be related to previous pain reports or anticipation and fear of injury, re-injury, or exacerbation of their pain.[26] These people appear to have a negative view of their abilities and expect increased pain if they performed physical exercises. Thus the rationale for their avoidance of exercise was not the presence of pain but their learned expectation of heightened pain and accompanying physical arousal that might exacerbate pain and reinforce patients' beliefs regarding the pervasiveness of their disability. If people view disability as a necessary reaction to their pain, that activity is dangerous, and that pain is an acceptable excuse for neglecting their responsibilities, they are likely to experience greater disability. These negative perceptions of their capabilities for physical performance form a vicious circle, with the failure to perform activities reinforcing the perception of helplessness and incapacity. Once again, we can see how behavioral (conditioning) factors interact with cognitive processes.

Certain beliefs may lead to maladaptive coping, increased distress, and greater disability. People who believe their pain will persist may be passive in their coping and fail to use strategies to cope with pain. People who consider their pain to be an unexplainable mystery may negatively evaluate their own abilities to control or decrease pain and are less likely to rate their coping strategies as effective in controlling and decreasing pain.[54] People's beliefs, appraisals, and expectancies regarding the consequences of an event and their ability to cope and adapt to their symptoms and changed life circumstances are hypothesized to affect functioning in two ways. They may have a direct influence on physiologic arousal and mood and an indirect one through their effects on coping efforts.[55]

Once beliefs and expectancies are formed, they become stable and rigid, and relatively impervious to modification. Individuals with chronic pain tend to avoid experiences that could invalidate their beliefs (disconfirmations) and guide their behavior in accordance with these beliefs, even in situations where these beliefs are no longer valid. As noted, they do not obtain corrective feedback. Thus people with chronic pain need to develop adaptive beliefs about the relationships among impairment, pain, suffering, and disability and de-emphasize the role of experienced pain in their regulation of functioning. Results from numerous treatment outcome studies have shown that changes in pain level do not parallel changes in other variables of interest, including activity level, medication use, return to work, rated ability to cope with pain, and pursuit of further treatment. If healthcare providers hope to achieve better outcomes and reduce their frustration from patients' lack of adherence to their advice, they need to learn about and address patients' concerns within this therapeutic context.

The biomedical, psychogenic, secondary gain, and behavioral views described are unidimensional. Reports of pain are ascribed to *either* physical *or* psychological factors. Rather than being categorical, either somatogenic or psychogenic, as suggested by the GCM, both physical and psychological components may interact to create and influence the perception and experience of pain.

Any physical abnormalities that are identified may be moderated by coexisting psychosocial influences. The complexity of pain is especially evident when pain persists over time as a range of psychological, social, and economic factors interact with physical pathology to modulate individuals' reports of pain and the impact of pain on their lives. In the case of chronic pain, healthcare providers need to search not only for the physical source of the pain through examination and diagnostic tests but also examine the patient's mood, fears, expectancies, coping efforts, resources, responses of significant others, and the impact of pain on the patients' lives (see Chapter 15 for measures to assess these cognitive factors).

Although in the majority of cases, biomedical factors appear to instigate the initial report of pain. Over time psychosocial and behavioral factors may serve to maintain and exacerbate the level of pain, influence adjustment, and contribute to excessive disability. Following from this view, pain that persists over time should not be viewed as solely physical or solely psychological; the experience of pain is maintained by an interdependent set of biomedical, psychosocial, behavioral, and contextual factors.[56,57]

People with chronic pain frequently terminate active efforts to manage pain and, instead, turn to passive coping strategies such as inactivity, medication, or alcohol to reduce pain and emotional distress. They also absolve themselves of personal responsibility for managing their pain and, instead, rely on family and healthcare providers. The thinking of chronic pain patients has repeatedly been shown to contribute to the exacerbation, attenuation, and maintenance of pain, pain behaviors, affective distress, adjustment to chronic pain, health care seeking, response to treatment, and disability.[58–61]

Biopsychosocial, Contextual Model

Although Melzack and Wall's GCM described previously introduced the role of psychological factors in the maintenance of pain symptoms, it focused primarily on the basic anatomy and neurophysiology of pain. The biopsychosoci, contextual model, which expands the CB model of pain, views illness as a dynamic and reciprocal interaction between biological, psychological, sociocultural, and contextual variables that shape the person's response to pain.[56,57,62] From this perspective, diversity in illness expression (which includes its severity, duration, and consequences for the individual) is accounted for by the interrelationships among biologic changes, psychological status, and the social and cultural contexts. All of these variables shape the person's perception and response to illness.

According to the biopsychosocial view of pain, pain experience results from a complex web of interaction among nervous and

physiologic systems (central and peripheral), psychological factors, and social variables.[56,63] For example, biologic factors may initiate, maintain, and modulate physical perturbations while psychological variables influence appraisals and perception of internal physiologic signs; social factors shape patients' behavioral responses to the perceptions of their physical perturbations. Conversely, psychological factors may influence biology by affecting hormone production,[64] brain structure and processes,[65] and the autonomic nervous system.[66] However, the picture is not complete unless we consider the direct effects of disease factors and treatment upon cognitive and behavioral factors. Biologic influences and medications (e.g. steroids, opioids) may affect the ability to concentrate, cause fatigue, and modulate peoples' interpretation of their state and of their ability to engage in certain activities.

At different points during the evolution of a disease or impairment, the relative weighting of physical, psychological, and social factors may change. For example, during the acute phase of a disease, biologic factors may predominate, but over time psychological and social factors may assume a disproportionate role in accounting for symptoms and disability. There is considerable variability in behavioral and psychological manifestations of dysfunction, both across persons with comparable symptoms and within the same person over time.

To understand the variable responses of people to chronic conditions, biologic, psychological, and social factors must be considered. A longitudinal perspective is essential. A cross-sectional approach will only permit consideration of these factors at a specific point, and chronic conditions continually evolve. At any one point in time, what is observed is a person's adaptation to interacting biologic, personal, and environmental factors. The hallmarks of the biopsychosocial perspective are (1) integrated action, (2) reciprocal determinism, and (3) development and evolution. No single factor in isolation—pathophysiologic, psychological, or social—will adequately explain chronic pain status. This can be contrasted with the traditional biomedical model, whose emphasis on the somatogenic-psychogenic dichotomy is too narrow in scope to accommodate the complexity of chronic pain.

From an integrative biopsychosocial perspective, pain is viewed as a subjective perception that results from the transduction, transmission, and modulation of sensory input filtered through a person's genetic composition and prior learning history and modulated further by their current physiologic state, idiosyncratic appraisals, expectations, present mood state, and sociocultural environment.

What is unique about the biopsychosocial model is that it considers the influence of higher order cognitions, including perception and appraisal and the environmental context in which these appraisals take place. It accepts that people are active processors of information and that behavior, emotions, and even physiology are influenced by interpretations of events rather than solely by physiologic factors.[56,62] Therefore people with chronic pain may have negative expectations about their own ability and responsibility to exert any control over their pain. Behaviors of people with pain elicit responses from significant others that can reinforce both adaptive and maladaptive modes of thinking, feeling, and behaving.

Loeser[67] originally formulated a general model that delineated four dimensions associated with the concept of pain: 1) nociception, the stimulation of nerves that convey information about possible tissue damage to the brain; 2) pain, the subjective perception that results from transduction, transmission, and modulation of sensory information; 3) suffering, the emotional responses triggered by nociception or some other aversive event associated with it, such as fear or depression; and 4) pain behavior, those things that people do when they are suffering or in pain, such as avoiding activities or exercise for fear of (re)injury. Then Waddell[68] emphasized that pain cannot be comprehensively evaluated without an understanding of the individual who is exposed to the nociception. Waddell also made a comparison between Loeser's[67] model of pain and the call by Engel[14] for a new, more biopsychosocial model in medicine. Engel proposed the important dimensions of the physical problem, distress, illness behavior, and the sick role, which corresponded to Loeser's dimensions of nociception, pain, suffering, and pain behavior, respectively. Thus with this general perspective, a diversity of pain or illness can be expected (including its severity, duration, and psychosocial consequences). To fully understand a person's perception and response to pain and illness, the interrelationships among biologic changes, psychological status, and the sociocultural context all need to be considered. Any model that focuses on only one of these dimensions will be incomplete.

Cognitive Factors: Predispositions, Appraisals, Beliefs, Perceived Control, and Self-Efficacy

Predispositions

Preexisting temperament and personality may show continuity and predispose individuals toward misinterpretation of pain sensations and maladaptive pain beliefs, or they can have a protective role contributing to resilience in the face of adversity.

Among the potential vulnerability factors that have been proposed are negative affectivity, anxiety sensitivity, and illness and injury sensitivity. *Negative affectivity* (NA), the tendency to experience negative emotional states in daily life,[69] may be considered as heritable, stable, and promoting a tendency to experience a broad range of negative emotions and to view the world as threatening and distressing.[70] NA has been associated with heightened vigilance to bodily sensations, symptom reporting, and interpretational biases toward ambiguous internal signals.[71–73] Studies in nonclinical populations have reported NA to predict lower pain tolerance.[74] While recent studies have suggested that NA is associated with greater pain intensity and functional impairment,[75,76] studies in chronic pain populations have so far not provided consistent evidence for a role of trait NA. Thus although NA has often been implicated as a vulnerability factor in chronic pain, convincing evidence is lacking.

More convincing has been the research on another potential vulnerability factor: *anxiety sensitivity* (AS). AS is defined as the fear of anxiety-related sensations and is conceived as a partly heritable personality trait.[77] Individuals with high AS interpret unpleasant physical sensations (such as rapid heart beating, feeling faint) more often as a sign of danger than individuals with low AS. There is growing evidence that AS may also be a risk factor for the maintenance and exacerbation of chronic pain and disability.[78] AS has been shown to correlate with measures of fear avoidance (described below) and is associated with distress, analgesic use, and impairment of physical and social functioning in patients across a wide range of different pain-related conditions.[79,80] Moreover, path analyses and mediation models suggest that AS exacerbates fear avoidance beliefs and the negative interpretation of bodily sensations, which in turn leads to enhanced pain experience and pain avoidance.[80–82]

In contrast to the extensive search after negative predisposing factors described, there has been relatively little research on protective factors for chronic pain and disability. Traditionally, research on resilience has focused on adaptive responses in the wake of significant adversity or challenge (e.g. developmental resilience, posttraumatic growth). In the context of pain, resilience might mean effective recovery from an injury, infection, or

other painful experience, both from a physical and psychosocial standpoint (e.g. effective resilience in the wake of an injury might ideally mean total resolution of pain and resumption of normal functioning). However, in patients for whom resolution of pain is unlikely, behavioral and cognitive responses to pain may have very different implications in terms of their adaptiveness. When a new and unfamiliar painful condition develops, a fearful and avoidant response may be protective; consistent with an evolutionary view of pain, new painful sensations may signal significant danger to the organism, such that mobilization of individual resources to escape pain and threat may prolong survival. However, prolongation of this fearful avoidant response tends to yield fewer benefits in cases of chronic pain and, instead, increases the risk of protracted physical disability, deconditioning, and psychosocial dysfunction.[83–86]

Several investigators[86,87] have proposed a model of resilience in chronic pain that follows a "temporal" order of adaptation, manifesting in three interrelated factors: *sustainability*, or prolonged and positive functioning despite the immediate presence of pain; *recovery*, or expedient and effective recovery from the negative consequences of pain; and *growth*, or long-term learning or personal development that may result in new strengths, protective attitudes, or skills because of chronic pain.

Three potential resilience factors are particularly relevant in chronic pain: optimism, hope, and psychological flexibility. A review of the literature suggests that optimism may be one of the most important personality traits in relation to adjustment to chronic pain. Dispositional optimism is defined as "the tendency to believe that one will generally experience good outcomes in life" and is distinguishable from neuroticism and trait anxiety.[88] In cross-sectional and prospective studies, optimism was found to be associated with better general health, adaptation to chronic disease, and recovery after various surgical procedures.[89–91]

Only a few studies have explored the role of dispositional optimism or hope in adaptation to chronic pain. For example, Buckingham and Richardson[92] found that dispositional optimism and psychological grit enhance the effect of resilience on pain threshold in moderation models. In studying rheumatoid arthritis patients, Treharne and colleagues[93] found that optimism was associated with less depression and pain and higher life satisfaction for patients in the early and intermediate stages of disease.

The primary mechanism of the beneficial effect of optimism may be differences in coping behavior between optimistic and pessimistic people.[94] In general, pessimists turn to avoidant coping strategies and denial more often, while optimists employ more problem-focused coping strategies. When problem-focused coping is not possible, they turn to coping strategies such as acceptance, use of humor, and positive reframing of the situation.[88] Thus it may not be the use of specific coping strategies, but the flexibility of coping that protects against disability and distress.[88] Snyder has described a similar pathway for hope, with people with low hope showing a tendency to catastrophize, whereas people with high hope seek means to encounter future challenges and show flexibility in finding alternative life goals when their original goals are blocked.[95] Psychological flexibility manifests as an ability to effectively and flexibly adjust behavioral efforts at goal-pursuit in a way that is consistent with one's values[96] despite the presence of pain and associated problems.

Individuals with chronic pain who better sustain their optimism, hope, and flexibility appear to be more able to persist in painful behavioral tasks,[97] and to be less susceptible to other pain-related difficulties, such as fatigue[98] and problematic opioid use.[99] Similarly, positive emotional states have been found to be predictors of better social,[100, 101] and physical functioning in some individuals with chronic pain.

Appraisal and Beliefs

Specific appraisal and beliefs are largely shaped by an individual's learning history through direct experience, observational learning, or information acquired from others. These experiences may interact with an individual's enduring traits, sociocultural background, prior learning and experiences, and the current context in which they reside. Personality factors may predispose some people to make certain kinds of appraisals and be more susceptible to some idiosyncratic beliefs than others.

Pain appraisal refers specifically to the meaning ascribed to pain by each individual.[102] In accordance with the transactional stress model,[103] a distinction can be made between a primary appraisal (evaluation of the significance of pain in terms of threatening, benign, or irrelevant) and secondary appraisal (evaluation of the controllability of pain and one's coping resources). Beliefs refer to assumptions about reality that shape how one interprets events and can thus be considered as determinants of appraisal. Pain beliefs develop throughout the lifetime because of an individual's learning history and cover all aspects of the pain experience (e.g. the causes of pain, its prognosis, appropriate treatments).

Appraisal and beliefs about pain can have a strong impact on an individual's response to pain. If a pain signal is interpreted as harmful (threat), it may be perceived as more intense, more unpleasant, and evoke more escape or avoidance behavior. For instance, Smith and colleagues[104] demonstrated that cancer patients who attributed pain sensations after physiotherapy directly to cancer reported more intense pain than patients who attributed this pain to other causes.

Pain appraisal and pain beliefs are also prominent determinants of adjustment to chronic pain.[102] Pain that is viewed as a signal of damage, leads to disability, is uncontrollable, and is a permanent condition has been shown to affect individuals' responses,[61,105] and these beliefs are widespread.[106,107]

Catastrophizing and Fear Avoidance Beliefs

Pain catastrophizing (note that people experiencing chronic pain hate this term as they view it as pejorative[108]) can be defined as an exaggerated, negative cognitive and emotional orientation toward actual or anticipated pain experiences. It is a cognitive process whereby one assumes the worst possible outcomes and interprets even minor problems as major calamities. For example, a patient with chronic pain might interpret a brief painful episode as a symptom of a serious underlying health problem.

A large volume of evidence suggests that catastrophizing about pain plays a significant role in defining the actual experience of pain. Pain-related catastrophizing thought patterns are fairly common in both acute and chronic pain; it has been associated with increased perceptions of both acute,[105,109] and chronic[110] pain severity and disability among groups with diverse pain diagnoses,[111–113] and is a significant predictor of pain-related functional disability.[114,115] Several studies have shown that inter-disciplinary pain rehabilitation programs, cognitive therapy, and mindfulness based interventions focused on reducing catastrophizing were related to significant reductions in pain intensity, disability, pain interference, medication usage, and maintenance of treatment benefits.[116–118]

Imaging studies may offer some explanations as to how catastrophizing influences pain perception. Catastrophizing appears to be

associated with specific brain regions.[119,120] For example, Seminowicz and Davis[120] examined functional MRI (fMRI) while pain-free subjects underwent laboratory pain testing. They found that the effect of catastrophizing on neural response to painful stimulation may depend on stimulus intensity levels. The neural response to mild pain was seen in regions representing attention, vigilance, and emotion. In contrast, the relationship was reversed with moderate pain level; this suggests that catastrophizing attenuates the descending inhibitory system to more intense stimuli, making it more difficult to disengage from pain. Similar results have been reported in an imaging study of fibromyalgia patients in which catastrophizing was related to the activation in the brain areas reflecting the attentional, anticipatory, and emotional activities in response to pain.[119] These studies suggest that catastrophizing adversely impacts pain experience through increased attention and negative anticipation of pain. Still other studies[94,121] used the diffuse noxious inhibitory control/conditioned pain modulation (DNIC/CPM) paradigm, demonstrating that catastrophizing may influence the pain modulatory process in pain-free individuals and predict pain following surgery.[122] Catastrophizing has also been associated with immune function (i.e. interleukin-6) responses to acute pain,[123] and stress hormones in response to laboratory-induced pain in individuals with chronic pain and pain-free individuals.[124]

Fear avoidance occurs when people with chronic pain anticipate that certain activities will increase their pain or induce further injury. These fears may contribute to the avoidance of activity and subsequently greater physical deconditioning, emotional distress, and, ultimately, greater disability.[125] Their failure to engage in activities prevents them from obtaining any corrective feedback about the associations among activity, pain, and injury.

Besides fear of movement, people with persistent pain may be anxious about the meaning of their symptoms for the future—will their pain increase, will their physical capacity diminish, will they have progressive disability where they ultimately end up in a wheelchair or bedridden? In addition to these sources of fear, people experiencing persistent pain may fear that on the one hand, people will not believe that they are suffering, and on the other, they may be told that they are beyond help and will "just have to learn to live with it." Such fears can contribute to additional emotional distress and to increased muscle tension and physiologic arousal that may directly exacerbate and maintain pain.

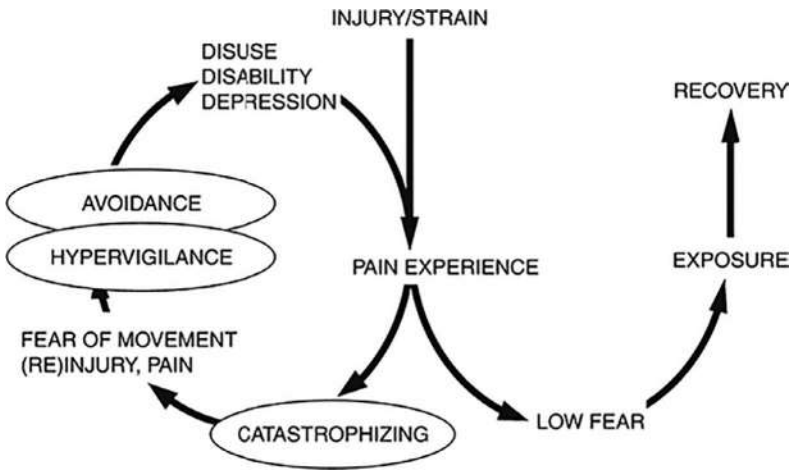
The role of catastrophizing and the belief that pain means harm and activity should be avoided has been most articulated in fear-avoidance models (FAMs) of chronic pain.[125,126] Although FAMs are multifaceted and include affective (fear) and behavioral (avoidance) components, cognitions are identified as the core determinants of entering into a negative pain cycle. The tenets of contemporary FAMs are depicted in Figure 14.1 and can be summarized as follows: When pain is perceived following injury, an individual's idiosyncratic beliefs will determine the extent to which pain is catastrophically interpreted. A catastrophic interpretation of pain gives rise to physiologic (arousal), behavioral (avoidance), and cognitive fear responses. The cognitive shift that takes place during fear enhances threat perception (e.g. by narrowing of attention) and further feeds the catastrophic appraisal of pain.[78,127]

There is substantial evidence that fear-avoidance beliefs are associated with disability and impaired physical performance in chronic pain.[126–128] A systematic review of the literature on psychological risk factors in back and neck pain indicated that the evidence for the association between fear-avoidance beliefs and increased pain and disability was of the highest level.[127,128] In addition, prospective studies have shown that fear-avoidance beliefs in patients seeking care for acute pain may be predictive of pain persistence, disability, and long-term sick leave.[129–131] Several treatment approaches have been developed and implemented to address pain-related fear and anxiety in chronic pain patients.[132]

Healthcare providers are not immune to fear-avoidance beliefs. Fear-avoidance beliefs of healthcare providers have also been found to be related to their treatment behavior and their recommendation for engaging in physical activities.[133,134] The beliefs of patients and healthcare providers may further interact with each other in a mutually reinforcing way because a patient's beliefs may guide the choice of which health care provider is visited.[135]

Perceived Control

Perceived control over pain refers to the belief that one can exert influence on the duration, frequency, intensity, or unpleasantness of pain. Perceived controllability of a pain stimulus may modify the meaning of this stimulus and directly affect threat appraisal.[136] As a consequence, pain may be rated as less intense or less unpleasant, and pain tolerance may increase.



• **Figure 14.1** Fear Avoidance Model. Reproduced with permission from Vlaeyen JW, Linton SJ. Fear-avoidance model of chronic musculoskeletal pain: 12 years on. *Pain.* 2012;153(6):1144-1147.

How people conceptualize their ability to control pain and associated stress seems to be an important determinant for how they cope with pain. Indeed, an increased sense of control has been shown to be linearly related to greater functionality in chronic pain patients.[61] Furthermore, improvement in control beliefs following inter-disciplinary pain treatment typically results in reduced pain and disability, perhaps because perceived control over the effects of pain has been shown to be more strongly related to better adjustment and less disability than perceived control over the pain itself.[61,137–139] The opposite end of the control spectrum is a sense of lack of control—helplessness. The literature generally supports that helplessness is associated with greater pain and poorer physical and psychological adjustment in chronic pain.[140]

Self-Efficacy

Related to perceived *control* is the construct of *self-efficacy* (SE). A SE belief is defined as a personal conviction that one can successfully execute a course of action (perform required behaviors) to produce the desired outcome in a given situation.[141]

SE is the conviction that one can successfully perform a certain task or produce a desirable outcome.[141] Given sufficient motivation to engage in a behavior, it is a person's SE beliefs that determine the choice of activities that he or she will initiate, the amount of effort that will be expended, and how long the individual will persist in the face of obstacles and aversive experiences. In this way, SE plays an important role in therapeutic change and compliance to psychological and medical regimes.[52]

SE judgments are based on four sources of information regarding one's capabilities, listed in descending order of importance:[141] one's own past performance at the task or similar tasks, the performance accomplishments of others who are perceived to be similar to oneself, verbal persuasion by others that one is capable, and perception of one's own state of physiologic arousal, which is, in turn, partly determined by prior efficacy estimation. Performance mastery can then be created by encouraging people to undertake subtasks that are initially attainable but become increasingly difficult and subsequently approaching the desired level of performance. It is important to remember that coping behaviors are influenced by the person's beliefs that the demands of a situation do not exceed their coping resources.

Recent reviews of psychological factors in chronic pain have concluded that the evidence for the role of SE across a broad range of pain populations is impressive.[142] Moreover, SE also influences the prognosis after acute physical interventions like surgery.[143] Prospective studies in patients who underwent surgery demonstrated that high SE before the start of rehabilitation and larger increases over the course of rehabilitation speed recovery and predict better long-term outcome.[144,145] Perceived SE has been shown to have a direct effect on the body's opioid and immune systems[146] confirming the important association between psychological constructs and physiology.

SE beliefs also play a role in the clinical presentation of chronic pain. Lower SE is consistently related to greater clinical pain ratings in various chronic pain conditions.[147–149] Low levels of SE beliefs are related to disability.[150,151] As was the case with a sense of control, SE beliefs mediate the relationship between pain and psychological functioning[152,153] in chronic pain. Furthermore, recent longitudinal studies suggest that poor SE beliefs are a risk factor for the development of functional disability associated with chronic pain[154] and work absenteeism.[155]

Whereas low SE beliefs are related to greater pain and dysfunction, improvement in SE is one of the best predictors for successful rehabilitation for pain patients. An elevated level of SE beliefs at pretreatment tends to predict better outcomes.[156,157] Furthermore, successful outcomes of pain therapy typically show associated improvement in SE, along with the improvement in depression and anxiety.[140,158–160]

Coping

Self-regulation of pain and its impact depends on people's specific ways of dealing with pain, adjusting to pain, and reducing or minimizing distress caused by pain; in other words, their coping strategies.[161] *Coping* is assumed to involve spontaneously employed purposeful and intentional acts, and it can be assessed in terms of overt and covert behaviors. Overt behavioral coping strategies include rest, use of relaxation techniques, or medication. Covert coping strategies include various means of distracting oneself from pain, reassuring oneself that the pain will diminish, seeking information, and problem solving. Coping strategies are thought to act to alter both the perception of pain intensity and the ability to manage or tolerate pain and to continue everyday activities.[7,56]

Some studies have found active coping strategies (efforts to function despite pain or to distract oneself from pain, such as engaging in an activity or ignoring pain) to be associated with adaptive functioning and passive coping strategies (such as depending on others for help in pain control and restricting one's activities) to be related to greater pain and depression.[151,162,163] However, beyond this, there is no evidence supporting the greater effectiveness of any one active coping strategy than any other. It seems more likely that different strategies will be more effective than others for some people at some times, but not necessarily for all people all the time.[164] This observation supports the importance of flexibility.

Several studies have been demonstrated that if patients are instructed in the use of adaptive coping strategies, their rating of the intensity of pain decreases and tolerance of pain increases.[165] More recently, some interventions have begun to incorporate smartphone apps to provide psychoeducation and coping strategies using an interactive platform and have found some efficacy using this approach.[166,167] Nevertheless, the most important factor in poor coping appears to be the presence of catastrophic thinking, not the nature of specific adaptive coping strategies.[168]

Emotion

Pain is ultimately a subjective, private experience, but it is invariably described in terms of sensory and affective properties. As defined by the revised definition, the International Association for the Study of Pain states that pain is "An unpleasant sensory and *emotional experience* associated with, or resembling that associated with, actual or potential tissue damage."[169] The central and interactive roles of sensory information and affective state are supported by an overwhelming amount of evidence.[63] The affective component of pain incorporates many different emotions. Depression and anxiety have received the greatest amount of attention in chronic pain patients. However, anger and hostility have received considerable interest as a significant emotion in chronic pain patients.[139,170,171] Additionally, the ability to maintain positive affect during times of stress has been investigated in relationship to pain.[172]

In addition to affect being one of the three interconnected components of pain, pain and emotions interact in several ways. Emotional distress may predispose people to experience pain, be a precipitant of symptoms, be a modulating factor amplifying or inhibiting the severity of pain, be a consequence of persistent pain,

or be a perpetuating factor. Moreover, these potential roles are not mutually exclusive, and any number of them may be involved in a particular circumstance interacting with cognitive appraisals. For example, the literature is replete with studies demonstrating that the current mood state modulates reports of pain and tolerance for acute pain.[173] Levels of anxiety have been shown to influence pain severity and complications following surgery and the number of days of hospitalization.[174,175] Individual difference variables, such as AS, have also been shown to play an important predisposing and augmenting role in the experience of pain.[176] Level of depression has been observed to play a significant role in premature termination from pain rehabilitation programs.[177]

Although most of the literature has focused on the relationship between negative affect and pain, research has indicated that the ability to maintain positive affect during stress is an important factor contributing to ongoing adaptation to chronic illness. Positive affect serves to decrease distress in chronic pain patients by broadening the individual's range of affective and cognitive responses permitting a wider range of experiences.[178] Positive affect can serve as psychological immunity in that chronic pain patients may experience more optimal functioning and improved quality of life while living with ongoing pain. Although we will provide an overview of research on the predominant emotions—anxiety, depression, and anger—associated with pain individually, it is important to acknowledge that these emotions are not as distinct when it comes to the experience of pain. They interact and augment each other.

Anxiety

Anxiety and fear-related problems are more prevalent in chronic pain patients than in the general public. The prevalence of any anxiety disorder may be twice as much (35% vs. 18%). Both panic disorder and post-traumatic stress disorder are three times more common in chronic pain patients.[179]

It is common for patients with symptoms of pain to be anxious and worried. This is especially true when the symptoms are unexplained, as is often the case for chronic pain syndromes. For example, in a large study of fibromyalgia patients, between 44% and 51% of patients acknowledged their anxiety.[180] In addition, up to 45% of patients with chronic pain will screen positive for an anxiety disorder.[181] Chronic pain patients with comorbid anxiety may have a lower pain tolerance, be more prone to medication side effects or fearful of having side effects, and be more fearful of pain itself.[182] One study indicated that 40% of patients with Panic Disorder also had chronic pain, particularly head, shoulder, and lower back pain.[183] Panic disorder involves a hyper-focus on somatic sensations that might increase subjective pain sensations. Patients with both chronic pain and panic may engage in more "illness behaviors."[183]

Fear and anxiety are known to have behavioral consequences expressed as escape and avoidance behaviors described previously. Pain-related avoidance and escape behaviors in pain patients may be conceptualized as a set of "safety-seeking behaviors," loosely defined as "behaviors utilized by patients in an attempt to avoid a feared outcome."[184] The revolving model of fear avoidance in chronic pain[128,185] is depicted in Figure 14.1. As the model suggests, pain-related fear and avoidance play a significant role in the interplay between pain, dysfunctional cognitive and affective experience, and disability resulting in the perpetuation of the chronic pain circle. Indeed, pain-related fear avoidance is significantly associated with functional limitation in various life domains and perceived disability in acute and chronic pain patients.[120,186–188]

People with persistent pain may be anxious about the meaning of their symptoms and for their futures—will their pain increase, will their physical capacity diminish, will their symptoms result in progressive disability where they ultimately end in a wheelchair or bedridden? Besides these sources of fear, individuals with persistent pain may be worried that, on the one hand, people will not believe that they are suffering and, on the other, they may be told that they are beyond help and will "just have to learn to live with it." Fear and anxiety will also relate to activities that people with pain anticipate will increase their pain or exacerbate whatever physical factors might be contributing to the pain. As noted in the discussion of the FAM previously, these fears may contribute to avoidance, motivate inactivity, and, ultimately, greater disability.[128] Continual vigilance and monitoring of noxious stimulation and the belief that it signifies disease progression may render even low intensity aversive sensations less bearable. In addition, such fears may contribute to increased muscle tension and physiologic arousal that may exacerbate and maintain pain.

The threat of intense pain captures attention from which it is difficult to disengage. The experience of pain may initiate a set of extremely negative thoughts, as noted previously, and arouse fears—fears of inciting more pain and injury, fear of their future impact. Fear and anticipation of pain are cognitive-perceptual processes that are not driven exclusively by the actual sensory experience of pain and can exert a significant impact on the level of function and pain tolerance.[189,190] Individuals experiencing chronic pain may become hypervigilant to their environment as a way of preventing the occurrence or amplification of pain.

Investigators[26,191] have suggested that fear of pain, driven by the anticipation of pain and not by the sensory experience of pain itself, produces strong negative reinforcement for the persistence of avoidance behavior and the putative functional disability in pain patients. Avoidance behavior is reinforced in the short term through the reduction of suffering associated with noxious stimulation.[192] However, avoidance can be a maladaptive response if it persists and leads to increased fear, limited activity, and other physical and psychological consequences that contribute to disability and persistence of pain.

Studies have demonstrated that fear of movement and fear of (re)injury are better predictors of functional limitations than biomedical parameters or even pain severity and duration.[51,186] For example, Crombez, Vlaeyen, and Heuts[186] showed that pain-related fear was the best predictor of behavioral performance in trunk-extension, flexion, and weightlifting tasks, even after partitioning out the effects of pain intensity. Moreover, Vlaeyen and colleagues[26] found that fear of movement/(re)injury was the best predictor of self-reported disability among chronic back pain patients and that physiologic sensory perception of pain and biomedical findings did not add any predictive value. The importance of fear of activity appears to generalize to daily activities and the clinical experimental context.

Approximately two-thirds of individuals with chronic nonspecific low back pain avoid back straining activities because of fear of (re)injury.[186] For example, fear avoidance beliefs about physical demands of a job are strongly related to disability and work lost during the previous year, even more so than pain severity or other pain variables.[26,193] Interestingly, reduction in pain-related anxiety predicts improvement in functioning, affective distress, pain, and pain-related interference with activity.[82] Fear, pain-related anxiety, and concerns about harm-avoidance all play important roles in chronic pain and need to be assessed and addressed in treatment.

Depression and Depressed Mood

Research suggests that 40% to 50% of chronic pain patients experience depressive symptoms.[194] Conversely, on average, 65% of

depressed individuals also report pain symptoms.[195] Epidemiologic studies provide evidence for a strong association between chronic pain and depression but do not address whether chronic pain causes depression or depression causes chronic pain. Prospective studies of patients with chronic musculoskeletal pain have suggested that chronic pain can cause depression,[196] that depression can cause chronic pain,[197] and that they can be synergistic.[22] A neuroanatomic link between depression and chronic pain via the hypothalamus, amygdala, and anterior cingulate gyrus pathway has been described. Reduced serotonin and norepinephrine are associated with both depression and increased pain sensation.[195]

One fact often raised to support the idea that pain causes depression is that the current depressive episode often began after the onset of the pain problem. The majority of studies appear to support this contention.[198] However, several studies have documented that many patients with chronic pain have often had prior episodes of depression that predated their pain problem by years.[59,60] Some studies also suggest that the pain-depression relationship is not linear but rather is mediated by how patients view their plight. For example, Turk, Okifuji, and Scharff [199] demonstrated that this relationship is mediated by a sense of control and life-interference appraisal of patients. The interaction between cognition and mood in chronic pain makes sense given the presence of individual differences in depression among patients with the same diagnoses at the comparable pain and physical findings.[19]

This is not to say that depression does not exert any contributions to pain. It is well established that depressed people tend to report elevated degrees of pain.[200] Longitudinal studies[60,201] suggest that depression is a risk factor for developing chronic pain. However, these results do not necessarily indicate that depression is the sole cause of pain. Regardless of the causal priority, once a person has a chronic pain diagnosis, it no longer matters which is the cause and which is the consequence—pain or depression. Both need to be treated. This is especially important, considering that depression is not only a significant determinant of pain-related disability.[202] It also drives the costs associated with disability and healthcare utilization upwards.[203]

One important prospective study[60] demonstrated that levels of depression predicted the development of low back pain three years following the initial assessment. Individual who were depressed were 2.3 times more likely to report back pain than those who did not report depression. Depression was a much stronger predictor of incident back pain than any clinical or anatomic risk factors. This has led some investigators to propose that there may exist a common trait of susceptibility to dysphoric physical symptoms (including pain) and negative psychological symptoms (including anxiety and depression). They conclude that "pain and psychological illness should be viewed as having reciprocal psychological and behavioral effects involving both processes of illness expression and adaptation."[60,204] For example, those who experience depression and chronic pain report more intense pain, less control of their lives, more unhealthy coping strategies, and reduced analgesic response to opiate medications.[195] In addition, negative thinking is a common feature of depression and chronic pain.

Research investigating how negative cognition is associated with depression in chronic pain typically shows that depressed pain patients exhibit greater negative thought processes than pain patients without depression.[205,206] Depressed pain patients seem to show greater negativity in thoughts and reduced positive thought processes than nondepressed pain patients.[207] Negative thought process appears to have reciprocal influences such that mood affects pain and conversely pain affects mood. Given the potential contributory role of negative attributions of pain and other somatic symptoms in pain patients, assessment of depression-related negative thoughts in depressed and nondepressed patients experiencing persistent pain seems essential, particularly if these thinking patterns impact how a person responds to pain treatment interventions by concluding "Nothing works for me."[195]

Given the scenario of chronic pain just described, it is hardly surprising that chronic pain patients are depressed. However, it is interesting to ponder the flip side of the coin—why are not *all* chronic pain patients depressed? Turk and colleagues[22,199] examined this question and determined that two factors appear to mediate the pain-depression relationship: patients' appraisals of the effects of the pain on their lives and appraisals of their ability to exert any control over their pain and lives. Those patients who believed that they could continue to function and that they could maintain some control despite their pain were less likely to become depressed. Here we see the interdependence of cognition and affect.

Substance Use

It is uncommon for people with chronic pain to be prescribed analgesics for their pain. When chronic pain does not respond to other therapies, opioid analgesics are often recommended. In recent years, rates of opioid prescriptions have escalated, as have rates of opioid overdose deaths in the United States.[208, 209] Although opioids can provide pain relief, there are concerns about their use in the long-term management of chronic pain, as they carry with them an increased risk for misuse (not in accordance with prescribed directions), abuse (intentional use for a nonmedical purpose), and addiction (use is harmful or has a high potential for harm).[210]

Some individuals with chronic pain use alcohol and prescribed medications to cope with pain and pain-related emotional distress. The DSM-V describes *Substance Use Disorder* (SUD) as a pattern of symptoms resulting from the use of a substance that the individual continues to take despite experiencing problems as a result, with additional specificity around types of substances (i.e. alcohol use disorder [AUD], opioid use disorder [OUD]).[13] The diagnostic criteria include problematic patterns of use leading to clinically significant impairment or distress (e.g. using the substance in larger amounts or over a longer period than was intended, unsuccessful efforts to cut down, strong desire, craving, or urge to use, continued use despite social or occupational consequences, tolerance, and withdrawal).[13] Among people with chronic pain who have been prescribed opioids, rates of misuse average between 21% and 29%; rates of addiction average between 8% and 12%.[208] Studies have suggested that up to 48% of chronic pain patients meet the DSM-V criteria for a SUD.[211,212]

In addition to misuse of prescription medication, alcohol use and misuse are also common among patients evaluated in chronic pain treatment settings, with up to 25% of patients noting a history of current or past alcohol dependence.[209,213] Recently, studies have begun to explore the co-use of alcohol and opioids, as concurrent use has been identified as a contributing factor in many opioid overdose deaths.[214] Studies have noted that 24% to 38% of people with chronic pain who have an OUD have a comorbid diagnosis of AUD.[209] The co-use of alcohol and opioids increases the risk of morbidity and mortality; emergency department visits for opioid-related visits have more serious outcomes with alcohol involvement,[215] and comorbid OUD and AUD has been shown to significantly increase the risk of fatal overdose and liver-related death.[216]

People with a history of SUD comprise a significant portion of chronic pain patients. However, they are often excluded from chronic pain intervention studies.[211] Treatment is thus limited by the lack of data for how best to treat this population. It has been suggested that a multi-disciplinary approach whereby pain reports, analgesia, and activities of daily living are regularly evaluated along with psychological interventions and supervision (urine drug tests, pill counts) may provide some efficacy.[211]

Anger and Hostility

Anger has been widely observed in people with chronic pain.[217] Between 53% and 98% of patients with chronic pain have independently reported feeling some degree of anger, including "bottled up anger."[218,219] One study showed that 88% acknowledged feelings of anger when these were explicitly sought.[220] Several empirical studies provide support for an association between pain intensity, pain severity, and anger/hostility (including trait anger, outward anger expression, hostile ideation, and inability to forgive others) in both healthy and clinical pain populations.[23,170,221–224]

Anger is not necessarily unreasonable—it can be a logical emotional response to the injustice that patients perceive. However, multiple studies have shown that perceived injustice is associated with greater pain, more severe depressive symptoms, pain behavior, and greater disability, with one study showing anger mediating the relationship between perceived injustice and pain intensity.[225–227] Therefore emotional regulation and anger reduction interventions have been suggested for patients with chronic pain.[228–230] This approach may be a good strategy, as anger seems to have an adverse impact on pain if it is suppressed. Kerns et al.[221] noted that the internalization of anger was strongly related to pain, perceived interference, and reported frequency of pain behaviors. Inhibition of anger expression has been found to be related to depression, pain severity, and overt pain behaviors, especially for those with severe pain.[221,231] Similarly, another study [232] showed efforts to suppress provoked anger attenuated blood pressure response to pain and was positively related to greater pain report. However, some patients tend to show strong reservations about expressing socially undesirable emotions that could create interpersonal conflict.[220] For these individuals, it seems that the expression of emotion is under conscious control. They are aware of their anger but choose not to express it. In contrast, some chronic pain patients may lack awareness of their angry feelings and have increased difficulties in recognizing and reporting these feelings.[233] It is thus reasonable to expect that the presence of anger may serve as a complicating factor, increasing autonomic arousal and blocking motivation and acceptance of treatments oriented toward rehabilitation and disability management rather than cure, which are often the only treatments available for chronic pain.[173]

The high prevalence of anger observed is perhaps not surprising, given the frustrations related to persistence of symptoms, limited information on etiology, and repeated treatment failures along with anger toward others (employers, insurance companies, the healthcare system, family members), and anger toward themselves, perhaps, for their inability to alleviate their symptoms and to move on with their lives.[219] Fernandez and Turk proposed that the specificity of targets toward which patients experience angry feelings may be important in the understanding of the relationship between pain and anger.[219] When an individual experiencing pain is angry, there are a range of possible targets (e.g. employer, insurance company, healthcare providers). The presence or intensity of anger directed toward different targets may be differentially related to the chronic pain experience. There may be some targets of anger that are more relevant to the chronic pain experience than others. As will be discussed later, Okifuji et al.[23] found that anger directed toward oneself was particularly common among chronic pain patients evaluated at a pain rehabilitation facility.

Anger in chronic pain has been considered by some to be attributable to enduring personality dispositions associated with unconscious conflicts.[234] In contrast, others have suggested that anger may be a reaction to the presence of recalcitrant symptoms that have been unsubstantiated by objective medical findings and unrelieved by medical treatments.[219] There is some evidence supporting the latter hypothesis. For example, a laboratory study demonstrated that the mere anticipation of pain was sufficient to provoke angry behavioral responses in healthy individuals.[235] Using the cross-lagged design with a clinical sample, Arena et al.[236] found that an increase in pain tends to precede anger, directly contradicting the anger-somatization association.

Frustrations related to persistence of symptoms, unknown etiology, and repeated treatment failures, along with anger toward employers, insurers, the healthcare system, family, and themselves, all contribute to the general dysphoric mood of patients with chronic pain.[23] Okifuji et al.[23] reported that 60% of patients expressed anger toward healthcare providers, 39% toward significant others, 30% toward insurance companies, 26% toward employers, and 20% toward attorneys. The target of anger most commonly acknowledged was anger toward themselves (endorsed by approximately 70% of the sample).

The precise mechanisms by which anger and frustration exacerbate pain are not known. One reasonable possibility is that anger magnifies pain by increasing physiologic arousal.[170] For example, Burns et al.[170] reported the results of a study that demonstrated anger-induced stress produced increased muscle tension, which in turn predicted a greater level of pain severity in chronic back pain patients. It was found that this effect was specific to anger. A measure of depression that was significantly correlated with pain was not associated with increased muscle reactivity.

It is important to know the significant role of negative mood in chronic pain because it is likely to influence treatment motivation and adherence to treatment recommendations. For example, individuals experiencing pain who are anxious may fear engaging in what they perceive as demanding activities; patients who are depressed and who feel helpless may have little initiative or motivation to comply, and patients who are angry with the healthcare system are not likely to be motivated to respond to recommendations from yet another healthcare professional. Thus clinicians who are treating people with persistent pain must focus on their mood states, physical pathology, and somatic factors. Pain cannot be treated successfully without attending to the patient's emotional state. This is true for acute pain, such as pain associated with surgery and persistent pain states.

Conclusion

For the person experiencing chronic pain, there is a continuing quest for relief that often remains elusive, leading to feelings of helplessness, hopelessness, and suffering. Emotional distress may be attributed to various factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disability, financial difficulties, litigation, disruption of usual activities, lack of social support, and sleep disturbance. Thus chronic pain is a demoralizing situation that confronts the person not only with the stress created by pain but with a cascade of ongoing stressors that compromise all

aspects of the life of the person experiencing chronic pain. Living with chronic pain requires considerable emotional resilience and tends to deplete emotional reserve and taxes not only the individual experiencing chronic pain but also the capacity of significant others to provide support. There is a large body of evidence to demonstrate that psychosocial and contextual factors can interfere with or hinder a person's ability to cope with the pain experience.

It is abundantly clear that pain is not a monolithic entity. No isomorphic relationship exists among tissue damage, nociception, and pain report. The variability of patients' responses to nociceptive stimuli and treatment is somewhat more understandable when we consider that pain is a personal experience influenced by attention, the meaning of the situation, prior learning history, and physical pathology. Usually, biomedical factors appear to instigate the initial report of pain. However, over time secondary problems associated with deconditioning may exacerbate and serve to maintain the problem. Inactivity leads to an increased focus on and preoccupation with the body and pain, and these cognitive-attentional changes increase the likelihood of misinterpreting symptoms, the overemphasis on symptoms, and the patient's self-perception as disabled. Reduction of activity, anger, fear of re-injury, pain, loss of compensation, and an environment that perhaps unwittingly supports the pain patient role can impede alleviation of pain, successful rehabilitation, reduction of disability, and improvement in adjustment.

Pain that persists overtime should not be viewed as either solely physical or solely psychological. Instead, the experience of pain is a complex amalgam maintained by an interdependent set of biomedical, psychosocial, and behavioral factors, whose relationships are not static but evolve and change over time. The various interacting factors that affect a person with chronic pain suggest that the phenomenon is quite complex and requires a biopsychosocial perspective.

From the biopsychosocial perspective, each factor outlined throughout this chapter contributes to the experience of pain and the response to treatment. The interaction among the factors is what produces the subjective experience of pain. There is a synergistic relationship whereby psychological and socioenvironmental factors can modulate nociceptive stimulation and the response to treatment. In turn, nociceptive stimulation can influence patients' appraisals of their situation and the treatment, mood states, and how they interact with significant others, including medical practitioners. An integrative, biopsychosocial model of chronic pain needs to incorporate the mutual interrelationships among physical, psychological, and social factors and the changes that occur among these relationships over time. A model and treatment approach that focuses on only one of these three core sets of factors will inevitably be incomplete.

Key Points

- The associations between physical pathology and reports of pain are not highly correlated.
- Reports of pain are not caused by biomedical factors or psychological factors; they are influenced by both.
- Presence of chronic pain impacts all domains of people's lives.
- Although physical pathology may be the cause for initial reports of pain, over time psychosocial and contextual factors play an increasingly important role.
- A range of psychosocial variables (beliefs, appraisals, and expectations) along with affective factors (e.g. anxiety, depression, anger) and contextual factors (e.g. environment, significant others) are related to the experience and reports of pain, adaptation, and disability associated with persistent pain.
- How individuals express their pain and related distress and suffering have a communicative function that can influence the responses of observes and in turn, the responses of others can affect the individual experiencing pain's response.
- Emotional distress may be attributed to various factors, including inadequate or maladaptive coping resources, iatrogenic complications, overuse of medication, disruption of usual activities, lack of social support, sleep disturbance, disability, financial difficulties, and litigation.
- Psychosocial factors can interfere with or hinder a person's ability to cope with the pain experience.
- Attempting to identify the physical basis for reported pain will, although necessary, will be insufficient in understanding and treating patients with chronic pain.
- Responses of significant others can have adaptive or maladaptive influences on the responses of patients.
- An integrative, biopsychosocial model of chronic pain needs to incorporate the mutual interrelationships among physical, psychological, and social factors and the changes that occur among these relationships as they evolve over time.

Comprehensive Approach to Evaluating Patients With Chronic Pain

DENNIS C. TURK, BRETT R. STACEY, ELISABETH B. POWELSON

Introduction

In the United States, chronic pain is one of the most common reasons adults seek medical care. It has been linked to anxiety, depression, poor mobility, dependence on opioids, and poor perceived health and quality of life. Based on epidemiologic data from the 2016 National Health Interview Survey, the Center for Disease Control and Prevention (CDC) estimated that approximately 20% of adults had chronic pain, and 8% had high impact chronic pain (chronic pain that inhibited daily functioning).[1]

Chronic pain patients are disparate, with varying underlying pathophysiology and widely diverse impacts on quality of life, function, and demands on the healthcare provider and society. All chronic pain reflects an amalgam of biologic, psychological, and social factors that is best assessed with a multidimensional perspective to determine further evaluation and treatment options. This evaluation requires a systematic examination of biomedical contributors to pain and the influences of psychosocial factors, sleep disturbances, physical capability, and medical comorbidities. The physical and psychological evaluation of chronic pain appropriately assesses a range of pathophysiologic and psychosocial processes that may underlie a patient's presentation. This evaluation can be straightforward in a patient with less complicated circumstances but may require a multi-disciplinary team in more complex situations. The basis for the evaluation is a comprehensive assessment that includes a complete and thorough history, physical examination with particular attention to the musculoskeletal and neurologic examination, and related functional limitations, as well as an assessment of psychosocial and contextual factors, including work and social roles.

In this volume, many specific chronic pain disorders are discussed, including particularly relevant physical examination and diagnostic procedures that are appropriate. In this chapter, we attempt to provide a conceptual approach that may serve to guide the assessment of all chronic pain patients regardless of any underlying pathology or disease. Depending on the specific presenting symptoms, imaging and laboratory testing and the focus of the physical examination will vary. We will focus on low back pain (LBP) as one of the most common chronic pain problems, but the principles apply to most chronic pain conditions.

Pain Definition

The International Association for the Study of Pain has recently updated the original 1979 definition to reflect advances in the understanding of pain and to acknowledge that pain may exist even in the absence of objective physical pathology.[2] The revised definition states that pain is "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage," and is expanded upon by the addition of six key notes and the etymology of the word pain for further valuable context:

- Pain is always a personal experience influenced to varying degrees by biologic, psychological, and social factors.
- Pain and nociception are different phenomena. Pain cannot be inferred solely from activity in sensory neurons.
- Through their life experiences, individuals learn the concept of pain.
- A person's report of an experience as pain should be respected.
- Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychological well-being.
- Verbal description is only one of several behaviors to express pain; inability to communicate does not negate the possibility that a human or a nonhuman animal experiences pain.

Pathophysiology of Chronic Pain

When pain persists beyond the typical time frame for acute pain to resolve, it has transitioned from acute pain to chronic pain, commonly reflecting different underlying mechanisms for the pain resulting in a sustained process. It may no longer be closely linked to actual or threatened tissue damage, even though an insult to the body may have initiated the pain. Processes contributing to the perception of ongoing pain variably include structural and biomedical causes, psychological factors both pre-existing and those arising coincident with the pain, family and social issues, prior pain experiences and trauma, and cognition. The development of chronic pain often involves both central and peripheral sensitization. However, it is often difficult to determine which of these mechanisms is predominant in a clinical context.

A detailed discussion of pain pathophysiology is beyond the scope of this chapter, and further details can be found elsewhere

in this text (see Chapters 8 and 9). We will touch on a clinically based way of thinking of pain classification and the implications for treatment. Pain is commonly classified as nociceptive, neuropathic, peripheral, or centralized, which reflect presumed mechanisms and influence treatment choices and responses, therefore making the distinction between these three broad concepts clinically meaningful.

Nociceptive pain is closely tied to activation by stimuli in the body that cause damage or threaten tissue damage. At least a component of nociceptive pain is associated with a bodily affront (e.g. trauma, surgery, disease progression) and is also associated with a range of chronic musculoskeletal conditions with mechanical, compressive, inflammatory, ischemic, or infectious insults. Medical disorders associated with ongoing nociceptive signaling include degenerative, inflammatory, and neoplastic diseases. Nociceptive pain is typically localized, provoked by use or stimulation of the painful area, and may respond to physical interventions (i.e. rest, heat, ice, bracing, surgical treatment) or traditional analgesics such as anti-inflammatories or opioids. Nociceptive pain often has characteristics familiar to most individuals—aching or sharp with intensity related to stimulation of the area.

Neuropathic pain is caused by a disease or lesion of the somatosensory nervous system that results in pain, often accompanied by increased sensitivity, sensory loss or alteration, and spontaneous or evoked pain.[3] The terms peripheral sensitization (PS) and central sensitization (CS), described in additional detail below, refer to states of abnormally increased responsiveness of the nociceptive system, which can be experienced in multiple painful conditions, including neuropathic pain. Neuropathic pain can be caused by trauma, compression, metabolic disease, toxins or medications, or autoimmune disorders. Neuropathic pain accompanies many conditions.[4,5] The initial insult can be in the peripheral or central nervous system with various conditions: diabetic neuropathy, surgery or trauma, stroke, or spinal cord injury. Chronic radiculopathy is an example of chronic neuropathic pain where there may be no detectable ongoing pathophysiology. Motor or sensory nerve damage typically leads to loss of function in either motor or sensory function, but in the case of neuropathic pain along with loss of function, there is an alteration in the peripheral and/or nervous system resulting in enhanced pain transmission. Patients often describe burning, tingling, or sensitivity with pain provoked by normal stimuli (allodynia) or increased painful response to a stimulus that normally provokes pain (hyperalgesia). Neuropathic pain rarely responds well to traditional analgesic medications.

Although nociceptive and neuropathic pain are familiar to most clinicians, the concepts of CS and PS may be less so. Changes in the central nervous system (CNS) and or peripheral nervous system (PNS) processing of pain are prominent components of many chronic pain conditions and are observed in the transition of acute pain to chronic pain.[6] Altered pain processing in the spinal cord and brain coupled with a decreased ability of the CNS to diminish response to peripheral stimuli known as impaired pain modulation are the key components of CS. These changes amplify the response to peripheral stimuli, at times leading to allodynia (a typically nonpainful stimulus is perceived as painful) and/or hyperalgesia (a normally painful stimulus that has heightened intensity) in a fashion similar to neuropathic pain but without evidence of specific insult or disease of the somatosensory nervous system.

In the case of PS, an afferent nerve in the periphery that has undergone an insult has increased responsiveness with a reduced threshold to stimulation of receptive fields. These changes may be near the injury site or at the dorsal root ganglia and likely involve multiple mechanisms. This leads to increased pain perception and can be a major factor in hyperalgesia or allodynia.[7]

Altered pain processing was initially recognized in less well understood pain conditions, with fibromyalgia (widespread chronic pain and other associated symptoms) as the prototypical example.[8] However, CS has been identified in many other conditions, including chronic back pain, cervical pain and whiplash, osteoarthritis, pelvic pain, and sickle cell disease.[9–14]

Clinicians should consider CS when there are multiple sites of pain, pain provoked with a low level of stimulus without obvious structural problem or associated nervous system injury, or pain that does not respond to traditional treatments (analgesics, modulating procedures—such as steroids or nonsteroidal anti-inflammatory drugs). An increasing number of chronic pain conditions have had CS identified in a subset of those with the condition. Therefore it is likely that many chronic pain patients have at least a component of CS. Findings to distinguish patients with CS from other chronic pain patients can be found using experimental diagnostic tools not typically used in clinical practice—functional magnetic resonance imagine (MRI), quantitative sensory testing, and conditioned pain modulation.

As there are no clinically relevant, commonly used diagnostic tests to determine CS, the diagnosis depends on clinical suspicion, history, and physical examination. Identifying CS is important as it allows for an appropriate treatment focus and can help avoid iatrogenic problems. For example, patients with CS and/or PS may have worsened outcomes after surgery, including more pain, higher complication rates, increased opioid consumption accompanied by increased costs.[15–17]

Assessing Chronic Pain

There is an understanding that given the range of overlapping etiologic, mediating, and moderating factors associated with a diagnosis of chronic pain and subsequent disability, the assessment appropriately takes a broad look from many perspectives. The key elements of the assessment include:

- history of the pain reports and treatments, along with a review of systems and medical, surgical, and social history to put the current pain in context;
- impacts of the pain of function, mood, sleep, social roles, and interactions with others;
- understanding the patient's perspective on the cause of pain, its impact, and expectations;
- physical examination including musculoskeletal and neurologic examinations plus careful observation of pain related behaviors; and
- diagnostic testing.

These assessments are affected by many factors that variably and uniquely interact and include:

- genetics,
- structural or physical changes and pathology,
- CNS and PNS processing such as sensitization and inhibition,
- prior experiences with pain and the medical system,
- psychological factors ranging from psychopathology to coping style,
- belief systems, and
- environmental influences (work, disability, family, societal, financial).[18]

A comprehensive evaluation examines each factor listed above and weighs its importance in the patient experience. The role of genetics in pain assessment and treatment has not yet been clearly defined. Therefore we will focus on a strategy for assessing the other factors that contribute to chronic pain in this chapter.

What Is the History of the Pain?

The first component of assessing patients reporting pain is centered on classic history taking:

- Onset—when did the pain start?
- Location—where does it hurt (all locations)?
- Duration—how long have they had pain; how long does it last when they experience pain?
- Character/description—what does the pain feel like?
- Intensity—how severe is the pain?
- Alleviating factors—what makes the pain better?
- Aggravating factors—what makes the pain worse?
- Radiation—does the pain spread?
- Temporal pattern—does the pain vary throughout the day, has it evolved over time?
- Associated symptoms—how does the pain impact the patient (function, mood, sleep, work, relationships)?

It is important to explore when the patient believes the pain began, whether its onset was insidious vs. attributable to a particular event, trauma, or underlying medical condition, and what the patient believes is the cause(s) of their ongoing pain. Patients' interpretation of their pain provocation and relief is very important to understand the illness narrative whether or not the provider feels it is "logical" or not. Investigating a patients' interpretation of cause, severity, variability over time, exacerbating and relieving factors, and any effects of prior treatment help frame the current situation and future treatment options.

A patient's illness narrative may not align with a providers' biologic model of pain but is critical to understanding the entirety of the patient's experience, which is needed to understand and treat the patient effectively. It is worth noting that in evaluating a patient with chronic pain, the healthcare provider should pay careful attention to certain historical items that are considered only cursorily in other clinical settings. In particular, the healthcare provider should be careful to assess the patient's history for early childhood physical and emotional trauma, early onset of painful conditions, chemical dependency, sleep disturbance and potential for obstructive sleep apnea, apparent severity of incapacitation, and his or her status with respect to litigation and compensation.

Using a body map/pain drawing where patients indicate the location(s) of their pain may be useful. Patients are asked to shade in on the drawing everywhere they experience pain, not just the present reason for evaluation. The assessment can be on paper or in a computerized form. The latter allows for the analysis of the data to make it more quantifiable.[19] This visual display of pain allows for quick recognition of patterns: diffusely filled in diagrams consistent with fibromyalgia, shaded areas that extend from the neck or back to the hand or foot typical of radicular pain, localized and unilateral drawing consistent with sacroiliac joint pain. More widespread pain filled in on a body diagram is associated with both increased disability and poor outcomes after a surgical intervention such as total knee arthroplasty.[19,20]

Assessment of Physical and Medical Factors

A thorough physical evaluation is a basic element in the evaluation of a patient with chronic pain, and while it serves many functions, examination findings are always placed in context with a thorough history. The examination serves many purposes, including:

- assessing function (e.g. gait, strength, range of motion, balance, speed, fluidity) and the patient's awareness of their functional status,
- making diagnoses and collaborating findings with history, imaging, and other diagnostic testing,
- determining if the pain problem is localized (one body region or system) or more generalized,
- determining treatment options and goals (palliation, correction of pathology, functional restoration), and
- determining if referral to a specialist is warranted.

Patients may focus on only their most recent or current pain, or a provider may only investigate the "chief complaint" and not put the pain in the appropriate context if a patient has more diffuse pain. Given the widespread nature of many chronic pain patients' conditions and the possibility of multiple pain sites or recurrent pain, all patients should have a thorough physical examination at their initial visit with an emphasis on musculoskeletal and neurologic examinations well as on their primary area where symptoms are reported. If pain is indeed focal, examining the normal areas confirms that the pain is localized, and the examination can be quickly and efficiently accomplished. Also, evaluating a pain patient depends on the chronicity of the patient's symptoms and the evaluations and diagnostic testing that the patient has already undergone.

To be reasonably specific, the discussion here focuses on evaluating a patient with a chief symptom of back pain. LBP is the most common chronic pain condition with a point prevalence of 13% in the United States and is a leading reason for seeking health care and cause of disability worldwide.[21] LBP is the most common reason for long term opioid use in the United States.[22] Patients with chronic LBP tend to be socioeconomically disadvantaged, visit healthcare providers frequently, and have a high burden of comorbidities.[23] The differential diagnosis of chronic LBP ranges from "non-specific" to serious, potentially life-altering illness. Many structures in the back can cause pain, including muscles, facet and sacroiliac joints, nerve roots, disc, ligaments, or adjacent structures. Thus the differential diagnosis list is long. Psychological and social factors have long been recognized as important and must be appropriately assessed and addressed.[24,25] We will discuss how the differential diagnoses can be further narrowed and a management plan developed through each assessment element.

Physical Examination

The details of physical examination are covered separately in Chapter 18 on specific disorders in this volume; however, we want to re-emphasize the importance of conducting a thorough physical examination of all patients. Decisions about imaging and diagnostic studies should be made when correlation and confirmation is needed between a physical finding, history, and possible pathology.

Red Flag Symptoms Associated With Back Pain

In any initial evaluation of a patient reporting persistent pain, the first concern is always to evaluate for any "red flag" symptoms indicative of a serious underlying medical condition that warrant additional evaluation and possible treatment. Examples of a serious medical condition would include malignancy, infection, significant trauma with damage to spinal elements, or neurologic injury. Symptoms, history, or findings that might represent a red flag include weight loss, profound fatigue, progressive motor or sensory deficits, constant new onset of severe pain, change in bowel

or bladder control, fever, history of cancer or infection, advanced age, prolonged use of steroids, or immune compromised. The presence of multiple red flag symptoms increases the probability of serious underlying pathology.[26,27]

Neurologic Injury

Healthcare providers should be alert for clinical evidence of either radiculopathy, neuropathy, or myelopathy and should recall that a peripheral nerve injury can at times mimic a spinal problem. Radiculopathy is a condition that affects the function of a nerve root, often accompanied by pain and changes in sensation, strength, and reflexes in a specific dermatomal distribution. Myelopathy refers to a neurologic deficit from injury or disease of the spinal cord. On pain history, patients often report a burning or intermittent stinging pain that radiates to various locations throughout their bodies. Patients may identify an inciting event in the lumbosacral region when radiculopathy is because of a disc herniation. Patients may report pain or numbness specifically in a known dermatomal distribution, but at times the complaint is vague, such as "my whole leg is numb," which requires investigation to determine if the complaint represents myelopathy or a more benign vague non-specific sensory change.[28] At other times, patients may complain of numb feet, but on further investigation, it becomes apparent that they have a separate peripheral neuropathy. Similarly, patients may report weakness or loss of fatigue that may represent myelopathy, radiculopathy, another medical condition, or simply deconditioning. Clinicians need to obtain the history in a manner that helps distinguish patterns and narrow the differential diagnosis. Additionally, if a patient has a history of significant trauma associated with the onset of pain or malignancy, urgent attention should be paid to evaluating instability of the spine, compression of neural elements, or metastasis.

Since it is not uncommon for patients to have complex multifactorial pain presentations, it is important to perform a careful sensory, strength, and reflex examination to determine differential diagnosis, need for further diagnostic testing, and treatment options. If needed, electrodiagnostic studies provide more objective evidence for radiculopathy and help distinguish it from peripheral nerve injury. MRI scan may also help provide evidence of an anatomic abnormality of nerve roots or anywhere along the spinal cord.[29] It is important to remember that there are high rates of incidental findings in asymptomatic patients, so imaging should be used to confirm clinical examination findings that are consistent with positive physical pathology. If the patient is asymptomatic for a given finding on examination but has incidental findings on imaging, they are unlikely to be meaningful.[29–31]

Spinal Stenosis

Lumbar spinal stenosis is a common condition (11%-39% of the population) with variable clinical presentation, multiple treatment options, and increased prevalence with age. Lumbar spinal stenosis refers to narrowing of one of three anatomic areas, most commonly of the central canal, but also the lateral recess or neural foramen.[32] The narrowing can be congenital, but more commonly, changes in the structure (disc protrusion, disc height loss, facet arthropathy, osteophytes, ligamentum flavum hypertrophy, spondylolisthesis, fibrosis) result in narrowing that compromises the neural elements. Typically, pain in the back or legs (neurogenic claudication) is brought on by activity such as walking or prolonged standing and relieved with rest or forward flexion. The physical examination findings for lumbar spinal stenosis are often non-specific.

Musculoskeletal Sources of Pain

The differential diagnosis of LBP is complex. Aside from neurologic injury or compression and spinal stenosis, many musculoskeletal structures in the back can be a source of pain: facet joints (paired joints at each level), sacroiliac joints (at the junction of the sacrum and pelvis), ligaments (multiple areas), muscles (back and gluteal), bone (compression fracture), and intervertebral disc (with degeneration). LBP that stays confined to the low back and does not radiate beyond the knee is also known as axial LBP. Commonly musculoskeletal pain can be because of an acute insult, degenerative processes, or chronic deconditioning and poor posture. During history gathering, patients may endorse insidious onset and difficulty with their overall range of motion. On physical examination, pain may be provoked with specific movements or palpation that may help focus the differential diagnosis. It is important to recall that multiple sources of pain can co-exist. In our clinical experience, muscle pain commonly co-occurs with all of the other sources of LBP.

Risk Factors for Poorer Outcome Or Delayed Recovery

Some patients do not respond as well to treatments as the "typical" patient, with persistent pain, dysfunction, and suffering despite treatment that appears to be "appropriate". It is difficult for a clinician to predict who is at risk for minimal benefit from treatment or who will experience slower recovery; the literature does not provide a clear guide. This list of possible risk factors for ongoing, poorly controlled pain includes medical and psychosocial factors. The more of these risk factors a patient has, the more likely they are to have pain that is difficult to treat.

- Identifiable progressive medical condition with known impact on the musculoskeletal or nervous system (e.g. rheumatologic diseases, multiple sclerosis, poorly controlled diabetes)
- More severe structural burden (e.g. failed fusion, uncorrected scoliosis, poly-trauma)
- High pain intensity, particularly pain that does not vary in intensity
- Repeated surgical or other procedures intended to relieve the same pain condition
- Widespread pain, other symptoms, or signs of CS
- Long term opioid use
- Substance abuse (opioid, alcohol, stimulants, tobacco, sedatives)
- Severely compromised function
- Preexisting mental health issues including post-traumatic stress disorder, poorly controlled anxiety, and depression
- Sleep disturbances both sleep apnea and difficulty initiating or maintaining sleep
- Social factors: unstable housing, poverty, low literacy, limited access to medical care, lack of support, physically demanding work conditions
- Medical illness that compromises function or limits treatment option[33,34]

Specific Evaluation for Procedures

The healthcare provider should screen patients for risk of poor response to treatment as outlined above by collecting data in the areas listed above and identify areas requiring additional evaluation or treatment. In addition, patients with several risk factors may be appropriate for team-based treatment by specialists to address what is potentially more difficult to treat pain. Broadly speaking, the information will come from the patient's history, the physical examination, assessment tools, and diagnostic studies.

Diagnostic Studies

Diagnostic studies can shed light on anatomy and structure (imaging including plain x-rays, computed tomography [CT], and MRI scans), nerve and muscle function (electrodiagnostic studies), bone metabolism/structure (bone scans), or systemic illness and inflammation (laboratory testing). For most chronic pain conditions, diagnostic imaging is the most ordered and clinically relevant, but also most overused, with up to two-thirds of studies not clearly indicated. Conversely, patients with "red flag symptoms" may not receive enough/appropriate imaging.[31] Additionally, imaging studies may reveal "abnormalities" including herniated discs and degenerative changes in asymptomatic people,[32] and imaging abnormalities that lack clinical correlation may lead to excessive treatment. While not an exhaustive guide to when/how/what imaging study to order, the following are reasonable and should be considered:

- In significant trauma with ongoing pain but no signs of radiculopathy or myelopathy, plain x-rays evaluate for fracture or instability; addition of MRI if signs or symptoms of neurologic injury.
- Patients with positive red flag symptoms coupled with clinical suspicion should receive MRI if they have any signs of myelopathy or radiculopathy, or severe pain.
- Patients with persistent pain who have not responded to initial conservative treatment are appropriate for screening x-rays and MRI if there are signs of radiculopathy or myelopathy.

CT scans and bone scans have more limited utility, such as identifying an occult fracture or assessing prior fusion hardware

Besides the traditional diagnostic tests discussed above, for patients with ongoing spinal pain who are deemed possible candidates for invasive treatment such as surgical decompression or radiofrequency ablation of the nerves to facet joints or sacroiliac joints, diagnostic local anesthetic blocks to identify a painful structure may have a role. If a patient has significant pain reduction (typically 80%) with image-guided, low volume injection of local anesthetic, it may be assumed that the targeted structure is a "pain generator." For persistent radiculopathy but uncertain imaging, the response to a selective nerve root injection provides important additional information for surgical decision making.[35] For selected patients with axial LBP thought to be from the facet joints, a positive response to a diagnostic medial branch block may lead to radiofrequency ablation of these nerves with a sustained reduction in pain.[36] Less commonly performed and more controversial is diagnostic provocative discography, which we do not recommend.

Summary

The previous section reviews the evaluation of a chronic pain patient with ongoing LBP. We emphasize a thorough history and physical, screening for serious medical conditions and risk factors for possible poor response to treatment, and selective use of diagnostic testing. Such an evaluation will provide a basis for making treatment decisions, deciding on further workup, and appropriate referral to other specialists or treatment providers. However, although necessary, the medical examination is insufficient to understand and develop an appropriate treatment plan for patients presenting with chronic pain. A range of psychosocial, behavioral factors should also be investigated to complement the medical evaluation.

Assessment of Psychosocial Factors

A comprehensive psychological evaluation of a pain patient should be a fundamental component of a multi-disciplinary evaluation. It addresses the specific psychosocial, behavioral, cognitive, and contextual factors such as current mood (anxiety, depression, anger), interpretation of the symptoms, expectations about the meaning of symptoms, and the responses to the patient's symptoms by significant others (e.g. family members, coworkers), each of which contributes to the subjective experience of pain. This information should augment the development of a comprehensive treatment plan.

Elements of the Psychological Evaluation

Interviews

A psychological interview with chronic pain patients is typically semi-structured. A structured format psychiatric interview can be incorporated as a tool to examine psychopathology.[37] However, a psychological interview with pain patients should go beyond assessing psychopathology since its main purpose is to assess a wide range of psychosocial factors (not just psychopathology) related to a patient's symptoms and disability.

Patients' Beliefs and Expectations

It is important to assess patients' expectations regarding diagnosis and management of their pain. Healthcare providers' expectations and patients' expectations may not be aligned, leading to conflict and dissatisfaction with care.

Chronic pain patients' beliefs about the cause of symptoms, their trajectory, and beneficial treatments will have important influences on emotional adjustment and adherence to therapeutic interventions. A habitual pattern of maladaptive thoughts may contribute to a sense of hopelessness, dysphoria, and unwillingness to engage in prescribed activities. The interviewer should also determine both the patient's and the significant others' expectancies and goals for treatment. An expectation that pain will be eliminated completely may be unrealistic and must be addressed to prevent discouragement when this outcome does not occur. Setting appropriate and realistic goals is an important process in pain rehabilitation as it requires the patient to understand chronic pain better and goes beyond the dualistic, traditional medical model—somatogenic vs. psychogenic.

To help patients with chronic pain understand the psychosocial aspects of pain, attention should focus on the patients' reports of specific thoughts, behaviors, emotions, and physiologic responses that precede, accompany, and follow pain episodes or exacerbation, as well as the environmental conditions and consequences associated with their responses in these situations. During the interview, the clinician should attend to the temporal association

of these cognitive, affective, and behavioral events; their specificity versus generality across situations; and the frequency of their occurrence to establish salient features of the target situations, including the controlling variables. The interviewer should seek information that will help to develop potential alternate responses, appropriate goals for the patient, and possible reinforcers for these alternatives.

Patients with chronic pain problems frequently consume various medications to alleviate their symptoms. However, recently the number prescribed has been decreasing, and many patients are becoming disillusioned about the benefits and risks of medications. If patients are taking medication for their pain, it is important to discuss a patient's medications during the interview, as many pain medications (particularly opioids) are associated with side effects that may mimic emotional distress and can have deleterious adverse effects. A clinician, for example, should be familiar with side effects that result in fatigue, sleep difficulties, and mood changes to avoid misdiagnosis of depression. A general understanding of commonly used medications for chronic pain is important, as some patients also may use opioid analgesics to manage dysphoric mood that accompanies pain and its impact. During the interview, potential psychological dependence and aberrant drug seeking behaviors on pain-relieving medications should be evaluated. In most states in the United States, a physician can obtain a record of prescriptions of controlled substances. When in doubt, a psychologist may recommend that such a record be obtained and request urine toxicology screening to rule out aberrant opioid-taking behaviors.[38]

When interviewing a patient with chronic pain, the healthcare professional should not only focus on gathering information that the patient provides but also observe patients' pain behaviors and how they convey information (e.g. facial expressions, movement patterns).[39]

Pain Behavior

Pain is a subjective perception, and there is currently no objective way to know about the experience of pain other than by patients' behavior. Patients display a range of responses that *communicate* to others that they are experiencing pain, distress, and suffering (verbal behaviors such as statements about pain, moaning, and nonverbal behaviors such as limping, grimacing, and rubbing painful body parts). Some of these pain behaviors may be consciously controllable by the patient, whereas others are not. These behaviors may be associated by patients' feelings that their pain is not appreciated as important by significant others, including providers, or they may be the result of physical alterations (e.g. limping associated with structural perturbations). There may be an increase in behaviors when patients feel that others "do not believe them."

Informally, a healthcare provider can observe patients' behaviors during their interviews and examinations. It is useful to observe patients in multiple contexts when possible (e.g. waiting room, ambulating to an exam room, during the interview with the clinician, during physical examination). When patients know they are being observed and are presenting information to a healthcare provider, they may use behavior to convey information in ways most likely to support the impact of their symptoms. They may feel a need to convince the healthcare provider of the severity of their symptoms, functional limitations, and distress. Thus observation of the patient in the waiting room, when ambulating to the examination room, and when departing may allow the clinician to establish the stability and consistency of pain behaviors. When possible, it is useful to observe patients in the presence of a significant other to note differences in behaviors when the significant other is present and absent and how the significant other responds to the patient's pain behaviors. Of course, the clinical interaction is different from the patient's normal environment, so the patient's presentation needs to be considered when interpreting patient behaviors.

Uses of the healthcare system and analgesic medication are other ways to assess pain behaviors. Patients can record the times when they take medication over a specified interval, such as a week. Despite the cautions regarding the use of patient diaries (described below), diaries can provide information about the frequency and quantity of medication and permit the identification of the antecedent and consequent events of medication use. Antecedent events might include stress, boredom, or activity. Examination of antecedents is useful in identifying patterns of medication use that may be associated with factors other than pain per se. Similarly, patterns of response to the use of analgesic may be identified. Does the patient receive attention and sympathy whenever he or she is observed by significant others taking medication? Do significant others positively reinforce taking analgesic medication and unwittingly increase medication use?

Brief Psychosocial Screening

A busy clinician may not have adequate time to completely assess the myriad of psychosocial and behavioral factors demonstrated to be important in chronic pain patients. Thus a brief screening might provide initial information on a range of factors and guide more in-depth evaluation by the provider or guide them in deciding upon referral for a more comprehensive evaluation. The PEG[39] is a brief measure consisting of three questions selected from the Brief Pain Inventory.[40,41] The items ask about pain, emotional distress, and general activity.

Another brief screening interview has been developed—ACT-UP (Activity, Coping, Think, Upset, People's responses).[42,43] Table 15.1 contains a brief set of salient issues covered with the acronym. Generally, a referral for evaluation may be indicated where disability greatly exceeds what would be expected based on physical findings alone, when patients make excessive demands on the healthcare system, when the patient persists in seeking medical tests and treatments when these are not indicated, when patients display significant emotional distress (e.g. depression or anxiety), or when the patient displays evidence of addictive behaviors or continual nonadherence to the prescribed regimen.

TABLE 15.1 Brief Psychosocial Screening: ACT-UP

Activities: How is your pain affecting your life (i.e. sleep, appetite, physical activities, relationships)?
Coping: How do you deal/cope with your pain (what makes it better/worse)?
Think: Do you think your pain will ever get better?
Upset: Have you been feeling worried (anxious)/depressed (down, blue)?
People: How do people respond when you have pain?

Self-Report Inventories

In addition to interviews, several standardized assessment instruments designed to evaluate patients' attitudes, beliefs, and expectancies about themselves, their symptoms, and the healthcare system have been published.[43]

Standardized instruments have some advantages over semi-structured and unstructured interviews. For example, they are easy to administer, require less time, assess a wide range of behaviors, obtain information about behaviors that may be private (sexual relations) or unobservable (thoughts, emotional arousal), and, most importantly, they have been submitted to analyses that permit demonstration of their psychometric properties (e.g. reliability and validity). These instruments should not be viewed as alternatives to interviews. Instead, they are compliments that may suggest issues to be addressed in more depth during an interview or investigated with other measures.

Assessment of Pain

Pain Intensity

Self-report measures of pain often ask patients to quantify their pain by providing a single, general rating of pain: "Is your usual level of pain 'mild,' 'moderate,' or 'severe?'" or "Rate your typical pain on a scale from zero to ten where zero equals no pain, and ten is the worst pain you can imagine." Several simple methods can be used to evaluate pain intensity—numeric rating scale (NRS), verbal rating scales (VRS), and visual analog scales (VAS) using different variations. For example, the Brief Pain Inventory (BPI) includes four individual questions using NRSs—right now, on average, at worst, and at least.[40,43]

NRS and VRS measures tend to be preferred over VAS measures by patients. Greater difficulty completing VAS measures is associated with increased age and greater opioid intake, and cognitive impairment has been shown to be associated with the inability to complete NRS ratings of pain intensity.[42] Other measures are available to assess pain in children and those who are unable to verbally communicate (e.g. stroke patients, mentally-impaired).[44,45]

There has been some concern that retrospective reports may not be valid, as they may reflect current pain severity that serves as an anchor for recall of pain severity over some interval.[46,47] More valid information may be obtained by asking about the current level of pain, pain over the past week, worst pain of the last week, and lowest severity over the last week (e.g. BPI). This has also led to the use of daily diaries believed to be more accurate as they are based on real-time rather than recall. For example, patients are asked to maintain regular diaries of pain intensity with ratings recorded several times each day (e.g. at meals and bedtime) for several days or weeks. One problem noted with paper-and-pencil diaries is that patients may not follow the instruction to provide ratings at specified intervals. Instead, patients may complete diaries in advance ("fill forward") or shortly before seeing a clinician ("fill backward").[48,49] These two reporting approaches undermine the potential validity of diaries. Electronic devices that can prompt patients for ratings and "timestamp" the actual ratings, thus facilitating real-time data capture, can be used as an alternative to paper-and-pencil diaries.[48–50] Although they may be appropriate for research studies, their usefulness in clinical settings may be limited. However, technological advances, including smartphone applications, make the use of these methods more available for clinical use.

Pain Quality

Pain is known to have different sensory and affective qualities in addition to its intensity, and measures of these components of pain may be used to describe an individual's pain experience more fully. The efficacy of pain treatments may vary for different pain qualities. Therefore pain quality measures may identify efficacious treatments for certain types of pain (i.e. nociceptive and neuropathic) but not for overall pain intensity. Assessment of specific pain qualities at baseline also makes it possible to determine whether certain patterns of pain quality moderate the effects of treatment. The Short-Form McGill Pain Questionnaire (SF-MPQ)[51] assesses 15 sensory and affective pain descriptors, and its sensory and affective subscales have demonstrated responsivity to treatment in several clinical trials.[52] More recently, a revision of the SF-MPQ (SF-MPQ-2) was developed to increase the range of items (rated on a zero to ten scale) and items added to assess characteristics of neuropathic pain that have not been adequately assessed in the SF-MPQ-2.[53]

Pain Modifiers

For the majority of people with chronic pain, pain severity varies. Thus it is useful to inquire about what the patient believes makes his or her pain worse. For example, are there specific activities that worsen their symptoms? Are there certain circumstances that contribute to an exacerbation of pain, such as specific activities, interpersonal conflicts? Does pain vary with time of day (e.g. morning, nighttime)? In the same way, it is important to identify factors that magnify or initiate pain episodes and ask about what factors result in reductions in pain. For example, do medication, rest, heat or cold, distraction, or exercise result in reductions of pain severity or even elimination of symptoms for some period? Pain may be influenced by the context or activities being undertaken. Thus it is important to address what factors modify pain, such as the nature of different activities and presence of significant others.

Assessment of Emotional Distress

Chronic pain is frequently associated with emotional distress, particularly depression, anxiety/fear, anger, and irritability. Emotional distress in people with chronic pain presents a challenge when assessing symptoms such as fatigue, reduced activity level, decreased libido, appetite change, sleep disturbance, weight gain or loss, and memory and concentration deficits. These symptoms are often associated with pain per se and have also been considered symptoms of depressive disorders. Therefore improvements or deterioration in such symptoms can result from changes in either pain or emotional distress.

Assessment of Depressed Mood and Anxiety

Several self-report instruments have been developed to assess emotional distress. The BDI and BDI-2,[54,55] the Hospital Anxiety and Depression Scale (HADS),[56,57] and Patient Health Questionnaire) (PHQ)-(9)[58] have well-established reliability and validity in the assessment of symptoms of depression and emotional distress, and they have been used in numerous clinical trials in psychiatry and an increasing number of studies of patients with chronic pain.[59] The HADS includes seven items assessing anxiety and depression. One advantage of the HADS is that it was developed and standardized with medical patients rather than

psychiatric patients. Shorter measures of anxiety (GAD-7)[60] and depression (PHQ-9)[61] have been reported to provide reliable and valid assessments and might also be considered for research and clinical use. Any of these measures are reasonable choices as brief measures of emotional distress.[62]

Assessment of Fear

Many patients with chronic pain, especially those who attribute their symptoms to trauma, fear engaging in activities they believe may either contribute to further injury or exacerbate their symptoms. Avoidance of activities may, in the short term, lead to symptom reduction. Nevertheless, restricting activities over time is likely to lead to decreased functional capacities because of deconditioning. Also, avoidance of activity has the unfortunate consequence of preventing corrective feedback where patients can learn about their erroneous beliefs. Healthcare providers may inadvertently contribute to the avoidance of activity by providing patients with braces that restrict movements and advising them to avoid activities that hurt (i.e. hurt = harm). They may contribute to the patient's fear that something is seriously wrong with their bodies by continuing to order sophisticated diagnostic tests in search of occult physical pathology) or in the description of non-specific diagnostic test results that are interpreted by the patient as representing serious pathology. Self-report measures of fear of movement that might increase pain or physical damage are available (e.g. Tampa Scale of Kinesiophobia [TSK], Fear Avoidance and Beliefs Questionnaires [FABQ]).[61,62]

Assessment of Substance Use and Abuse

A significant percentage of the population frequently use alcohol and illicit substances. Individuals with chronic pain are no different and may use these substances to self-medicate. Opioid misuse is a particular problem for individuals with chronic pain as they may be prescribed opioids to treat their pain.[63] Estimates of the percentage of chronic pain patients who misuse or abuse opioids and other mood altering drugs are variable, but the numbers are not insignificant. Thus healthcare providers need to evaluate their chronic pain patients prior to prescribing these substances and use this information to inform their decisions regarding treatment. Moreover, when they deem an opioid treatment as appropriate, they need to carefully monitor them. Several self-report inventories and structured interview methods have been developed to accomplish these objectives (e.g. Screener and Opioid Assessment for Patients with Pain-Revised [SOAPP-R],[64] Current Opioid Misuse Measure [COMM],[65] Opioid Use Inventory).[66] However, they need to be used with caution as they each have significant limitations.[67]

Assessment of Beliefs, Coping, and Psychosocial Adaptation To Pain

Several measures have been developed to assess pain patients' beliefs, coping, and adaptation. Two particularly potent beliefs (i.e. self-efficacy and catastrophizing) held by patients have been demonstrated to play important roles in chronic pain. *Self-efficacy* (SE) is the conviction that one can perform a certain task or produce a desirable outcome.[68] A major determinant of SE is prior mastery experience. In chronic pain patients, SE positively affects physical and psychological functioning,[69,70] and improvements in SE after self-management and cognitive-behavioral interventions are associated with improvements in pain, functional status, and psychological adjustment. Self-report instruments to assess SE with chronic pain patients have been developed and used in clinical research and practice.[71,72]

Pain catastrophizing can be defined as an exaggerated negative orientation toward actual or anticipated pain experiences. Current conceptualizations most often describe it in terms of appraisal or as a set of maladaptive beliefs.[73] A cognitive and emotional process that involves magnification of pain related stimuli, feelings of helplessness, and a negative orientation to pain and life circumstances includes obsessive rumination about pain and its meaning and magnification of symptoms. These are associated with increase in pain severity ratings and functional disability. Catastrophizing has been an important predictor of response to both acute and chronic pain. Catastrophizing has been associated with increased perceptions of pain severity in both acute[74] and chronic pain severity[75] and disability among groups with diverse pain diagnosis.[76,77]

Several self-report measures of catastrophizing have been developed and shown to have good psychometric properties (Coping Strategies Questionnaire [CSQ],[77] Pain Catastrophizing Scale (PCS)).[78] These measures have been used in both clinical research and contexts and have shown to have predictive validity for disability and response to various treatments. A brief, two-item measure of catastrophizing has been shown to have a high correlation with the longer form and may be helpful as a screening device.[79]

An important caution regarding the term "catastrophizing." Patients tend to view this term as extremely negative and stigmatizing.[80] Although the construct is important, providers should be careful in using this term or referring to self-report measures as measures of catastrophizing when interacting with patients.

Assessing Functional Impact

Physical functioning and activity can be considered from three complementary perspectives, namely, the patient's perspective on his or her functioning (self-report), observation during performance on structure tasks in a clinical or laboratory setting (e.g. timed walking, gait pattern), and objective assessment of activity in the naturally occurring environment (e.g. using technical instruments and devices such as accelerometry).[81,82] Each of these perspectives will provide different information about performance and are complementary. Objective assessment of physical functioning will depend on the nature of the physical capacity and diagnostic condition being assessed. A detailed discussion about this goes beyond the scope of this chapter (see Ware and Sherbourne[83] for a comprehensive review).

Self-Report Measures of Function

Self-report measures have been developed to assess people's reports of their abilities to engage in a range of functional activities such as the ability to walk upstairs, to sit for specific periods, the ability to lift specific weights, perform activities of daily living, as well as the severity of the pain experienced upon the performance of these activities.[82] There are several well-established, psychometrically supported generic (e.g. Short-Form 36 [SF-36])[83] and pain specific (e.g. Brief Pain Questionnaire Interference Scale;[40] Pain Disability Index [ODI];[84] Multidimensional Pain Inventory [MPI]

Interference Scale),[85] and diagnosis back pain specific (Oswestry LBP Disability Questionnaire;[86] Western Ontario McMaster Assessment of Knee and Hip Osteoarthritis [WOMAC])[87] measures of functional status (for an extensive review see Taylor et al.[82])

The Oswestry LBP Disability Questionnaire is a widely used, 10-item scale that asks patients about disability associated with back pain.[86] It has the advantage of being a disease-specific instrument. In general, disease-specific measures are designed to evaluate the specific effects of a disorder that may not be assessed by a generic measure.[81,82] In addition, responses on disease-specific measures will generally reflect the effects of comorbid conditions on physical functioning, which may confound the interpretation of change over the course of a trial when generic measures are used. Disease-specific measures may be more sensitive to the effects of treatment on function, but generic measures provide information about physical functioning and treatment benefits that can be compared across different conditions and studies.[82,88] Each of these approaches has strengths. Decisions regarding whether to use a disease-specific or a generic measure or some combination will depend on the purpose of the assessment. For individual patients in clinical practice, it would be most appropriate to use measures developed on samples with comparable characteristics. If the healthcare provider wishes to compare across a group of patients, then one of the broader-based pain specific measures should be considered. If the assessment is being performed as part of a research study, some combination might be appropriate to compare chronic pain samples with a larger population of people with diverse medical diseases (e.g. SF-36[83]).

One aspect of physical functioning that is particularly important to those with chronic pain is sleep.[89] Pain is frequently reported to have a significant impact on sleep quality and duration.[90] Patients being evaluated should be asked about their sleep, and depending on the information acquired during an interview, more detailed methods are available to assess sleep objectively using formal sleep laboratory evaluation, accelerometry, and self-report measures (e.g. Medical Outcomes Study [MOS] sleep scale).[91]

Besides physical functioning, work status is important for LBP patients. In the absence of a standard instrument, and when appropriate, clinicians assessing LBP patients should investigate the following issues regarding work: (1) Is the patient working? (2) If the patient is not working, is this related to his or her health? (3) How long has the patient been out of the workforce, and what is their work history? (4) Is he or she receiving any work disability benefits? Which ones? (5) Have they been trained for their work and skills/knowledge required? and (6) What does/did it mean to them (e.g. source of pride, onerous)?

A significant proportion of individuals involved in LBP injuries file personal injury claims. There is some evidence that injured workers with workers' compensation claims respond more poorly to a variety of treatments compared to individuals with these same medical conditions but without workers' compensation claims.[92] Research on the relationship between litigation and clinical course, however, has been contradictory. For example, several studies have reported a negative effect of attorney involvement and litigation on recovery from whiplash disorders.[93,94] Others have not supported the prognostic role of these factors.[95] It is beyond the scope of this chapter to review the often contentious literature on the effect of litigation/attorney involvement on outcomes of chronic pain.[96–100]

Assessment of Physical Capacity

The physical capacities of pain patients are typically assessed by physical and occupational therapists. In some clinical settings, evaluation protocols are developed informally by individual therapists, sometimes in conjunction with a physician. In other settings, formal assessment protocols are used. Although the validity of such protocols has been questioned,[82] they are frequently used, particularly when injured workers are evaluated. Such evaluations obtain objective information about the capabilities of patients. In clinical settings, this information is used in the planning of rehabilitative treatment. In more adversarial settings (e.g. workers' compensation), physical capacities data are used when adjudicative decisions about claims are made.

Assessment of Social Supports

Social support factors are construed as factors in the social (interpersonal) environment that influence people independent of their individual psychological characteristics. The availability, nature, and quality of social supports and the responses of significant others play an important role in how individuals respond to their pain. As noted, patients' pain behaviors communicate to others the severity of their symptoms, emotional distress, and suffering. Since these behaviors are observable, they are capable of eliciting responses. How significant others respond to patients' behaviors may be adaptive (e.g. encouraging) or maladaptive (e.g. punishing, solicitous). Several instruments have been developed to assess patients' perceptions of the responses of others to their plight (e.g. MPI-Spouse Response Scale).[85] For example, there is good evidence that pain patients generally demonstrate more dramatic pain behaviors when they are in the presence of solicitous spouses.[101]

Conclusion

Pain and associated symptoms result from a complex interplay of factors. Assessment and treatment of chronic pain can be complicated by the web of influential factors that modulate the overall pain experience and associated disability. Pain research in the last half-century has repeatedly shown that pain is not just a physiologic phenomenon and that a range of "person variables," such as psychosocial, environmental, and behavioral factors, play a significant role in determining the occurrence, severity, and quality of pain. Given the multifactorial nature of chronic pain, adequate assessment requires a comprehensive approach. This chapter discussed the assessment of medical factors, altered CNS processing, psychological factors, and social factors in patients with chronic pain. We described several self-report inventories that can be used in conjunction with interviews and medical examinations. As we have repeatedly stressed, an adequate assessment of patients with chronic pain means the evaluation of the person with the symptoms and not just the symptoms and physical pathology. Although there is no shortcut in this, the delineation of relevant medical, psychosocial, and behavioral factors contributing to pain in a patient is critical in planning and executing a successful treatment plan. We did describe some brief measures that might be informative regarding areas worthy of further investigation.

Key Points

- Assess the person and not just the reported pain.
- A thorough history and physical, screening for serious medical conditions and risk factors for possible poor response to treatment, and selective use of diagnostic testing are essential ingredients of a comprehensive assessment of patients with chronic pain. Although necessary, they are not sufficient.
- Diagnostic imaging can be overused and is appropriate to confirm information gathered during the history taking and physical examination.
- A range of psychosocial, behavioral, and contextual factors all contribute to the experience of chronic pain and pain related disability. These factors need to be evaluated to better understand patients with chronic pain and contribute to the treatment plan.
- Patients' beliefs about the cause and meaning of their symptoms and expectations for treatment are important to investigate before prescribing any treatment as their erroneous beliefs, and unrealistic expectations can undermine patients' engagement in prescribed treatment regimens and outcomes.
- Observation of patients during clinical interactions can provide useful information about patients' conscious and nonconscious motivations.
- Self-report measures can be used to acquire information about patients' beliefs, mood, and activity.
- Self-report of functional activities may not provide accurate information of physical capabilities, and more objective means of assessment should be considered as complements. However, self-reports of function are important sources of information because they convey the patients' perceptions even if not consistent with objective measures and should not be dismissed.

Mechanism-Based Treatment and Precision Medicine

JIANGUO CHENG, YUL HUH, RU-RONG JI

Introduction

The advancement of pain medicine is driven by the continual search for new and innovative solutions to a wide range of chronic pain conditions that affect more than 50 million Americans.[1] An important approach is to better understand the mechanisms of pain and factors that determine the transition from acute to chronic pain states. By doing so, new and effective mechanism-guided preventive measures and therapeutics may be discovered, developed, and translated to serve the urgent needs of our patients. However, mechanism-guided therapies often cannot achieve the desired therapeutic outcomes for several reasons. First, our understanding of pain development, maintenance, and chronification or resolution is limited, as the cellular and molecular mechanisms of these pain stages in different pain conditions are not fully understood. Second, most complex pain conditions are determined by an interplay of multiple mechanisms, including other comorbidities, psychological factors, and social determinants. Third, the mechanisms of many therapies are complex, often with multiple targets and mechanisms associated with significant off-target side effects. Fourth, mechanism-guided therapies typically do not consider individual variability in genetics, sex, tolerability to treatment, and many developmental and environmental factors. For these reasons, the future of pain therapeutics will be personalized precision medicine, an emerging approach for disease treatment and prevention that considers individual variability in genetics, prior history, environment, and lifestyle. Thus precision pain medicine has great potential to enhance the biopsychosocial modal of patient-centered care.[2] In the biologic sphere, effective mechanism-based treatment depends on proper assessment and accurate diagnosis/differential diagnosis that is based upon the anatomic location/structure, the pathologic nature, the cellular, molecular mechanisms, and genetic predisposition of pain. Patient phenotyping by quantitative sensory test has been shown to identify subgroups that better respond to specific pharmacologic treatments. At the psychosocial levels, clinical outcomes are highly influenced by such psychological factors as catastrophizing, depression, and anxiety, and social factors such as lifestyle, social economic status, and access to care. Often, these psychosocial factors may be predominant in determining patients' outcomes.

Evidence-based medicine, by definition, is the conscientious, explicit, judicious, and reasonable use of best evidence in decision-making about the care of individual patients.[3] Evidence-based pain therapy integrates clinical experience and patient values with the best available research information. Thus mechanism-guided treatment and precision medicine are the foundation for the development of evidence-based pain therapy and clinical practice guidelines, which consider individual variability and other confounders to inform clinical decision-making between clinicians and patients with the goal to maximize therapeutic benefits and minimize side effects. Given the futuristic perspective of precision pain medicine, it will be discussed in a dedicated part of this chapter (Precision Pain Medicine Section).

A comprehensive review of all mechanism-based therapies in pain medicine is beyond the scope of this chapter. Instead, we will concisely review the commonly used and mechanism-based therapies that include pharmacologic treatments, interventional procedures/surgeries, and physical/cognitive/and behavioral therapies. We will focus on the recent development of promising and innovative new therapies using biologics such as monoclonal antibodies and cell therapies and neuromodulatory approaches such as spinal cord stimulation (SCS). It cannot be overemphasized that all of these treatment modalities have to be guided by proper assessment and accurate diagnosis and tailored to each patient's needs as part of patient-centered, multi-disciplinary, and integrated care.[4]

Current and Developing Mechanism-Based Treatments

State-of-the-art therapies in pain medicine are used to modulate the transduction, conduction, transmission, and perception of pain sensation through specific molecular, cellular, and neural network (circuitry) targets (Table 16.1). At the molecular level, pain therapies may work by affecting ion channels, receptors, and other critical signaling molecules. At the cellular level, pain treatment may influence the firing rate and firing pattern of neurons and the state of inflammatory and immune cells, including glia, microglia, and macrophages. At the circuitry level, therapies may influence the function and connectivity of ascending pain pathways, interneurons in the spinal cord, descending modulatory pathways from the brainstem to the spinal cord, and various regions of the brain responsible for the sensory and emotional aspects of pain perception, and behavioral reaction and adaptation to pain.

Pharmacologic Therapies

Current Treatments

Current pharmacologic therapy involves the use of local anesthetics, nonsteroidal anti-inflammatory drugs (NSAIDs), anti-depressants, anti-convulsants, muscle relaxants, and opioids (Table 16.1), among other drugs. These therapies achieve analgesic effects through a wide range of mechanisms. For example, local anesthetics reversibly block pain impulses by blocking voltage-gated sodium channels. Anti-inflammatory drugs selectively or non-selectively inhibit cyclooxygenases (Cox-1 and Cox-2) to reduce inflammation and sensitization of pain. Most muscle relaxants act centrally. They may activate α2-adrenergic receptor (tizanidine), leading to reduction of excitatory amino acid release from spinal interneurons,[5] or to inhibit 5-HT2 receptor (cyclobenzaprine), leading to diminishing serotonergic descending tone in the spinal cord ventral horn.[6] Anti-convulsants block sodium (e.g. carbamazepine, oxcarbazepine, topiramate, valproic acid) or calcium channels (gabapentinoids, valproic acid).[7,8] Opioids activate μ, delta, or κ opioid receptors to produce analgesia.[9] Anti-depressants, such as serotonin-norepinephrine reuptake inhibitors (SNRIs, e.g. duloxetine, tramadol, and TCAs), selective serotonin reuptake inhibitors (SSRIs, e.g. Fluoxetine), and selective norepinephrine reuptake inhibitors (NRIs, e.g. tapentadol), activate the descending inhibitory pathways to dampen nociceptive transmission. It is common for one drug to have multiple therapeutic targets or mechanisms. For example, tapentadol acts as a norepinephrine transporter inhibitor and a μ-opioid receptor agonist; Gabapentin primarily works by blocking the α2δ1 subunit of voltage-gated Ca^{2+} channels,[10] but may also modulate other targets such as transient receptor potential channels and N-methyl-D-aspartate (NMDA) receptors.[11] In addition, it may also inhibit γ-aminobutyric acid (GABA) release in the locus coeruleus and stimulate noradrenaline-mediated descending inhibition in the spinal cord.[12]

Monoclonal antibodies are antibodies produced by identical immune cells that are clones of a unique parent cell. Given their high selectivity and long half-lives (weeks), monoclonal antibodies are emerging as the main type of pain therapeutic for multiple targets. Monoclonal antibodies antagonizing the calcitonin gene-related peptide (CGRP) signaling pathway represent a novel and mechanism-specific approach to the prevention and treatment of migraine headaches, as CGRP plays a critical role in neurogenic inflammation and the pathogenesis of migraine.[13] Monoclonal antibodies against CGRP (fremanezumab, galcanezumab, and eptinezumab)[14–16] or CGRP receptor (erenumab)[17,18] have shown efficacy in preventing or aborting migraine headaches in high-profile controlled trials without safety issues to date (Table 16.1).

Treatments Under Development

It is noteworthy that Oliceridine is recently FDA-approved for short-term use to treat moderate to severe pain in hospitals or other controlled clinical settings.[19] (Table 16.2). However, pharmacologic inhibitors for these new targets for G protein-coupled receptors, ion channels, and enzymes have achieved limited success.[19] For example, pre-clinical studies have indicated an important role of p38 mitogen-activated protein kinase (MAP) kinase in microglia activation and the pathogenesis of pain.[20] However, most of the p38 inhibitors have failed in clinical trials for different disease conditions either because of poor pharmacokinetic profiles or lack of selectivity.[21] Nerve growth factor (NGF) plays an important role in inflammatory pain[22–24] and cancer pain,[25] NGF monoclonal antibodies such as Tanezumab, Fulranumab, and Fasinumab are developed for managing chronic pain in humans and in dogs and cats.[26] Anti-NGF treatment alleviated joint pain in patients with osteoarthritis, but also resulted in joint safety events. Further research is needed to determine the clinical importance of these efficacy and adverse event findings.[27] The voltage-gated

TABLE 16.1 Therapeutic Agents in Clinical Practice

Therapeutic Target/ Mechanisms	Representative Drugs
μ opioid receptor agonists	Opioids: Morphine, Hydrocodone, Hydromorphone, Methadone, Fentanyl, Tramadol, Tapentadol
Cyclooxygenase (Cox-1 and Cox-2) non-selective inhibitors	Meloxicam, Ibuprofen, Naproxen
Cox-2 selective inhibitor	Celecoxib (NSAIDs)
Voltage-gated sodium channels: non-selective blockers	Antiepileptic drugs: Carbamazepine, Oxcarbazepine; Local anesthetics: Lidocaine, Bupivacaine, Ropivacaine
Voltage-gated calcium channels: $Ca_v2.2$ blocker	Ziconotide (used intrathecally for cancer and chronic non-cancer pain)
Ca^{2+} channel α2δ1 subunit blocker	Gabapentinoid: gabapentin, pregabalin (Antiepileptic drugs)
NMDA Receptor antagonist	Ketamine, a dissociative anesthetic
5HT1B/D agonist	Triptans for Migraine
5HT/NE transporter, serotonin-norepinephrine reuptake inhibitors (SNRIs)	Duloxetine (Anti-depressants); Tramadol, Tricyclic anti-depressants: Amitriptyline, Nortriptyline, Desipramine
5HT transporter, serotonin selective reuptake inhibitors (SSRIs)	Fluoxetine (alleviation of nociceptive pain and attenuation of opioid tolerance and dependence)
Norepinephrine transporter, Norepinephrine reuptake inhibitors (NRI)	Tapentadol
Adrenergic α2 receptor agonist	Tizanidine (muscle relaxant)
5HT2 receptor antagonist	Cyclobenzaprine (muscle relaxant)
Synaptosome-associated protein (SNAP-25)	Botulinum toxin A
Vesicle-associated membrane protein (VAMP)	Botulinum toxin B
CGRP receptor monoclonal antibody	Erenumab for migraine headache prevention
CGRP monoclonal antibodies	Fremanezumab, Galcanezumab, and Eptinezumab for migraine headache treatment and prevention

TABLE 16.2 Therapeutic Targets That Have Been Or Are Being Tested

Therapeutic Target/ Mechanisms	Representative Agents
TRPV1 antagonists (nociceptor & pain transduction)	MK2295, SB705498, GRC6211, AMG517, ABT102, ADZ1386
$Na_V1.7$ sodium channel inhibitors (nociceptor excitability & pain conduction)	PF-05089771, CNV1014802, funapide, DSP-2230, Ralfinamide
$Ca_V3.2$ T-type calcium channel inhibitors (synaptic transmission)	TTA-P2; epipregnanolone [(3β,5β)-3-Hydroxypregnan-20-1]
K_V7 potassium channel activator (nociceptor excitability)	Retigabine, flupirtine
CCR2 chemokine receptor antagonists (neuroinflammation)	RS504393, AZD2423, RAP-103
NMDA receptor blockers (synaptic transmission)	Nitrous oxide, dextromethorphan
p38 MAP kinase inhibitors (intracellular signal transduction, microglial activation, neuroinflammation)	Acumapimod (BCT197), Neflamapimod (VX-745), PH-797804, dilmapimod (SB-681323), losmapimod (GW856553X), Talmapimod
NGF monoclonal antibodies (pain sensitization)	Tanezumab, Fulranumab, Fasinumab
Biased μ-opioid receptor agonist (pain transmission)	TRV130 (Oliceridine)
k-opiod receptor agonists (pain transmission)	Pentazocine; JT09 (agonists, peripheral analgesic effects without central side effects)
P2X purinergic receptors antagonist (pain sensitization)	AF-219 (P2X3 antagonist)
GABA receptors subtype-selective modulator (pain transmission)	NS11394 (subtype-selective positive allosteric modulator at $GABA_A$ receptors)

sodium channel subtype Nav1.7 is one of the best validated targets for human pain.[28] However, the effect of a selective, peripherally restricted Nav1.7 sodium channel blocker PF-05089771 was smaller than that seen with pregabalin.[29]

Nonpharmacologic Therapies

Interventional Procedures

Interventional procedures employ an array of therapeutic mechanisms. Nerve blocks with local anesthetics, often combined with a corticosteroid, reversibly block nociceptive afferents and reduce irritation/inflammation of the target nerve. Since nerve blocks often only provide short-term therapeutic effects, nerve ablations are sometimes used to provide longer term relief of joint pain (e.g. facet joint, sacroiliac joint, knee, hip, shoulder, and intervertebral disc), neuropathic pain (e.g. trigeminal neuralgia, nerve entrapments), or visceral pain (chronic abdominal or pelvic pain) through radiofrequency denervation, cryoneurolysis, chemoneurolysis, or balloon compression. These procedures provide an irreversible block of nociceptive afferents until nerve regeneration and reinnervation occur.

Surgical Approaches

A wide range of surgical procedures are performed to treat pain by decompressing specific nerves that are compressed or entrapped. Examples include microvascular decompression for trigeminal neuralgia, laminectomy or minimal invasive lumbar decompression for spinal canal stenosis, foraminotomy for foraminal stenosis, and discectomy for intervertebral disc encroachment of the spinal nerve root. These surgeries are performed to mitigate physical compression and/or chemical irritation of the target nerve, improve the blood circulation of the nerves, and relieve pain and other symptoms.

Physical/Cognitive/Behavioral Therapies

The role of physical, cognitive, and behavioral therapies is increasingly recognized in pain management. Although the mechanisms for most of these therapies remain to be elucidated, influential hypotheses or theories have been proposed and frequently cited. Physical therapy, such as exercise, manual therapy, and transcutaneous electrical nerve stimulation, can be used to target specific changes in peripheral tissues and nociceptors, neuropathic pain signs and symptoms, reduced central inhibition and enhanced central excitability, psychosocial factors, and alterations of the movement system.[30] These five categories of pain mechanisms (nociceptive, central, neuropathic, psychosocial, and movement system) are often cited in physical therapies. Cognitive behavior therapy (CBT) is based on the belief that thought distortions and maladaptive behaviors play a role in the development and maintenance of psychological disorders and disability, including chronic pain disorders, and that symptoms and associated distress can be reduced by teaching new information-processing skills and coping mechanisms. Clinical trials and clinical practice support the use and efficacy of these treatments in specific patient populations.[31–33]

Neuromodulation

The field of neuromodulation has witnessed the fastest progress in innovation and clinical application.[34] New modalities such as high frequency spinal cord dorsal column stimulation,[35,36] burst stimulation,[37,38] high density stimulation,[39] differential targeted multiplexed stimulation,[40,41] closed-loop stimulation,[42,43] dorsal root ganglion stimulation,[44] peripheral nerve stimulation,[45] vagus nerve stimulation (VNS),[46,47] and transcranial direct current stimulation[48] among others have yielded exciting results. Several randomized comparative trials have recently been conducted to provide strong evidence in support of clinical applications of several new modalities of neuromodulation to treat a wide range of severe and refractory pain conditions. Meanwhile, investigations have also been intensified to better understand the mechanisms of action of these modalities of neuromodulation.

Progress in Neuroimmune Modulation of Pain and Emerging Targets

Over the past decade, we have seen tremendous progress in revealing neuronal mechanisms of pain. First, using transcriptional profiling analysis at the whole population and single-cell levels, studies have

revealed molecular diversity of primary sensory neurons, including nociceptors in mouse dorsal root ganglia (DRG).[49–52] Second, using the cutting-edge technologies of optogenetics and chemogenetics, we have greatly expanded our knowledge of pain circuits, including the circuit that mediates "gate control" and mechanical allodynia in the spinal cord.[53–56] These circuits also modulate central sensitization, an enhancement of pain processing within the CNS (spinal cord and brain). Notably, central sensitization can manifest not only as an increase in excitatory neurotransmission but also as a disinhibition (i.e. reduction or loss of inhibitory synaptic transmission in the central pain circuits).[57] Central sensitization can rapidly open the spinal cord "gate," enabling tactile stimulation to induce mechanical allodynia (tactile allodynia), a cardinal feature of many chronic pain conditions.[56]

Glia Activation, Gliopathy, and Neuroinflammation in Chronic Pain

Our neuro-centric view of pain is changing, as we have seen an exponential increase in publications on neuroimmune modulation of pain.[58–61] Especially, activation of glial cells, such as microglia and astrocytes following painful insults (e.g. nerve injury), is emerging as a key mechanism for the pathogenesis of pain.[59,62–66] In addition to neuropathy, "gliopathy" is being recognized as a driving force for the development and maintenance of chronic pain.[67] Bidirectional signaling between the immune and nervous systems has been revealed in chronic pain condtions.[61,68,69]

Our expanded knowledge in glial modulation of pain has led to increasing appreciation of "neuroinflammation" as a key contributor to central sensitization and chronic pain. Compared to inflammation, neuroinflammation is a local inflammation in the nervous system. Neuroinflammation can be characterized by 1) glia activation in the peripheral nervous system (PNS) (e.g. Schwann cells and satellite glial cells) and the CNS (e.g. microglia and astrocytes), 2) infiltration of immune cells (e.g. macrophages and T cells), and 3) production of inflammatory cytokines and chemokines.[70–72] It is important to define different types of inflammation, as they play different roles in different stages of pain and in different types of pain.[13] For example, neurogenic inflammation is evoked by activation of nociceptive primary afferents and contributes to pain conditions such as headache and complex regional pain syndrome (CRPS). Blood testing could detect inflammation but might be difficult to assess neuroinflammation. Notably, neuroinflammation can still be present in the PNS and CNS, even when inflammation is largely resolved. Thus neuroinflammation plays an important role in pain chronification.[70] Neuroinflammation could be detected in the cerebrospinal fluid (CSF); and circulating CSF can spread pain to remote parts of the body. It is conceivable that neuroinflammation contributes to widespread chronic pain conditions, such as fibromyalgia and temporomandibular disorders.[73]

The most critical step to understanding neuroimmune and neuro-glial interactions in pain modulation is to figure out how inflammatory mediators (IFMs, such as cytokines and chemokines), produced by immune cells and glial cells, regulate neuronal activities in the pain circuit. It was generally believed that cytokines such as IL-1β enhance pain states via induction of cyclooxygenase-2 (COX-2) and subsequent production of prostaglandins (e.g. PGE2), and this process occurs both in the PNS and CNS.[74] However, COX-2 inhibition is not so effective in treating chronic pain such as neuropathic pain. Instead, recent progress has demonstrated a direct modulation of pain transmission by cytokines, as neurons express cytokine receptors (e.g. IL-1 receptor [IL-1R1], IL-6 receptor [IL-6R], and tumor necrosis factor [TNF] receptors p55 [TNF-RI] and p75 [TNF-RII]). Strikingly, cytokines are powerful neuromodulators and synaptic modulators: electrophysiologic evidence shows that IL-1β, IL-6, and TNF can rapidly (within a minute) and potently (at low nM range concentration, as compared to mM range of the neurotransmitter glutamate) modulate both excitatory and inhibitory synaptic transmission.[75,76] This finding has changed our view of the time-scale and effectiveness of glial modulation of pain circuits.

Proinflammatory Cytokines and Chemokines

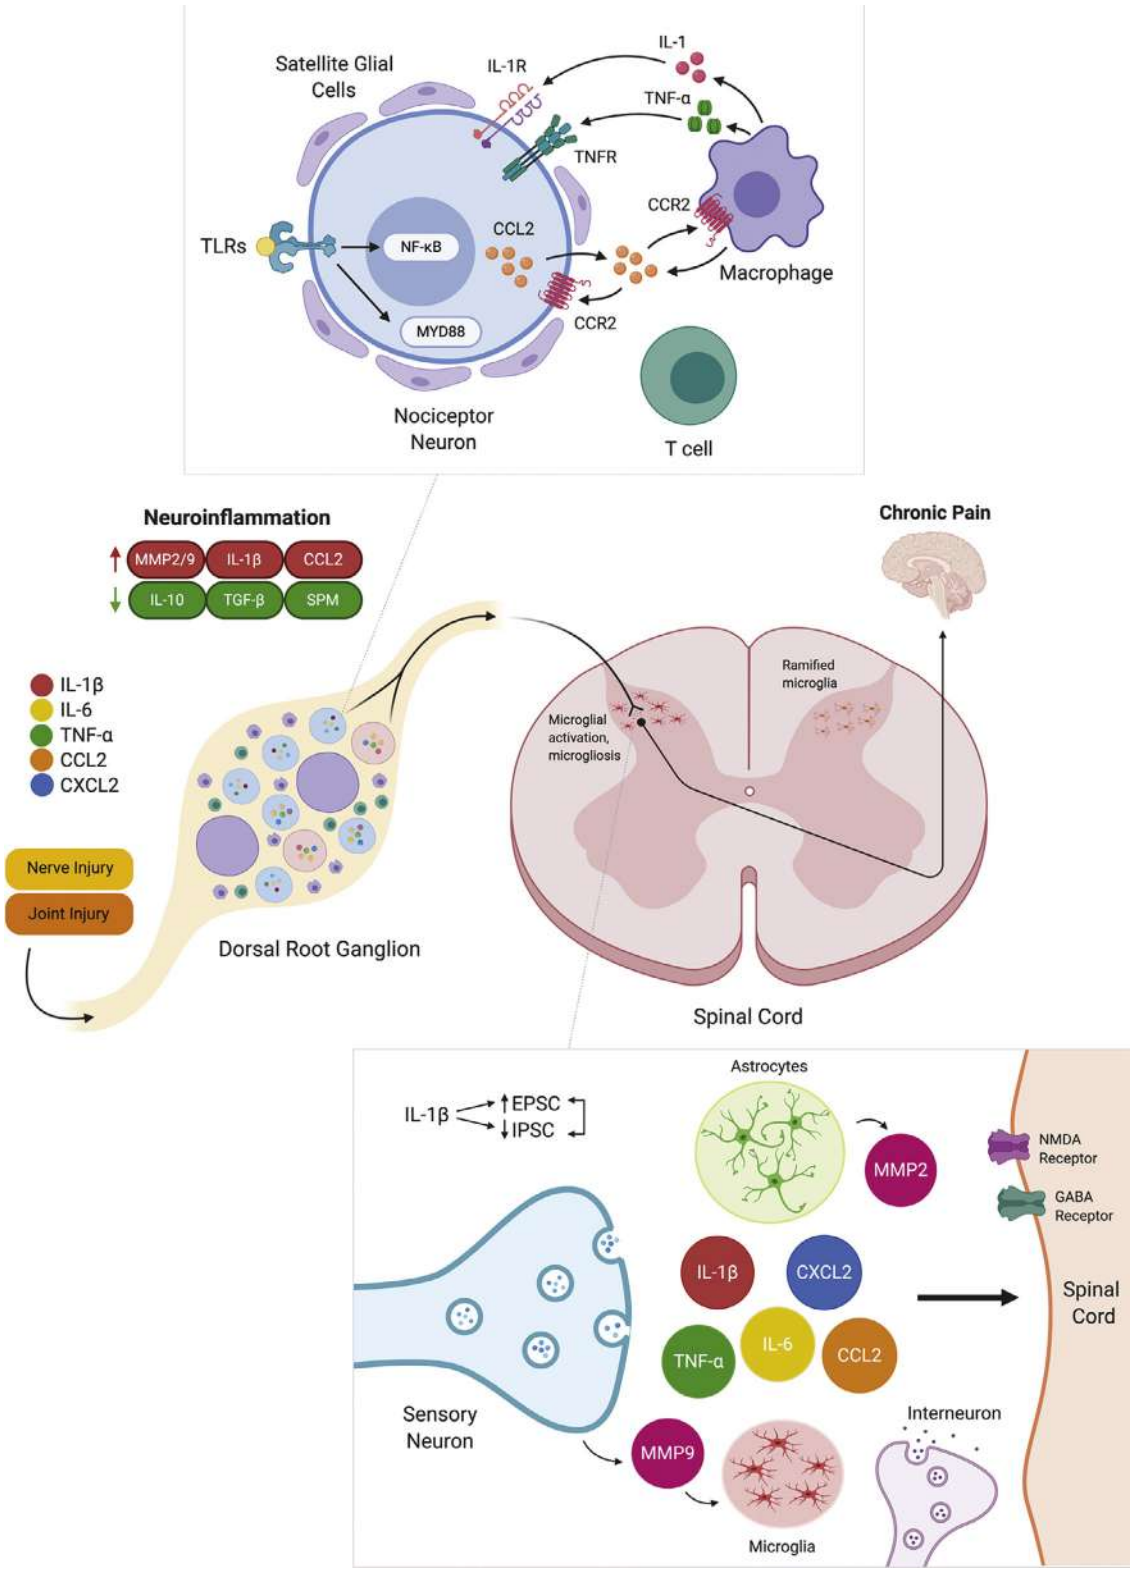
Upon activation, glial cells produce proinflammatory cytokines such as TNF, IL-1β, and IL-6 to promote pain.[63,64,77] IL-1β regulates different types of pain conditions, such as inflammatory pain, neuropathic pain, and cancer pain.[61] Administration of recombinant IL-1β via different routes, such as perineural, intraplantar, and intrathecal administration of IL-1β itself, is sufficient to elicit pain hypersensitivity, while blocking IL-1β signaling via genetic deletion of the IL-1 receptor (IL-1R) or intrathecal injection of IL-1R neutralizing antibodies or antagonists attenuate pain in a variety of rodent models.[61,64] Intriguingly, central (intrathecal) but not peripheral administration of the IL-1 receptor antagonist anakinra at 16 weeks post-bone fracture reduced chronic postoperative pain in rodents,[78] supporting an important role of IL-1β signaling in the maintenance of chronic pain. In contrast to IL-1β upregulation, IL1-receptor antagonist (IL1-Ra), a natural inhibitor of IL-1β secreted by immune cells, epithelial cells, and adipocytes, which opposes the actions of IL-1β, is downregulated in chronic pain conditions.[79]

Chemokines are small cytokines and signal through G protein-coupled receptors (GPCRs). As two of the best studied chemokines, CCL2 and CXCL1 are produced by astrocytes in the spinal cord and primary sensory neurons. CCL2 and CXCL2 promote inflammatory, neuropathic, and cancer pain via their respective CCR2 and CXCR2 receptors that are expressed by neurons.[80–83]

Mechanistically, glia-derived cytokines (TNF, IL-1β, IL-6) and chemokines (CCL2 and CXCL1) can rapidly evoke central sensitization and produce pain by both enhancing excitatory α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and NMDA-mediated synaptic transmission and concurrent inhibition of GABAergic and glycinergic neurotransmission in the superficial layers of the dorsal spinal cord.[75] Additionally, these cytokines and chemokines elicit peripheral sensitization by increasing the activities of key ion channels such as transient receptor potential (TRP) channels (TRPA1 and TRPV1) and voltage-gated sodium channels (Nav1.7-1.9)[70,84] (Figure 16.1).

Anti-inflammatory Cytokines

IL-10, produced by various immune cells, has been extensively investigated for its anti-inflammatory and antinociceptive actions. In the early life of rodents, neuropathic pain is masked by IL-10-mediated anti-inflammatory regulation in the spinal cord, which can be unmasked by spinal anti-IL-10 treatment.[85] Sustained production of IL-10 in the spinal cord via gene therapy produces long-term relief of neuropathic pain in rats.[86] Exercise has been shown to alleviate pain through the endogenous release of IL-10.[87] IL-10 is an important mediator for neuron-glial interaction. The anti-inflammatory cytokine TGF-β1 is downregulated



• **Figure 16.1** Schematic illustration of neuroimmune modulation of chronic pain in the peripheral nervous system (PNS; dorsal root ganglion) and central nervous system (CNS; spinal cord). Painful insults, such as nerve injury and joint injury (arthritis), activate glial cells, including satellite glial cells in the dorsal root ganglia and microglia and astrocytes in the spinal cord, and infiltration of immune cells such as macrophages and T cells, leading to neuroinflammation in the PNS and CNS. Neuroinflammation is associated with increased production of proinflammatory cytokines and chemokines (interleukin [IL]-1β, IL-6, tumor necrosis factor [TNF]-α, CCL2, CXCL1) and decreased production of antiinflammatory cytokines (IL-10, transforming growth factor [TGF]-β) and specialized pro-resolving mediators (SPMs, e.g. resolvins and protectins). SPMs may serve as novel biomarkers of neuroinflammation and chronic pain. The above-mentioned immune mediators can act on their receptors on neurons to regulate neuronal activities and pain sensitivity. Notably, IL-1β can modulate both excitatory and inhibitory synaptic transmission (excitatory and inhibitory postsynaptic currents, EPSC and IPSC) in the spinal cord pain circuit to promote central sensitization. Painful insults also activate Toll-like receptors in nociceptors and glial cells to drive neuroinflammation and chronic pain. Matrix metalloproteases (MMP-2 and MMP-9) are upregulated after painful insults and critically contribute to glial activation and neuroinflammation in chronic pain.

in chronic pain conditions in both animals[88] and patients.[89] TGF-β1, released from most immune cells and platelets, potently inhibits neuropathic pain and suppresses spinal cord glial activation and neuroinflammation after nerve injury in rodents.[90,91] TGF-β1 plays a non-canonical role in rapid and direct neuromodulation: within minutes it activates TGF-β1 receptors (TGFBR1) on neurons, normalizing nerve injury-induced DRG neuronal hyperexcitability and spinal cord synaptic plasticity.[90]

Matrix Metalloproteases (MMPs)

Accumulating evidence suggests an active role of proteases, such as matrix metalloproteases (MMPs), in neuroinflammation and the pathogenesis of chronic pain[70,92] (Figure 16.1). Among a large family of MMPs, the gelatinases MMP-2 and MMP-9 have been implicated in the development and maintenance of neuropathic pain in mice.[93] Nerve injury induces a rapid but transient upregulation in MMP-9 expression and activity in DRG neurons with axonal injury. Notably, secreted MMP-9 is sufficient and required to activate microglia, leading to early-phase neuropathic pain through p38 phosphorylation in spinal microglia.[94–96] In contrast to the rapid induction of MMP-9, nerve injury produces delayed but persistent MMP-2 production in glial cells, leading to late-phase neuropathic pain mediated by astrocyte activation.[94] MMP-9 and MMP-2 participate in IL-1β cleavage/activation and signaling in neuropathic pain.[94] To control tissue damage by MMPs, humans and animals also produce endogenous tissue inhibitors of MMPs (TIMP), with relative selectivity of TIMP-1 for MMP-9 and TIMP-2 for MMP-2. TIMPs are potent suppressants of neuropathic pain: TIMP-1 and TIMP-2 attenuate early-phase and late-phase neuropathic pain, respectively, in mice.[94] Conversely, knockout mice lacking TIMP-1 displayed rapid onset of thermal and mechanical hyperalgesia after injury.[97] MMPs are also implicated in clinical pain. Like MMP-9, TIMP-1 is an injury marker and rapidly induced in neurons and glial cells after painful insults[98] Human genetic pathway analysis revealed a major role for extracellular matrix organization and MMP-9 in patients with inflammatory and neuropathic pain.[99] Pharmaceutical development of small molecule inhibitors of MMPs for treating inflammation and cancer has been attempted, though with limited success, because of liver toxicity and lack of specificity.[93,100] Through functional selection, a highly selective monoclonal antibody against MMP-9 was recently developed, which shows efficacy in a mouse model of chemotherapy-induced neuropathic pain.[100]

Resolvins, SPMs, and Resolution of Pain

Resolution of acute inflammation is an active process that requires the production of specialized pro-resolving mediators (SPMs).[101] Thus SPMs are produced during the resolution phase of inflammation, including sham surgery, a resolution condition associated with acute inflammation and acute pain in mice.[102] A production failure in SPMs could impair inflammation resolution resulting in a transition from acute inflammation to chronic inflammation.[101,103] SPMs consist of several different families, such as resolvins, maresins, and protectins derived from the omega-3 unsaturated fatty acids docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA).[101] In different mouse models of inflammation, SPMs demonstrate potent anti-inflammation and pro-resolution actions.[104] Strikingly, SPMs also produce powerful antinociceptive and antihyperalgesia in rodent models of inflammatory pain, neuropathic pain, and cancer pain.[105] For example, resolvins D1 and E1 (RvD1 and RvE1) inhibit inflammatory pain in mice at a dose that is 100-fold lower than morphine,[106] and neuroprotectin D1 (NPD1) reduces neuropathic pain at a dose that is 500-fold lower than gabapentin.[107] SPMs control pain via both immunomodulation and neuromodulation[101,106] through acting on distinct GPCRs to regulate the resolution of inflammation.[101] GPR37 is a recently identified receptor for NPD1 and contributes to the resolution of inflammatory pain, as inflammatory pain fails to resolve in mice lacking GPR37.[108]

Sex Dimorphism in Immune Regulation of Pain

Recent pre-clinical studies have demonstrated sex dimorphism in neuroinflammation regulation of pain.[109] For example, spinal microglia, TLR4, P2X4, and p38 MAP kinase regulate inflammatory and neuropathic pain in male animals,[110–113] whereas T-cell signaling appears more critical in female animals.[110] Sex differences in peripheral immune regulation of pain have also been revealed. For example, macrophage-derived TLR9 regulates chemotherapy-induced peripheral neuropathy related mechanical allodynia in male mice.[114] Thus it is important to test neuroimmune-based pain therapeutics in both sexes.

Targeting Neuroimmune Mechanisms by Emerging Regenerative Pain Medicine

Among the emerging therapies in pain management, the use of biologics has shown promise and provided new insights into the neurobiologic mechanisms of pain.[115] Regenerative pain medicine seeks to harness the body's own reparative capacity and is a fast-growing field within pain medicine.[115] Current biologic therapies make use of several general categories of biologics: cellular products such as mesenchymal stem cells (MSC) derived from the bone marrow, adipose tissue, and umbilical cord, and blood-derived products such as platelet rich plasma (PRP) and autologous conditioned serum (ACS).[115] This approach may reduce pain as a symptom and modify disease processes in animals and humans. Although multiple cellular and molecular mechanisms may be at play, neuroimmune modulation by regenerative medicine has emerged as the main mechanism underlying pain relief.

Cell Therapy and Regenerative Approaches in Pre-Clinical Studies

Several lines of pre-clinical studies have demonstrated sustained pain relief by MSCs or bone marrow stem cells (BMSCs) via neuroimmune modulation.[116] Single intravenous or local injection of rat BMSCs reversed mechanical allodynia in rats after tendon injury for several months involving monocyte activation.[117,118] Intrathecal administration of BMSCs via lumbar puncture results in a long-term relief of neuropathic pain after nerve injury.[90] Visualization of dye-labeled BMSCs showed migration to the DRG and spinal cord meninges, where they survived for up to 3 months after intrathecal injection. Intriguingly, neuroimmune interaction guides migration and targeting of BMSCs. After a nerve ligation injury, injured DRG neurons upregulated CXCL12, a chemotactic signal that guides BMSCs to damaged DRGs via a CXCR4/CXCL12 homing mechanism.[90] Furthermore, secretion of the anti-inflammatory cytokine TGF-β1 is responsible for conferring the potent pain relief of the intrathecally injected BMSCs.

Intrathecal administration of anti-TGF-β1 neutralizing antibody selectively reversed the analgesic effect conferred by intrathecal BMSC treatment. Intrathecal BMSCs also control the nerve injury-induced neuroinflammation in the spinal cord, as revealed by microglia and astrocyte activation and increased expression of IL-1β, IL-6, and TNF.[90] It was also shown that intravenous or intrathecal application of MSCs could prevent and reverse opioid-induced tolerance and hyperalgesia and inhibit chronic opioid-induced glial activation in the spinal cord.[119] Intrathecal injection of exosomes, collected from human umbilical cord MSCs, relieves neuropathic pain in rats, by inhibiting nerve injury-induced neuroinflammation.[120] Additionally, neurogenesis of inhibitory neurons has been used for regenerative pain medicine. After spinal transplantation, embryonic cortical GABAergic interneuron precursors from the medial ganglionic eminence could generate inhibitory neurons that can integrate into nociceptive circuits and alleviate neuropathic pain.[121]

Cell Therapy and Blood-Derived Products in Clinical Studies

Cell therapy: Several clinical studies have shown long-term benefits of cell therapy in patients with low back pain. In a prospective, open-label, non-randomized, and single arm study, 26 patients with moderate to severe discogenic low back pain received an injection of autologous bone marrow concentrate into the nucleus pulposus of injured lumbar discs. After 36 months, 20 patients had 71% improvement in Oswestry Disability Index and 70% improvement in visual analog scale scores and no adverse events were noted from the treatment.[122] In another study, 33 patients were treated for degenerative disk disease with a single intradiscal injection of cultured autologous bone marrow mesenchymal stem cells (BM-MSCs). Numeric pain rating scale values were significantly changed at 3, 36, 48, 60, and 72 months post-treatment. No serious adverse effects were associated with the procedure. Twenty of treated patients underwent MRI studies with 85% reporting reduction in disc bulge size.[123] Adipose tissue-derived MSCs also offered a therapeutic option for chronic pain because of their immunomodulatory functions. A single arm phase I clinical trial showed not only safety and tolerability but also relief of low back pain after a single intradiscal injection of autologous adipose tissue-derived MSCs.[124]

Platelet rich serum (PRP): The past decade has seen a substantial increase in using PRP to treat musculoskeletal conditions.[115,125] PRP contains multiple growth factors, such as platelet-derived growth factors, α-granule-based growth factor, TGF-β, and hepatocyte growth factor. TGF-β inhibits inflammation and promotes chondrocyte activity and cartilage growth.[89] PRP-based factors reduced proinflammatory cytokines[126] and increased collagen and proteoglycan production *in vitro*.[127] However, PRP provides limited contribution to the radiographic restoration of cartilage in humans.[128] Randomized PRP-based clinical trials support its functional benefits in treating patients with knee osteoarthritis.[129,130]

ACS. ACS is another blood-derived product for regenerative medicine, boosting the levels of IL-1Ra, an inhibitor of cytokine IL-1 receptor and a cartilage-protective cytokine.[115] Whole blood, in proper incubation conditions, produces IL-1Ra and anti-inflammatory cytokines TGF-β1, IL-4, and IL-10, and extracellular vesicles such as exosomes.[115] ACS was shown to reduce both pain and joint damage in arthritis.[131] A randomized, blinded trial on 376 participants revealed superior outcomes of ACS over intra-articular hyaluronan or placebo, and the beneficial effects of ACS lasted for more than 104 weeks.[132]

Targeting Neuroimmune Mechanism by Neuromodulation

In the following sections, we discuss neuromodulation with a specific focus on SCS and VNS. A unifying theme, regulation of neuroimmune interactions, is a key element of these therapies for pain control.

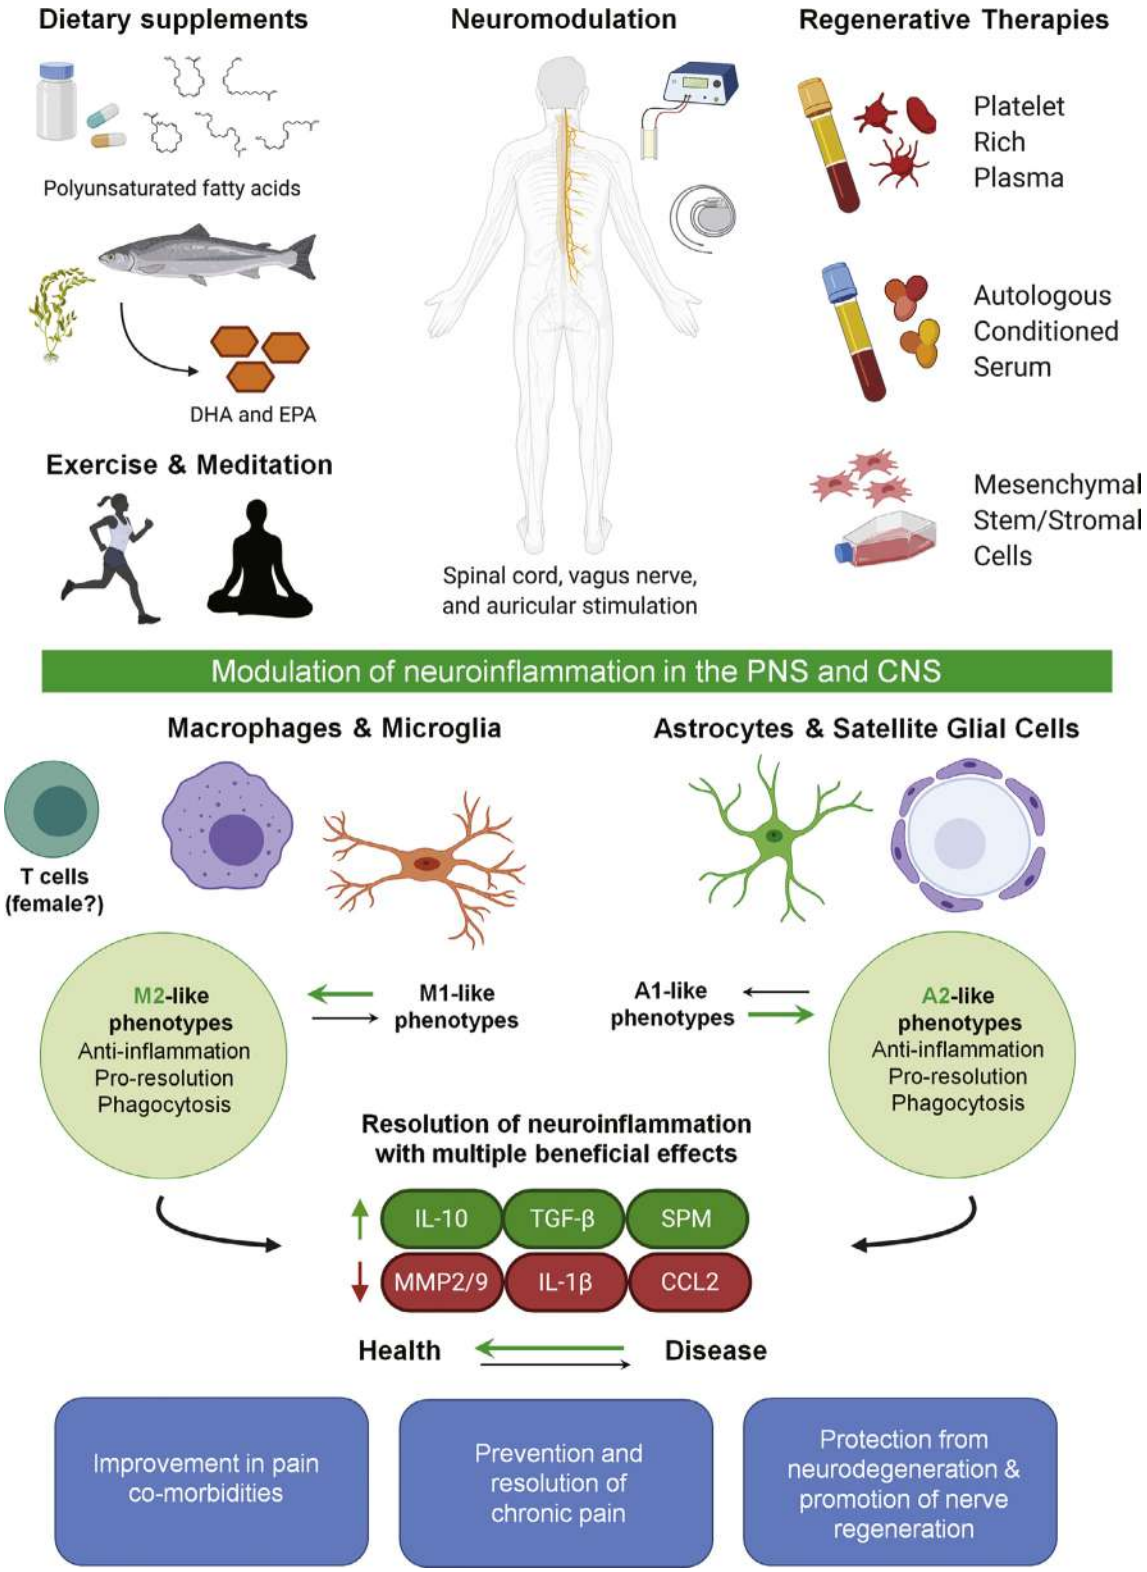
Neuromodulation via SCS

Several new SCS modalities have been developed and investigated in adequately powered and randomized trials. For example, high frequency (10 kHz, HF-10) stimulation has been shown to achieve ≥50% pain reduction of low back pain and leg pain in more than 80% of patients with failed back pain syndrome, compared to 44% for back pain and 55% for leg pain with conventional low frequency stimulation in a multicenter randomized comparative trial.[35] This superiority is maintained in one year and two year follow-ups.[133]

A novel SCS system was developed to continuously monitor evoked compound action potentials (ECAPs) in the dorsal column in response to SCS in patients.[42] These ECAPs are used to optimize programming and deliver closed-loop SCS by adjusting the stimulation current to maintain activation within a patient's therapeutic window. Closed-loop SCS was recently compared with conventional open-loop SCS in a multicenter randomized trial that demonstrates that more than 80% of patients with chronic, intractable pain of the back and legs achieved ≥50% pain reduction in the closed-loop group, versus 61% in the open-loop group.[42,134] It is noteworthy that the study enrolled patients with or without failed back surgery, suggesting that this technology may be applicable to patients without previous back surgery.

A few other modalities of SCS were investigated. Burst stimulation appears to be superior to tonic stimulation.[37] High density stimulation may provide better pain relief in patients who failed conventional SCS for failed back surgery syndrome, CRPS, or neuropathic pain.[39] Differential target multiplexed programming has also shown promise in improving outcomes in a difficult-to-treat population of patients in a recent study.[41]

Several frameworks have been put forward to elucidate the mechanisms of action of SCS.[135–137] The gate control theory, first described by Melzack and Wall in 1965,[53] proposes that non-painful sensory input, via large-diameter sensory fibers, closes the "gates" in the spinal cord dorsal horn laminae, thereby preventing transmission of painful input, via small-diameter fibers. Thus the patient would experience less pain. However, the true mechanisms of neuromodulation are much more complex and remain to be determined. The gate control theory cannot explain the efficacy of HF-10 SCS in the absence of evidence of large fiber activation in this paresthesia-free mode of stimulation. Postulated mechanisms of action for pain relief with high frequency stimulation include axonal conduction block, desynchronization of axonal activity, and glial-neuronal interactions.[40] However, blocking or desynchronizing axonal transmission by HF10 was not supported by experiments in animals or with computational approaches.[137] Pre-clinical and human mechanistic studies suggest that many neuromodulatory techniques likely modulate the conduction, transmission, and perception of pain signals,[137] as well as processes



• **Figure 16.2** Schematic illustration of neuroimmune modulation by therapies such as regenerative therapies (platelet rich plasma, ACS, mesenchymal stem/stromal cells), dietary supplements (polyunsaturated fatty acids, including fish oil DHA and EPA), neuromodulation (spinal cord stimulation and VNS, and auricular stimulation), and exercise and meditation. These therapies can control neuroinflammation in the peripheral nervous system (PNS) and central nervous system (CNS) by downregulation of proinflammatory mediators (e.g. matrix metalloproteases [MMP] -2/-9, interleukin [IL] IL-1β, and CCL2) and upregulations of anti-inflammatory mediators (IL-10, transforming growth factor [TGF] -β) and pro-resolving mediators (SPMs). These therapies could change the activation and phenotypes of immune cells and glial cells, such as M1 and M2-like phenotypes of macrophages and microglia and A1 and A2 phenotypes of astrocytes and satellite glial cells. M2- and A2-like phenotypes are associated with anti-inflammation, pro-resolution, and pro-phagocytosis benefits. These health benefits will help prevent and resolve chronic pain, protect against neurodegeneration, promote regeneration, and improve chronic pain-associated comorbidities (e.g. cognitive impairment and depression). Recent pre-clinical studies have revealed distinct sex dimorphism in microglial and T-cell regulation in chronic pain, which requires validation in clinical studies.

involving non-neuronal cells in the spinal cord that contribute to central sensitization and chronification of pain.[40] A significant finding is that electrical stimulation can profoundly modulate the immune system in the central and peripheral nervous systems that constitute the essential substrate of central and peripheral sensitizations of pain. Accumulating evidence from pre-clinical studies shows that SCS modulates glial activation in rodent models of neuropathic pain.[138] A recent study shows that the expression of glia-related genes such as Tlr2, Cxcl16, Cd68, Gfap, Ccl2, and Itgam was associated with the effects of SCS on a neuroinflammatory state induced by nerve injury in rats.[40] However, the detailed signaling mechanisms underlying this neuroimmune modulation are largely unknown.

Neuromodulation via Vagus Nerve Stimulation (VNS)

VNS has been tested to treat patients with fibromyalgia, pelvic pain, migraine, and cluster headaches.[105,139] Inflammation in the cavernous sinus and tributary veins might be responsible for cluster headaches.[140] In a randomized sham-controlled study, noninvasive VNS provided significant and sustained benefits for episodic cluster headaches without showing efficacy for chronic cluster headaches.[46] It will be of great interest to investigate how VNS activates afferent inputs to suppress inflammation and relieve episodic cluster headaches. Notably, the human vagus nerve contains SPMs (e.g. resolvin E1 and D5, protectin D1, and maresin 1), and electrical stimulation of the vagus nerve *in vitro* further increased SPM production but decreased proinflammatory prostaglandins and leukotrienes.[47,141] VNS has also been shown to regulate basal pain sensitivity in healthy volunteers. Both mechanically evoked pain and noxious tonic heat-induced temporal summation were suppressed by percutaneous VNS.[142]

Pre-clinical studies have provided new insights into inflammation and pain control by VNS. Stimulation of the right vagal nerve trunk was shown to produce antinociception.[143] The "inflammatory reflex" hypothesis proposed a vagus nerve-mediated neural circuit that is capable of providing information in real-time to the brain about the body's inflammatory status. This vagus nerve-mediated inflammatory reflex enables a rapid neural regulation of inflammation.[144] Interestingly, vagotomy (transection of the vagus nerve) reduced local production of SPMs in exudates and impaired the resolution of inflammation.[145] Auricular VNS via electroacupuncture was shown to reduce neuropathic pain in a mouse model of paclitaxel-induced neuropathy. Auricular VNS treatment effectively alleviated neuropathic pain and increased SPM levels (resolvin D1/RvD1) in mice.[105] Several SPMs, including RvD1, are sufficient to attenuate mechanical allodynia in mice.[146] Thus VNS may alleviate neuropathic pain via the production of SPMs (RvD1, Figure 16.2).

Precision Pain Medicine

Precision medicine was initially proposed for cancer treatments, given the well-recognized cancer diversity and individual variability in anti-cancer drug therapy. While a "one-drug-fits-all" model could be mechanism-based, it ignores individual differences in genetic and environmental factors. Precision medicine is an approach to "personalized medicine" that proposes the customization of health care so that medical treatments are specifically tailored to the unique needs of each individual patient. Precision medicine is based on the context of the genetic makeup and other molecular or cellular properties of each patient, and, therefore, diagnostic testing could be employed for selecting appropriate and optimal therapies.

The term "precision pain medicine" has been loosely used in different places to mean different things. For example, it is used by many clinics to mean anatomic precision when performing nerve blocks under the guidance of advanced imaging technologies or to mean disease-specific interventions, such as "regenerative medicine" to regenerate specific tissue (e.g. joint cartilage) for pain management. While these interventions may be precise, they are not based on each patient's genetic and environmental factors. Thus there is a need to clearly define the concept of "precision pain medicine." Specifically, precision pain medicine has to be based on genomic testing and lifestyle information of each individual patient to achieve personalized treatment.

While clinical applications of precision pain medicine are still in their infancy, specific genes associated with specific pain conditions have been identified. For example, the gain-of-function mutations of the voltage-gated sodium channel subtype Nav1.7 (encoded by *SCN9A* gene) has been associated with inherited erythromelalgia, which is characterized by recurrent attacks of bilateral, symmetrically intense pain accompanied by redness, warmth, and swelling.[147] Pharmacotherapy guided by genomic analysis, molecular modeling, and functional profiling has been shown to attenuate neuropathic pain in patients carrying the Nav1.7 S241T mutation.[148] This finding provides proof-of-principle that, using genomics and molecular modeling, a specific pain medicine can be matched to a particular person's DNA to achieve individualized and effective treatment. This line of work signifies the beginning of a transformation from mechanism-based, trial-and-error practice to precision pain management.

Both nociception and the risk of clinical pain have been associated with Catechol-O-methyltransferase (COMT) genetic variants, which metabolize catecholaminergic neurotransmitters and modulate adrenergic pathway transmission. Genetic variations in COMT isoforms may contribute to individual variability in pain phenotypes.[149,150] COMT inhibition is associated with neuroinflammation and pain hypersensitivity in rodents.[151] Genetic analysis also suggests that epidermal growth factor (EGF) receptor modulates human nociception via the PI3 kinase and MMP-9 pathway.[152]

Human genetic studies further revealed an association between GTP cyclohydrolase 1 (GCH1) polymorphisms and reduced pain in patients. GCH1 is involved in the production of monoamine neurotransmitters, the generation of nitric oxide, and the expression of the rate-limiting enzyme for the production of tetrahydrobiopterin (BH4).[19] The contribution of the GCH1-BH4 pathway to neuropathic pain is validated in a mouse model of neuropathic pain after nerve injury, which causes GCH1 upregulation in sensory neurons leading to increased BH4 synthesis.[19] Furthermore, BH4 regulates T-cell proliferation in mouse and human tissues and contributes to autoimmunity.[153] Thus the GCH1-BH4 pathway may control pain via both neural and immune regulations.

There are other examples of specific genes associated with specific pain conditions. Evidence exists to support an association of the TWIK-related spinal cord potassium (K^+) channel (TRESK) gene,[154] and the methylene tetrahydrofolate reductase (MTHFR) gene in migraine pain.[155,156] Furthermore, three causative genes have been identified in familial hemiplegic migraine families: CACNA1A, ATP1A2, and SCNA1A *encoding the* alpha 1A subunit of voltage-dependent calcium channel type P/Q (MIM601011),

the alpha 2 subunit of Na+/K+–ATPase (MIM182340), and the α subunit of the neuronal voltage-gated Na+ channel *respectively*. Recently, several mutations in KCNK18 have also been found as causative factors in migraine development.[157]

Pharmacogenetics considers a patient's unique genetic information and allows for the prediction of an individual's response to medication. Pharmacogenomic testing is increasingly recognized in pain management to identify individual differences in the perception of pain and sensitivity to drugs based on genetic markers. Streamlining relevant polymorphisms of genes encoding receptors, transporters, and drug-metabolizing enzymes influencing the pain phenotype can guide personalized pain management. While recognizing the challenges and barriers in clinical adoption of pharmacogenomic testing, recent progress in this emerging field has shown enormous promise toward the development of precision pain medicine.[158]

Conclusion and Perspective

It has been estimated that one in five Americans is affected by chronic pain, with an annual cost of over 600 billion dollars. Given the rapid increase of an aging population, the prevalence of chronic pain and pain-related disability is also rising. There is a critical and urgent need to develop new strategies to address the dual crises of chronic pain and the opioid epidemic in the United States. Mechanism-based and precision pain medicine represents the best and most promising approach to safe, efficacious, and cost-effective care of patients with chronic pain.

In this chapter, we reviewed state-of-the-art, mechanism-based treatments. We discussed the current treatments that are partially effective for a proportion of patients with appropriate indications (Table 16.1). We also discussed treatments that are under development but show limited success (Table 16.2). We highlighted biologics, including recently approved therapies such as monoclonal antibodies against CGRP and CGRP receptor that have shown great success in treating migraine headaches, as well as emerging therapies including cell therapies (mesenchymal stromal cells/MSCs) and blood-derived products (PRP, ACS) that have shown long-term benefits with support from a body of literature.

As a main focus of this chapter, we highlighted neuroimmune modulation as a key mechanism of chronic pain (Figure 16.1) and a promising therapeutic target of current treatment (neuromodulation with SCS and VNS and emerging therapies MSCs, PRP, and ACS). Notably, SPMs exert potent analgesic actions while simultaneously promoting inflammation resolution in rodents. SPMs may also serve as a biomarker of chronic pain with reduced production and a biomarker for effective treatment.[102,159,160] Interestingly, a battery of effective treatments such as neuromodulation and regenerative medicine may alleviate pain through inducing SPM production. Dietary supplements such as fish oil may produce beneficial effects by conversion to SPMs. The Food and Drug Administration (FDA) recently approved an omega-3 fish oil-based medication, Vascepa (4 mg/day), to reduce the risk of cardiovascular disease. A randomized clinical trial shows that dietary omega-3 fatty acids could alleviate headaches and increase SPM levels.[160,161] It will also be of great interest to study the synergistic effect between a healthy diet, exercise,[162] and neuromodulation for the resolution of pain through regulation of neuroinflammation (Figure 16.2).

The significance of genetic predisposition has been increasingly recognized in determining the vast individual variability in pain sensitivity, responses to pain, transition from acute to chronic pain, and susceptibility and sensitivity to therapies. The current mechanism-based therapies fail to consider the genomic and environmental factors, leading to large individual variations in clinical outcomes (efficacy and adverse events) in response to the same treatments for the same indications. The extraordinarily high numbers-need-to-treat for most pharmacologic agents to treat neuropathic pain,[163] illustrate the eminent deficiency of current mechanism-based pain therapies. Precision pain medicine based on genomic testing and streamlining of relevant polymorphisms of genes encoding receptors, transporters, and drug-metabolizing enzymes influencing the pain phenotype represents a future direction of personalized pain management. Environmental factors, including lifestyle, cognitive-behavioral patterns, and social determinants, are also indispensable elements of precision pain medicine. Only when individual genetic, psychosocial, and environmental factors are accounted for in applying mechanism-guided and evidence-based therapies can we genuinely practice patient-centered and individualized precision pain medicine and fundamentally improve the efficacy, safety, and cost-effectiveness of patient care.

Key Points

- Chronic pain is prevalent and has a high impact on public health and individual lives. Effective treatment of pain depends on adequate assessment, accurate diagnosis, and mechanistic understanding of the complex causes of pain for each patient.
- As we deepen our understanding of pain at cellular and molecular levels, therapeutic targets and strategies are expanding and becoming more mechanism-based, particularly in the field of neuroimmune modulation, regenerative pain medicine, and electrical neuromodulation.
- Current mechanism-based therapies include state-of-the-art approaches to modulating the transduction, conduction, transmission, perception, and adaptation of pain through pharmacologic, interventional, surgical, and physical/psychological/behavioral treatments of specific molecular and cellular targets and neural networks.
- Pharmacologic therapy achieves analgesic effects through a wide range of mechanisms by the use of local anesthetics, NSAIDs, anti-depressants, anti-convulsants, muscle relaxants, and opioids, among other drugs (Table 16.1). Besides these clinically used agents, new mechanism-informed agents are being investigated or developed (Table 16.2).
- Interventional therapy is used to block nociceptive conduction through nerve blocks and/or neural ablation through radiofrequency ablation, cryoneurolysis, chemoneurolysis, or mechanical compression to provide a variable duration of pain relief. Surgical procedures are often required to relieve pain by decompressing specific nerves that are compressed, entrapped, or injured.
- The roles of physical, cognitive, and behavioral therapies are increasingly recognized in pain management, even though the mechanisms for most of these therapies are complex and remain to be elucidated.
- The investigation and appreciation of neuroimmune modulation of pain has revealed new and emerging therapeutic

targets. Pathogenesis of chronic pain is highly related to neuroinflammation mediated by the interaction between neurons, glial cells, and immune cells in the peripheral and central nervous systems through proinflammatory cytokines, chemokines, and matrix metalloproteases and anti-inflammatory cytokines, chemokines, and specialized pro-resolving mediators. The latter are key mediators in an active process of resolution of inflammation and pain.

- Targeting neuroimmune mechanisms of chronic pain by biologics and regenerative medicine has shown promise in pre-clinical and clinical investigations. For example, clinical applications of biologics such as monoclonal antibodies against CGRP or its receptor have changed the landscape of migraine headache management. MSCs have shown promise in mitigating degenerative joint disease (including degenerative disc disease), neuropathic pain, and opioid tolerance. Both PRP and ACS have been shown to provide significant pain relief and functional benefit in patients with knee osteoarthritis in randomized clinical trials through neuroimmune interactions.
- Neuromodulation through modalities such as SCS, dorsal root ganglion stimulation, and VNS has been shown to regulate neuroimmune interaction as a key element of long-term pain relief. Many technological advances in neuromodulation have been made in recent years to significantly improve clinical outcomes in several high impact randomized clinical trials. The potential signaling pathways underlying glial cell activation and neuroimmune interactions have been implicated in pre-clinical studies.
- Any treatment has to be tailored to the unique needs of each individual patient. Precision medicine is based on genomic testing and psychosocial information of each patient to achieve personalized treatment. While clinical applications of precision pain medicine are still in their infancy, multiple specific genes associated with specific pain conditions have been identified and pharmacotherapy guided by genomic analysis, molecular modeling, and functional profiling has shown promising outcomes in pain relief. Subgroup analyses examining physical and psychosocial factors should inform the development of treatments and the matching of treatments to unique characteristics of patients.

Placebo and Nocebo Effects in Clinical Trials and Clinical Practice

FABRIZIO BENEDETTI, ELISA FRISALDI, AZIZ SHAIBANI

The Magnitude of Placebo Analgesia

Pain is by far the most studied placebo condition, and a large number of studies on the placebo effect have been performed in experimentally induced pain in healthy subjects or patients experiencing a painful condition. There are at least two explanations for this finding. First, pain is a subjective experience that undergoes psychological and social modulation more than any other condition. The fine tuning of the global pain experience by many psychosocial factors makes pain an excellent model for identifying and understanding the placebo effect. The second explanation stems from the influential work of Beecher in the 1950s. In fact, in 1955, Beecher reviewed 15 controlled trials involving 1802 patients.[1] Defining positive outcomes as the "percent satisfactorily relieved by placebo," Beecher reported effect sizes ranging from 26% to 58%, with an average of 35%. The notion that about one-third of patients respond to a placebo has since permeated medical texts and teachings, even though this work has been criticized on methodological grounds.[2,3] In fact, a real figure of Beecher's study was that the magnitude of placebo analgesia might range from no responses to large responses. For example, Levine et al.[4] found that 39% of patients had an analgesic response to placebo treatment, and in a study of ischemic arm pain in normal volunteers, Benedetti[5] found that 26.9% of them responded to a placebo analgesic compared to a no treatment control group. Another study involving cutaneous heating of the left hand found that 56% of subjects responded to placebo treatment compared to the no treatment controls.[6]

Assessing the magnitude of the placebo analgesic effect is not an easy task, as the experimental conditions and the psychological state of the subjects change across different studies. Several studies measured the average change in pain experienced by those receiving placebo and compared this figure to the average change in the no treatment group, and found that the magnitude of the placebo analgesic effect is about two out of ten units on a visual analog (VAS) or numeric rating scale (NRS).[7–10] In studies where the known placebo responders in a group are separated for analysis, the average magnitude of analgesia has been found, not surprisingly, to be significantly greater. For example, when Benedetti (1996)[5] looked only at responders, he found an average placebo analgesia magnitude of five units on the ten unit NRS. This is similar to a postoperative dental study that found a 3.3 cm (out of ten) lower mean post-treatment VAS score for placebo responders compared to nonresponders.[11]

The experimental manipulation used to induce placebo analgesia played a fundamental role in the magnitude of the response. Verbal suggestions that induce certain expectations of analgesia induce larger placebo analgesic responses than those that induce uncertain expectations. This is illustrated by a study carried out in a clinical setting that investigated the differences between the double-blind and deceptive paradigms.[12] Postoperative patients were treated with buprenorphine, on request, for three consecutive days consecutively and with a basal infusion of saline solution. However, the symbolic meaning of this saline basal infusion was varied in three different groups of patients: the first group (natural history or no-treatment group) was told nothing; the second group was told that the infusion was either a potent analgesic or a placebo (classic double-blind administration); and the third was told that the infusion was a potent painkiller (deceptive administration). The placebo effect of the infusion was measured by recording the doses of buprenorphine requested over the three day treatment. It is important to stress once again that the double-blind group received uncertain verbal instructions ("It can be either a placebo or a painkiller. Thus, we are not certain that the pain will subside"), whereas the deceptive administration group received certain instructions ('It is a painkiller. Thus the pain will subside soon. Compared to the natural history group, a 20.8% decrease in buprenorphine intake was observed with double-blind administration. An even greater decrease (33.8%) was observed in the deceptive administration group. It is important to point out that the time course of pain was the same in all three groups over the three day treatment period. The same analgesic effect was observed with different doses of buprenorphine. Thus subtle differences in the verbal context of the patient may have a significant impact on the magnitude of the response. Verne et al.[13] and Vase et al.[14] conducted two similar studies in which patients with irritable bowel syndrome (IBS) were exposed to rectal distension using a balloon barostat, a type of visceral stimulation that simulates their clinical pain. They tested patients with untreated natural history (baseline), rectal placebo, and rectal lidocaine. Pain was rated immediately after each stimulus in each condition. The first study was conducted as a double-blind crossover clinical trial, so patients were given an informed consent form stating that they "may receive an active pain reducing medication or an inert placebo agent."[13] In this study, there was a significant pain-relieving effect of rectal lidocaine compared to rectal placebo, and a significant pain-relieving effect of rectal placebo compared

to the no-treatment condition. In the second study, at the onset of each treatment condition (rectal placebo, rectal lidocaine), patients were told, "The agent you have just been given is known to significantly reduce pain in some patients."[14] A much larger placebo analgesic effect was found, which did not significantly differ from that of rectal lidocaine. These two studies show that adding an overt suggestion for pain relief can increase placebo analgesia to a magnitude that matches that of an active agent.

Experience can also influence the magnitude of placebo analgesia. In one study, the intensity of painful stimulation was reduced surreptitiously after placebo administration, leading subjects to believe that an analgesic treatment was effective.[15] This procedure induced strong placebo responses after minutes, and these responses, albeit reduced, lasted up to four to seven days. This procedure was repeated four–seven days after totally ineffective analgesic treatment in the second group of participants. The placebo responses were markedly reduced compared to those in the first group. These results emphasize that the placebo effect may represent a learning phenomenon involving several factors and may explain the large variability in the magnitude of placebo responses among studies. The number of learning trials carried out in a conditioning procedure is also related to the subsequent magnitude of the placebo effects.[16] Learning processes are not only important for psychophysical measurements such as pain rating, but also affect neurophysiologic parameters, such as laser-evoked potentials.[17] Furthermore, and Colloca and Benedetti[18] showed that social observational learning, whereby placebo responses can be learned by merely observing others, plays an important role.

As the magnitude of placebo analgesia depends on many factors, and learning is crucial in several circumstances, the clinical trial setting does not seem to be the best model for studying the placebo analgesic response. In the study by Hrobjartsson and Goetzsche,[19] a meta-analysis was performed of 130 trials in which placebo and no treatment groups were identified in different pathologic conditions. No difference was found between the two groups for many conditions, but a significant placebo effect was found for pain in 29 clinical trials, indicating that pain is one of the best conditions where the placebo effect is present and can be studied. To further investigate the placebo effect in analgesic studies only, Vase et al.[20] conducted two meta-analyses: one covered 23 of the 29 clinical trials included in Hrobjartsson and Goetzsche's meta-analysis,[19] and the other covered only 14 studies investigating the mechanisms of placebo analgesia. They found that the magnitude of placebo analgesic effects was higher in studies that investigated placebo analgesic mechanisms than in clinical trials in which the placebo was used only as a control condition.

Modulation of pain perception by placebos critically depends on expectation, as shown in many studies[21–23]; for example, Price et al.[22] applied placebo creams and graded levels of heat stimulation on three adjacent cutaneous regions of the forearm, suggesting that cream A was a strong analgesic, cream B was a weak analgesic, and cream C was a control agent. Immediately after these conditioning trials, participants rated their expected pain levels for the placebo test trials, wherein the stimulus intensity was the same for all three regions. The conditioning trials led to graded levels of expected pain (C ≥ B ≥ A) for the three creams and graded magnitudes of actual pain (C ≥ B ≥ A) when tested during placebo test trials. Thus the magnitude of placebo analgesia could be graded across three adjacent skin areas, demonstrating a high degree of somatotopic specificity for placebo analgesia. Expected pain levels accounted for 25% to 36% of the variance in post-manipulation pain ratings. In another study,[24] one group of subjects was pharmacologically pre-conditioned with ketorolac (a non-opioid analgesic) for two days in a row. The ketorolac was then replaced with a placebo on the third day, along with verbal suggestions for analgesia. This procedure induces a strong placebo analgesic response. To determine whether this response was because of pharmacologic pre-conditioning, the second group of subjects was also pre-conditioned with ketorolac, but the placebo was administered on the third day along with verbal suggestions that the drug was a hyperalgesic agent. These verbal instructions were sufficient not only to completely block the placebo analgesia but also to produce hyperalgesia. This study clearly shows that placebo analgesia depends on the expectation of a decrease in pain, even when analgesic preconditioning is performed.

The expectation of analgesia can also make a big difference in clinical trials, so the patient's expectations must be considered whenever a clinical trial is conducted. In one clinical trial, real acupuncture was compared with sham acupuncture. Patients were asked which group they believed they belonged to (either placebo or real treatment). Patients who believed they belonged to the real treatment group experienced larger clinical improvement than those who believed they belonged to the placebo group.[25] while in another clinical trial, patients with higher expectations about acupuncture experienced greater clinical benefits than those with lower expectations, regardless of their allocation to real or sham groups.[26] It did not matter whether the patients actually received the real or the sham procedure—what mattered was whether they believed in acupuncture and expected a benefit from it.

Some of the best evidence underscoring the crucial role of positive and negative expectations in the outcome of analgesic treatments is the decreased effectiveness of hidden treatments. This involves giving an analgesic covertly (unexpectedly), so the patient is unaware a drug is being injected; the outcome following the hidden (unexpected) administration is compared with that following an open (expected) administration.[27,28] Careful analysis of the differences between open (expected) and hidden (unexpected) injections in postoperative settings was performed for five widely used painkillers (morphine, buprenorphine, tramadol, ketorolac, metamizole).[10,27]

That the hidden administration of a pharmacologic agent is less effective than an open one may suggest a different pharmacodynamic action of the drug in the absence of expectations. Although we do not know whether expectations and therapeutic rituals can modify a receptor to change the drug-receptor binding properties, to the best of our knowledge, this mechanism seems unlikely. The global effect of a drug derives from its specific pharmacodynamic action plus the psychological (placebo) effect coming from the very act of its administration. A recent study suggested that these two components operate independently from each other.[29]

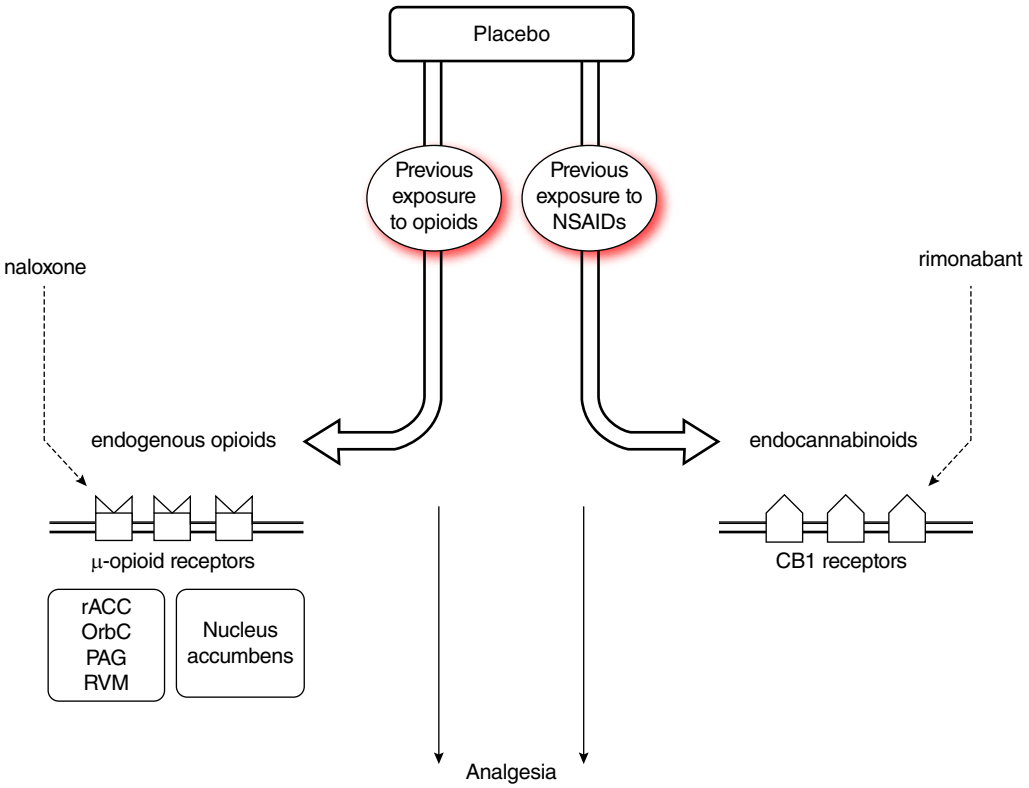
Expectations may also be associated with other factors, such as the desire for relief and reduction of anxiety. In other words, placebo phenomena occur within the context of emotional regulation, and symptoms should be influenced by desire, expectation, and intensity of emotional feeling.[23] Desire and expectation interact and underlie common human emotions like sadness, anxiety, and relief,[30] thus in the context of analgesic studies, it is quite plausible that patients and study participants have some degree of desire to avoid, terminate, or reduce evoked or ongoing pain.

Placebo-Induced Activation of Endogenous Painkillers (Fig. 17.1)

Placebo administration has been found to activate endogenous mechanisms of analgesia, and the placebo effect represents one of the most interesting models for understanding when and how these mechanisms are activated.[31] The organization of the endogenous antinociceptive systems is complex. Thanks to the pioneering work on producing analgesia in rats by stimulation of the periaqueductal grey[32] and the discovery of stereospecific binding sites for opioids,[33] endogenous enkephalins[34] in the central nervous system, we know that a complex endogenous network exists, which includes both opioid and non-opioid systems.[35,36]

Most of our knowledge about placebo analgesia is based on the opioid mechanisms. Opioid receptors can be found throughout the brain, brainstem, and spinal cord.[37–41] These receptors may exert analgesic effects through different mechanisms,[42] such as modulation at the spinal level and/or control of cortical and brainstem regions. The modulation of the spinal cord is one of the best described.[40,41] The opioid system in the brainstem consists of different regions, such as the periaqueductal gray, parabrachial nuclei, and the rostral ventromedial medulla.[40,41] Although opioid receptors are less characterized in the cortex, autoradiographic studies indicate high concentrations of opioid receptors in the cingulate cortex and prefrontal cortex,[37–39] and one of the highest levels of opioid receptor binding has been found in the anterior cingulate cortex.[43] Studies performed using positron emission tomography, and the radioactive opioid 11C-diprenorphine confirms previous animal and human autoradiographic findings.[44,45] In addition, opioid receptor agonists, such as remifentanil and fentanyl, have been shown to act on several regions that are known to be involved in pain processing and contain high concentrations of opioid receptors.[6,46]

One of the main problems of this endogenous opioid network is understanding when and how it is involved in analgesic effects. The first study of the biologic mechanisms of placebo analgesia used the opioid antagonist naloxone to block opioid receptors.[11] It was performed in a clinical setting in patients who had undergone extraction of their third molar tooth. The investigators found disruption of placebo analgesia after naloxone administration, which indicates the involvement of endogenous opioid systems in the placebo analgesic effect. Since the publication of the study by Levine et al.[11] attempts have been made to verify and reproduce the findings. For example, by using the experimental pain model of arm ischemia (the tourniquet technique), Grevert et al.[47] found a partial reversal of placebo analgesia by naloxone, thus confirming previous findings. Likewise, Levine and Gordon[8] adopted an elegant experimental design that showed naloxone-reversed placebo analgesia in a clinical situation, namely postoperative pain after extraction of the third molar. However, in 1983, Gracely et al.[7] demonstrated that naloxone might have hyperalgesic effects



• **Figure 17.1** During a placebo procedure, pain perception may be reduced through opioid and/or non-opioid mechanisms. The previous exposure to opioids leads to opioid-mediated placebo analgesia (disrupted by naloxone). The previous exposure to nonsteroidal anti-inflammatory drugs (NSAIDs) leads to cannabinoid-mediated placebo analgesia (disrupted by rimonabant). Endogenous opioids inhibit pain through a descending inhibitory network – involving rostral anterior cingulate cortex (rACC), orbitofrontal cortex (OrbC), periaqueductal gray (PAG), rostral ventromedial medulla (RVM) – and/or other mechanisms. High opioid and dopamine activity in the nucleus accumbens are also involved in placebo analgesia. Little is known about CB1 cannabinoid receptors' localization and activation.

on postoperative pain, thus shedding some doubt on the opioid hypothesis of placebo analgesia.

From 1995 to 1999, a long series of experiments with rigorous experimental designs were performed by Benedetti et al. Many unanswered questions have been clarified during these years, and the role of endogenous opioids in placebo analgesia has been explained. The experimental ischemic arm pain model was used to show that naloxone does not affect this type of pain. Therefore any effect following naloxone administration could be attributed to the blockade of placebo induced opioid activation.[5] At the same time, these investigators tested the effects of a cholecystokinin (CCK)-antagonist, proglumide, on placebo analgesia. Based on the anti-opioid action of CCK, it was hypothesized that blockade of CCK receptors would enhance the opioids released by the placebo. Indeed, it was found that proglumide potentiated the placebo analgesia and presented a novel and indirect way to test the opioid hypothesis.[5,48] More recently, the activation of the CCK type-2 receptors was performed using the agonist pentagastrin, which disrupted placebo responses completely.[49] Therefore the activation of the CCK type-2 receptors has the same effect as the μ-opioid receptor antagonist naloxone, suggesting that the balance between cholecystokinergic and opioidergic systems is crucial for placebo responsiveness in pain. Therefore one of the most interesting models involves two opposing neurotransmitter systems, opioids and CCK.

Specific placebo analgesic responses can be obtained in different parts of the body.[21,22] It was found that these responses are naloxone reversible.[50] If four noxious stimuli are applied to the hands and feet, and a placebo cream is applied to one hand only, then pain is reduced only on the hand on which the placebo cream had been applied. This highly specific effect is blocked by naloxone, suggesting that the placebo-activated endogenous opioid systems have a precise and somatotopic organization.[50]

Petrovic et al.[6] found that some brain regions in the cerebral cortex and brainstem are affected by both a placebo and the rapidly acting opioid agonist remifentanil, indicating a related mechanism in placebo induced and opioid-induced analgesia. Administration of a placebo induced activation of the rostral anterior cingulate cortex and orbitofrontal cortex. Moreover, there was significant co-variation in activity between the rostral anterior cingulate cortex and the lower pons and medulla, and sub-significant co-variation in activity between the rostral anterior cingulate cortex and the periaqueductal gray. This suggested that the pain modulating circuit of the descending rostral anterior cingulate-periaqueductal gray-rostral ventromedial medulla is involved in placebo analgesia, as previously hypothesized by Fields and Price.[51] The first direct evidence of opioid-mediated placebo analgesia was published in 2005.[52] *In vivo* receptor binding techniques using the radiotracer carfentanil, a μ-opioid agonist, were used to show that a placebo procedure activates μ-opioid neurotransmission in the dorsolateral prefrontal cortex, the anterior cingulate cortex, the insula, and the nucleus accumbens. A more detailed account of μ-opioid neurotransmission after placebo administration was carried out in another study that used noxious thermal stimulation.[53]

Placebo treatment affected opioid activity in several opioid-rich regions that play central roles in pain and affect, including the periaqueductal gray, dorsal raphe, nucleus cuneiformis, amygdala, orbitofrontal cortex, insula, rostral anterior cingulate, and lateral prefrontal cortex. Opioid activity in many of these regions was correlated with placebo effects in reported pain. Connectivity analyses of individual differences in opioid binding revealed that placebo treatment increased connectivity between the periaqueductal gray and the rostral anterior cingulate cortex and increased functional integration among limbic regions and the prefrontal cortex. Overall, the results suggest that endogenous opioid release in core affective brain regions is an integral part of the mechanism whereby expectations regulate affective and nociceptive circuits.

Our knowledge about the involvement of endogenous opioids in placebo analgesia has increased even more in the past few years. For example, it is now clear that a specific descending pain-modulating network mediates the analgesic effect following placebo administration. Eippert et al.[54] combined naloxone administration with functional magnetic resonance (fMRI) imaging and found that naloxone reduced both behavioral and neural placebo effects as well as placebo induced responses in pain modulatory cortical structures such as the rostral anterior cingulate cortex. A brainstem-specific analysis also found a similar naloxone modulation of placebo induced responses in key structures of the descending pain control system, such as the hypothalamus, periaqueductal gray, and rostral ventromedial medulla. Interestingly, naloxone abolished the placebo-induced coupling between the rostral anterior cingulate cortex and the periaqueductal gray, which predicted both behavioral and neural placebo effects as well as the activation of the rostral ventromedial medulla. The same group found that the activation of this descending system following placebo administration extends to the dorsal horns of the spinal cord, although we do not know whether the spinal effects are mediated by endogenous opioids.[55]

It has long been known that endogenous opioid systems are not the only mechanisms involved in placebo analgesia. One example of non-opioid-mediated placebo responses is represented by previous exposure to a non-opioid drug, such as ketorolac.[56] When ketorolac is administered for two days in a row and then replaced with a placebo on the third day, the placebo analgesic response is not reversed by naloxone, indicating that specific pharmacologic mechanisms are involved in a learned placebo response, depending on the previous exposure to opioid or non-opioid substances. Other examples of placebo analgesic effect that are not mediated by opioids have been described in people with IBS[57] and experimental pain in brain imaging studies.[36] Based on these considerations, Benedetti et al.[58] induced opioid or non-opioid placebo analgesic responses and assessed the effects of the CB1 cannabinoid receptor antagonist rimonabant. Unlike naloxone, rimonabant had no effect on opioid-induced placebo analgesia following morphine pre-conditioning, whereas it completely blocked placebo analgesia following non-opioid pre-conditioning with the nonsteroidal anti-inflammatory drug (NSAID) ketorolac. These findings indicate that the placebo analgesic responses elicited by NSAID conditioning are mediated by CB1 cannabinoid receptors.

Since the involvement of CB1 cannabinoid receptors in placebo analgesia is a recent finding, little is known about their localization and activation. To the best of our knowledge, they are activated following a previous exposure to NSAIDs, which suggests that these drugs, besides the inhibition of cyclooxygenase and prostaglandin synthesis, activate an endocannabinoid pathway.[58] Indeed, non-opioid drugs, such as metamizole, have been found both to inhibit the enzyme cyclooxygenase and to act on the CB1 cannabinoid receptors in rodents.[59] Based on these considerations, a change in the availability of endogenous ligands for CB1 cannabinoid receptors, such as anandamide, should be expected to modulate placebo analgesia in some circumstances. Indeed, Pecina et al.[60] investigated the role of the common, functional missense variant Pro129Thr, of the gene encoding fatty acid amide hydrolase

(FAAH), the major degrading enzyme of endocannabinoids, on psychophysical, dopaminergic, and opioid responses to pain and placebo induced analgesia in humans. FAAH Pro129/Pro129 homozygotes reported higher placebo analgesic responses and more positive affective states immediately and 24 hours after placebo administration. Pro129/Pro129 homozygotes also showed greater placebo induced μ opioid, but not D2/D3 dopaminergic enhancements in neurotransmission in regions known to be involved in placebo effects.

Neuroimaging of Placebo Analgesia (Fig. 17. 1)

Modern brain imaging techniques have been fundamental in the understanding of placebo analgesia, and many brain imaging studies have been carried out to describe the functional neuroanatomy of the placebo analgesic effect[6,52–55,61–65] As described above, the first imaging study of placebo analgesia showed that a subset of brain regions is similarly affected by either a placebo or a μ-opioid agonist.[6] In an fMRI imaging study of experimentally induced pain in healthy participants, Wager et al.[61] found that placebo analgesia was related to decreased neural activity in pain processing areas of the brain. Pain-related neural activity was reduced within the thalamus, anterior insular cortex, and anterior cingulate cortex during the placebo condition compared with the baseline condition. The magnitude of these decreases correlated with reductions in pain ratings. Not only did Wager et al.[61] image the time period of pain as well as the time period of the anticipation of pain. They hypothesized an increase in neural activity within the brain areas involved in expectation. Indeed, they found significant positive correlations between increases in brain activity in the anticipatory period and decreases in pain and pain-related neural activity during stimulation within the placebo condition. The brain regions showing positive correlations during the anticipatory phase included the orbitofrontal cortex, dorsolateral prefrontal cortex, rostral anterior cingulate cortex, and midbrain periaqueductal gray. The dorsolateral prefrontal cortex is a region that has been associated with the representation and maintenance of information needed for cognitive control, consistent with a role in expectation.[66] In contrast, the orbitofrontal cortex is associated with functioning in the evaluative and reward information relevant to the allocation of control, consistent with a role in affective or motivational responses to anticipation of pain.[67] The anterior cingulate cortex is often reported to be involved in placebo analgesia, although some discordant results have been obtained. For example, it was found to have increased activity in a study by Petrovic et al.[6] and decreased activity in a study by Wager et al.[61] which might be explained based on the different experimental settings.

Most brain imaging studies aimed at investigating placebo analgesia have been performed in experimental settings in healthy volunteers. In contrast, Price et al.[62] conducted an fMRI imaging study in which brain activity of IBS patients was measured in response to rectal distension using a balloon barostat. A large placebo effect was produced by suggestions and accompanied by large reductions in neural activity in the thalamus, primary and secondary somatosensory cortices, insula, and anterior cingulate cortex during the period of stimulation. It was accompanied by increases in neural activity in the rostral anterior cingulate cortex, bilateral amygdala, and periaqueductal gray. This study is important and informative, as it shows that placebos act on the brain in a clinically relevant condition in the same way as they do in the experimental setting. Therefore the involvement of key areas in placebo analgesia, such as the anterior cingulate cortex, is not limited to experimental noxious stimuli but also extends to clinical pain. The study by Price et al.[62] is also interesting because reductions in brain activity occurred during the stimulus presentation itself, not just when subjects reported pain. It has been argued that the length of the painful stimulation may be critical for the measurement of placebo effects, as most studies used short heat or electric shock as pain stimuli and recorded activity decreases during periods extending after the stimulus offset. This may include a later cognitive reappraisal of the significance of pain and/or late neural activity influenced by report bias.

To determine whether the expectation of analgesia exerts its psychophysical effect through changes in the perceptual sensitivity of early cortical processes (in the primary and secondary somatosensory areas) or on later cortical elaborations, such as stimulus identification and response selection in the anterior cingulate cortex, Lorenz et al.[68] used high temporal resolution techniques (magnetoencephalography). They found that activity in the secondary somatosensory cortex was highly correlated with the extent of influence of the subjective pain rating by pre-stimulus expectation. In contrast, anterior cingulate cortex activity seemed to be associated only with stimulus intensity and related attentional engagement. In another study on laser evoked potentials by Wager et al.,[69] early nociceptive components were found to be affected by placebos. Therefore a late cognitive reappraisal of the significance of pain and/or late neural activity influenced by report bias may not be responsible for this early modulation. This indicates that the early sensory components are affected by placebo manipulation.

Overall, all these brain imaging data were summarized using a meta-analysis approach with the activation likelihood estimation method.[70] Nine fMRI studies and two positron emission tomography studies were selected for the analysis. During the expectation phase of analgesia, areas of activation were found in the left anterior cingulate, right precentral, and lateral prefrontal cortex, and the left periaqueductal gray. In the phase following pain stimulation, activation was found in the anterior cingulate and medial and lateral prefrontal cortices, in the left inferior parietal lobule and postcentral gyrus, anterior insula, thalamus, hypothalamus, periaqueductal gray, and pons. Conversely, deactivations were found in the left mid- and posterior cingulate cortex, superior temporal and precentral gyri, left anterior and right posterior insula, claustrum putamen, and right thalamus and caudate body. These meta-analytic data summarize all brain imaging studies and provide a global figure of the sequence of events following placebo administration. After the activation of a pain modulatory network during the expectation and early pain phases, several deactivations occur in different areas involved in pain processing. Further clarification to the functional neuroanatomy of placebo analgesia and the meta-analysis performed by Amanzio et al.[70] comes from a more recent meta-analysis aimed at assessing whether the neurologic pain signature, which represent the set of brain regions involved in pain processing, is specifically affected by placebos.[71] In this analysis, Medline (PubMed) was searched from inception to May 2015 and involved studies of functional neuroimaging of the human brain with evoked pain delivered under stimulus intensity-matched placebo and control conditions. Data were obtained from 20 of the 28 identified eligible studies, resulting in a total sample size of 603 healthy individuals. The responses to painful stimulation compared with baseline conditions were positive in 575 participants (95.4%). Placebo treatment resulted in significant behavioral outcomes on pain ratings in 17 of 20 studies

(85%). However, placebo effects on the neurologic pain signature response were significant in only 3 of 20 studies (15%) and were very small. Similarly, analyses restricted to studies with low risk of bias indicated very small effects, and analyses of placebo responders indicated small effects. These findings indicate that placebo treatment has moderate analgesic effects on pain reports. The very small effects on neurologic pain signature are probably attributable to the fact that placebos affect pain via brain mechanisms largely independent of effects on bottom-up nociceptive processing. Placebos may act in regions other than the neurologic pain signature.

Brain connectivity has also been claimed to play a role in placebo analgesia, although this approach requires further clarification. For example, Tetreault et al.[72] found that clinical placebo response is predictable from resting-state functional magnetic resonance imaging brain connectivity in patients with chronic knee osteoarthritis pain. However, whether brain imaging can predict who will respond to a placebo and who will not remain an open question.[72]

The Reward Dopaminergic System (Fig. 17.1)

In a brain imaging study in which both positron emission tomography and fMRI imaging were used, Scott et al.[63] tested the correlation between responsiveness to placebo and a monetary reward, using a model of experimental pain in healthy subjects. They found that placebo responsiveness was related to the activation of dopamine in the nucleus accumbens, a region involved in reward mechanisms,[73] as assessed using *in vivo* receptor binding positron emission tomography with raclopride, a D2/D3 dopamine receptor agonist. The same subjects were then tested using fMRI imaging for monetary responses in the nucleus accumbens. These investigators found a correlation between the placebo responses and the monetary responses—the larger the nucleus accumbens responses to monetary reward, the stronger the nucleus accumbens responses to placebos. This study strongly suggests that placebo responsiveness depends on the functioning and efficiency of the reward system. This explains why some individuals respond to placebos, while others do not. Those who have a more efficient dopaminergic reward system would also be good placebo responders. Interestingly, Scott et al.[63] used an experimental approach that is typical of clinical trials, whereby the subjects know they have a 50% chance of receiving either placebo or active treatment and whereby no prior conditioning was performed. Thus more powerful placebo responses should have been expected if the subject knew they had a 100% chance of receiving active treatment but actually received the placebo (deceptive administration) or if prior pharmacologic conditioning had been carried out.

In a different study by the same group, Scott et al.[64] studied the endogenous opioid and dopaminergic systems in different brain regions, including those involved in reward and motivational behavior. The participants underwent a pain challenge in the absence and presence of a placebo with the expected analgesic properties. Positron emission tomography with 11C-labeled raclopride was used to analyze dopamine and 11C-carfentanil for analyzing opioids. Placebo induced the activation of opioid neurotransmission in the anterior cingulate, orbitofrontal and insular cortices, nucleus accumbens, amygdala, and periaqueductal gray matter. Dopaminergic activation was observed in the ventral basal ganglia, including the nucleus accumbens. Both dopaminergic and opioid activity were associated with both anticipation and perceived effectiveness of the placebo, as shown by the reduction in pain ratings. Large placebo responses were associated with greater dopamine and opioid activity in the NAc. Interestingly, nocebo responses were associated with the deactivation of dopamine and opioid release. The release of dopamine in the NAc accounted for 25% of the variance in the placebo analgesic effects. Therefore placebo and nocebo effects seem to be associated with opposite responses of dopamine and endogenous opioids in a distributed network of regions that form part of the reward and motivation circuit.

No Prefrontal Functions, No Placebo Effects

A common finding across different neuroimaging studies is the involvement of the prefrontal areas in the placebo response, such as the dorsolateral prefrontal cortex. Interestingly, Eippert et al.[54] found that the opioid antagonist naloxone blocks placebo analgesia, along with a reduction in the activation of the dorsolateral prefrontal cortex, confirming that a prefrontal opioidergic mechanism is crucial in the placebo analgesic response.

In Alzheimer's disease, the frontal lobes are severely affected, with marked neuronal degeneration in the dorsolateral prefrontal cortex, orbitofrontal cortex, and anterior cingulate cortex,[74] and the prefrontal lobes are responsible for complex mental functions. It is reasonable to expect a disruption of placebo responsiveness in these patients. Based on these considerations, Benedetti et al.[75] studied Alzheimer patients at the initial stage of the disease and after one year to see whether the placebo component of the therapy was affected by the disease. The placebo component of the analgesic therapy was found to be correlated with both cognitive status and functional connectivity among different brain regions; according to the rule, "the more impaired the prefrontal connectivity, the smaller the placebo response." In a more recent study, Stein et al.[76] used diffusion tensor magnetic resonance imaging to test the hypothesis of the role of white matter integrity in placebo responsiveness. The individual placebo analgesic effect was found to be correlated with white matter integrity indexed by fractional anisotropy, particularly in the right dorsolateral prefrontal cortex, left rostral anterior cingulate cortex, and periaqueductal gray. Probabilistic tractography seeded in these regions showed that stronger placebo analgesic responses were associated with increased mean fractional anisotropy values within the white matter tracts connecting the periaqueductal gray with the rostral anterior cingulate cortex and the dorsolateral prefrontal cortex.

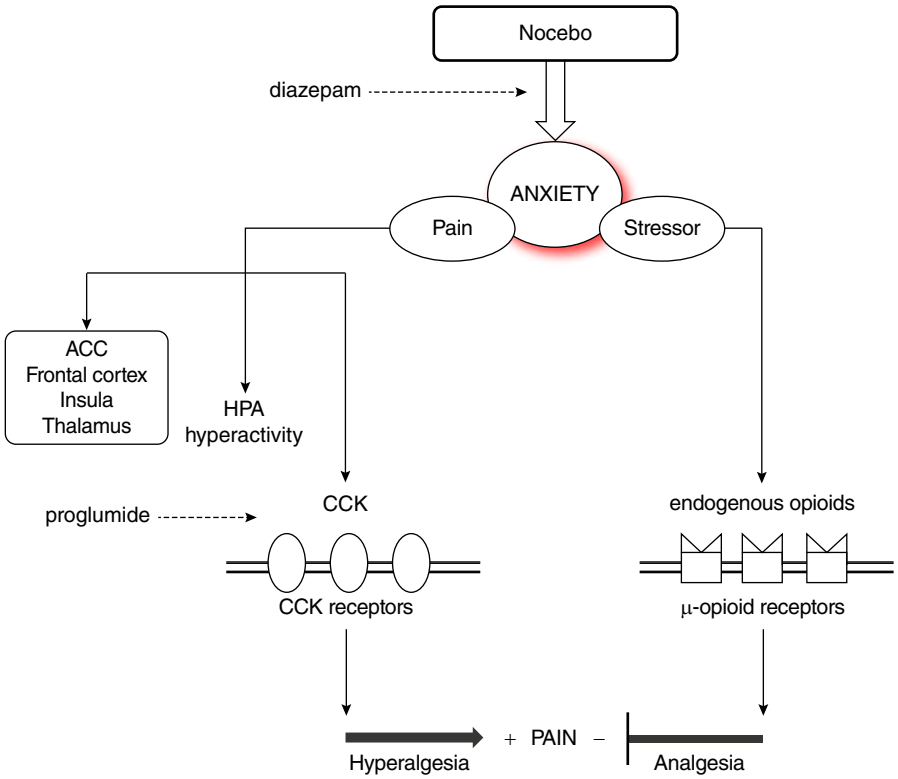
To support the crucial role of the prefrontal cortex in the occurrence of placebo responses, Krummenacher et al.[77] used repetitive transcranial magnetic stimulation (rTMS) to inactivate the prefrontal cortex during placebo analgesia. These investigators inactivated the left and right dorsolateral prefrontal cortex during a procedure inducing placebo analgesia and found that rTMS completely blocked the analgesic placebo response. Therefore inactivation of the prefrontal lobes has the same effects as those observed in prefrontal degeneration in Alzheimer disease and reduced integrity of the prefrontal white matter.

These findings have two clinical implications. First, to compensate for the disruption of placebo/expectation-related mechanisms, we need to consider a possible revision of some therapies in Alzheimer patients. Second, we should consider the potential disruption of placebo mechanisms in all conditions where the prefrontal regions are involved, as occurs in vascular and frontotemporal dementia and any lesion of the prefrontal cortex.

Nocebo Hyperalgesia (Fig. 17.2)

The nocebo hyperalgesic effects go in the opposite direction to the placebo analgesic effect because of expectations of negative outcomes. Although not always studied under strictly controlled conditions, many interesting nocebo effects and/or nocebo-like effects are present in daily life and routine clinical practice.[78,79] For example, negative diagnoses and prognoses can lead to an amplification of pain intensity and, more generally, negative communication within the healing context may have important effects on patients' emotions.[80,81] Likewise, nocebo and/or nocebo-related effects may occur when distrust toward medical personnel and therapies are present. In the latter case, unwanted effects and side effects may occur because of negative expectations,[82,83] which may reduce or even conceal the efficacy of some treatments. For example, it has been found that verbal suggestions can change the direction of nitrous oxide action from analgesia to hyperalgesia.[84] Another example is the health reports commonly issued in Western societies; negative warnings sent out by the mass media may have an important impact on the perceived symptoms of many people. Diseases with an important psychological component such as IBS are also affected by nocebo effects; sedatives and opioids in postoperative pain management have been found to be influenced by supposed nocebo effects.[85,86] Similarly, some negative expectation-inducing procedures, such as voodoo magic, may lead to symptom worsening. Finally, the fear-avoidance model of pain can be seen as a sort of nocebo-like effect, whereby the fear of pain may lead to pain worsening.[87]

The clinical trial setting is also important for nocebo effects. For example, in analgesic clinical trials, adverse events (AEs) are reported for painkillers under evaluation and compared with AEs in the placebo group. Patients who receive placebo often report a high frequency of AEs. Amanzio et al.[88] compared the rates of AEs reported in the placebo arms of clinical trials for three classes of anti-migraine drugs: NSAIDs, triptans, and anti-convulsants. It was found that the rate of AEs in the placebo arms of trials with anti-migraine drugs was high. In addition, the AEs in the placebo arms corresponded to those of the anti-migraine medication against which the placebo was compared. For example, anorexia and memory difficulties, which are typical AEs of anti-convulsants, were present only in the placebo arm of these trials. These results suggest that the adverse events in placebo arms of clinical trials of anti-migraine medications depend on the AEs of the active medication against which the placebo is compared. These findings are consistent with the expectation theory of placebo and nocebo effects. Similar findings were obtained by Mitsikostas et al. [89] for headache, Mitsikostas et al.[90] for fibromyalgia, Häuser et al.[91] for diabetic peripheral neuropathy, and Papadopoulos



• **Figure 17.2** Nocebo procedures induce anticipatory anxiety, which can be about the pain itself or about a stressor that shifts the attention from the pain. In the first case, nocebo-induced anxiety affects both the hypothalamic-pituitary-adrenal (HPA) axis and pain mechanisms; it also activates different brain regions involved in pain processing, such as the anterior cingulate cortex (ACC), frontal cortex, insula, and thalamus. Diazepam can block anxiety, thus preventing both HPA hyperactivity and hyperalgesia. CCK antagonists, such as proglumide, only block the CCK-ergic anxiety-pain link. When the general state of arousal stems from a stressful situation in the environment, an analgesic effect is observed, which derives from the activation of the endogenous opioid systems.

and Mitsikostas[92] for neuropathic pain. These authors emphasized how dropouts because of nocebo effects may confound the interpretation of many clinical trials.

In both experimental and clinical settings, it has long been known that the perceived intensity of a painful stimulus following a negative expectation of pain increase is higher than in the absence of negative expectations. For example, the expectation of painful stimulation amplifies the perceived unpleasantness of innocuous thermal stimulation,[93] and the level of expected pain intensity alters perceived pain intensity. In fact, by using two visual cues, each conditioned to one of two noxious thermal stimuli (high and low), Keltner et al.[94] showed that participants reported higher pain when the noxious stimulus was preceded by the high-intensity visual cue. Using a real nocebo procedure, whereby an inert substance was administered along with verbal suggestions of hyperalgesia, Benedetti et al.[95,96] showed expectation-induced hyperalgesia in clinical and experimental settings. In the clinical setting, the situation was a postsurgical manipulation that induced expectations of pain increase so that the patients were given an inert treatment that they expected to be painful.[95] A straightforward increase in pain was found, and this also occurred in the experimental setting using the tourniquet technique, whereby ischemic pain was induced in one arm.[96] These effects can be quite powerful, and sometimes pain can be generated from a nonpainful stimulus. For example, a study by Colloca et al.[97] used a nocebo procedure, in which verbal suggestions of painful stimulation were given to healthy volunteers before the administration of either tactile or low-intensity painful electrical stimuli. This study showed that these anxiogenic verbal suggestions could turn tactile stimuli into pain and low-intensity painful stimuli into high-intensity pain. Therefore by defining hyperalgesia as an increase in pain sensitivity and allodynia as the perception of pain in response to innocuous stimulation, nocebo suggestions of a negative outcome can produce hyperalgesic and allodynic effects. Several studies have shown that negative expectations have a significant effect on pain perception. Indeed, many recent studies have shown that nocebo effects occur in various painful conditions, ranging from experimental to clinical pain.[98,99]

Heightened anticipatory anxiety in the form of elevated autonomic arousal is important in nocebo hyperalgesia. Colagiuri and Quinn[100] found that nocebo hyperalgesia persists longer than placebo analgesia, and this difference can be explained by elevated autonomic arousal. Healthy volunteers were randomized to receive placebo conditioning, nocebo conditioning, or no conditioning using an experimental pain model with surreptitious decreases (placebo group) and increases (nocebo group) in pain stimulation paired with sham treatment during training. The pain was then assessed in the test phase with and without sham treatment at equal pain stimulation. The conditioning procedure successfully induced placebo analgesia and nocebo hyperalgesia in the relevant groups, with nocebo hyperalgesia outlasting placebo analgesia, highlighting nocebo hyperalgesia's resistance to extinction. Autonomic arousal mediated the effect of nocebo versus placebo training on extinction.

The nocebo effects can be learned through observation. Swider and Bąbel[101] and Vögtle et al.[102] studied simultaneously, but independently, voluntary participants observing a model who simulated more pain in association with either a red light[101] or the application of an ointment on the skin.[102] After the observation phase, the experimental subjects showed robust nocebo responses (i.e. hyperalgesic responses, following the presentation of the red light, and this was correlated to empathy scores).[101] Likewise, substantial nocebo responses were found after observing the ointment application, which was correlated to pain catastrophizing.[102] In addition, Swider and Babel[101] found a gender effect, whereby nocebo hyperalgesia was greater after a male model was observed compared to a female model, regardless of the sex of the experimental volunteers.

Negative expectations and nocebo effects can spread across individuals quickly by propagating negative information and communication, which may produce biochemical changes that negatively impact health and may modify the baseline of many physiologic parameters. In this context, high-altitude headaches have been studied as a model for the investigation of the products of cyclooxygenase (i.e. prostaglandins and thromboxane).[103] In this experimental model, a participant (the trigger) received negative information about the risk of headache at high altitude and disseminated this negative information across several other participants. In one week, this negative information was propagated across the 36 participants. The nocebo group showed a significant increase in headache, salivary prostaglandins, and thromboxane at high altitudes compared to the control group. In this novel experimental model, negative information propagated across 36 participants in one week.[103] Over more extended periods, hundreds or even thousands of individuals might get "socially infected," thus emphasizing the possible important role of negative social communication in the dissemination of symptoms and illness across the population. It is worth noting that interindividual communication may play a crucial role in the outcome of a clinical trial. The same authors[103] ran two "aspirin versus placebo" clinical trials at high altitudes for the control of high altitude headaches. The first trial was performed in control participants, whereas the second trial was performed in socially infected individuals. Aspirin was effective in reducing both pain and prostaglandin synthesis in the control group, whereas placebo was ineffective. Conversely, both aspirin and placebo reduced pain and prostaglandin levels in socially infected individuals. Whereas no placebo effect was present in the controls, a placebo effect occurred in the socially infected participants, a difference that is attributable to the different baseline levels of prostaglandins induced by the spread of negative information. The placebo effect occurred only in socially infected individuals because the placebo acted only on the nocebo component of the prostaglandins, and pain increased. As becomes clear from these findings, the social propagation of expectations may influence the baseline of biochemical and behavioral parameters before patients are randomized to either placebo or active treatment, thereby potentially affecting the outcome of a study. Future clinical trials should therefore consider this aspect.[104]

Nocebo-Induced Activation of Cholecystokinin (Fig. 17.2)

Compared with placebo analgesia, much less is known about nocebo hyperalgesia, mainly because of ethical limitations. Although the induction of placebo responses is acceptable in many circumstances,[105] the induction of nocebo responses is a stressful and anxiogenic procedure. To induce nocebo hyperalgesia, an inert treatment is provided along with verbal suggestions for pain increase. In 1997, a trial in postoperative patients was run with the non-specific cholecystokinin CCK-A/CCK-B (or CCK 1 and 2) receptor antagonist proglumide.[95] The situation was

a postsurgical manipulation that induced expectations of pain worsening. It was found that proglumide prevented nocebo hyperalgesia in a dose-dependent manner, even though it is not specifically a painkiller, suggesting that the nocebo hyperalgesic effect is mediated by CCK. A dose as low as 0.05 mg was completely ineffective, while a dose of 0.5 mg and 5 mg proved to be effective. As CCK is also involved in anxiety mechanisms, it was hypothesized that proglumide affects anticipatory anxiety.[95,106] Importantly, this effect was not antagonized by naloxone. However, because of ethical constraints, these effects have not been investigated further in these patients. To better understand the mechanisms underlying nocebo hyperalgesia and overcome the ethical constraints inherent to the clinical approach, a similar procedure was used in healthy volunteers in whom experimental pain was induced.[96] It was found that the oral administration of an inert substance and verbal suggestions of hyperalgesia induced both hyperalgesia and hyperactivity of the hypothalamic-pituitary-adrenal (HPA) axis as assessed using adrenocorticotropic hormone (ACTH) and cortisol plasma concentrations. Both nocebo-induced hyperalgesia and HPA hyperactivity were blocked by benzodiazepine diazepam, suggesting the involvement of anxiety mechanisms. In contrast, the administration of the mixed CCK-A(1)/CCK-B(2) receptor antagonist, proglumide, blocked nocebo hyperalgesia completely but did not affect HPA hyperactivity, suggesting a specific involvement of CCK in the hyperalgesic but not in the anxiety component of the nocebo effect. Interestingly, neither diazepam nor proglumide showed analgesic effects on baseline pain, as they acted on the nocebo-induced pain increase only. These data suggest that a close relationship between anxiety and nocebo hyperalgesia exists but that proglumide does not act by blocking anticipatory anxiety, as previously hypothesized.[95,106] Instead, it interrupts a CCK-ergic link between anxiety and pain. Therefore in contrast to the anxiolytic action of diazepam, proglumide blocks a CCK-ergic pronociceptive system that is activated by anxiety and is responsible for anxiety-induced hyperalgesia. Nocebo hyperalgesia is an interesting model to better understand when and how endogenous pronociceptive systems are activated. The pronociceptive and anti-opioid action of CCK has been documented in many brain regions.[78,107,108] CCK has been shown to reverse opioid analgesia by acting at the level of the rostral ventromedial medulla,[109,110] and activates pain-facilitating neurons within the rostral ventromedial medulla.[111]

The discrepancy between anxiety-induced hyperalgesia and stress-induced analgesia may only be apparent. Stress is known to induce analgesia in a variety of situations, both in animals and humans. When one is under stress, the pain threshold increases. However, the nature of the stressor is likely to play a central role. Although hyperalgesia may occur when the anticipatory anxiety is about the pain itself,[93,94,96,112] analgesia may occur when anxiety is about a stressor that shifts the attention from the pain.[113] We should therefore use these two definitions in two different ways.[79] In the case of anxiety-induced hyperalgesia, we are talking about the anticipation of pain, in which attention is focused on the impending pain. We have seen that the biochemical link between anticipatory anxiety and pain increase is represented by the CCK-ergic systems. Conversely, stress-induced analgesia should be considered whenever a general state of arousal stems from a stressful situation in the environment, so that attention is now focused on environmental stressors. There is experimental evidence that analgesia results from the activation of endogenous opioid systems.[113]

Neuroimaging of Negative Expectations and Nocebo Hyperalgesia (Fig. 17.2)

Modern brain imaging techniques are fundamental to our understanding of the neurobiology of negative expectations. No inert substance is generally provided in these studies, and the experimenter typically uses verbal suggestions. Therefore in this case, it is better to discuss the nocebo-related effects. Typically, the experimenter told the participant about the forthcoming pain to make the subject expect a painful stimulation, and both the anticipatory and post-stimulus phases were analyzed. Using this experimental approach, Sawamoto et al.[93] found that the expectation of painful stimulation amplifies the perceived unpleasantness of innocuous thermal stimulation. These psychophysical findings were correlated with enhanced transient brain responses to non-painful thermal stimuli in the anterior cingulate cortex, parietal operculum, and posterior insula. This enhancement consisted of both a higher intensity signal change (in the anterior cingulate cortex) and a larger volume of activated voxels (in the parietal operculum and posterior insula). Therefore expecting a painful stimulus enhances both the subjective unpleasant experience of an innocuous stimulus and the objective responses in some brain regions.

Overall, negative expectations may result in the amplification of pain,[114,115] and several brain regions, such as the anterior cingulate cortex, prefrontal cortex, and insula, have been found to be activated during the anticipation of pain.[68,94,112] These effects are opposite to those elicited by positive expectations, whereby expectations of reduced pain are investigated. In fact, in some studies in which both positive and negative outcomes have been studied using the same experimental approach, modulation of subjective experience and brain activation has been found. For example, in a study by Koyama et al.,[112] as the magnitude of expected pain increased, activation increased in the thalamus, insula, prefrontal cortex, and anterior cingulate cortex. In contrast, expectations of decreased pain reduced activation of pain-related brain regions, such as the primary somatosensory cortex, insular cortex, and anterior cingulate cortex. In a different magneto-electroencephalographic study in which source localization analysis was performed, Lorenz et al.[68] found modulation of the dipole in the secondary somatosensory cortex by nocebo-like and placebo-like suggestions. The dipole was modulated in the same direction as expectations, shrinking when a decrease in pain was expected and expanding when an increase in pain was anticipated. In another study, Keltner et al.[94] found that the level of expected pain intensity alters the perceived pain intensity, along with the activation of different brain regions. By using two visual cues, each conditioned to one of two noxious thermal stimuli (high and low), these investigators showed that subjects reported higher pain when the noxious stimulus was preceded by the high-intensity visual cue. By comparing the brain activation produced by the two visual cues, they found significant differences in the ipsilateral caudal anterior cingulate cortex, head of the caudate, cerebellum, and contralateral nucleus cuneiformis. Interestingly, the imaging results of this study indicate that expectation and noxious stimulus intensity act in an additive manner on afferent pathways activated by cutaneous noxious thermal stimulation.

Somehow, unlike previous studies, Kong et al.[116] investigated nocebo responses by administering an inert treatment that the participants believed to be hyperalgesic. These investigators showed that, after administering the inert treatment along with

negative suggestions, subjective pain intensity ratings increased significantly more in nocebo regions than in the control regions in which no expectation manipulation was performed. fMRI analysis of hyperalgesic nocebo responses to identical calibrated noxious stimuli showed signal increases in brain regions, including the bilateral dorsal anterior cingulate cortex, insula, superior temporal gyrus, left frontal and parietal operculum, medial frontal gyrus, orbital prefrontal cortex, superior parietal lobule, and hippocampus; right claustrum/putamen, lateral prefrontal gyrus, and middle temporal gyrus. Functional connectivity analysis of spontaneous resting-state showed a correlation between two seed regions (left frontal operculum and hippocampus) and pain network, including the bilateral insula, operculum, anterior cingulate cortex, and left primary somatosensory and motor cortices. Therefore nocebo hyperalgesia may be predominantly produced through an affective-cognitive pain pathway (medial pain system), and the left hippocampus may play an important role in this process.

The early enhancement of pain signals in the dorsal horn of the spinal cord has also been found in a study in which nocebo hyperalgesia was investigated in combination with spinal fMRI in healthy volunteers.[117] The local application of an inert nocebo cream on the forearm increased pain ratings compared with a control cream and reduced pain thresholds on the nocebo-treated skin. Pain stimulation induced a strong activation in the spinal cord at the level of the stimulated dermatomes C5/C6, and comparison of the nocebo with the control condition revealed enhanced nocebo-related activity in the ipsilateral dorsal horn of the spinal cord. Therefore the nocebo hyperalgesic effect envisages a pain-facilitating mechanism at a very early stage of pain processing, particularly in the spinal cord, well before cortical processing. The effects of nocebo on the spinal cord have also been found for complex psychological factors, such as information about a drug, for example, the price tag. Tinnermann et al.[118] discovered that labeling an inert treatment as an expensive medication led to stronger nocebo hyperalgesia than labeling it as an inexpensive medication. This effect was mediated by activity in the prefrontal cortex and coupling between the prefrontal areas, brainstem, and spinal cord. This might represent a mechanism through which higher cognitive representations, such as values, can modulate early pain processing.

Nocebo effects have also been found to be associated with a decrease in dopamine and opioid activity in the nucleus accumbens, thus underscoring the role of the reward and motivational circuits in nocebo effects.[64]

Communication Strategies

Overall, these findings may have implications both in clinical trial settings and in medical practice. Communication strategies that reduce the development of nocebo side effects while maintaining informed consent are of considerable interest. For example, framing how information about the likelihood or significance of side effects is presented (e.g. negative frame: 30% will experience headache vs. positive frame: 70% will not experience headache) may reduce nocebo effects.[119] In addition, a study was specifically aimed at testing whether positive mood induction can block the development of nocebo effects.[120] Healthy participants were assigned to one of four conditions. First, participants took part in a mood induction procedure, with half receiving a positive mood induction and the other half a neutral mood induction. Then, participants were told they would experience transcranial direct current stimulation (tDCS); half of them were informed that headache pain is a side effect of tDCS, whereas the other half were not given this information. Positive mood was induced using a video (a portion of the movie "City Slickers 2"), whereas the neutral video contained a portion of a history of golf documentary. Both video compilations had a total viewing time of approximately 15 min. In the neutral mood condition, the provision of headache side effect information led to a greater occurrence of headaches, more frequent headaches, and a higher maximum level of headache pain compared to those with no side effect information. In the positive mood condition, a similar increase in headache pain did not manifest from the provision of side effect information. Therefore, a positive mood induction can block the formation of nocebo effects that arise from side effect information.

Conclusions

The neuroscientific approach to placebo research and the consequent new knowledge on the neurobiological underpinnings is to pay dividends and bodes well for the future. At least three important implications can be envisaged: First, the neuroscience of placebo and nocebo effects helps us understand several complex brain functions, such as the top-down modulation of pain. Second, new experimental designs can be devised that can help better interpret clinical trials, such as the measurement of patients' expectations. Third, the doctor-patient relationship can be improved by adopting communication strategies that affect the endogenous mechanisms of pain modulation.

Key Points

- Most knowledge about the neurobiologic mechanisms of the placebo effect comes from the field of pain and analgesia.
- The expectation of pain reduction plays a crucial role in placebo analgesia. This is shown by the reduced effectiveness of painkillers when administered covertly (unexpectedly).
- The placebo analgesic effect is mediated by endogenous opioid systems and antagonized by cholecystokinin in some circumstances. In other conditions, the endocannabinoid system is involved.
- Many brain imaging studies indicate that several areas are involved in placebo analgesia, including the dorsolateral prefrontal cortex and the regions involved in dopaminergic reward mechanisms.
- The prefrontal lobes are fundamental to a placebo response. If there was no prefrontal control, there was no placebo response.
- The nocebo hyperalgesic effect is mediated by anxiety, which activates a cholecystokinin system that facilitates pain transmission.
- Endogenous pain modulatory descending circuits represent a biological substrate for the action of placebos on pain.
- This new knowledge about the mechanisms of placebo and nocebo effects has important implications for both clinical trials and medical practice.

History and Physical Examination of the Patient With Pain

CHARLES E. ARGOFF, GRACE FORDE, SAYED E. WAHEZI, ROBERT DUARTE

This chapter provides an overview of appropriate history taking and a structured approach to the physical examination of a pain patient, along with the anatomic and physiologic basis of the physical findings. Physical examination serves to further explore and confirm the findings from the clinical history. Data obtained from the history are essential to pair with the physical exam to create a thoughtful differential diagnosis of the etiology of the pain so that the need for further diagnostic testing can be determined and further assist in treatment planning.

The history is one of the most important pillars of proper pain assessment. The importance of this aspect of clinical evaluation cannot be overemphasized. Many practitioners adopt the "PQRST" approach to historical evaluation. Using such, a patient is asked what provokes or palliates their symptoms (P), the nature of its quality (Q), whether/where it radiates (R), the severity of their pain (S), and temporal components (T). Assessing the person in pain also requires additional careful consideration of pain physiology, anatomy, functional limitations, and the patient's ability to convey the information. The practitioner needs to understand the onset of symptoms (insidious or traumatic), types of daily activities limited by pain, psychological effects of pain, and the presence of neuroanatomic vs. referral or co-incidental pain radiation. This information is required to discern whether the patient's pain is nociceptive, neuropathic, nociplastic, or other types of pain. It is important to understand that many people experiencing chronic pain are not exclusively experiencing one type or the other, but rather may have varying degrees of each, thus mixed pain types. Complete and personalized history taking is essential to understanding a patient's pain and properly devise a treatment strategy to improve life quality. The time and effort spent completing this are likely to be of value when treating a person in pain.

The key components of the physical examination include a general physical examination, a detailed neurologic examination, a detailed musculoskeletal examination, and an examination for cutaneous or trophic findings. The musculoskeletal examination includes inspection, palpation, percussion, auscultation, and provocative maneuvers.[1]

General Physical Examination

Vital signs, including temperature, heart rate, respiratory rate, blood pressure, and weight, should be noted at each visit. This information is useful in forming an impression of the overall health and comorbid conditions of the patient.

A few moments should be spent observing and documenting the general appearance and gait of the patient. Whenever possible, the examining physician should make every effort to bring the patient back to the examining room from the waiting room. This allows the physician the opportunity for examination as the patient transitions from sitting to standing and ambulates to the examining room. This observation time allows an "unofficial" examination that may reveal inconsistencies not noted on the "official formal" examination.

Observations include how the patient dresses and personal hygiene. Pain behavior, posture, and anatomic abnormalities such as contractures, amputation, and asymmetries should also be noted. Maladaptive postural dynamics play an important role in generating myofascial pain. Excessive lumbar lordosis places strain on the lumbar extensor muscles and results in low back pain. Similarly, forward flexion of the cervical spine with drooping of the shoulders strains the cervical paraspinous and scapular muscles and thereby causes neck and upper back pain.

Evaluation of gait includes assessment of stride length, base, arm swing, and stability. An unsteady, wide-based ataxic gait can be seen in patients with cerebellar and proprioceptive disorders. In patients with hip and lower extremity pain, the stance phase is reduced in the affected limb, along with a shortened swing phase on the uninvolved side, which results in an antalgic gait pattern. A waddling gait can occur in patients with weakness of the hip girdle muscles or bilateral degenerative hip joint disease. Many gait deviations can occur in patients with foot drop, including vaulting, steppage gate, circumduction, and persistent abduction of the affected limb.[2]

Neurologic Examination

Components of the neurologic examination include:

- mental status examination
- cranial nerve testing
- motor strength examination
- deep tendon reflexes
- sensation
- coordination
- special tests

Mental Status Examination

A reasonable assessment of mental status can often be made as part of history taking and inquiry into activities of daily living and function. A basic mental status examination includes assessment

of the level of consciousness; orientation to person, place, time, and situation; registration and short-term memory; attention and concentration; and assessment of language for aphasia. The Folstein Mini-Mental Status Examination is a useful screening tool for detecting cognitive deficits and dementia.

Assessment of mood, affect, suicidal and homicidal ideation, and neurovegetative symptoms such as sleep, appetite, and energy level should be assessed routinely. This helps uncover comorbid psychiatric conditions (e.g. depression, anxiety, and psychosis), which can have a profound impact on the treatment of pain patients.

Cranial Nerve Testing

The cranial nerve examination localizes pathology primarily at the level of the brainstem. Central pain conditions associated with brainstem pathology (e.g. strokes, tumors, demyelinating disease, and vascular malformations) can be associated with cranial nerve deficits.[2]

Cranial Nerve I

Olfactory Nerve

Test one nostril at a time. Odors such as coffee, mint, or cloves can be used. Noxious odors such as ammonia are avoided because they activate trigeminal nerve receptors in the nasal passages.

The most common cause of smell dysfunction is nasal and sinus pathology. Dementia, neurodegenerative conditions, and basal frontal tumors can also result in smell dysfunction.

Cranial Nerve II

Optic Nerve

Visual acuity is determined with a Snellen chart. Visual fields are tested by the confrontation method at the bedside. More formal visual field testing with perimetry can be requested if indicated. Pupillary reaction to light and accommodation tests the optic and ophthalmic nerves. Funduscopic examination is done to evaluate the optic disc and retina. Papilledema and enlargement of the blind spot can occur in conditions associated with elevated intracranial pressure, including idiopathic intracranial hypertension, which is a relatively common cause of intractable headache.

Cranial Nerves III, IV, and VI

Ophthalmic, Trochlear, and Abducens Nerves

These nerves control eye movement and can be tested by asking the patient to track a moving object in the eight positions of cardinal gaze. Eyelid elevation and pupillary constriction are controlled by the third cranial nerve and are evaluated by assessing the direct, consensual, and accommodation reflexes. Sympathetic fibers innervate the pupillary dilator muscles. Horner's syndrome exists in several clinical conditions, including after stellate ganglion blockade. This syndrome includes ipsilateral ptosis, miosis, and anhidrosis. However, the mechanism of these changes involves sympatholysis and is independent of cranial nerve function.

Cranial Nerve V

Trigeminal Nerve

This nerve supplies sensory input to the face, mouth, tongue, and scalp up to the vertex. The mandibular division of the trigeminal nerve also supplies the muscles of mastication (i.e. temporalis, masseter, medial, and lateral pterygoid muscles).

Sensation along the ophthalmic, maxillary, and mandibular divisions of the trigeminal nerve are tested with temperature, pinprick, and light touch. The trigeminal nerve also provides the afferent limb of the corneal blink reflex.

Peripheral lesions of the trigeminal nerve result in ipsilateral loss of facial sensation with weakness and atrophy of the ipsilateral jaw muscles.

Cranial Nerve VII

Facial Nerve

The facial nerve innervates the muscles of facial expression, the submandibular and lacrimal glands, and taste in the anterior two-thirds of the tongue. Testing is usually limited to checking facial motor function (e.g. forehead wrinkling, eye closure, smile, pursing lips, and corneal blink). Supranuclear lesions of the seventh nerve typically spare the forehead, whereas nuclear and infranuclear lesions do not.

Sensory testing of the facial nerve is not routinely performed but can be accomplished by applying sweet, sour, and salt stimuli to the ipsilateral half of the anterior two-thirds of the tongue.

Cranial Nerve VIII

Vestibulocochlear Nerve

The vestibulocochlear nerve mediates hearing and balance. Hearing can be assessed with a 512 Hz tuning fork. The Rinne and Weber tests are commonly used to assess for sensorineural and conductive deafness.

In the Weber test, the base of a gently vibrating tuning fork is placed on the midforehead or the vertex. The patient is asked which ear hears the sound better. Normally, the sound is heard equally in both ears. With unilateral sensorineural hearing loss, the sound is better in the unaffected ear. With unilateral conductive hearing loss, sound is perceived better in the affected ear.

The Rinne test is conducted by placing the base of a gently vibrating tuning fork on the mastoid bone behind the ear. When the patient can no longer hear the sound, the fork is quickly moved next to the patient's ear. In patients with sensorineural deafness and normal hearing, air conduction is better than bone conduction. With conductive deafness, bone conduction is better than air conduction.

Nystagmus noted on eye movement testing may be a sign of vestibular dysfunction. In patients with complaints of episodic vertigo, the Dix-Hallpike maneuver is useful for making the diagnosis of benign paroxysmal positional vertigo. The test is performed by rapidly moving the patient from a sitting to a supine position while the patient's head is turned 45° to the right. The patient should remain supine with head turned for 20-30 s and then returned to the sitting position. The observation of rotatory nystagmus with limited duration is what is considered clearly positive. The response is noted, and then the test is repeated as described above with the head now turned to the left.[3]

Examination of the vestibulocochlear nerve can be informally done by observing the patient when conversing to determine grossly if they are having difficulty hearing speech. To formally test the vestibulocochlear nerve, the examiner should create a soft sound, usually through a whisper or finger rubbing, next to each ear. This should be done with each ear individually and the opposite ear covered. The patient should be asked if the sound was equal on both sides, and a normal finding would be that there was no difficulty hearing the noise in either ear or that it was equal in both ears. If the patient notices decreased sound on either ear, the ear canals should be inspected with an otoscope to ensure that the tympanic membrane is intact and that there is no material such as wax or exudate physically blocking the canal that would interfere with the patient's hearing.

Cranial Nerve IX

Glossopharyngeal Nerve

The glossopharyngeal nerve subserves taste in the posterior third of the tongue and sensation in the pharynx. It provides the afferent limb of the gag reflex.

Cranial Nerve X

Vagus Nerve

The vagus nerve innervates the pharyngeal and laryngeal muscles and forms the efferent limb of the gag reflex. Symptoms of vagus nerve lesions include dysarthria and dysphagia.

Cranial Nerve XI

Accessory Nerve

The cranial segment of the accessory nerve supplies the muscles of the larynx, whereas the spinal segment innervates the trapezius and sternocleidomastoid muscles. These muscles are tested by an ipsilateral shoulder shrug and contralateral head turn maneuvers.

Cranial Nerve XII

Hypoglossal Nerve

The hypoglossal nerve provides motor supply to the tongue. Testing is performed by tongue protrusion and pushing the tongue against the cheek on either side. Lesions of the hypoglossal nerve produce ipsilateral deviation on tongue protrusion.

Motor Strength Examination

Before muscle testing, the examiner should observe for any involuntary movements, for example, resting tremor, which could suggest extrapyramidal dysfunction or fasciculations observed in peripheral nerve disorders. Next, tone should be assessed by passively moving the patient's upper or lower extremity while in a seated position, determining normal, increase, or decrease in tone. An increase in tone can be divided into spasticity, which is velocity dependent seen in upper motor neuron disease involving the brain or spinal cord, and rigidity, defined as an increase in tone persisting throughout the entire range of motion. Decrease in tone is typically seen in peripheral nerve pathology

Manual muscle testing is performed by asking the patient to place each muscle in its position of maximal mechanical advantage. Muscle strength is commonly assessed with the Medical Research Council scale (Table 18.1).[3] Grades one to three are relatively objective and less prone to interobserver variation. Grade one implies a palpable contraction but with no associated movement noted. Grade two implies an ability to move the limb with gravity eliminated (this may require special positioning to assess). A grade three finding on motor examination is consistent with the ability to move against gravity but an inability to move against further resistance. The gastrocnemius muscle presents unique challenges when performing a manual muscle test. In the case of the gastrocnemius, a grade three muscle is able to perform one toe raise with the patient standing and lightly holding onto something for balance. A grade four muscle is able to perform five toe raises, and a grade five gastrocnemius is capable of performing ten toe raises. Grades four and five are difficult to standardize among different examiners. Factors such as a patient's body habitus, age, and expected functional status, and examiner strength, contribute to the difficulty of grading muscle strength above grade three.[3]

The screening muscle strength examination should correspond to a template that evaluates sequential nerve roots and peripheral nerves. Tables 18.2 and 18.3 summarize the commonly tested muscles along with their corresponding nerve root and peripheral nerve innervation.[4]

The muscle strength examination depends significantly on patients' comprehension and effort. Suboptimal or volitional lack

TABLE 18.1 Medical Research Council Grading of Muscle Strength

Grade 0	No movement
Grade 1	Flicker of movement
Grade 2	Movement only with gravity eliminated
Grade 3	Full range of movement against gravity
Grade 4	Full range of movement against some resistance
Grade 5	Full power against resistance

TABLE 18.2 Upper Extremity Muscles: Innervation and Action

Muscle	Action	Nerve Root	Nerve
Infraspinatus	Shoulder external rotation	C5-6	Suprascapular
Deltoid	Shoulder abduction, extension, and flexion	C5-6	Axillary
Biceps	Forearm flexion and supination	C5-6	Musculocutaneous
Triceps	Forearm extension	C7-8	Radial
Brachioradialis	Forearm flexion in the midprone position	C6	Radial
Extensor carpi radialis longus and brevis	Wrist extension	C6-7	Radial
Flexor carpi ulnaris	Wrist flexion with ulnar deviation	C8-T1	Ulnar
Flexor digitorum profundus	Flexion at the distal interphalangeal joints	C7-8	Anterior interosseus branch of the median nerve
Abductor pollicis brevis	Abduction of the thumb	C8	Median
Adductor pollicis longus	Abduction of the thumb	C8-T1	Ulnar

TABLE 18.3 Lower Extremity Muscles: Innervation and Action

Muscle	Action	Nerve Root	Nerve
Iliopsoas	Hip flexion	L2-4	Femoral
Adductor longus and brevis	Hip adduction	L2-4	Obturator
Gluteus maximus	Hip extension	L5-S2	Inferior gluteal
Gluteus medius and minimus	Hip abduction	L5-S2	Superior gluteal
Quadriceps femoris	Knee extension	L2-4	Femoral
Hamstrings (i.e. semitendinosus, semimembranosus, and biceps femoris)	Knee flexion	L5-S1	Sciatic
Tibialis anterior	Foot dorsiflexion	L4-5	Deep peroneal
Extensor hallucis longus	Extension of the big toe	L5	Deep peroneal
Peroneus longus	Foot eversion	L5	Superficial peroneal
Gastrocnemius/soleus	Foot plantar flexion	S1-2	Tibial
Tibialis posterior	Foot inversion and plantar flexion	L5-S1	Tibial

of effort may be apparent as "give-way weakness," with the patient applying intermittent resistance to the examiner interspersed with moments of nearly complete cessation of effort. Weakness resulting from radiculopathy, focal compressive peripheral neuropathy, diffuse peripheral neuropathy, or myopathy fit specific patterns. A nonphysiologic pattern should raise suspicion for potential psychogenic weakness. The Hoover test is useful to detect psychogenic weakness of the lower extremities. The patient is examined while lying supine in bed and is asked to elevate the paretic leg. The examiner's hand should be placed underneath the contralateral heel. A positive Hoover test result occurs if the patient fails to exert a downward force on the examiner's hand. The Hoover sign is based on the crossed extensor reflex mediated by interneurons in the spinal cord. This reflex was first described by Sherrington and can be demonstrated in decorticate animals.[2]

Reflex Testing

The deep tendon reflexes are mediated by a monosynaptic arc. The afferent limb is provided by sensory fibers, which innervate muscle spindles. These fibers project centrally toward the spinal cord and synapse with alpha motor neurons in the ventral horn. The alpha motor neurons comprise the efferent limb of the reflex arc. It is important to note that normal individuals can have diminished deep tendon reflexes. The Jendrassik maneuver can be used to elicit deep tendon reflexes in this situation. The patient is asked to interlock the fingers of both hands and pull them apart. Jaw clenching can also be used to achieve a similar effect. Lesions of the afferent or efferent limb of this arc can cause diminished or absent deep tendon reflexes. This includes conditions such as peripheral neuropathy and radiculopathy. However, patients with small-fiber neuropathy have preserved deep tendon reflexes because the neural deficit spares large myelinated Ia fibers.

TABLE 18.4 Grading of Deep Tendon Reflexes

Grade 0	Absent
Grade 1+	Hypoactive
Grade 2+	Normal
Grade 3+	Spread of reflex contraction to muscles innervated by the adjacent root level
Grade 4+	Sustained clonus

TABLE 18.5 Nerve Root Innervation of the Deep Tendon Reflexes

Muscle Tendon	Nerve Root Level
Biceps	C5-6
Brachioradialis	C6
Triceps	C7-8
Quadriceps femoris	L3-4
Gastrocnemius/Achilles tendon	S1-2

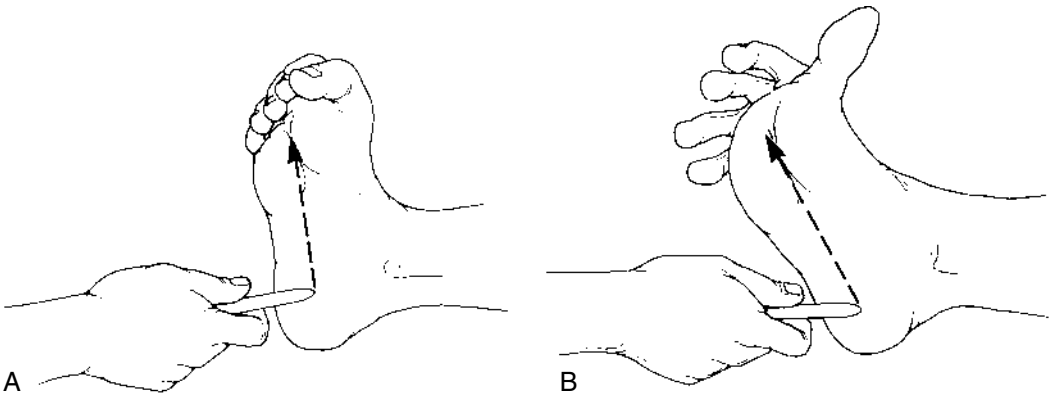
Deep tendon reflexes are best examined with a Queen Square or Troemner hammer while the patient is seated comfortably in the upright position. Table 18.4 explains the grading of deep tendon reflexes. Table 18.5 reviews the important deep tendon reflexes and their corresponding nerve root level.

Upper motor neuron lesions cause hyperreflexia. The Babinski and Hoffman signs may be present in patients with upper motor neuron dysfunction. A subtly positive Hoffman response can be seen in young women and people taking selective serotonin reuptake inhibitor anti-depressants, and in these scenarios may not represent pathology. The Babinski sign is elicited by stroking the lateral aspect of the sole of the foot with a blunt object (e.g. a disposable wooden spatula). A positive sign is indicated by the extension of the great toe (Fig. 18.1). Care should be taken to not stimulate the more medial aspect of the sole, which will evoke a withdrawal response. Hoffman's sign is elicited by briskly flicking the dorsal or volar aspect of the distal phalanx of the middle finger. Reflex flexion of the index finger and thumb constitutes a positive response.[5]

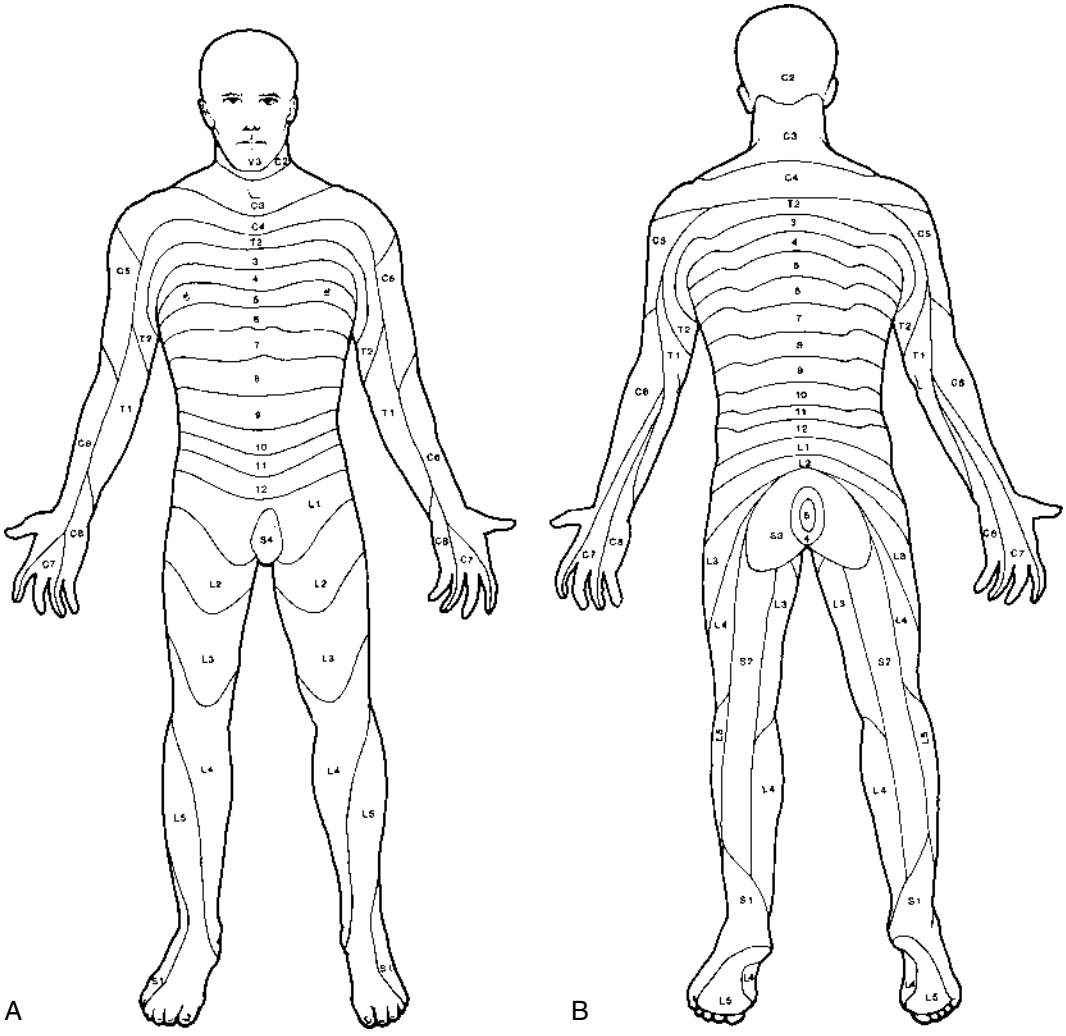
Sensation

A sensory examination should include the modalities of temperature, pinprick, proprioception, and vibration. Pinprick and temperature are mediated by Aδ and C small fibers and are transmitted in the spinal cord by the lateral spinothalamic tract. Proprioception and vibration are mediated by Aβ large fibers and are carried by the dorsal columns in the spinal cord.

Pinprick testing can be performed with a clean disposable safety pin. A distal-to-proximal pattern of testing is useful in evaluating patients with length-dependent peripheral neuropathy. In patients with nerve root pathology, testing in a dermatomal



• **Figure 18.1** Babinski test. **A**, Normal. **B**, Abnormal.



• **Figure** 18.2 Anterior (**A**) and posterior (**B**) dermatomes of the body. (From Baker AB, Baker LH. *Clinical neurology*. Vol 1. New York: Harper & Row, 1983.)

pattern is recommended (Fig. 18.2). Temperature sensation can be assessed rapidly using the cold metal portion of a tuning fork and warm water in a test tube. The format for testing is identical to that for pinprick testing.

Patients with neuropathic pain (pain as a consequence of a lesion of the somatosensory system) may demonstrate several key findings during the neurologic examination, including allodynia, hyperalgesia, hypoalgesia, wind up, and hyperpathia. Allodynia is defined as experiencing pain when a stimulus that normally does not generate pain is applied. To test for allodynia, a stimulus that normally does not generate pain, such as light touch, is applied, and if present, the patient will experience pain. Hyperalgesia is defined by increased sensitivity and response to painful stimuli beyond what is expected normally. Testing for hyperalgesia should

be done through sensory testing methods that generate mild amounts of pain using a sharp object such as a clean disposable safety pin. While a mildly painful reaction to these stimuli is normal, a patient with hyperalgesia will indicate increased pain in the affected area.

Hypoalgesia is decreased sensitivity and response to painful stimuli. Wind up is the increase in pain intensity over time when a given stimulus is delivered repeatedly above a critical rate.

Hyperpathia is characterized by an exaggerated and often delayed pain response to stimuli.

Proprioception is assessed at individual synovial joints. The most sensitive test for proprioception involves the interphalangeal joint of the big toe. The toe is grasped at its lateral margins between the thumb and index finger of the examiner's hand. The big toe is then abducted from the remaining toes and moved superiorly and inferiorly in increments of 5 degrees while the patient's eyes are closed. The patient is then asked to identify whether the toe is being moved up or down. If proprioception is impaired at the toe, the same test can be repeated at the ankle, knee, and distal interphalangeal joint of the index finger.

Vibration sense is usually examined by placing a vibrating 128 Hz tuning fork over a distal bony prominence. The dorsal surface of the interphalangeal joint of the big toe, medial malleolus, tibial tuberosity, and patella are the relevant lower extremity landmarks. The distal phalanx of the index finger, distal end of the radius, and olecranon process of the ulna are the important sites for testing vibration in the upper extremity. Recently, the Rydel-Seiffer 64 Hz quantitative tuning fork has been shown to have a better correlation than the traditional 128 Hz tuning fork with sural nerve sensory nerve action potential and ankle reflex results.[6]

Coordination

The cerebellar function can be divided into midline/vermal and hemispheric functions. The vermis controls axial coordination and balance, whereas the hemispheres coordinate the limbs. Vermal function is assessed by observation of gait and standing balance. The hemispheric function is assessed with the finger-to-nose and heel-to-shin tests. Other tests include rapidly alternating movements (e.g. sequential hand pronation and supination) and examination for motor tone, which is reduced in patients with cerebellar disease. Chronic alcohol abuse and long-term use of medications such as phenytoin can cause acquired cerebellar degeneration.[5,7,8,9]

Musculoskeletal Examination

The musculoskeletal examination serves to evaluate the integrated functioning of bones, joints, supporting ligaments, muscle, and tendon. Information from the examination can be used to assess complicating sources of pain in various structures, including the skin, subcutaneous tissue, peripheral nerves in entrapment zones, and viscera. The format of the musculoskeletal examination follows the steps of inspection, palpation, range of motion, and special tests. The components tested are the spine (cervical, thoracic, lumbar), upper and lower trunk girdles, and their respective extremities and joints.

Spinal Examination

Inspection of the cervical and thoracolumbar spine provides information on posture and alignment. Abnormal kyphosis, lordosis, or scoliosis should be noted when the patient is not aware of being formally examined (i.e. when the patient is sitting or standing upon providing history). Reduction of the scoliosis angles may be observed when the patient flexes the spine, which may also change the treatment. Percussion of the spinous processes can reveal localized tenderness, which is seen in patients with conditions such as vertebral compression fractures, epidural tumors, or abscesses. The spinous process should have a similar inter-spinous process distance in the patient who does not have appreciable kyphosis or lordosis; an increase in inter-spinous process distance across 1-2 may be indicative of a vertebral compression fracture with appreciable height loss (>50%). Tenderness in the paraspinous regions can be seen in patients with facet arthropathy and myofascial pain syndrome. Special tests, such as facet loading, may distinguish the two, but it is not uncommon for patients to have both pathologies. The normal range of motion of the cervical spine is 60 degrees of forward flexion, 75 degrees of extension, 45 degrees of lateral flexion, and 80 degrees of lateral rotation. Range of motion testing should be performed with the patient in both the supine and sitting positions. Improvement in range of motion in the supine position suggests that posterior muscle spasm is responsible for restricting cervical mobility. Anterior cervical spasms/range of motion may worsen when a patient is placed supine. However, there is no positional improvement in cervical range of motion with cervical arthropathy.

A positive abduction tension release sign is highly specific in determining whether the shoulder pain is secondary to C5-6 root compression or shoulder pathology. The test is performed by asking the patient to abduct the affected arm such that the forearm is placed in a resting position on top of the patient's head. With shoulder pathology, attempts to achieve this position will cause pain. In patients with C5-6 root compression, this test position will commonly result in a marked reduction in pain in the shoulder and medial scapular (rhomboid) region. The Spurling maneuver is highly specific for confirming the diagnosis of cervical radiculopathy. The patient is asked to perform simultaneous lateral flexion and extension of the neck toward the symptomatic side. Provocation of the ipsilateral neck and arm pain constitutes a positive Spurling sign.[10,11]

The normal thoracolumbar spine range of motion is 90 degrees of forward flexion, 30 degrees of back extension, 25 degrees of lateral flexion, and 60 degrees of lateral rotation. Pain provoked by simultaneous lumbar extension and lateral rotation is suggestive of ipsilateral facet arthropathy because these maneuvers result in zygapophyseal joint loading. Pain provoked by forward flexion may suggest with a discogenic or vertebral body source of pain because flexion causes axial loading. However, lumbar flexion can also induce pain of the pathologic sacroiliac ligaments and facet capsules. Therefore the practitioner must use ROM in the context of other examinations for a more targeted diagnosis. Lumbar discogenic pain symptomatology is controversial but commonly agreed to be restricted to the axial spine and can be associated with intolerance of the sitting position and pain provoked by coughing, sneezing, and Valsalva maneuvers.

Myofascial Examination

Myofascial pain is manifested by the presence of tender palpable bands of muscle called trigger points. Active myofascial trigger points are associated with complaints of spontaneous pain and restricted range of motion. Latent trigger points are tender and palpable on direct examination, but they do not produce spontaneous pain.

A myofascial examination should start with an assessment of posture and joint function to determine any underlying cause of the regional myofascial pain. Myofascial trigger points can be identified by gentle palpation in the direction of muscle fibers. Trigger points can be felt as a ropelike region of nodularity. Trigger points also are exquisitely tender, and palpation produces local and referred pain. The referral pain pattern may mimic a radicular or peripheral nerve distribution. Commonly affected muscles include the trapezius, gluteus, and cervical and lumbar paraspinous musculature, but many others may be affected as well. Tender points are painful to palpation but do not radiate.[12]

Examination of the Extremities

Inspection and, when indicated, measurement of the extremities may reveal discrepancies in limb length, deformities, and alterations in muscle bulk. Multiple upper extremity joint range of motion can be demonstrated by asking the patient to perform specific tasks such as raising the hands above the head. Gross shoulder, elbow, wrist, and finger movement can be assessed using this compound maneuver. If the patient can place both palms on the back of the head and dorsum of the hand behind at the mid lumbar region without significant difficulty, it can be reasonably concluded that the patient can perform most basic daily activities of living. The lower extremities can be assessed during the evaluation of gait. The pattern of gait abnormality can direct the clinician to the underlying cause of dysfunction, such as foot drop, leg length discrepancy, or hip or knee pain.[10,11,13,14]

Upper Extremity

Shoulder Joint Examination

The inspection should evaluate the symmetry, bulk of the deltoid muscles, and posture. Palpation of the shoulder joint should include the sternoclavicular joint, clavicle, acromioclavicular joint, glenohumeral joint, and the scapular spine and scapulothoracic articulation. The normal range of motion for the shoulder joint is 180 degrees of flexion and extension in the sagittal plane, 180 degrees of abduction and adduction in the frontal plane, 90 degrees of external rotation, and 40 degrees of internal rotation. Common chronic causes of shoulder pain include glenohumeral arthritis, acromioclavicular arthritis, subacromial or subdeltoid bursitis, rotator cuff, and bicipital tendonitis, calcific tendonitis, and adhesive capsulitis. Traumatic acute and subacute shoulder pain may be because of dislocations, labral lesions, commonly noted as superior labrum anterior to posterior lesions. Various special tests are used to diagnose these conditions. The tests most commonly used in clinical practice are described below.

Pain on shoulder abduction (arm 90 degrees from torso) and internal rotation are seen with impingement syndrome. The etiology involves the entrapment of supraspinatus between the humeral head and the coracoacromial arch. Subacromial bursitis, and supraspinatus strains, can result as a consequence of chronic impingement syndrome. In case of a complete supraspinatus tear, the patient will be unable to hold the arm in an abducted position after passive abduction to 90 degrees. Horizontal abduction in the plane of the scapula (45 degrees from the torso) with the thumb turned down—the empty can test—is a sensitive test for rotator cuff pathology. It is important to note that all examinations with shoulder abduction should be done with the practitioner placing their hand on the top of the shoulder to prevent scapular rotation, which can artificially increase the degree of abduction. Untreated tears of the rotator cuff tendons result in disuse atrophy of the scapular muscles, and a dip seen in the supraspinatus fossa can suggest a chronic tear. The drop arm test is used to diagnose complete rotator cuff tears. The patient's arm is passively abducted to 90 degrees and then released. Failure to maintain shoulder abduction suggests a complete rotator cuff tear. The diagnosis can be investigated further with magnetic resonance imaging. Complete tears in atraumatic settings are often because of chronic supraspinatus tendonitis.

Adhesive Capsulitis

Frozen shoulder, or adhesive capsulitis, is characterized by a diminished range of motion at the scapulothoracic and glenohumeral joints. There is progressive fibrosis of the shoulder joint capsule, which disrupts normal shoulder mobility and scapulothoracic rhythm. Normally, the shoulder joint can be abducted to 180 degrees. Scapulothoracic motion begins at 90 degrees of shoulder abduction, and there is a 2:1 ratio of glenohumeral to scapulothoracic motion. Adhesive capsulitis results in gradual loss of range of motion, with little to no shoulder movement present in advanced cases. Adhesive capsulitis is diagnosed when extension and abduction in the affected shoulder is less than 50% of the non-affected shoulder.

Elbow Joint

Inspection of the elbow joint includes assessment of humeral and radial-ulnar symmetry. The carrying angle between the arm and forearm is measured with the patient standing and the arms at the side and facing anteriorly. The normal carrying angle is 10 to 15 degrees of valgus for men and up to 18 degrees for women. Readily palpable landmarks of the elbow joint include the olecranon process and the medial and lateral epicondyles. Normal range of motion at the elbow starting from the anatomic position is 0 degrees of extension to 150 degrees of flexion at the humeroulnar joint and 170 degrees of pronation and supination at the radioulnar joint.

Lateral Epicondylitis

Overuse of the forearm extensor muscles results in inflammation of the common extensor tendon insertion at the lateral epicondyle. Patients report constant elbow pain that is worse with resisted or weighted wrist extension. Pain over the lateral epicondyle confirms the diagnosis of lateral epicondylitis. In severe cases, a passive extension of the wrist or mild palpation of the lateral epicondyle may also replicate pain in the extensor mass.

Medial Epicondylitis

This condition is similar to lateral epicondylitis and results from overuse of the forearm flexor muscles. Pain is experienced over the medial epicondyle and can be reproduced by resisted or weighted resisted wrist flexion. Severe cases can be reproduced with mild palpation of the medial epicondyle.

Wrist Joint

Inspection plus palpation of the wrist joint is used to evaluate joint symmetry. The range of motion is 60 degrees of extension, 70 degrees of flexion, 20 degrees of abduction, and 30 degrees of adduction. The most common clinically encountered specific wrist joint pain disorder is carpal tunnel syndrome. This entity results from entrapment of the median nerve at the wrist, which causes numbness of the #1-3 digits. In more severe cases, symptoms present with pain. Thumb

weakness results from very significant median nerve entrapment; thumb abduction is the most compromised movement because of abductor pollicis brevis wasting. A diagnosis of carpal tunnel syndrome is supported by the presence of the Tinel and Phalen signs. In the Tinel sign, percussion of the proximal volar wrist crease produces paresthesia in the thumb and index and middle fingers of the symptomatic hand. To elicit the Phalen sign, the patient is asked to flex both wrists and place the dorsum of each hand against one another for 1 min, mechanically compromising the carpal tunnel space. An already irritated nerve will respond by causing painful numbness when affected this way. Reproduction of sensory dysesthesias in a median nerve distribution is consistent with a positive Phalen test. Caution must be used when interpreting the results of these tests because neither test has a high degree of specificity or sensitivity. The "gold standard" test for the evaluation of suspected carpal tunnel syndrome is formal electrodiagnostic testing.

Evaluation of the Digits

The digits are inspected to evaluate for symmetry and the presence of any deformities. Heberden's nodes at the distal interphalangeal joints and Bouchard's nodes at the proximal interphalangeal joints can be seen in patients with osteoarthritis. Range of motion can be assessed by asking patients to open and close their fist. The normal range of motion in the sagittal plane is 90 degrees at the metacarpophalangeal joints, 120 degrees at the proximal interphalangeal joints, and 70 degrees at the distal interphalangeal joints. The first metacarpophalangeal joint has 50 degrees of motion in abduction, 50 degrees in adduction, and 35 degrees in opposition. Metacarpal phalangeal swelling with or without ulnar deviation of digits may suggest rheumatoid arthritis; this finding can direct diagnosis and treatment strategies with patients who have neck, hip, or knee pain, as these symptoms are commonly associated with the condition.

Evaluation of the Hip Joint

Inspection of the hip joint should pay attention to symmetry, muscle bulk, and surgical scars. The normal range of motion at the hip is 100 degrees of flexion, 30 degrees of extension, 20 degrees of adduction, and 40 degrees of abduction. With the hip joint in a flexed position, the range of motion is 45 degrees for internal rotation and 40 degrees for external rotation. Hip pain may result from the pathology of the acetabulum, femoral neck or head, periosteum, or joint capsule. It may also result from abnormalities in a surrounding structure such as the bursae or may be referred from the lumbar spine or sacroiliac joint. Hip joint pathology classically presents as groin pain and anteromedial thigh pain, especially when crossing the affected thigh over the non-affected thigh in a seated position. Upper lateral thigh pain over the greater trochanter region, when palpated, can be because of greater trochanteric bursitis or gluteus medius tendinopathy. Practitioners must consider that hip pain complaints because of knee pathology can also cause anteromedial thigh pain. Additionally, lateral thigh pain can be seen as a "typically atypical" referral pain pattern of L5 radiculopathy, with pain involving the L5-innervated gluteal muscles.

As one can see, pain referral patterns alone are often insufficient to diagnose the etiology of hip pain, and an appropriate imaging evaluation is helpful in this regard.

Trochanteric Bursitis

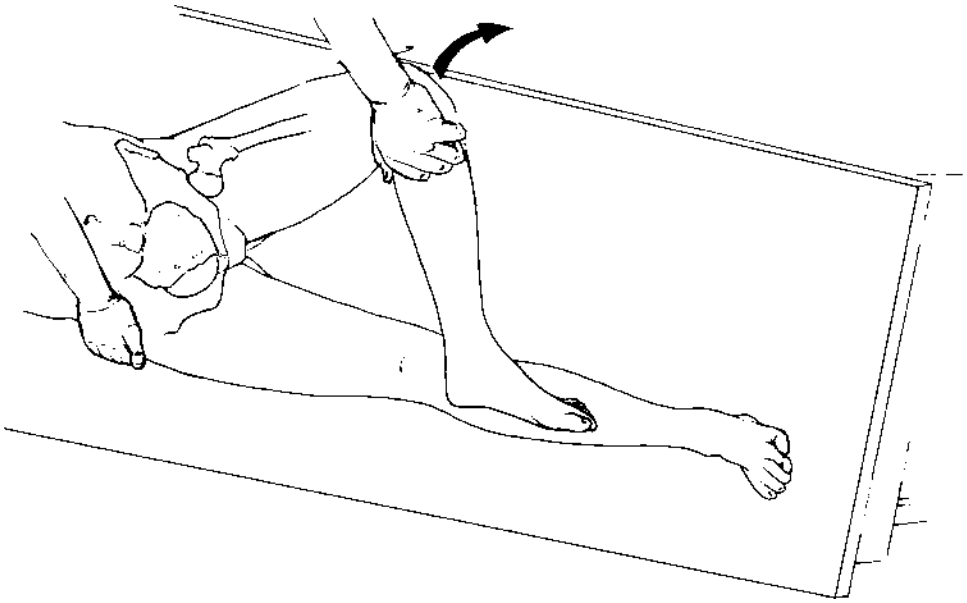
Patients report a deep, dull, aching pain with radiation to the lateral hip region. The pain is worse when the patient lies on the affected side. Serious cases can cause difficulty with walking and sit to stand transfers. Inflammation primarily involves the trochanteric bursa, which lies between the gluteus maximus and gluteus medius tendons. The diagnosis is supported by the tenderness with palpation over the greater trochanter and pain on hip extension and resisted hip abduction.

Patrick's Test

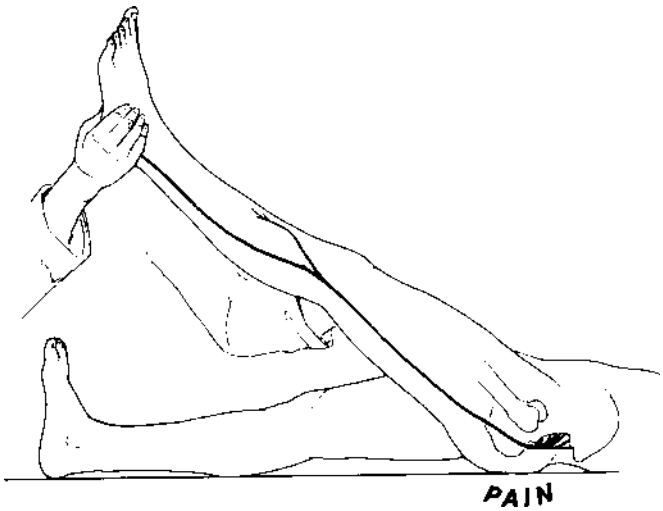
Patrick's test evaluates hip and sacroiliac joint pathology. With the patient in the supine position, the examiner passively flexes, abducts, and externally rotates the hip. Pain in the groin suggests hip joint pathology, whereas sacroiliac pain indicates dysfunction of the sacroiliac joint (Fig. 18.3).

Straight-Leg Raise Test

The examiner passively elevates one leg with the patient in the supine position by holding it at the ankle. The hip is flexed to an angle of 70 to 90 degrees, with the knee extended (Fig. 18.4).



• **Figure 18.3** The Patrick or flexion abduction external (FABER) test.



• **Figure 18.4** Straight-leg raise test (Lasègue's sign).

A positive straight-leg raise test produces pain starting at the hip with radiation down to the ankle. Pain that remains localized to the posterior thigh region is caused by tension on the hamstrings. A crossed straight-leg raise sign is present if testing of the uninvolved leg produces contralateral symptoms. Both the straight and crossed straight-leg raise tests place the lumbosacral nerve roots under tension, and a positive test is suggestive of lumbosacral radiculopathy. Straight-leg testing can also be performed with the patient in the seated position. In this setting, the patient is asked to extend the knee. This stretches the lumbosacral roots as the hip is flexed to 90 degrees when the patient is seated. If augmentation is needed, the patient can be asked to dorsiflex the foot, or the examiner can passively dorsiflex the patient's foot if needed.

Evaluation of the Knee

Inspection should assess symmetry, the position of the patella, surgical scars, and the bulk of the surrounding musculature, including the quadriceps femoris muscle. The patient should be visualized when they are performing stand to sit and sit to stand transfer, as an extended knee may suggest knee pathology. Particular attention should be placed on inspection of the vastus medialis because this muscle atrophies rapidly when patients have chronic knee pain and reflex inhibition of quadriceps function. Varus deformity (knees bowed outward, away from the midline) of the knee results from medial compartment loss, whereas valgus deformity (knees bowed inward, toward the midline) is caused by lateral compartment loss. Palpation should include the surrounding bursae (i.e. the pes anserinus and prepatellar bursae) because these are common sources of pain. The normal range of motion at the knee joint is 150 degrees in the sagittal plane.

Special Tests

Drawer Sign

With the patient's knee in the flexed position and the foot anchored to stabilize the lower part of the leg, the examiner draws the tibia anteriorly. Movement of the tibia in the forward direction constitutes a positive anterior drawer sign and suggests a tear of the anterior cruciate ligament. Similarly, if the tibia moves posteriorly when pulled backward, this is a positive posterior drawer sign and is caused by a torn posterior cruciate ligament (Fig. 18.5).

Patellar Femoral Grinding Test

Knee pain on rising to a standing position or while climbing stairs can occur with chondromalacia patellae. With the patient's knee extended, the examiner exerts downward pressure on the patella into the femoral groove. Patients with chondromalacia patellae will complain of pain with this maneuver.

Apley's Compression or Grinding Test

This test is used to evaluate for medial and lateral meniscal tears. With the patient in the prone position, the knee is flexed to 90 degrees, a downward force is applied to the heel, and the tibia is rotated medially and laterally against the femur (Fig. 18.6). Pain provoked in the medial or lateral aspect of the knee indicates a tear in the respective collateral ligament.

Evaluation of the Ankle

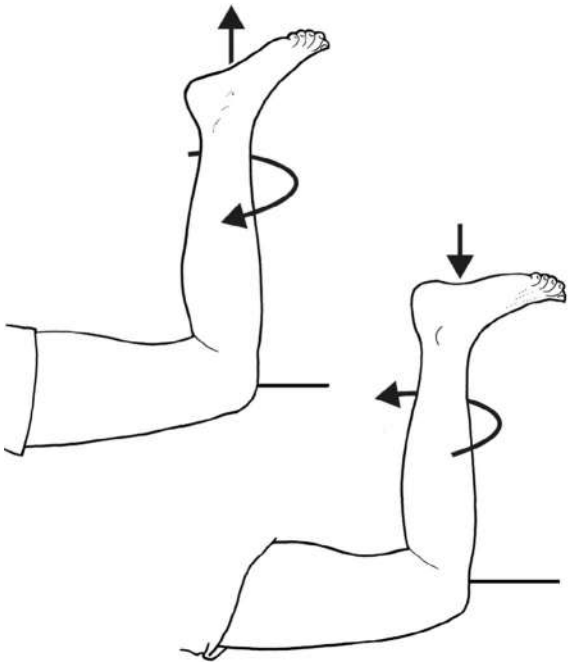
Inspection should include evaluation of bony landmarks, symmetry, and edema. The normal range of motion of the ankle is 20 degrees of dorsiflexion and 40 degrees of plantar flexion through the tibiotalar joint. The 30 degrees of inversion and 15 degrees of eversion noted at the ankle result from subtalar motion, not tibiotalar motion.

Pain and excessive motion on pulling the ankle joint anteriorly indicate a tear in the anterior talofibular ligament, whereas similar findings on forced inversion occur with tears of the calcaneofibular ligament. The posterior talofibular ligament is usually damaged only in patients with a significant history of preceding trauma.

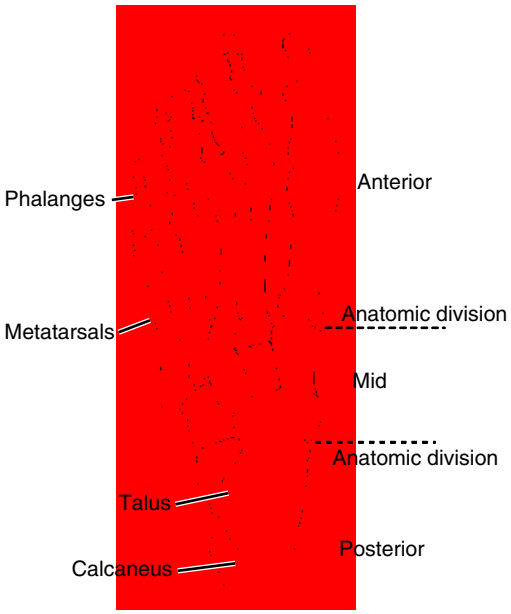
Evaluation of the Foot

Functional assessment of the foot is targeted toward its anterior, middle, and posterior segments. The anterior segment consists of the five metatarsal and 14 phalangeal bones; the middle segment includes the navicular, cuboid, and three cuneiform bones; and the posterior segment includes the talus and calcaneus (Fig. 18.7).

• **Figure 18.5** Drawer sign test for the cruciate ligaments. The standard drawer sign test for the cruciate ligaments immobilizes the foot and stresses the lower part of the leg on the femur. Pulling the leg forward tests the anterior cruciate ligament, whereas posterior pressure tests the posterior cruciate ligament. (Redrawn from Calliet R. *Knee pain* and *disability*. 3rd ed. Philadelphia: FA Davis; 1992, pp. 1–69.)



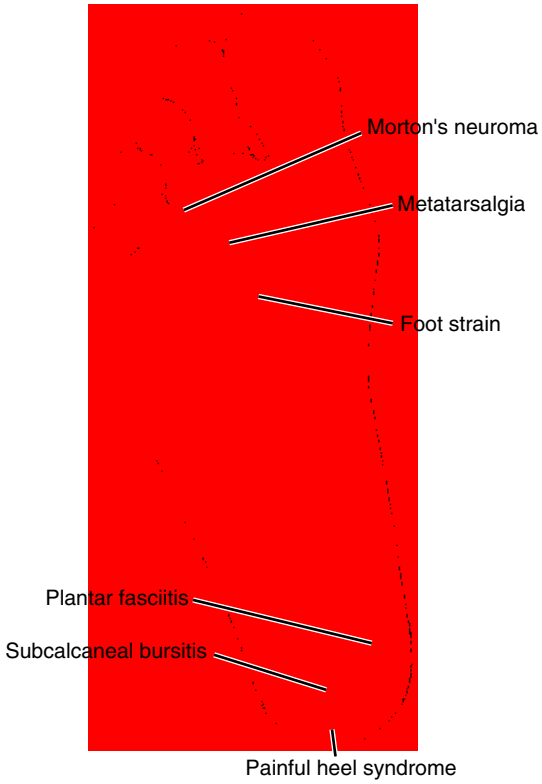
• **Figure 18.6** Examination of ligament injury, including the meniscus (Apley's test). The Apley test checks the integrity of the knee ligamentous structures and the menisci. It is performed in two aspects. *Left*, With the patient prone and the knee flexed to a right angle, downward pressure is applied to the lower part of the leg. The leg is then rotated to test the menisci. This maneuver compresses the menisci between the femoral condyles and the tibial plateau, as in the McMurray test. With the lower part of the leg internally rotated, the medial meniscus is tested. Grating, crepitation, limitation, and pain imply meniscal damage. From the same position, the leg is elevated (*right*), which places traction on the ligaments. Excessive motion, deduced by comparison to the contralateral side, indicates laxity or injury to the knee ligaments and capsule. (Redrawn from Calliet R. *Knee pain and disability*. 3rd ed. Philadelphia: FA Davis; 1992, pp. 1–69.)



• **Figure 18.7** Anatomy of the foot with functional segmentation. (Redrawn from Abrams B, Glaser L. Painful conditions of the foot and ankle: evaluation and treatment. *Pain Diagn* 1997;7:351–363.)

The posterior segment of the foot transmits body weight to the ground. The middle segment provides flexibility and the ability to adapt gait to uneven surfaces. The anterior segment acts as a fulcrum to provide forward thrust during ambulation. The impact of the foot against the ground is cushioned by its longitudinal and transverse arches.

Foot pain is a common symptom in patients (Fig. 18.8). The more common pain syndromes that are diagnosed by physical examination are described in the following sections.



• **Figure. 18.8** Location of common painful conditions involving the plantar surface of the foot. (Redrawn from Abrams B, Glaser L. Painful conditions of the foot and ankle: evaluation and treatment. *Pain Diagn* 1997;7:351–363.)

Tarsal Tunnel Syndrome

In tarsal tunnel syndrome, the posterior tibial nerve is entrapped beneath the lancinate ligament, posterior to the medial malleolus. Patients complain of pain and paresthesia affecting the toes and sole of the foot. Physical examination may demonstrate atrophy of the intrinsic foot muscles and hypoesthesia of the sole of the foot. Percussion posterior to the medial malleolus can provoke paresthesia in the ipsilateral sole and toes in patients with tarsal tunnel syndrome.

Morton's Neuroma

Morton's neuroma is characterized by pain between the metatarsal bones, usually between the third and fourth toes and less commonly between the second and third toes. The pain is reproducible on palpation of the space between the metatarsal heads. The etiology of Morton's neuroma is not well understood, but it probably represents a form of interdigital neuritis. Interestingly, surgically resected specimens in patients with Morton's neuroma do not show any significant changes in nerve histology when compared with control tissue obtained from cadavers.[15]

Metatarsalgia

Pain in patients with metatarsalgia occurs on weight bearing and is localized to the plantar aspect of the metatarsal heads. The pain occurs maximally over the first metatarsal head and can be reproduced by direct palpation. With foot inversion, weight is shifted to the heads of the second and third metatarsal bones, and repetitive stress can result in pain over these sites. Patients may walk with a characteristic antalgic gait, with the foot being held in the inverted position. This can serve as a useful clue to the diagnosis.

Foot Strain

Foot strain affects the middle segment of the foot. Repetitive patterns of overuse result in elongation of the longitudinal arch and alterations in the normal alignment of the talus and calcaneus. Elongation of the longitudinal arch produces excessive strain on the plantar fascia, medial collateral ligament, and talocalcaneal ligament. Physical findings include flattening and pain on compression of the longitudinal arch.

Plantar Fasciitis

Plantar fasciitis is manifested as plantar foot pain on weight bearing. Patients often have a history of prolonged standing in footwear lacking arch support or on hard surfaces. Inflammation develops at the point of attachment of the plantar fascia to the calcaneus. Calcaneal bone spurs can develop from chronic straining of the plantar fascia. Clinically, tenderness on palpation can be elicited over the anterior portion of the calcaneus with radiation into the plantar fascia. A common finding is pain the first thing in the morning. Patients will frequently note severe plantar foot pain with weight bearing on arising and temporary improvement with weight bearing or after the morning shower.

Painful Heel Syndrome

Painful heel syndrome results from degenerative changes in the weight bearing aspect of the calcaneus and occurs primarily in morbidly obese individuals or those who stand or walk excessively. Pain is often worse in the morning on waking up or after prolonged rest. The examination is significant for tenderness on palpation over the posterior portion of the plantar aspect of the calcaneus.[1]

Tests for a Nonorganic Etiology of Pain

Waddell's Signs

Waddell's tests were intended to evaluate patients with low back pain for functional overlay. There are five signs in total, and the presence of any three of these five signs in a patient was considered suggestive of a nonorganic pain etiology.[16]

- Tenderness to palpation
  - Widespread skin tenderness with a light touch
  - Tenderness on deep palpation that is not restricted to a single anatomic area
- Simulation
  - Low back pain provoked by axial loading pressure on the skull of a standing patient or rotation of the shoulders and pelvis in the same plane resulting in increased low back pain
- Distraction
  - For example, a patient with a positive response to the straight-leg raise test in the supine position but no pain on the same test repeated in the sitting position
- Regional disturbance in function
  - Weakness involving multiple muscle groups in a nonmyotomal distribution with "give-way" effort
  - Sensory loss in a segmental pattern (e.g. glove-stocking rather than a dermatomal distribution) observed in a patient in whom polyneuropathy is not an appropriate diagnosis

Overreaction

Disproportionate facial or verbal behavior (e.g. moaning and grimacing on light touch, posturing, and withdrawing from the examiner)

A higher number of Waddell signs have been associated with failure of interventional treatments for low back pain.[17] However, there are several limitations of Waddell's signs. Widespread superficial tenderness is commonly found in patients with fibromyalgia, and tenderness on deep palpation is part of myofascial pain syndrome. Sensory loss in a glove-stocking distribution is present with peripheral polyneuropathy. Moreover, studies have not found a consistent relationship between the presence of Waddell's signs and subscale scores on the Minnesota Multiphasic Personality Inventory. Data suggest that Waddell's signs cannot accurately distinguish between organic and nonorganic causes of pain.[18,19]

History taking and completing an appropriately thorough physical examination is helpful in elucidating the cause of a patient's pain complaints, especially when conducted and interpreted in the context of appropriate diagnostic studies. The COVID-19 pandemic has brought about with it many challenges to health care and, with respect to the content of this chapter, conducting a history and physical examination of the person in pain. When many patient encounters are being completed through telemedicine, the initial pain consultation is currently often not completed face-face in person but through a phone and/or video link. As this trend may continue for the foreseeable future and perhaps even after the pandemic, a multi-disciplinary group of pain specialists convened and have published a guide to best practices for the multi-disciplinary approach for assessment via telemedicine of the person in pain. In addition, a different group has developed a video guide to the virtual neurologic examination. While each of the assessments described in this chapter may not be able to be completed through telemedicine, many can and must be considered when completing a telemedicine visit with a pain patient in keeping with best practices.[20,21] Whether in person or virtually, the history and physical examination of the person in pain is an essential component of that person's treatment.

Electromyography and Evoked Potentials

ANDREW DUBIN

In almost all instances, tests and/or studies can help elucidate the cause of a problem. However, of equal, and possibly greater, importance is the potential for a test to introduce data that clouds the picture and adds complicating factors that can result in a delay in diagnosis or in arriving at the wrong conclusions.

In the evaluation of a patient with pain, particular caution must be taken to guard against the thought process of "if the test is abnormal, that must be the cause of the problem."

Electrodiagnostic medicine (EDX) is potentially a powerful tool that allows for the objective quantification of the function of the peripheral nervous system. However, in all instances, the data must be interpreted within the context of the patient, and ideally, the test should be tailored to address questions and concerns that arose from the detailed history and physical exam that preceded the EDX study.

The question of the utility of EDX in the evaluation of a patient with pain, and more importantly, the limitations and potential pitfalls must always be first and foremost in the mind of the EDX physician and referring physician when setting up, performing, and interpreting the data.

Understanding the role of EDX in evaluating the pain patient is critical to avoid the over and under interpretation of the data. In all instances, the successful evaluation and treatment of a patient lie in the blending of the history and physical with appropriate data utilization.

Electrodiagnosis is a broad term that includes multiple techniques. This chapter will focus on needle electrode examination (NEE) and motor and sensory nerve conduction studies (NCSs), including late responses. Needle electromyography (EMG) and standard motor and sensory nerve conduction techniques, including in limited scenarios the use of late responses, can be useful adjuncts to the physical examination of patients in pain, with the understanding that the history and objective findings on the physical exam drive the electrodiagnostic examination (EDX) investigation, as opposed to the pitfall of attempting to retrofit the EDX data to the patient.

Conditions in which EDX may be of use include painful peripheral neuropathies, entrapment neuropathies, traumatic nerve injuries, radiculopathies, lumbar spinal stenosis, arachnoiditis, and painful myopathies.

More recently, there has been an increased reliance on anatomic measures such as intradermal nerve biopsy for small fiber neuropathy and magnetic resonance imaging for larger neural structures. Unfortunately, this "anatomic" approach is a snapshot in time and cannot fully delineate if the process is acute versus chronic nor assist in delineating the relapsing/remitting nature of many chronic pain disorders. Additionally, the "anatomic" approach fails to recognize the inherently complex nature of pain, a subjective experience with a myriad of modifiers that can only be correlated with the clinical picture.

The problems inherent in applying electrodiagnostic techniques to diagnose and manage pain are no different from those encountered in history taking, physical examination, radiologic evaluation, and therapeutic diagnostic testing (e.g. nerve blocks). Pain is a subjective experience, often without an objective, gold standard test. As such, the final diagnosis of the probable cause and presumptive treatment of a pain syndrome is a clinical one that can be supported only by relevant data, including findings on EDX.

The standardization of EDX techniques and robust data on normal individuals allows for the objective electrophysiologic assessment of the peripheral nervous system to gain an overall understanding of the distribution of abnormalities, if present, or relative normalcy, if not. The distribution of abnormalities may correlate strongly with the cause of a disease process causing pain or can be an incidental finding of unclear significance. The ability to distinguish between these two scenarios rests in the correlation of EDX data to symptoms. Hence the physical exam findings and historical data should drive the EDX study. EDX testing should not be undertaken to address the question of "let us see what could be wrong?"

Questions that can be posed and potentially answered through using electrodiagnostic techniques include some of the following:

Is a disease of large myelinated nerve fibers present?

What is its pattern of distribution? Is it mononeuropathy, polyneuropathy, or mononeuritis multiplex?

Does it equally affect motor and sensory fibers, or does one dominate?

Does the distribution of abnormalities suggest involvement at the nerve root, plexus, or more distal nerve level?

If there is a disease process involving a single (or multiple) nerve, such as injury or compression, is it improving, worsening, or static? Understand that this may require serial studies over time.

Is the nerve involved motor, sensory, or mixed?

Is a disease of muscles present?

Is the process one of nerve, muscle, or both?

Are small fibers selectively involved, or is this mainly a large-fiber disorder, or are both involved? (Understand that patients with isolated small fiber neuropathy will have normal EDX findings on needle EMG and NCSs. In these instances, skin biopsy assessment for intra-epidermal nerve fiber density and sweat gland analysis may aid in the diagnosis).

Is there autonomic and somatic involvement?

Are more proximal structures rather than distal ones involved?
Is the central nervous system involved? Standard EDX testing in this scenario is utilized to rule out peripheral nervous system involvement.
Is the process acute, chronic, acute on chronic, or old?

EDX testing satisfies two fundamental steps in the assessment of a neuropathic pain syndrome before any attempt at therapy: (1) rigorously establishing the presence or absence of a peripheral nervous system lesion and (2) determining the relevance of an established peripheral neuropathic lesion or myopathic process to the subjective clinical complaint. In addition, with the advent of new treatments, including enzyme replacement and the potential insertion of genetic material into cells, early diagnosis and the ability to monitor treatment outcomes objectively become of great importance. Recent enzyme replacement therapy for Pompe's disease is an example of the potential diagnostic, therapeutic, and prognostic importance of electrodiagnosis.[1]

The parent organization of electrodiagnosis is the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM), which has promulgated a Recommended Policy for Electrodiagnostic Medicine Position Statement.[2] This document seeks to lay out the scope of electrodiagnosis by using consensus expert opinion to ensure adequate examination while attempting to conserve scarce resources by listing the indications for testing and the maximum number of studies per diagnosis in 90% of cases. Since there has been some abuse of the number of studies done on patients and since many pain specialists are not familiar with the techniques of electrodiagnosis, this serves as an important source of information on the appropriate measures to be used when these diagnostic methods are being considered.

Electromyography

EDX is a method of testing both the anatomic and physiologic integrity of lower motor neuron structures (anterior horn cells, nerve roots, plexuses, peripheral nerves, neuromuscular junction, and muscles), sensory components, and some spinal and brainstem reflex pathways.[3–5] The term electromyography previously caused considerable confusion because strictly speaking, it was NEE of muscle function but often was expanded to include nerve conduction velocity (NCV) or NCSs and other tests. However, its common usage has come to mean needle EMG, determination of NCV, and less frequently, testing such as the H-reflex and F-response, cranial nerve reflexes (e.g. the blink reflex), and studies of the neuromuscular junction. The all-inclusive term EDX (electrodiagnostic examination) is used here to avoid confusion among tests.

A puzzling dichotomy regarding pain and electrodiagnostic testing in the medical literature is well documented. The reason for the paucity of references appears to be at least in part the attitudes of pain specialists themselves, who point out that "large caliber afferent fibers are physiologically unrelated to pain," a submodality mediated by small caliber fibers. Additionally, the test is unable to explore the basis for positive sensory phenomena generated by dysfunction even of large caliber afferent channels.

Electrical Testing of Nerves and Muscles

All electrodiagnostic equipment can fundamentally be thought of as containing the following componentry:

Electrodes: Electrodes allow for the recording of an evoked signal. The recording device may be surface or needle electrodes. The size (area) of the recording surface directly impacts the amplitude and duration characteristics of the recorded response. As such, the consistency of electrode size is paramount when comparing studies across time and between examiners and institutions.[3]

Stimulator: Stimulators can be constant voltage or constant amperage; typically, they are now constant current. An understanding of Ohms law (V=IR) quickly allows one to appreciate that If R (resistance) varies (skin impedance, sweat) over time, holding I (current) constant allows for the maintenance of a constant and stable electrical field (load despite variations in resistance). This results in improved tolerance for the test with less pain (stable intensity) and more stable recordings over time.[4–7]

High-gain differential amplifier: Differential amplifiers have both high frequency (low pass) and low frequency (high pass) characteristics. The frequencies that pass between the filters is the band path and is adjustable for environmental situations. Changing the amplifiers will impact on amplitude, duration, and latency of the recorded responses. It is critical to appreciate this phenomenon to avoid over or under interpretation of data accumulated in electrically challenging environments such as ICUs.[4–7]

Recording display or central processing device with A to D conversion capability: A to D conversion refers to the mathematical manipulation of the analog signal into a stable static waveform "seen" on the oscilloscope screen. The waveform "seen" is the digital representation of the analog wave resulting from multiple digitized (x, y coordinate) points.[6,7]

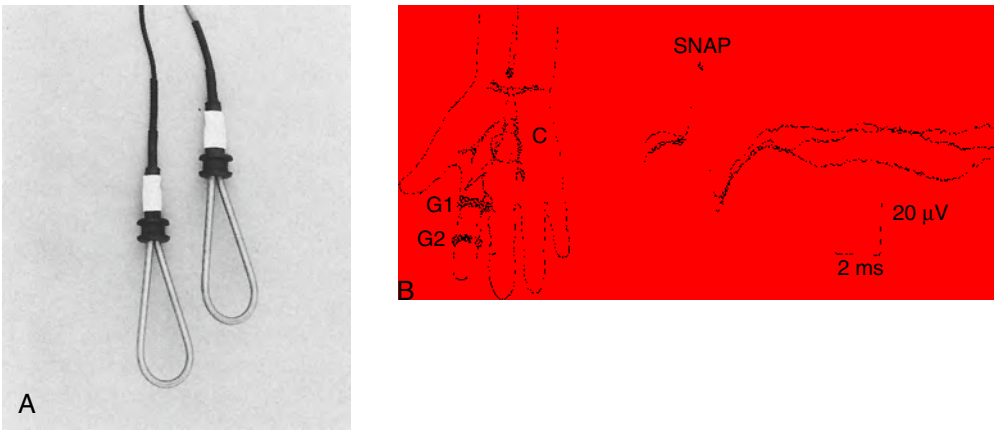
The EMG apparatus amplifies and displays biologic information derived from either surface or needle electrodes. Electrical information may be recorded from muscles, nerves, or other nervous system structures and is displayed on an oscilloscope. Besides the visual display on the oscilloscope, a permanent recording may be made, audio amplification may allow it to be heard over a loudspeaker, and analog-digital analysis of signals may be used. Nerves are electrically stimulated to measure conduction.[6,7]

For NCSs, skin surface electrodes are generally used for recording compound muscle or nerve action potentials. Rarely, needle electrodes are used.

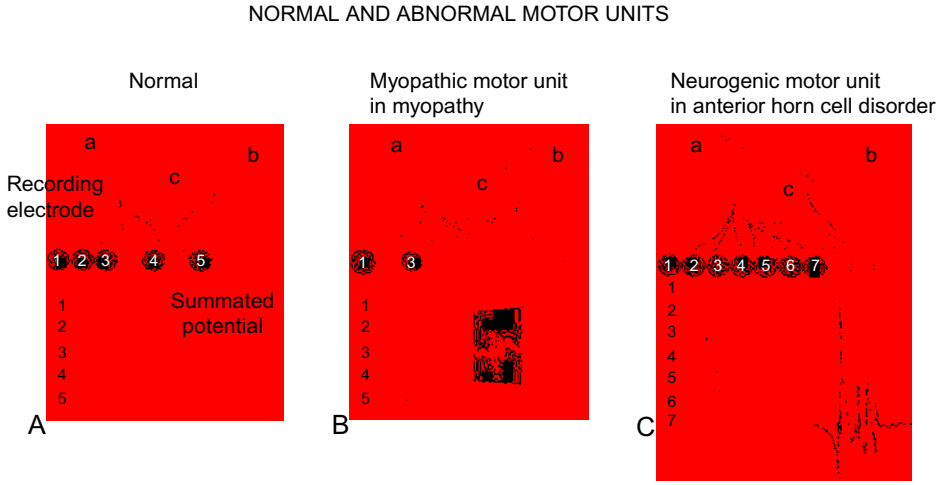
For needle EMG, needle electrodes are used. They are typically monopolar or concentric. Each has unique characteristics and does impact on amplitude, duration, and phase complexity. Understanding these factors is important when comparing studies conducted by different examiners and different labs.[3,6,7]

For sensory testing, ring electrodes, self-adhering surface electrodes, and disc electrodes are used for measurement (Fig. 19.1). Modern EMG equipment is manufactured by numerous companies and is generally standardized to allow reliable and reproducible testing by different laboratories, but normative data, including data for special populations such as geriatric, pediatric, diabetic, and even active workers, may differ among laboratories and require standardization by each laboratory.[5–7]

NEE is an invasive procedure, but complications are rare. However, patients should be apprised of them. The most common is transient muscle soreness. Aseptic precautions should be observed. Safeguards for testing include extra care with patients who are taking warfarin or other anticoagulants or who have hemophilia or other blood dyscrasias, but since most muscles tested are superficial, they can easily be compressed, and the bleeding abated. Severe thrombocytopenia is a relative contraindication and should be considered carefully. Patients positive for human immunodeficiency virus (HIV) represent a transmission risk, but the use of disposable needles (which should be universal) protects against this hazard. One should carefully consider persons with a cardiac pacemaker or transcutaneous stimulator when doing stimulation



• **Figure 19.1** **A**, Commonly used ring electrodes for measurement of median and ulnar sensory nerve conduction studies. **B,** Placement of electrodes for median sensory nerve conduction studies and sensory nerve action potentials obtained on stimulation of the median nerve at the wrist. **C,** Ground electrode; G1, recording electrode; G2, reference electrode. (**A,** Courtesy of Oxford Instruments Medical, Inc., Hawthorne, NY.)



• **Figure 19.2** **A,** Schematic illustration of three normal motor units, "a," "b," and "c." *Note:* Muscle fibers of different motor units are normally intermingled. Below the motor units are action potentials of five individual muscle fibers of a motor unit and its summated motor unit potential. **B,** Myopathic changes in motor unit "a." Of the original five muscle fibers, three have undergone degeneration, thus reducing the size of the motor unit. **C,** Neurogenic transformation of motor unit "a." Anterior horn cell "b" is shown undergoing degeneration, and its two muscle fibers are not innervated by axons of anterior horn cell "a," thus leading to an increase in the territory and size of motor unit "a."

for NCSs. Certain muscles, such as the rhomboids and abdominals, which are sometimes interrogated by NEE in pain patients, and the diaphragm (rarely), carry a risk for infectious peritonitis and pneumothorax, respectively. Beyond placing a needle through an infected site, there are probably no absolute but only relative contraindications to EMG. Extremely anxious patients and some children occasionally require some sedation. Aftereffects are negligible, with rare bruising, although occasionally a highly disturbed, suggestible, or litigious patient may complain of increased pain or disability vehemently.

Functional Physiology

When recording extracellularly, as with EMG, the electrode picks up the action potential as it is conducted through the medium that surrounds the active fiber. The impedance of the external medium is small compared to the impedance of the fiber interior, and hence the voltage of the extracellularly recorded potentials is maximally only 2%–10% of the intracellularly recorded potential changes. The functional unit (Fig. 19.2) in reflex or voluntary activity is the motor unit; a motor unit is the group of muscle fibers innervated by a single anterior horn cell.[7]

Conduction along the fine intramuscular branches of the anterior horn cell axon occurs so rapidly that all muscle fibers in a motor unit are activated nearly simultaneously. The number of muscle fibers per motor unit varies considerably from muscle to muscle; for example, in the gastrocnemius, the motor unit consists of about 1600 muscle fibers, whereas in the small muscles of the eye, there are only 5–10 fibers. The motor units in various muscles cover different areas of the muscle's cross-section (e.g. brachial biceps, 55 mm; rectus femoris, anterior tibial, and opponens pollicis, 8–9 mm). The distribution of fibers is such that fibers

from several different motor units are intermingled, which is why four to six motor units can be identified by EMG from the same intramuscular recording point.[7]

In normal muscle, these single motor unit potentials can be differentiated only during weak voluntary effort. Utilization of sub-maximal effort during the recruitment phase of needle EMG recording and evaluation is critical to allow for the objective assessment of motor unit morphology and recruitment parameters. The potentials from different motor units are recognized by their frequency of discharge, which varies for each motor unit (some are more or less excitable). The various potentials often differ in appearance because of the differential distance of the recording electrode from the individual fibers of the activated motor units and the differential distribution of the motor end plates in the several units within "range" of a concentric or single needle electrode in one position in the muscle.[7]

An upward deflection on the oscilloscope is considered electrically negative, and a downward deflection is considered electrically positive. Motor unit morphology will vary as a direct consequence of distance from the recording electrodes. Only motor units with an initial negative deflection and a rapid rise time should be evaluated in terms of amplitude, duration, and presence of an abnormal number of turns or phases. These parameters are critical in evaluating potential neuropathic and myopathic processes and help determine the acuity versus chronicity of the suspected disorder.[4,5,7]

Physiology of Nerve Conduction

The cell membrane (axolemma) of a nerve axon separates the intracellular axoplasm from the extracellular fluid. The unequal distribution of ions between these fluids produces a difference in potential across the cell membrane. This resting potential is about 70 mV and is negative on the inside with respect to the outside of the cell membrane. When a nerve fiber is stimulated, it causes a change in the membrane potential; a rapid but brief flow of sodium ions occurs through ionic channels inward across the cell membrane and gives rise to an action potential.[5,7]

The way in which an action potential is conducted along an axon depends on whether the axon is myelinated or unmyelinated. In a myelinated fiber, the action potential is regenerated only at the nodes of Ranvier, resulting in action potentials that "jump" from node to node or saltatory conduction. The velocity of nerve conduction depends on the diameter of the myelinated fiber. Small myelinated fibers may conduct as slowly as 12 m/s, whereas large motor and sensory fibers conduct at a rate of 50–70 m/s in humans. In an unmyelinated fiber in humans, the conduction rate is about 2 m/s.[5,7]

Several factors affect conduction velocity other than whether the axon is myelinated:

Temperature of the limb (low temperatures decrease conduction velocity).

Age of the patient (infants have slow conduction velocities and older adults have increasingly slowed conduction velocities).[5,7]

Height of an individual (increased height may increase the internodal distances of the nodes of Ranvier and potentially lead to erroneous interpretation of numeric data).[8]

Basic Electromyography Examination

EMG must be combined with clinical examination of the patient by the electromyographer. This includes grading of muscle strength and elicitation of muscle stretch reflexes. It is of prime importance for the electromyographer to personally correlate the clinical data and that obtained by EMG. With the understanding that the EMG examination is an extension of the clinical examination, the patient must be evaluated fully, and the problem tentatively assigned to the portion of the anterior horn cell system that seems most likely to be involved. The electromyographer determines the segment or segments of the peripheral nervous system suspected to be involved, and the examination is planned to either substantiate or invalidate the presumptive clinical diagnoses. EDX data that are discordant with the clinical examination are not to be ignored, but rather an explanation and rationale for that data are required, and its significance, or lack thereof, needs to be addressed.

Needle Findings in Normal Muscle

Insertional Activity

When the needle is inserted into a normal muscle, it evokes a brief burst of electrical activity that lasts no more than 2–3 ms after the needle ceases to move. This point is critically important because persistent pressure on the needle can potentially lead to spurious determination of increased insertional activity and possible pathologic condition.[5,7,9] This activity is described as insertional activity and is generally 50–250 mV in amplitude (Fig. 19.3A). These insertional potentials are believed to represent discharges from muscle fibers produced by injury, mechanical stimulation, or irritation of the muscle fibers.

Spontaneous Activity (Activity at Rest)

When the needle is stationary, and the muscle is relaxed, there is no electrical activity present in normal muscle except when the needle is in the area of the endplate (Fig. 19.3B). Two types of endplate "noise" are normal (Fig. 19.3C): (1) low amplitude and undulating, which probably represents extracellularly recorded miniature endplate potentials as a result of the release of individual quanta of acetylcholine, and (2) high amplitude highly irregular intermittent spike discharges, which probably represent non-propagated discharges of single muscle fibers excited by intramuscular nerve terminals irritated by the needle. Any other spontaneous activity at rest is abnormal. An increased duration of insertional activity may be seen with loss of innervation or with the primary disease of muscle fiber.[9] Reduction may occur in patients with myopathies or more advanced degeneration in which muscle tissue has been replaced by fat or fibrous connective tissue.

Voluntary Activity

The voluntary activity of the muscle is analyzed after the muscle is studied at rest (Fig. 19.3D). Electrical activity (termed a motor unit action potential) is noted. A motor unit refers to the number of muscle fibers supplied by one motor neuron and its axon. This number varies from muscle to muscle and maybe as few as 10 to more than 1000 muscle fibers. When a motor neuron discharges, it activates all the muscle fibers of the motor unit.

The force of contraction determines the number of motor units brought into play.[5,9,10] This begins with a single motor unit that fires and can be identified on the screen by its distinctive morphology. As effort is increased, other motor units come into play, which can still be individually discerned and have their own individual morphology and audio representation on the loudspeaker. As the contraction increases, the firing rate of each individual motor unit action potential increases, and the action potential is subsequently joined by other motor unit action potentials,

whose firing rates also increase. This phenomenon is known as recruitment (Fig. 19.4). In normal muscles, the strength of a voluntary muscle contraction is directly related to the number of individual motor units recruited and their firing rate. Analysis of motor units includes (1) waveform, (2) amplitude, and (3) interference patterns.

Waveform

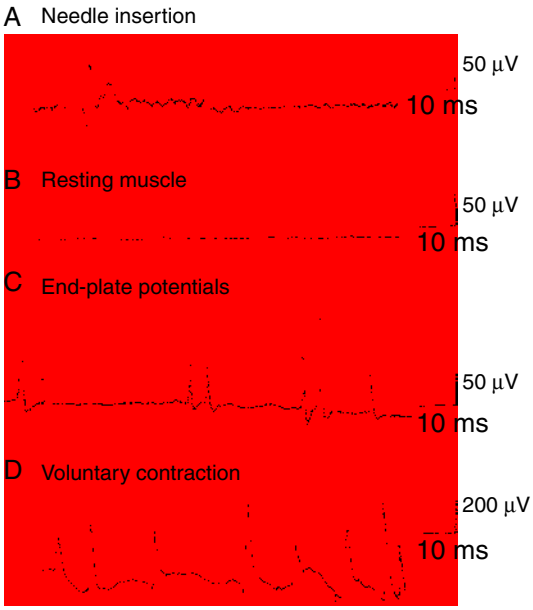
Typical motor units are biphasic or triphasic. The number of phases is determined by the "baseline crossings." Motor units that cross the baseline more than four times are called polyphasic motor units. Polyphasic motor units are determined by the number of baseline crossings plus one. Four baseline crossings plus one equals five, and by definition, that is a polyphasic motor unit potential. Changes in phase not associated with baseline crossings are referred to as turns and can be seen as a consequence of a reinnervated maturing polyphasic motor unit potential after axonal injury in the past. Though occasionally seen in healthy muscle, they do not exceed 15% of the total number of motor units. In some muscles, polyphasic motor units are more prevalent. Polyphasic potentials are a measure of fiber synchrony.[5,7]

Amplitude

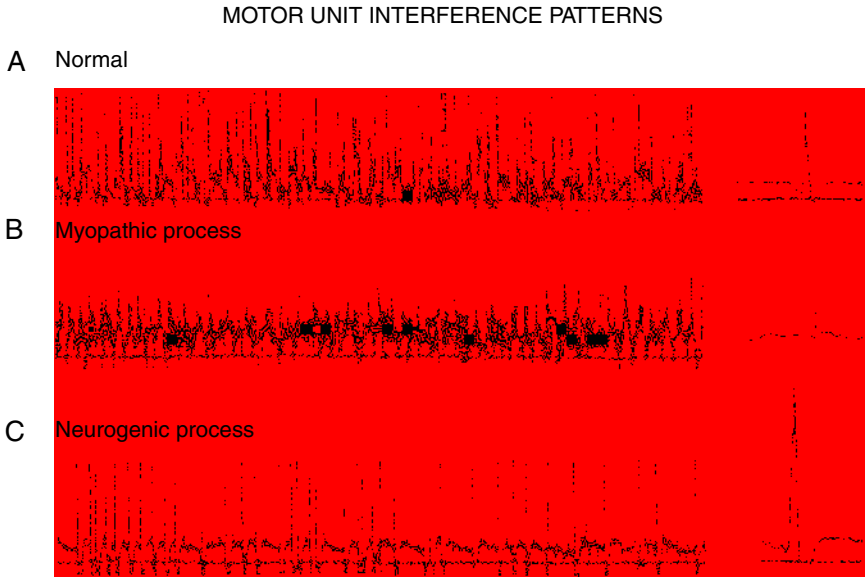
The amplitude depends on the number of fibers in the motor unit, the synchronization of the firing of the fibers in the motor unit, and the type of EMG needle used. Monopolar needles are associated with higher amplitude potentials than bipolar or coaxial needles are. Normal amplitude ranges from 1–5 mV. Because the motor unit is the sum of the action potentials of each muscle fiber of the unit, a large motor unit has a larger amplitude; conversely, a smaller motor unit has a smaller amplitude (Table 19.1).[5,7,10]

Interference Patterns

With maximum voluntary effort, a large number of motor units are brought into play, and their firing rate increases. They tend to "interfere" with each other and are not recognized further as individual units. This gives rise to a situation called an interference pattern (Fig. 19.4). A normal muscle has a "full" interference pattern. With improvement in EMG equipment and the development of A to D conversion, interference pattern analysis is of limited utility. Analysis of sub-maximal contraction allows for evaluation of individual motor units, which in turn offers much richer detail and data in the evaluation of suspected neuropathic or myopathic processes.



• **Figure 19.3** **A,** Trace showing normal insertional activity. **B,** No spontaneous activity in a normal muscle at rest. **C,** Spontaneous endplate potentials. **D,** Normal biphasic and triphasic motor unit potentials during weak voluntary contraction.



• **Figure 19.4** **A,** Full interference pattern on maximum effort in a normal muscle. **B,** Full interference pattern in a myopathic muscle on sub-maximal effort. The number of spikes is greater (each spike represents a motor unit) because of an increase in the firing rate of motor units with early recruitment. **C,** Reduced interference pattern in a denervated muscle on maximal effort resulting from loss of motor units. *Note:* The decreased number of spikes is evident by an increased gap between spikes.

Needle Findings in Abnormal Muscle

Various abnormalities may occur that indicate the presence of muscle dysfunction, which can be neurogenic or myogenic in etiology. The appreciation for the dynamic interplay and synchrony of abnormal EDX findings with a detailed, organized physical exam, buttressed by patient specific historical data, will ease the delineation of radiculopathy, generalized neuropathy, focal neuropathy, or mononeuropathy, or plexopathy.

The following are needle abnormalities in abnormal muscle:

Insertional activity (decreased or increased).

Spontaneous activity (fibrillations, positive sharp waves, CRDs [complex repetitive discharges] or fasciculations) (Fig. 19.5).

Abnormalities in voluntary motor unit activity, especially recruitment (Fig. 19.4).

Abnormal motor unit morphology (e.g. excessive or extreme polyphasia).

NCSs are of value in the following cases:[11]

Determining whether a disease of the nerve is present.

Determining the distribution of neuropathy (e.g. mononeuritis, polyneuropathy, mononeuritis multiplex; this may be a valuable point in the differential diagnosis of the cause of a neuropathy).

Determining at what point in a nerve a conduction block is present and locating an entrapment site.[11]

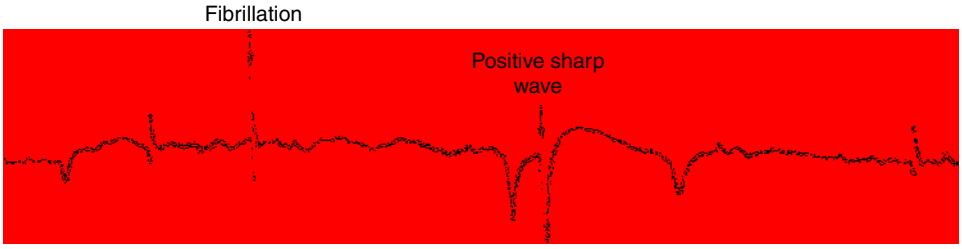
Studying the progress of disease of a peripheral nerve (e.g. Is it getting better? Worse? Staying the same?).

Seeing whether reinnervation of a previously sectioned nerve has taken place.

Establishing in a disease of the myoneural junction (e.g. myasthenia gravis) the fact that conduction along the nerve is adequate or normal.[5,7]

There are a few important limitations to the use of NEE in diseases of muscle and nerve, but particularly muscle. Some disorders may not result in abnormal findings on EMG, including certain congenital conditions and endocrine disorders such as steroid myopathy and polymyalgia rheumatica, an important cause of muscle pain and weakness in an older person. Rarely are the findings specific for a particular type of myopathy within the family of primary muscle disorders.[5,10]

Conduction velocity studies are carried out by inserting a needle electrode into a muscle innervated by the nerve under study or by the use of surface electrodes over that muscle (Fig. 19.6). For example, the first dorsal interosseous muscle may be examined to determine the function of the ulnar nerve (Fig. 19.7). The nerve is stimulated at the elbow in the case of the ulnar nerve, and the latency of the response is determined. The response is generally a spike-like large motor unit action potential. The ulnar nerve is then stimulated in the wrist or the axillary region, or both. The difference in latencies between the

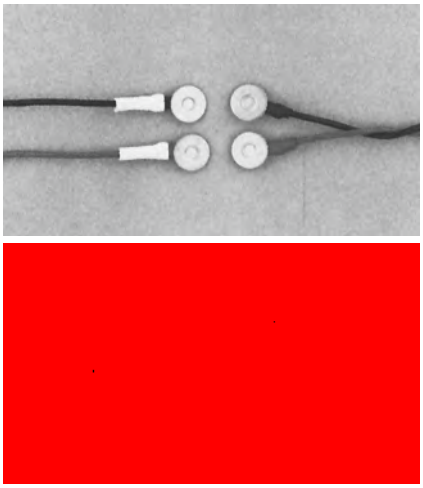


• **Figure 19.5** Positive sharp wave and fibrillation potentials recorded from a denervated muscle.

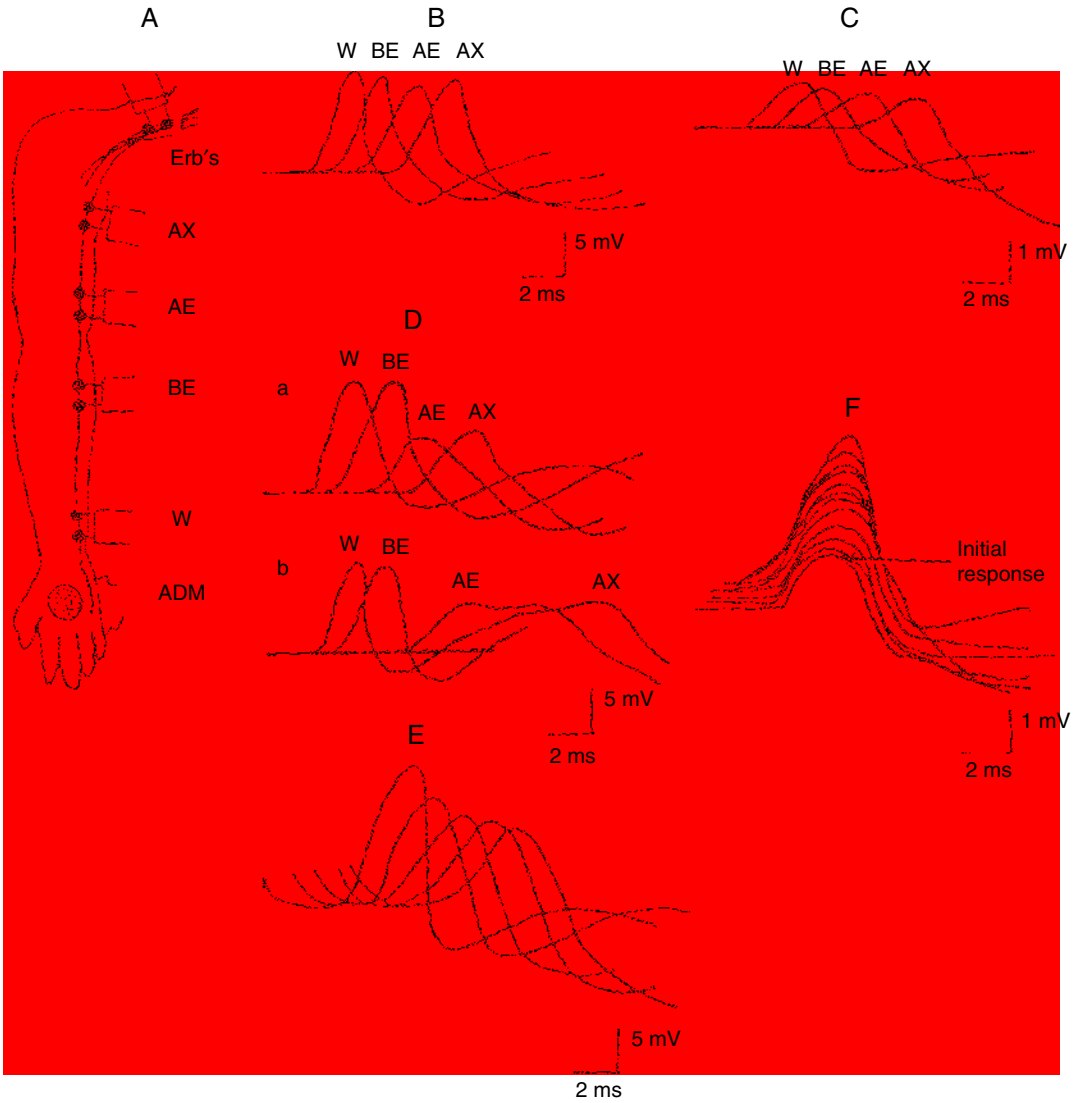
TABLE 19.1 Normal Values for Commonly Tested Sensory and Motor Nerves

Nerves	Amplitude (Avg.)	Distal Latency in msec (Avg.)*	Conduction Velocity in m/sec (Avg.)
Median (sensory)	10–85 μV (20)	2.0–3.7 (3.2)	
Ulnar (sensory)	5–70 μV (15)	1.6–3.2 (2.8)	
Radial (sensory)	10–60 μV (18)	1.7–2.8 (2.4)	
Median (motor)	5–25 mV (8)	2.0–4.0 (3.3)	48–69 (54)
Ulnar (motor)	5.5–20 mV (8)	1.6–3.1 (2.6)	50–69 (55)
Sural (sensory)	3–38 mV (8)	2.3–4.6 (4.1)	41–61 (46)
Peroneal (motor)	2.5–18 mV (4)	2.3–6.0 (4.1)	41–58 (45)
Posterior tibial (motor)	4–38 mV (11)	2.1–6.0 (4.3)	

*Distal latencies are based on standard distance: 13 cm for the median (S), 11 cm for the ulnar (S), 10 cm for the radial (S), 14 cm for the sural (S), 4–6 cm for the median (M) and ulnar (M), 6–8 cm for the peroneal (M), and 8–12 cm for the posterior tibial (M) nerves.



• **Figure 19.6** Disk surface electrodes and a ground electrode are used for the measurement of motor nerve conduction velocity. (Courtesy of Oxford Instruments Medical, Inc., Hawthorne, NY.)



• **Figure 19.7** **A,** Commonly used site of stimulation of the ulnar nerve at the wrist, below the elbow, above the elbow, and at the axilla. The ulnar nerve can also be stimulated at Erb's point in the supraclavicular fossa. **B,** Normal amplitude compound motor action potentials (CMAPs) recorded from the abductor digiti minimi manus following stimulation of the ulnar nerve at these various sites. **C,** Low amplitude CMAPs in a patient with axonal neuropathy. All CMAPs are of the same amplitude but are much smaller than normal. **D,** Decremental response *(a)* and decremental and dispersed response *(b)* on stimulation above the elbow and at the axilla and normal response on stimulation below the elbow and wrist. **E,** Repetitive nerve stimulation of the ulnar nerve at the wrist in a patient with myasthenia gravis. Note the initial normal response and subsequent decremental response at the slow rate (3 pulses/s). **F,** Repetitive nerve stimulation in Lambert-Eaton syndrome. With a rapid rate (20–50 pulses/s), a marked incremental response occurs. Note the very low initial response and the two-fold to four-fold increase following the rapid rate of stimulation. *AE*, Above the elbow; *AX*, axilla; *BE*, below the elbow; *W*, wrist.

two points of stimulation and the distance between the two points of stimulation provide the basis for the calculation of conduction velocity.[11]

F-Wave

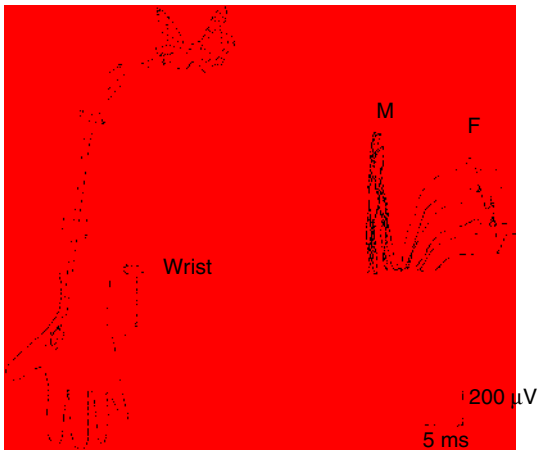
Definition

Motor conduction velocity along the whole axon, including the proximal portions, can be studied by eliciting the F-wave response, a small, late muscle response resulting from backfiring of anterior horn cells. F-waves may be obtained from almost any mixed nerve that can be stimulated, but the median, ulnar, peroneal, and posterior tibial nerves are the most commonly used (Fig. 19.8). If the standard distal motor conduction velocities are normal, but the F-wave value is prolonged, slowing must be occurring somewhere more proximal to the distal normal segment. (The method used to determine F-wave latency varies from laboratory to laboratory; the F-wave value with each successive shock stimulus shows variability of several milliseconds, with some examiners averaging 10, 30, or 50 responses and some taking the shortest of 10, 20, or more responses.) Limb temperature and arm or leg length may also be important to know. Comparison with the opposite limb may be most helpful if that limb is asymptomatic. The determination of F-wave latency can be as simple as accepting the fastest

onset latency after 10 consecutive stimulations or may include analyzing the number of potentials recorded after 10–20 consecutive stimulations and accessing the distribution and spread of the responses. This allows for the development of a scattergram to see where the preponderance of the values reside. In all instances, comparison to textbook standardized onset F-wave latency data is helpful.[12,13]

Pitfalls and Comments

In addition to the variability in F-waves and how they are obtained in different laboratories, many electromyographers overuse (or at least over perform) the F-wave study when proximal slowing in a nerve or nerve root is not even in the differential diagnosis. The most accepted use of the study is for suspected early Guillain-Barré syndrome when the results of the usual studies are still normal, typically in the first 10 days of the illness. It is highly controversial in the evaluation of radiculopathies.[13]



• **Figure 19.8** Consecutive tracings showing M responses and F-waves recorded from the abductor pollicis brevis after stimulation of the median nerve at the wrist.

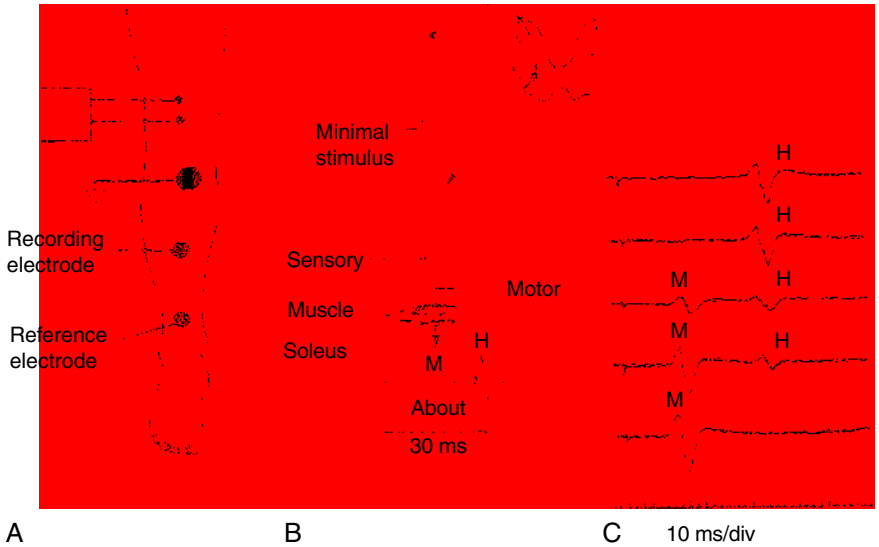
Hoffman Reflex (H-Reflex)

Definition

The H-reflex is obtained by electrostimulation of the posterior tibial nerve in the popliteal space at a slow rate with a long duration and sub-maximal electrical shock; it is recorded with surface electrodes over the gastrocnemius-soleus (Fig. 19.9). The impulse travels up the sensory fibers to the spinal cord, synapses with the α motor neuron, and returns down the motor fibers to the calf muscle. Therefore H-reflex latencies are long, ranging from 40–45 ms. They are carried mostly in the S1 nerve root distribution and cannot be recorded consistently from other muscles. To determine a delay or an asymmetry, one should always study the opposite leg for comparison.[14]

Pitfalls and Comments

The H-reflex is somewhat more useful than the F-wave, but the main reason for the study is to evaluate patients with suspected S1 radiculopathy whose history or findings on physical examination are suggestive, but the EMG is normal. Usually, when an absent H-reflex is noted, which suggests a problem with S1 nerve root conduction, an absent or depressed ankle reflex has already been noted on the physical examination; thus the study is, for many, redundant. Pitfalls occur when the opposite leg is not studied to show a normal H-reflex as a contrast. If the H-reflex is absent bilaterally, it may reflect more generalized disease, such as peripheral neuropathy. Older patients rarely have good H-reflexes as a normal finding. In addition, a unilaterally absent H-reflex with normal findings on needle EMG does not indicate when the injury occurred; the findings may have resulted from



• **Figure 19.9** **A,** Placement of recording electrodes and site of stimulation of the posterior tibial nerve for the recording of the Hoffman (H) reflex from the soleus muscle. **B,** H-reflex pathways. An electrical impulse generated on stimulation of the tibial nerve travels along the sensory axon (afferent) within the spinal cord and along the motor axon (efferent). **C,** Motor response *(M)* and H-reflex *(H)*. Five consecutive traces are shown. Starting from the top, each trace is obtained with increasing stimulus intensity. With minimal stimulus only, the H response is obtained. As the intensity of the stimulus increases, the M response appears, and the H response begins to decrease until it finally becomes unobtainable.

a previous injury. Utilizing prolongation of latency as a determinant of the pathologic condition must be approached with caution. For side to side comparison to be potentially useful, the distance between electrodes, distance between the recording electrode and stimulator, and location of electrodes must be meticulously addressed and recorded.[14,15]

Clinical Correlations of Electromyographic Testing

Electrodiagnostic studies are best for distinguishing neuropathy from myopathy and determining whether a neuropathy is generalized axonal, demyelinating, mixed, focal, or multifocal, thus giving important clues about the cause. Nerve trauma can be monitored serially to determine recovery. Often, a diagnosis of plexopathy or radiculopathy can be made.[4,10,16]

Nerve Trauma

Often after an injury, such as a laceration, the nerve is completely severed. At rest, denervation potentials are recorded in the muscles supplied by that nerve in the form of positive sharp waves or fibrillation potentials, and on EMG, no motor unit action potentials are seen. However, sometimes an injury is incomplete, and the type of nerve lesion is uncertain.[17]

Neurapraxia

Neurapraxia is the mildest form of nerve injury. It consists of loss of conduction without associated changes in axonal structure. The degree of conduction block can be partial to complete. Complete conduction block mimics a complete nerve lesion on physical examination, and in this scenario, NCS lends valuable information regarding the location of the lesion and potentially of greater importance prognosis for recovery. An important physical examination finding suggestive of neuropraxia as opposed to axonotmesis is the preservation of muscle mass with a neuropraxic injury. This form of conduction block often occurs with compressive or ischemic nerve injuries, such as a mild entrapment syndrome or compression (e.g. "Saturday night palsy"). In neurapraxic injuries, focal demyelination occurs.[4,5,7,17]

Axonotmesis

In axonotmesis, a more severe form of nerve injury, the axon is disrupted in its myelin sheath. The neural tube, which consists of the endoperineurium and epineurium, remains intact. The nerve undergoes Wallerian degeneration, with the fragmentation of the axon distal to the site of injury. Motor and sensory paralysis occur along with associated atrophy of the muscles supplied and loss of reflexes. After about four to five days, the distal segments of the nerve become unexcitable. The development of injury potentials, which can include fibrillations and positive sharp waves, proceeds in a proximal to distal fashion relative to the site of injury. Fibrillation potentials may appear as early as two weeks in proximal muscles, with similar findings occurring as late as four to six weeks in distal muscles. The intact neural tube forms a lattice for the regenerating axon, and the prognosis for recovery is generally good, with caveats of age, underlying medical conditions, such as diabetes, and a history of chemotherapy, impacting recovery potential.[4,5,17]

Neurotmesis

Neurotmesis is the most severe form of nerve injury and consists of severe disruption or transection of the nerve. Nerve regeneration and recovery are often incomplete, and surgical reanastomosis may be required. Neuromas may form and are commonly associated with pain. Only serial determinations over time can determine the difference between axonotmesis and neurotmesis.[4,5,17]

Nontraumatic Neuropathies

In a patient with nontraumatic neuropathy, segmental demyelination is generally associated with slowing of NCV and temporal dispersion of evoked responses. With axonal degeneration, however, a reduction in the evoked response amplitudes with mild or minimal slowing of NCV is typical. EMG provides early information regarding reinnervation before clinical recovery is evident. The earliest positive evidence of reinnervation is the appearance during the voluntary effort of motor unit potentials that are of low amplitude in the beginning but are highly polyphasic ("nascent") units. They may be present several weeks before clinical evidence of functional recovery is apparent.[4,5]

Polyneuropathy

EMG and evaluation of nerve conduction are useful in diagnosing polyneuropathy and determining whether the pathologic process is primarily axonal or demyelinating or a combination of the two. Additionally, it helps distinguish predominantly motor versus sensory versus mixed. A diagnosis of polyneuropathy is made when abnormal nerve conduction and EMG findings are bilateral and symmetric.

The following electrodiagnostic findings are characteristic of axonal neuropathy:

Abnormally low or absent sensory nerve action potentials and compound muscle action potential amplitudes.

If a disease process affects the large-diameter axons, some slowing of conduction occurs; the velocity is seldom reduced by 20%–30% of normal. However, fibrillation and positive sharp waves are present in muscles innervated by the affected nerves and are generally worse distally. The feet are more involved than the hand muscles, and the leg muscles are involved more than the arm muscles. Motor unit potentials are decreased in number with deficient recruitment and an incomplete interference pattern. Some motor units have increased amplitude and duration.

In contrast, diffuse demyelinating neuropathy is characterized by a reduction in conduction velocity, usually more than 40% of the normal range. Distal latencies are also prolonged. The sensory nerve action potentials and compound muscle action potentials usually exhibit low amplitudes and temporal dispersion. Needle EMG shows no fibrillations or positive sharp waves unless secondary axonal degeneration is present. In pure demyelinating neuropathy, without associated secondary axonal dropout, there is no denervation of muscle fiber, and clinically, muscle bulk is relatively maintained. Motor units are decreased in number; the decreased recruitment is attributable to conduction block in some fibers. Usually, no significant change in the duration, amplitude, or morphology of motor units occurs, but the number of polyphasic potentials may be increased if the terminal axons have become demyelinated.

Once it has been determined by EMG whether a neuropathy is primarily axonal or demyelinating, one can then consider clinically which neuropathies are diffusely axonal and which are demyelinating. Subacute and chronic diffuse axonal types include most toxic and nutritional neuropathies, uremia, diabetes, hypothyroidism,

HIV infection, Lyme disease, paraneoplastic disease, dysproteinemia, and amyloidosis. Demyelinating polyneuropathies include hereditary motor and sensory neuropathy types I and III, Refsum's disease, multifocal leukodystrophy, and Krabbe's disease. Acute nonuniform demyelinating diseases include Guillain-Barré syndrome, diphtheria, and acute arsenic intoxication, whereas chronic versions include inflammatory demyelinating peripheral neuropathy, idiopathic disease, and neuropathies accompanying HIV disease, as well as various paraproteinemias, dysproteinemias, and osteosclerotic myeloma.[4,5,18]

Mononeuropathies and Entrapment Neuropathies

The most commonly involved nerves with entrapment neuropathy are the median, ulnar, radial, common peroneal, and tibial. Entities such as trauma, vasculitis, diabetes mellitus, leprosy, and sarcoidosis can affect any nerve in the body. Electrophysiologic studies are of great assistance in localizing the lesion in the individual nerve and in differentiating mononeuropathy from diffuse polyneuropathy, plexopathy, and radiculopathy.

Median Nerve

The median nerve is most commonly entrapped at the wrist as it passes through the carpal tunnel, but it may also be injured at the elbow where it passes between the two heads of the pronator teres or, less frequently, is compressed by a dense band of connective tissue (the ligament of Struthers immediately above the elbow) (Fig. 19.10). The median nerve is derived from the C6 through T1 nerve roots (lateral and medial cords of the brachial plexus). The diagnosis of carpal tunnel syndrome is made by demonstrating localized slowing of sensory and motor conduction across the wrist as evidenced by prolonged sensory and motor distal latencies.[3] It is critical to understand that slowing by itself does not cause symptoms. Slowing with partial conduction block or complete conduction will cause symptoms. Only when part of the signal fails to reach the target will there be symptoms. In addition, with late changes, there may be denervation in the form of fibrillation, positive sharp waves, and reduced motor units with polyphasia in the hand muscles innervated by the median nerve. The need for reference values for special populations, including people with diabetes and active workers, has been emphasized in a recent AANEM monograph. A recent review also emphasized that carpal tunnel syndrome may represent a focal intracanal condition such as pregnancy, lipoma, an arterial condition, and the hereditary neuropathy of amyloidosis.[19]

Pronator Teres and Anterior Interosseous Syndromes

The pronator teres and anterior interosseous syndromes consist of proximal compression or entrapment neuropathies of the median nerve. Patients with pronator teres syndrome may also have normal distal latency but no evidence of denervation in the median-innervated hand and forearm muscles except for the

pronator teres. The anterior interosseous nerve is a motor branch of the median nerve, with its origin just distal to the pronator teres

In anterior interosseous syndrome, a common complaint is deep aching pain in the forearm.

Ulnar Nerve

The ulnar nerve is derived from the C8 and T1 cervical nerve roots (medial cord of the brachial plexus). It is usually injured at the elbow but occasionally at the wrist in the canal of Guyon or deep in the palm (silver beater's palsy). EMG helps differentiate C8 and T1 radiculopathies from plexopathy or distal ulnar nerve palsy (Fig. 19.8). When the lesion is in the wrist at the canal of Guyon, usually both sensory and motor fibers are involved, and the amplitude of the sensory nerve action potential and muscle action potential is reduced. Distal sensory and motor latency across the wrist is prolonged, and there is no focal slowing of motor NCV or decrement in compound muscle action potential across the elbow. With a lesion in the deep palmar branch, no sensory abnormality occurs, and all the changes are in the motor distribution distal to the lesion. When the abnormality is at the elbow, there may be localized slowing of NCV across the elbow, often as much as 25%–40% below normal. Normal values may depend on the method used (arm straight vs. arm bent). The sensory potential may be affected, as may EMG findings in the ulnar hand muscles.[11]

Radial Nerve

The radial nerve is a continuation of the posterior cord of the brachial plexus and receives fibers from the C5–C8 cervical roots. It is usually involved at the spiral groove of the humerus, often secondary to a humeral fracture. With a lesion at the spiral groove, the triceps muscle is noted to be spared on EMG, but the brachioradialis and all the extensor muscles of the forearm are involved. An isolated superficial radial nerve palsy sometimes occurs at the wrist, with the only abnormality being in the radial sensory nerve action potential.[4]

Posterior Interosseous Syndrome

The posterior interosseous nerve syndrome (sometimes known as complicated lateral epicondylitis) is caused by entrapment of this branch of the radial nerve at the arcade of Fröhse between the two heads of the supinator. EMG shows the involvement of the extensor carpi ulnaris, extensor digitorum longus, extensor pollicis longus, and extensor indicis with sparing of the more proximal supinator and extensor carpi radialis longus and brevis. Sensation is unaffected.

Common Peroneal Nerve

The common peroneal nerve is derived from the L4 through S1 roots but primarily from L5. It may be compressed at the head of the fibula. Peroneal NCSs show reduced compound action potentials, as recorded from the extensor digitorum brevis on stimulation above the fibular head and normal compound action potentials below the fibular head and at the ankle.

Posterior Tibial Nerve at the Ankle

The posterior tibial nerve is derived from the L4 through S3 roots and may be compressed in the tarsal tunnel. NCSs show prolongation of the distal motor and sensory latency of the tibial nerve. A side-by-side comparison of mixed plantar nerve amplitudes and motor amplitudes to the adductor hallicus (AH) and abductor digiti quinti pedis is imperative to avoid over interpretation of the data. Needle EMG of the AH and abductor digiti quinti (ADQ) pedis is required to establish the diagnosis of this rather rare entity.

Sciatic Nerve

The sciatic nerve arises from the L4, L5, S1, S2, and S3 nerve roots. Piriformis syndrome is secondary to the entrapment of the sciatic nerve by the piriformis muscle as it passes through the greater sciatic notch.[20] A theoretical "hallmark" finding on EDX is the prolongation of F-wave latency with certain leg positions; however, as previously noted, slowing does not cause symptoms unless it is associated with an element of conduction block and functional axonal dropout. Detailed needle EMG evaluation will typically reveal that the more common cause is lumbar radiculopathy involving the L5 nerve root or S1 nerve root. The isolated finding of F-wave latency prolongation when noted is of unclear significance at best, regardless of the positioning of the leg. A lesion of the sciatic nerve is defined and localized by a detailed needle examination of muscle in the lower limb.

Other Uncommon Neuropathies

There are numerous potential mononeuropathies, including those involving the long thoracic nerve, dorsal scapular nerve, suprascapular nerve, musculocutaneous nerves, and axillary nerves in the shoulder girdle and upper extremity, as well as those in the pelvic girdle, including the femoral, obturator, saphenous, lateral femoral cutaneous, genitofemoral, ilioinguinal, and superior and inferior gluteal nerves. Needle EMG reveals denervation changes in muscles innervated by individual nerves. NCSs are rarely useful in their evaluation.

Radiculopathies

Radiculopathies are diseases of the nerve roots and must be differentiated from plexopathies and complex individual nerve root lesions. Roots are commonly involved by compression, especially in the cervical and lumbar region. However, they may also be involved in diseases such as diabetes mellitus, herpes zoster, carcinomatous infiltration, and lymphomatous infiltration of nerves, as well as by rare (sarcoidosis) and infectious processes. Determination of motor and sensory nerve conduction is rarely useful because the lesion in radiculopathy is proximal to the dorsal root ganglion and motor conduction studies are usually normal. However, they may be reduced in amplitude if the lesion is severe enough to cause axonal loss. The H-reflex is absent or latency-delayed when the S1 root is involved. Typically, nerve root lesions are identified by abnormal needle examination results in the appropriate paraspinal and limb muscles. Understand that with reinnervation, abnormalities may be fully resolved in the proximal paraspinal muscles as reinnervation proceeds from proximal to distal. As such, the "footprint" of the radiculopathy may only be manifest in the more distal arm or leg muscles, respectively. Because most limb muscles are supplied by more than one nerve root (Tables 19.2 and 19.3), a normal study does not exclude the diagnosis of radiculopathy. However, when the findings on EMG are abnormal, they provide objective evidence of functional impairment in the nerve root and localize the lesion to one or more roots in addition to revealing the severity of involvement.[21]

TABLE 19.2 Segmental Innervation of Commonly Tested Muscles in the Upper Extremity

Muscle	Spinal Segment	Nerve Supply
Cervical paraspinal	C2–C8	Corresponding cervical root
Trapezius	C2, C3, C4	Spinal accessory
Supraspinatus	C5, C6	Subscapular
Infraspinatus	C5	Subscapular
Deltoid (circumflex)	C5, C6	Axillary
Biceps brachii	C5, C6	Musculocutaneous
Brachioradialis	C6, C7	Radial
Flexor carpi radialis	C6, C7, C8	Median
Pronator teres	C6, C7	Median
Triceps brachii	C7, C8	Radial
Extensor digitorum communis	C7, C8	Radial
Extensor indicis	C7, C8	Radial
Flexor carpi ulnaris	C8, T1	Ulnar
Abductor pollicis brevis	C8, T1	Median
First dorsal interosseus	C8, T1	Ulnar
Abductor digiti minimi manus	C8, T1	Ulnar

TABLE 19.3 Segmental Innervation of Commonly Tested Muscles in the Lower Extremity

Muscle	Spinal Segment	Nerve Supply
Lumbosacral paraspinal	L1–S1	Corresponding roots
Iliacus	L2, L3, L4	Femoral
Adductors of the thigh	L2, L3, L4	Obturator
Quadriceps femoris	L2, L3, L4	Femoral
Tibialis anterior	L4, L5	Deep peroneal
Gluteus medius	L4, L5, S1	Superior gluteal
Gluteus maximus	L5, S1	Inferior gluteal
Peroneus longus	L5, S1	Superficial peroneal
Biceps femoris—long head	L5, S1	Sciatic
Biceps femoris—short head	L5, S1	Sciatic
Flexor digitorum longus	L5, S1	Posterior tibial
Tibialis posterior	L5, S1	Posterior tibial
Extensor digitorum brevis	L5, S1	Deep peroneal
Gastrocnemius—lateral	L5, S1	Posterior tibial
Gastrocnemius—medial	S1, S2	Posterior tibial
Abductor hallucis	S1, S2	Posterior tibial
Abductor digiti quinti	S1, S2	Posterior tibial
Tensor fasciae latae	L5, S1	Superior gluteal

Plexopathies

In plexopathies, motor NCSs are useful in excluding a peripheral nerve lesion; otherwise, the findings are normal except that the amplitudes of compound muscle action potentials may be reduced. Sensory NCSs are usually helpful in excluding other causes. Again, needle examination is most helpful, but it requires knowledge of which muscles are supplied by which portions of the plexus.

Anterior Horn Cell Disease

Disorders of the anterior horn cell rarely cause pain except for acute poliomyelitis (acute febrile stage). When diseases such as amyotrophic lateral sclerosis cause pain, the cause is usually multifactorial (spasticity, musculoskeletal, positioning) and not usually discernible using EMG.

Disorders of the Central Nervous System

Findings on EMG are almost always normal in diseases of the central nervous system.

Primary Muscle Disorders

One of the clearest applications of EMG is for differentiating myopathies from neuropathic processes. The differentiation in EMG studies between myopathy and neuropathy should be obvious by needle examination. In myopathy, the potentials are reduced in amplitude and may be very polyphasic, recruit paradoxically (i.e. more potentials seen on the screen than expected for the corresponding amount of effort), and are accompanied by marked signs of irritability. In polymyositis and metabolic muscle disorders, sensory nerve conduction is always normal. The compound muscle action potential amplitude may be low, but otherwise, motor conduction results are normal.[10]

In polymyositis and metabolic muscle disorders (e.g. glycogen and lipid storage disease), muscle pain, cramps, and weakness can occur, and needle EMG may reveal findings of membrane instability and irritability. Unusual diseases characterized by muscle cramping, including stiff-man syndrome (Moersch-Woltman syndrome), simply show muscle contraction and spasms. Conditions with continuous muscle fiber activity (Isaacs-Mertens syndrome) show continuous, low amplitude, fibrillation-type potentials.[10]

EMG findings are commonly normal in myofascial pain syndromes and fibromyalgia.

Usefulness and Limitations of Electromyography

EMG and NCSs are useful in localizing neuromuscular disease sites and providing information about the nature of the process (demyelinating, axonal, primary muscular, radicular) but cannot give the cause (diabetes, Guillain-Barré syndrome, myositis, tumor, ruptured disk).

A normal result does not mean that the patient does not have pain. Electrodiagnostic studies in the EMG laboratory, as usually performed, measure only activity related to the motor nerve fibers, the larger sensory nerve fibers, and the muscles. Sympathetic and small unmyelinated nerve fiber functions are not evaluated by standard electrodiagnostic techniques.

In summary, EDX as a stand-alone test is of limited utility. In concert with a detailed history and a well conducted physical examination, the findings noted on EDX testing become very powerful and helpful in delineating the diagnosis and potentially focalizing the treatment decision pathway.

Key Points

1. Electrodiagnostic tests and/or studies can help elucidate the cause of a problem involving the peripheral nervous system.
2. Electrodiagnostic testing has the potential to introduce data that clouds the picture and adds complicating factors.
3. Failure to appreciate the limitations of electrodiagnostic testing can delay diagnosis or lead to wrong conclusions being arrived at.
4. In the evaluation of a patient with pain, particular caution must be taken to guard against the thought process of "if the test is abnormal, that must be the cause of the problem."
5. Data must be interpreted within the context of the patient, and ideally, the test should be tailored to address questions and concerns that arose from the detailed history and physical exam that preceded the electrodiagnostic study.
6. The utility of EDX in the evaluation of a patient with pain, and more importantly, the limitations and potential pitfalls must always be first and foremost in the mind of the electrodiagnostic physician and referring physician when setting up, performing, and interpreting the data.

Radiologic Assessment of Patient With Spine Pain

FELIX E. DIEHN, JOHN C. BENSON, TIMOTHY P. MAUS

Imaging is a significant but not independent component of the multifaceted evaluation of a patient with spine or limb pain. Imaging must be interpreted in concert with the history, physical exam, electrodiagnostic evaluation, and responses to image guided anesthetic or provocative procedures. Imaging alone should not be considered; it can only be understood in its proper context: the individual patient's unique syndrome of pain or neurologic dysfunction.

Pain of spinal origin is extremely common. Low back pain is the second most common cause of symptomatic office visits in the United States.[1,2] The lifetime prevalence of back pain in the United States is approximately 75%,[3] and one-third of United States adults experienced back pain in the previous three months.[1] Advanced imaging is performed in such cases with ever-increasing frequency; the number of lumbar magnetic resonance imaging (MRI) scans among Medicare beneficiaries rose four-fold from 1994–2005.[4] Over 40% of patients with acute low back pain underwent immediate imaging in a private insurance claims database study.[5] In another Medicare-based study of low back pain patients without red flags for systemic disease, nearly 30% underwent imaging (radiography or advanced imaging) within 28 days.[6] In a study in an emergency department environment, the use of advanced imaging (computed tomography [CT] or MRI) for low back pain tripled from 2002–2006.[7] Approximately one-third of Medicare low back pain patients who undergo outpatient MRI studies have received no prior conservative therapy.[8]

Despite this intensity of imaging and the downstream effects of increasing minimally invasive interventions and surgical procedures that flow from them, there is no evidence that patient outcomes are improving. Measures of physical functioning, work/school limitations, and mental health in United States adults with back or neck complaints were similar or worse in 2005 than in 1997.[9] A regional study (North Carolina) demonstrated that the proportion of adults with chronic low back pain causing activity impairment rose from 3.9% in 1992 to 10.2% in 2006.[10] A review article by Chou, Deyo, and Jarvik examined the evidence of inefficient utilization of imaging in back pain patients and the underlying causal forces and mechanisms for initiating improvements.[11] The purpose of this chapter is to foster the rational decision making they advocate in the use of spine imaging, based on evidence, as we in the pain management community seek to improve patient outcomes.

The Goal of Imaging

The primary goal of imaging in patients with spine or limb pain is to identify patients suffering from an undiagnosed systemic process causal of the pain/dysfunction syndrome. This is an uncommon phenomenon. An analysis by Jarvik and Deyo[12] suggests that 95% of low back pain is because of benign processes. In patients presenting to a primary care setting with low back pain, only 0.7% suffer from undiagnosed metastatic neoplasm. Spine infection, including pyogenic and granulomatous discitis, epidural abscess, or viral processes, is present in only 0.01% of subjects. Noninfectious inflammatory spondyloarthropathies, such as ankylosing spondylitis (AS), account for 0.3% of presentations. Osteoporotic compression fractures are the most common systemic pathologic process to present as back pain, accounting for 4% of patients.[12] Imaging seeks to identify the approximately 5% of patients with back or limb pain with undiagnosed systemic disease as the etiology of their pain. A related imaging goal is to characterize and assist in therapy planning in the very small percentage of patients with neural compressive disease resulting in radiculopathy or radicular pain syndromes that fail conservative therapy and require surgical or minimally invasive intervention.

Specificity: Asymptomatic Imaging Findings

The low prevalence of systemic disease as a cause of back pain implies that most imaging studies primarily describe what are often, and inappropriately, termed "degenerative" phenomena. These may include anterior and lateral vertebral body osteophytes, loss of T2 signal in the intervertebral disc, and structural changes of facet arthrosis. Degeneration is a pejorative term implying disease; these changes have no relationship to pain syndromes and correlate only with age. They are best called age or age-related changes. These age changes are typically relatively uniform across the spine, although the lowest lumbar segments are over-represented. Evidence for the lack of specificity of such imaging findings for spine pain syndromes is evident in cadaver studies, imaging studies in asymptomatic populations, and population studies.

Nathan[13] described the presence of anterior and lateral osteophytes in 100% of cadavers at the age of 40 years, whereas posterior osteophytes are present only in a minority of cadavers at 80 years. Hult[14] studied adults with spine radiographs and showed that by

the age of 50 years, 87% will have radiographic evidence of age-related disc change (narrowing of the disc space, marginal sclerosis with osteophytes, vacuum phenomena). In a second study including a cohort of asymptomatic workers, Hult[15] noted radiographic evidence of disc "disease" in 56% of those aged 40–44 years, which rose to 95% in subjects 50–59 years old. With the evolution of more sophisticated spine imaging techniques, this lack of specificity of degenerative findings has not improved. Hitselberger and Witten[16] studied plain myelography of asymptomatic volunteers and noted that 24% showed abnormalities that would have been considered significant in the clinical context of back or leg pain. A study of lumbar spine CT in asymptomatic volunteers by Wiesel and colleagues[17] showed that in patients older than 40 years, 50% had "significant" abnormalities. Similarly, Boden and colleagues[18] evaluated MRI of the lumbar spine in asymptomatic volunteers. In patients older than 60 years, 57% had abnormalities considered significant in an appropriate clinical setting. Jarvik and colleagues[19] studied a large patient population with MRI. Their study noted that only extrusions, moderate to severe central spinal canal stenosis, and direct visualization of neural compression were likely to be significant and would separate patients with pain from asymptomatic volunteers. Disc protrusions, zygapophysial joint (z-joint or facet joint) arthrosis, and anterolisthesis or retrolisthesis were virtually always asymptomatic findings. Imaging studies of asymptomatic volunteers are compiled in Table 20.1.[20–25]

A study by Kanayama[26] in 200 healthy adults (mean age 40 years, with no current complaint or therapy for back pain nor any history of lumbar surgery) segregated lumbar MRI findings by segmental level (Table 20.2). Asymptomatic T2 signal loss and disc herniations were most common at the L4 and L5 segmental levels; this series also had a high prevalence of asymptomatic high intensity zones (HZ) (24% at L4 and L5). More recent studies have addressed the prevalence of disc "degenerative" imaging findings (T2 signal loss, loss of disc space height) in younger populations, primarily in Scandinavian countries; these are MRI population-based studies without regard to symptomatology. Kjaer and colleagues,[27] studying children aged 13 years, found a 21% prevalence of disc "degeneration." In a study of adolescents, Salminen and colleagues[28] found a 31% prevalence of disc "degeneration" in 15-year-olds, which rose to 42% in 18-year-olds. Takatalo and colleagues[29] evaluated 558 young adults aged 20–22 years. Using the five-point Pfirrmann classification of disc degeneration, they noted disc degeneration of grade three or higher in 47% of these young adults. There was a higher prevalence in males (54%) than in females (42%). Multilevel degeneration was identified in 17%.

A 2015 systematic literature review included 33 articles and again found a high prevalence of degenerative imaging findings among asymptomatic individuals, which increases with age.[30] For instance, disc protrusions were found in 29% of asymptomatic individuals who were 20 years old and 43% of those 80 years old. Meanwhile, in the same year, a meta-analysis of 14 different studies meeting inclusion criteria provided some conflicting evidence to the concept that degenerative findings on advanced imaging are likely not clinically relevant.[31] For patients 50 years old and

TABLE 20.1 Imaging Abnormalities in Asymptomatic Subjects

Test	Author (reference), Date	Patients (N)	Age Range (mean)	Disc Herniation	Disc Bulge	Disc Degeneration	Central Spinal Canal Stenosis	Annular Fissure
X-ray	Hult[15] 1954	1200	40–44 55–59			56% 95%		
X-ray	Hellstrom[20] 1990	143	14–25			20%

TABLE 20.2 Segmental Distribution of Asymptomatic Lumbar Age-Related Change

Segment	Disc Herniation	Nuclear T2 Signal Loss	Modic Change	HIZ
L1	0.5%	7%	1%	0%
L2	3.5%	12%	3%	4%
L3	16.5%	15.5%	4%	5%
L4	25%	49.5%	11%	23.5%
L5	35%	53%	10%	24%

Data abstracted from Kanayama M, Togawa D, Takahashi C, et al. Cross-sectional magnetic resonance imaging study of lumbar disc degeneration in 200 healthy individuals. *J Neurosurg Spine.* 2009;11:501–507.

younger, Brinjikji and colleagues found that several MRI findings were statistically significantly more prevalent in those with low back pain than those who are asymptomatic. These included disc bulges, degeneration, extrusions, protrusions, and Modic one changes. Spondylolysis demonstrated a similar higher prevalence in patients suffering from back pain. Panagopoulos and colleagues similarly demonstrated that a change over time in some findings (specifically annular fissure, disc herniation, and nerve root compromise) was twice as common in subjects with low back pain than in pain free controls. However, this higher frequency was not statistically significant.[32] However, as acknowledged by the authors of both studies, such association neither is evidence of causation, nor does it provide prognostic information or specific treatment strategies.

As in the lumbar region, age changes in the cervical and thoracic spine are common, asymptomatic, and increase in prevalence with age. Matsumoto studied nearly 500 asymptomatic patients with MRI; he noted a loss of T2 signal within cervical discs in 12%–17% of patients in their 20s, but in 86%–89% of patients older than 60 years old.[33] Asymptomatic cervical cord compression was observed in 7.6% of patients, largely over the age of 50 years. Similarly, Boden studied 63 asymptomatic subjects with MRI and noted cervical disc "degeneration" in 25% of those younger than 40 years and in excess of 60% of patients older than 40 years.[34] Asymptomatic subjects older than 40 years had a 5% rate of disc herniations and a 20% rate of foraminal stenosis. Teresi studied 100 asymptomatic subjects with MRI and noted asymptomatic cervical cord compression in 7% and either disc protrusion or annular bulge in 57% of subjects older than 64 years.[35] In the thoracic spine, Wood studied 90 asymptomatic patients with MRI.[36] In this population, 73% of the patients had positive thoracic imaging findings, 37% had disc herniations, 53% demonstrated disc bulges, and 29% had asymptomatic cord deformity.

The evidence is deep and overwhelming. The structural spine imaging findings most commonly referred to as "degenerative changes" or "degenerative disc disease," including anterior and lateral osteophytes, loss of T2 signal in the disc, loss of disc space height, disc bulges and protrusions, and facet arthrosis, are ubiquitous and unassociated with pain syndromes; their only association is with age. They can only be avoided by a youthful death. They are not a disease state and are best referred to as normal age change or age-related change. Spondylosis (or spondylotic changes) is an alternative term for these maturational changes frequently used in radiology reports.

A consequence of this high prevalence of asymptomatic age-related changes is that the imager must know the nature of the pain syndrome if he or she is to properly focus on findings significant to the unique patient under consideration. There must be concordance of the imaging finding and the pain syndrome it is postulated to elicit. Imaging cannot prove causation; hence, there is a need for anesthetic and provocative procedures. Communication regarding the nature of the pain syndrome is essential, whether this occurs through a robust electronic medical record, an intake document at the imaging site, or direct interaction of the imager with the patient.

Sensitivity: Physiologic Imaging

There is also a major sensitivity fault associated with spine imaging. Most patient symptoms referable to the spine occur in axially loaded positions, either sitting or standing. A substantial portion of radiographs and most advanced imaging (CT and MRI) are obtained in a recumbent position, removing the effects of axial load and physiologic posture. This may fail to reveal the lesion responsible for the index pain.

There is ample evidence of the effect of axial load and physiologic posture on the biomechanical and structural characteristics of the spine, derived from biomechanical, cadaver, and imaging studies. Lumbar intradiscal pressures are higher when sitting or standing than when in a recumbent position.[37] The cadaver study of Inufusa demonstrated a reduction in the cross-sectional area of the lumbar central spinal canal and lateral recesses in extension, with an increase in flexion.[38] Lumbar neural foraminal cross-section is also diminished in extension and increased in flexion. Fujiwara noted a reduction in the cadaveric lumbar neural foraminal area with side bending or rotation toward the index foramen; an increase in area was observed with side bending or rotation away from the foramen.[39] Studying normal volunteers, Schmid observed a 40 mm^2 reduction in the cross-sectional area of the dural sac at the L3–L4 level with movement from flexion to extension.[40] The lumbar neural foraminal cross-sectional area was reduced by 23% in moving from an upright neutral to an upright extended position. Danielson[41] noted a significant decrease in the dural sac cross-sectional area with axial loading in 56% of subjects, most commonly at L4–L5; this was more common with increasing age. Dynamic reduction in dural sac area with loading was less frequent in normal volunteers than in a population of patients with neurogenic intermittent claudication. Hansson and colleagues identified the ligamentum flavum as the most important

structure resulting in a dynamic reduction in the lumbar central spinal canal area under physiologic loading.[42] Physiologic posture (lumbar lordosis) is likely more important than axial load.[43] Multiple studies in patients with upright imaging have demonstrated the enlargement of lumbar disc bulges or protrusions with axial load, which may be further exacerbated with extension.[44,45] Synovial cysts, which may be provocative of radicular pain syndromes or contribute to neurogenic intermittent claudication, may be undetectable on recumbent imaging when synovial fluid remains in the facet joint space. Upon the assumption of axial load and apposition of the facet articular surfaces, the fluid is forced from the joint space into the cyst, where it may act as a neural compressive lesion.

The cervical spine similarly exhibits dynamic physiologic change with posture and load. Cadaveric studies have demonstrated increased disc bulging and buckling of the ligamentum flavum in cervical spine extension; the ligamentum flavum effect was most significant.[46] MRI studies of patients[47,48] noted an increase in central spinal canal stenosis with both extension and flexion of the cervical spine relative to neutral posture; the decrease was most marked in extension. Cervical neural foramina diminish in cross-section, width, and height in extension and increase in all these parameters in flexion.[49]

In summary, physiologic extension and axial load reduce the area of all lumbar spine compartments; these are increased in flexion. The cervical central spinal canal is diminished in areas in extension more so than in flexion; it is maximal in the neutral position. Cervical foramina increase in all dimensions in flexion and diminish in extension. These dynamic changes constitute the greatest sensitivity fault in imaging: conventional supine imaging may fail to reveal a lesion causal to the patient's symptoms when that lesion is only expressed in physiologic postures.

Several methods have been devised to overcome this sensitivity fault. Radiographs should always be obtained upright; this allows assessment of sagittal and coronal balance in a physiologic posture. Flexion-extension radiographs may detect instability not observed on neutral, upright views, but the yield of diagnostic information is very low. In studies in both the lumbar and cervical spine segments, less than 1% of flexion-extension radiographic studies provided information that was noted on static upright radiographs.[50,51] The cost and radiation exposure are best deferred to a pre-surgical setting, and not during the initial evaluation of the patient's back or neck pain.

Advanced imaging can be performed with axial loading devices on conventional CT or MRI scanners. These devices can improve the sensitivity to the detection of clinically significant central spinal canal compromise.[52] The 2011 North American Spine Society's evidence based guidelines on evaluation and treatment of spinal stenosis suggest axially loaded imaging in the setting of suspected neurogenic intermittent claudication and stenosis unconfirmed by conventional imaging, with a canal diameter of less than 110 mm.[22,53] Willén and colleagues demonstrated that surgical results of cases of occult lumbar spinal stenosis detected only by axially loaded MRI were comparable to those of stenosis observed in unloaded MRI examinations.[54]

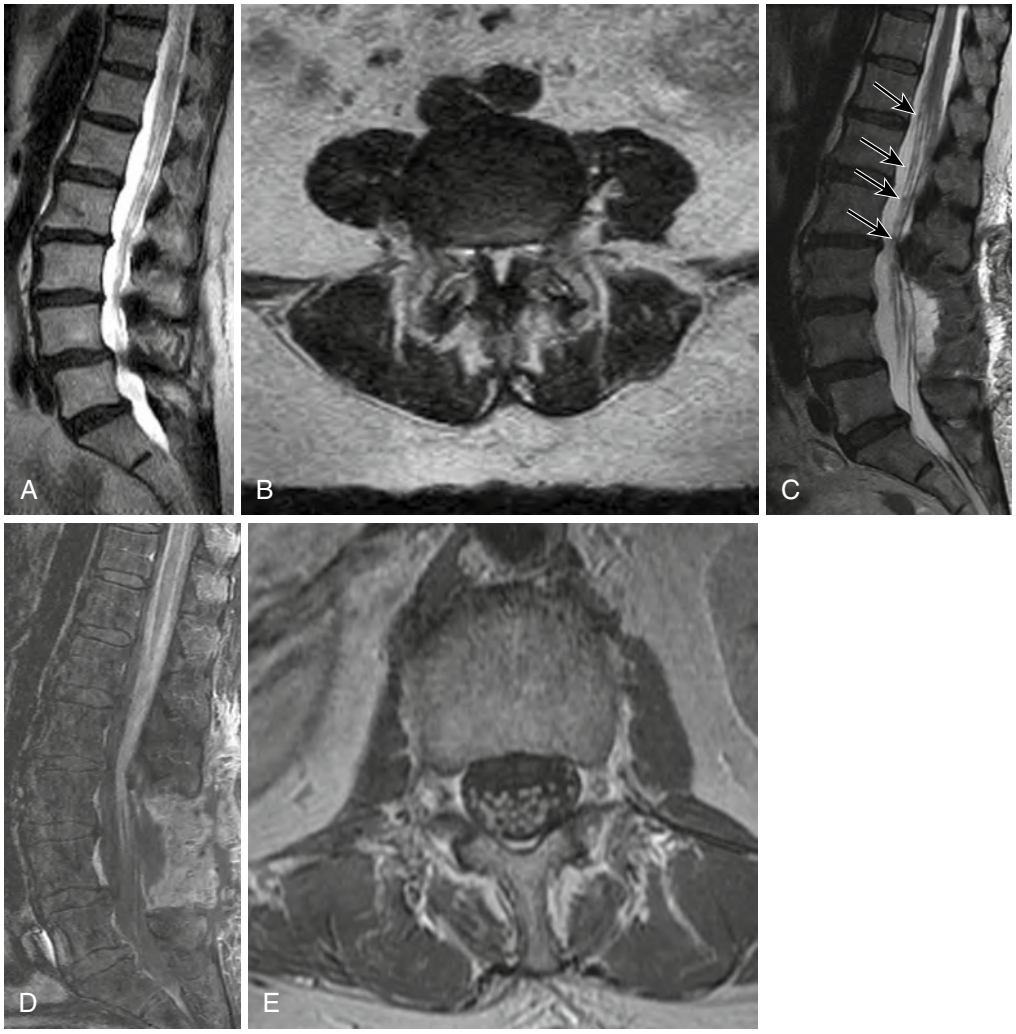
MRI scanning in an upright position—sometimes referred to as dynamic, positional, or kinetic MRI—is now commercially available and widely marketed. Depending on the specific open MRI system, images can be obtained in the standing or seated weight bearing position or during flexion, extension, rotation, bending, or even real-time spinal movement.[55] Performing MRI in a physiologically relevant position offers the possibility of improved sensitivity to detecting central spinal canal, lateral recess, or neuroforaminal stenosis, including spondylolisthesis, as recently reviewed by Baker and MacKay as well as Botchu and colleagues.[56,57] However, studies confirming the clinical and prognostic relevance (specificity) of such increased detection remain lacking.[58] Indeed, no existing literature has demonstrated improved clinical outcomes for treatments based on weight bearing MRI evaluation.[55] A practical challenge is that currently available systems are of low field strength (0.25–0.6 T), significantly lower than standard clinical field strengths (1.5 or 3 T), with an unavoidable reduction in image quality. This reduction in image quality can have important consequences for clinical image interpretation. If current low field strength dynamic systems were applied selectively to cases where conventional imaging failed to demonstrate a correlative lesion causal of the patient's pain, the patient would likely benefit. However, all too often, the cost of these systems or promotion as the best available imaging tool for all spine conditions results in their routine use. This practice could harm patients, as diminished image quality reduces sensitivity to the detection of sinister lesions, which is the primary goal of imaging the back pain patient (Fig. 20.1).

Validity

Spine imaging must be undertaken to fully understand the specificity and sensitivity faults inherent in its use. The ultimate question is one of validity: Does performing an imaging study of the spine segment in question result in improved patient outcomes through a more timely and accurate diagnosis of the process causing the patient's pain? This is well studied, particularly in the application of imaging to the acute presentation of back pain. Chou and colleagues performed a meta-analysis of the six randomized controlled trials (n = 1804) examining the role of imaging in the acute presentation of back or limb pain with no clinical features suggesting systemic disease.[59] They identified no benefit in pain, function, quality of life, or patient-rated improvement in patients undergoing imaging (radiographs, CT, or MRI) at presentation versus those undergoing clinically directed conservative care. Although routine imaging might have been expected to provide reassurance, imaged patients did not have better psychological outcomes.

Carragee and colleagues elegantly demonstrated the lack of utility of imaging in the acute setting in a five-year prospective observational study.[60] A cohort of asymptomatic subjects deemed to be at-risk for back pain resulting from labor-intensive vocations underwent lumbar spine MRI. This patient cohort was followed periodically over the subsequent five years; a subset of these subjects presented to a medical care provider with acute back or leg pain during this five-year period, and a second lumbar MRI was obtained. Less than 5% of the MRI scans obtained during acute presentations with back or leg pain showed clinically relevant new findings; virtually all of the "positive findings" noted on the images at the time of presentation with back/leg pain had been present in the baseline data obtained when the patient was asymptomatic. Only direct evidence of neural compression in patients with a corresponding radicular pain syndrome was considered useful imaging information. Of particular note, psychosocial factors, not the morphology seen on imaging, were the best predictors of the degree of functional disability caused by back or leg pain.[60]

A study by Modic,[61] also in the acute presentation of low back pain or radiculopathy, showed no relationship between the extent of disc herniations and presenting signs or symptoms. The type,



• **Figure 20.1** Diminished sensitivity of low field strength upright MRI to sinister lesions. A 74-year-old female presented with bilateral lower extremity weakness and pain with a low field strength upright MRI from another institution. Sagittal T2 image **(A)** and axial T2 image **(B)** at the L4 level show degenerative spondylolisthesis at L4 with central spinal canal compromise. She underwent an L3–L5 decompression without change in symptoms. A 1.5 Tesla MRI performed three weeks postoperatively demonstrated nodularity *(arrows)* in the cauda equina on a T2 sagittal image **(C)**. Gadolinium-enhanced fat-saturated T1 sagittal **(D)** and axial **(E)** images demonstrate diffuse leptomeningeal metastases from breast cancer. She died in two months. A high quality preoperative MRI would have likely led to the diagnosis and avoided an unnecessary operation. *MRI,* Magnetic resonance imaging. (From Khalil JG, Nassr A, Maus TP. Physiologic imaging of the spine. *Radiol Clin North Am.* 2012;50:599–611.)

size, or location of a herniation at presentation, or change in size or type over time, did not correlate with clinical outcomes. MRI imaging characteristics did not have measurable value in planning conservative care. The study emphasized that surgical decisions must be made on clinical grounds, given the inability of imaging to predict outcomes. The Modic study, like that of Carragee, demonstrated that psychosocial factors predict functional disability better than imaging parameters.[61]

Although the depth of evidence regarding the inability of imaging to improve outcomes in back and limb pain patients is most profound in the acute setting, it applies more broadly. Chou and colleagues[11] explored the seemingly counterintuitive finding that routine imaging does not lead to better back or limb pain outcomes. This lack of utility can be attributed to the favorable natural history of back and limb pain, the low prevalence of sinister disease as causal of back pain, the weak correlation between imaging findings and symptoms (the specificity fault), and the minimal impact of imaging on clinical decision making. Given the demonstrable modest utility of imaging, the decision to undertake this path must be a carefully reasoned one.

Imaging Risk/Benefit

The decision to proceed with any medical test or procedure should be preceded by a consideration of likely benefit weighed against risk or actual harms. There are benefits to be derived from imaging. Foremost, imaging may suggest the diagnosis of previously unsuspected systemic disease. In patients with a radicular pain syndrome or radiculopathy that has not responded to conservative therapy, imaging may supply invaluable information that allows planning minimally invasive or surgical procedures. Negative imaging could also be valuable in providing reassurance that there is no sinis-

ter disease present and stopping further workup in appropriate circumstances. In patients with chronic pain syndromes, imaging may help to identify the structural or inflammatory cause of such pain. Only when a specific pain generator is identified can a specific therapeutic intervention plan be developed, whether conservative or invasive. Advanced imaging, specifically MRI, can also help plan minimally invasive procedures, such as epidural steroid injections. In this setting, information on anatomy and pathology obtained from MRI allows the interventionalist to rationally plan a procedure in an attempt to maximize its efficacy and minimize patient risk.[62] Although, at a minimum, it is helpful on a case-by-case basis, debate exists as to whether such pre-epidural steroid injection MRI examinations are routinely needed. Based on a randomized controlled trial, the availability of MRI results to the proceduralist performing epidural steroid injections has not been conclusively shown to improve outcomes or significantly affect decision making.[63] However, subgroup analyses of the study cohort suggest that both leg pain score and functional assessment at three months after injection demonstrated greater improvement for those who had injections at optimal levels compared to those in whom the injected location occurred at levels disparate from the MRI findings.[62] Moreover, in one-third of patients for whom the MRI was withheld, an injection different than what would have been recommended if MRI results were available was performed.[62,63] We (the authors of this chapter) do support the use of preprocedural MRI when epidural steroid injections are being considered.

There are direct harms and potential risks associated with imaging, which must be balanced against potential benefits. These include radiation dose, cost, the labeling effect, and the downstream risk of provoking minimally invasive or surgical interventions of dubious efficacy.

Radiation dose in radiography, CT, or CT/myelography, and nuclear medicine studies, constitutes direct patient harm. Radiation exposure from radiographs, CT, and nuclear medicine studies carries a cumulative risk of neoplasm induction. This risk becomes particularly problematic when serial studies are performed. The biologically effective absorbed radiation dose is measured by the Sievert (Sv); in North America, the average annual natural background exposure is approximately 3 mSv.[64] A frontal and lateral chest radiograph is often considered the common currency of radiation exposure, incurring a dose of approximately 0.1 mSv. A three-view lumbar spine radiographic series is then worth approximately 15 chest radiographs or 1.5 mSv; cervical spine radiographs incur a dose of 0.2 mSv. A dose of 6 mSv is typical for a lumbar spine CT scan, a value of 60 chest radiographs. Cervical spine CT incurs 2 mSv or 20 chest radiographs. A technetium bone scan has a dose of 6.3 mSv. The cumulative radiation exposure creates real harm; the 2.2 million lumbar spine CT scans performed in the United States in 2007 were projected to result in 1200 future cancers.[65] Although less radiation intensive, lumbar radiography is performed much more frequently than CT and contributes nearly five-fold the cumulative radiation burden to the United States population.[66] The average annual radiation exposure from lumbar radiographs is 75 times that of chest radiography.[66] Radiation risks of spine imaging are made more significant by the necessary inclusion of radiosensitive tissues, the gonadal structures in the pelvis, and the thyroid in the neck.

Imaging studies of the spine are costly. In the United States, the medical imaging community incurs more than $100 billion of societal cost per year. The 2020 Medicare reimbursements[67] for lumbar spine imaging include radiographs: $42; non-contrast CT: $172; CT-myelogram: $504; non-contrast MRI: $241; whole-body positron emission tomography (PET)/CT: $1621; and bone scan with single-photon emission CT (SPECT): $340.[67] Nominal fees are typically three to five times the Medicare reimbursements. It is easy to appreciate how quickly imaging costs can accrue.

The labeling effect refers to the inevitable identification of age-related change, usually described as "degenerative change" or "degenerative disc disease" on imaging studies obtained in the evaluation of back or limb pain. The patient may then perceive that he or she suffers from a degenerative spine condition; the term "degenerative" has only negative connotations. Fearing further damage to their "degenerative" spine, they may give up favorite activities and exercise, resulting in deconditioning and contributing to depression. These fear-avoidance behaviors can be a major impediment to recovery. In a study in which back pain patients were randomized to either receiving or being blinded to the results of their MRI imaging, those who were privy to the results (which were all benign) had a lesser sense of wellbeing.[61] A study of subacute or chronic back pain patients showed that those who underwent spine radiography reported more pain, had a diminished global health state, and consumed more follow up care than those who were not imaged. These findings emphasize the need for patient education regarding the insignificance of age-related imaging findings; imaging professionals should carefully choose descriptive language in imaging reports and avoid the use of pejorative terms such as "degenerative change."

Finally, and most ominously, imaging may precipitate interventions with little evidence of efficacy and expose the patient to harm. Jarvik and colleagues[68] documented that obtaining advanced imaging (MRI) early in a patient's spine pain syndrome leads to increased surgical interventions despite equivalent pain and disability profiles compared with un-imaged patients. Likewise, Lurie and colleagues[69] examined the dramatic regional variation (12-fold) in the rate of surgical intervention for central spinal canal stenosis. These investigators noted that the rate of surgical intervention correlated directly with the intensity of CT and MRI use. In evaluating subjects with acute job-related back pain, Webster and colleagues noted that undergoing an MRI in the first month of symptoms was associated with an eight-fold increased risk for surgery and a five-fold risk for more medical care consumption than that noted for clinically matched, un-imaged subjects.[70] Even in healthcare settings largely unaffected by fee-for-service incentivization, such as the United States Department of Veterans Affairs, early lumbar spine MRI is associated with increasing utilization, such as surgery.[71] Many of the interventions directed toward spine pain, both surgical and minimally invasive, have only modest, if any, evidence basis. Unfortunately, as evidenced by a recent study by Jarvik and colleagues, even including spine imaging reports, epidemiologic data on the high prevalence of lumbar spine degenerative imaging findings seem unlikely to affect subsequent spine related utilization (further imaging, clinical evaluation, or procedure/surgery). However, subsequent opioid prescriptions may be slightly reduced.[72] As noted by the authors, there may be unmeasured benefits from patients and their providers better being able to interpret the significance of imaging findings.

Imaging Recommendations

Imaging is performed to identify the cause of a patient's back or limb pain. Spine imaging has major specificity and sensitivity faults. The decision to initiate imaging must occur as a reasoned decision, weighing potential benefits against the real harm and

risks. The evidence is clear there is no benefit to imaging in the acute presentation of uncomplicated back or limb pain in the absence of signs or symptoms of systemic disease. These principles are firmly based on evidence and have led to the imaging guidelines promulgated by several scientific societies. A 2015 study by Jarvik and colleagues is an example of a relatively recent investigation that confirms these principles. Based on a prospective cohort of over 5,000 patients aged 65 years or older with a new primary care visit for back pain from 2011–2013, early imaging (radiographs or MRI/CT) in the first six weeks after the index visit was not associated with better outcomes at 12 months.[73]

These guidelines are not new. In 1994, the Agency for Health Care Policy and Research recommended against imaging patients with back pain within the first month of a pain syndrome without signs of systemic disease.[74] The American College of Radiology (ACR) consensus practice guidelines were restated in 2016.[75] Imaging is not indicated in the patient who presents with acute low back pain with or without radiculopathy except in the presence of "red flag" features raising the suspicion for serious underlying conditions, including:

Potential cancer or infection:

- History of cancer
- Unexplained weight loss
- Immunosuppression
- Urinary infection
- Intravenous drug use
- Prolonged use of corticosteroids
- Back pain not improved with conservative management (up to six weeks of medical management and physical therapy)

Potential spinal fracture:

- History of significant trauma
- Minor fall or heavy lift in a potentially osteoporotic or elderly individual
- Prolonged use of corticosteroids

Potential cauda equina syndrome or severe neurologic compromise:

- Acute onset of urinary retention or overflow incontinence
- Loss of anal sphincter tone or fecal incontinence
- Saddle anesthesia
- Global or progressive motor weakness in the lower limbs

A 2007 joint recommendation from the American College of Physicians (ACP) and the American Pain Society stated that imaging should not be obtained in patients with nonspecific low back pain.[76] More recent guidelines/recommendations of other societies, including the Choosing Wisely initiative established by the American Board of Internal Medicine, continue to align with this 2007 recommendation. Imaging should only be performed when severe or progressive neurologic deficits are present or when serious underlying systemic disease is suspected. Furthermore, patients with signs or symptoms of radiculopathy or spinal stenosis should be imaged only if they are candidates for surgical or minimally invasive intervention (e.g. epidural steroid injection). In a further elaboration on these guidelines, the ACP, in its initiative to promote high-value medical care, provided more specific imaging recommendations based on clinical scenarios (Table 20.3).[77]

There is evidence that of the small proportion of subjects with a sinister disease as the cause of their back or limb pain, virtually all have risk factors that trigger imaging under these guidelines. A retrospective study of 963 patients presenting with acute low back pain noted that the eight subjects with neoplasm all had clinical risk factors.[78] In a prospective study of 1170 acute low back pain patients without clinical risk factors, no cases of neoplasm were found.[79] No sinister disease was missed in the absence of clinical risk factors in a subsequent systematic review.[80]

Despite these well-supported, evidence based guidelines, clinical practice in the United States remains greatly divergent from this ideal. By one estimate, between one-third and two-thirds of all advanced spine imaging is inappropriate when measured against existing guidelines.[4] Utilization of spine imaging is accelerating despite a complete

TABLE 20.3 Suggestions for Imaging in Patients With Acute Low Back Pain

Imaging Action and Clinical Situation	Suggestions for Initial Imaging
Immediate Imaging Radiography plus erythrocyte sedimentation rate* Magnetic resonance imaging	Major risk factors for cancer (new onset of low back pain with history of cancer, multiple risk factors for cancer, or strong clinical suspicion for cancer). Risk factors for spinal infection (new onset of low back pain with fever and history of intravenous drug use or recent infection). Risk factors for or signs of the cauda equina syndrome (new urine retention, fecal incontinence, or saddle anesthesia). Severe neurologic deficits (progressive motor weakness or motor deficits at multiple neurologic levels).
Defer Imaging After a Trial of Therapy Radiography with or without erythrocyte sedimentation rate Magnetic resonance imaging	Weaker risk factors for cancer (unexplained with weight loss or age >50 years). Risk factors for or signs of ankylosing spondylitis (morning stiffness that improves with exercise, alternating buttock pain, awakening because of back pain during the second part of the night, or younger age [20 to 40 years]). Risk factors for vertebral compression fracture (history of osteoporosis, use of corticosteroids, significant trauma, or older age [>65 years for women or >75 years for men]). Signs and symptoms of radiculopathy (back pain with leg pain in an L4, L5, or S1 nerve root distribution or a positive result on straight leg raise or crossed straight leg raise test) in patients who are candidates for surgery or epidural steroid injection. Risk factors for or symptoms of spinal stenosis (radiating leg pain, older age, or pseudoclaudication) in patients who are candidates for surgery.
No imaging	No criteria for immediate imaging and back pain improved or resolved after a one-month trial of therapy. Previous spinal imaging with no change in clinical status.

*Consider magnetic resonance imaging if the initial imaging result is negative, but a high degree of clinical suspicion for cancer remains.

Adapted from Chou R, Qaseem A, Owens DK, et al. Diagnostic imaging for low back pain: advice for high-value health care from the American College of Physicians. *Ann Intern Med.* 2011;154:181–189, Table 4.

lack of evidence of its effectiveness in improving the outcomes of back and limb pain patients. Chou and colleagues have enumerated the causes of this overutilization: inappropriate patient expectations, direct and indirect financial incentives on the part of providers, defensive medicine, and provider time constraints.[11,76,77] These issues present great challenges to imaging professionals and those who utilize imaging to improve the clinical state of their patients. Solutions will undoubtedly be multifactorial,[81] but the education of the patient, the imaging professional, and imaging consumers would seem to be at the heart of the matter. It is hoped that the evidence presented here will assist in more rational decision making regarding imaging the spine pain patient (Box 20.1).

Clinical decision support tools represent an emerging array of applications for helping providers decide whether to order spinal imaging and, if so, what modality. Electronic templates can be and have been created to assist practitioners in various clinical scenarios, including acute low back pain.[82] The use of such templates can decrease total imaging and MR imaging rates in ambulatory care and emergency department settings, though providers may still have valid reasons for over-riding the decision support tool's recommendation not to image.[83,84] Feedback on evidence based guideline adherence ("report cards" for ordering providers) can reduce outpatient lumbar spine MRI ordering.[85] Such relatively low cost health information technology tools can promote evidence based, high-value, and cost-conscious care for patients experiencing spinal pain.[86] Hopefully, they will be increasingly utilized.

Radiographs

With the failure of clinically directed conservative care and having made a reasoned decision to initiate imaging of the spine pain patient, the choice of imaging modality should, according to the ACR, be based on the working diagnosis, the urgency of the clinical problem, and the comorbidities of the patient.[75] Radiographs are not routinely recommended for acute nonspecific low back pain, because of their inherently low value in making a specific diagnosis. However, radiography is the initial modality of choice for patients with low back pain who have a history of low velocity trauma, osteoporosis, or steroid use, or for those who are elderly (i.e. for those who are suspected of having vertebral compression fractures). Such radiographs should ideally be upright, weight bearing, and include the appropriate spine segment. Radiography is also recommended to evaluate a young patient for AS.[75] The ACR and the ACP are consistent in their recommendations that patients with "red flag" features of recent low velocity trauma, osteoporosis, age greater than 70 years, or chronic steroid use (i.e. possible vertebral compression fracture), or young patients with clinically suspected inflammatory spondyloarthropathy should initially undergo radiographs; advanced imaging (specifically, MRI as the first line) should be reserved for patients with progressive neurologic deficits or a strong clinical suspicion of infection or neoplasm or immunosuppression, or in those with persistent symptoms after six weeks of conservative management.[75–77] Radiographs provide a modest sensitivity screen for sinister conditions, establish spine enumeration, and assess the sagittal and coronal plane balance when performed in physiologic positions.

• Box 20.1 Spine Imaging Principles

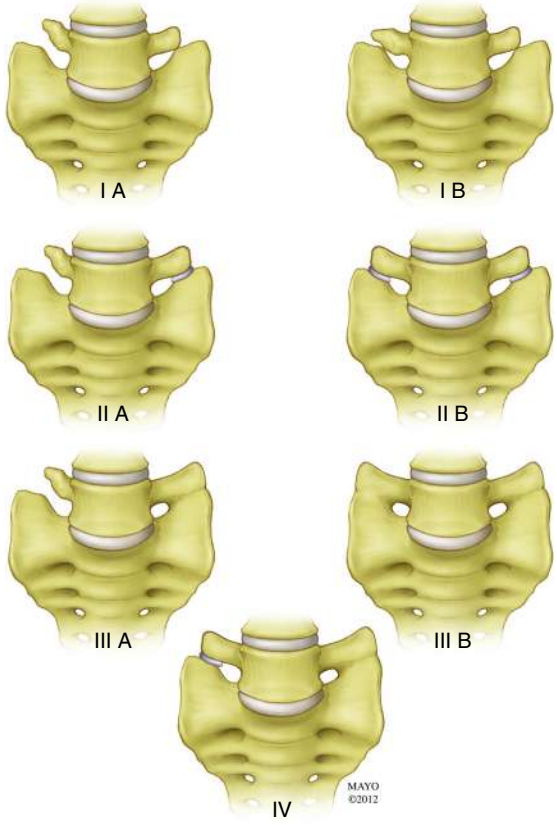
- The primary role of imaging is the identification of undiagnosed systemic disease.
- Spine imaging has a significant specificity fault: a high prevalence of asymptomatic age-related "degenerative" findings.
- Significance of imaging findings depends on concordance: the imager must know the pain/dysfunction syndrome.
- Spine imaging may be insensitive to dynamic lesions.
- No imaging is indicated in the acute presentation of back or limb pain in the absence of "red flag" features.
- The decision to undertake imaging must be a reasoned harms and risk/benefit judgment.
- Imaging correlates poorly with clinical presentation and course.

Spine enumeration is a critical but underappreciated role of radiographs. The typical spine morphology of 24 mobile, presacral spine segments (seven cervical, 12 rib-bearing thoracic, and five lumbar type vertebral bodies) is not uniformly present; deviation can cause confusion in establishing the origin of pain syndromes, or wrong segment minimally invasive or surgical interventions. It can be reasonably assumed in the human species that there are seven cervical vertebrae. Considerable variation in the number and distribution of thoracic and lumbar segments may be difficult to appreciate on MRI alone; radiographs can establish this enumeration and serve as the foundation for subsequent advanced imaging description.

In a study by Carrino and colleagues using complete spine radiographs, 91.8% of subjects had 24 presacral vertebral segments: 4.8% had 23, and 3.4% had 25.[87] Using full spine sagittal MRI localizer images, Akbar and colleagues identified 23 presacral segments in 3.3% of subjects and 25 in 3.3%; these anomalies of spine enumeration were not mentioned in the radiology report in nearly 70% of cases.[88] In Carrino's study, if one considers both anomalous number and distribution (e.g. 13 rib-bearing vertebrae + 4 lumbar type vertebrae) of thoracolumbar spine segments, 10.9% of subjects had nonclassical anatomy.[87] For the spine interventionalist, this implies that these situations are encountered in the procedure room regularly; failure of recognition virtually guarantees wrong segment procedures.

Anomalous segmentation is predicted by the presence of transitional thoracolumbar or lumbosacral vertebral bodies, which may be a source of confusion. Thoracolumbar transitional segments have hypoplastic ribs at the lowest rib-bearing segment; they were present in 4.1% of subjects in Carrino's study.[87] Lumbosacral transitional segments have characteristics of both the L5 lumbar body and the superior sacral segment; their described prevalence ranges from 4%–30%.[89] The Castellvi classification (Fig. 20.2) describes the morphologic types, ranging from an expanded (height >19 mm) dysplastic transverse process (type I), through a pseudoarticulation between the transverse process and sacral ala (type II), to osseous fusion between the transverse process and the sacrum (type III).[90] Type IV denotes the presence of a type II transition on one side and a type III on the other. Unilateral (a) and bilateral (b) subtypes are also described. On lateral radiographs or sagittal MRI images, a transitional segment can be suggested in the presence of a perceived narrow S1–S2 disc, which extends for the entire anterior-posterior (AP) width of the sacral body with parallel endplates and a squared upper sacral segment (Fig. 20.3).[89] The presence of a transitional lumbosacral segment increased by seven-fold the likelihood of an anomalous number of presacral segments. In patients with radicular pain syndromes and lumbosacral transitional anatomy, the pain practitioner must also know the possibility of an extraforaminal nerve entrapment between the enlarged transverse process and sacral ala.

Correlation of pain syndromes with imaging findings can be confounded in patients with transitional anatomy or anomalous segmentation. It is best to consider that radicular innervation



• **Figure 20.2** Castellvi Classification of lumbosacral transitional segments.

patterns remain relatively constant when counted caudally from the skull base, but the skeletal anatomy may change about them. For example, the 26th nerve (eight cervical, 12 thoracic, five lumbar, first sacral nerves) from the skull base most commonly innervates the medial head of the gastrocnemius and the soleus muscles, the basis of the S1 radicular pain pattern. A patient with 25 presacral vertebral segments may exit under the pedicle of the lowest lumbar type vertebral body, creating confusion for the unwary practitioner (Fig. 20.4). There is also variation in typical innervation patterns in the presence of transitional anatomy, which may introduce further localization challenges. Only meticulous attention to spine enumeration, best provided by plain radiographs, sometimes supplemented by total spine MRI localizer images, will protect the spine pain patient and interventionalist from wrong segment invasive procedures (Box 20.2). Sometimes, available chest or spinal radiographs or CT examinations of the chest/abdomen/pelvis or thoracic/lumbar spine can be similarly useful in establishing enumeration.

When radiographs are obtained, they should be upright, weight bearing images. Only in a physiologic posture can one assess sagittal and coronal balance (Fig. 20.5). Upright radiographs demonstrate more thoracic kyphosis and lumbar lordosis than do recumbent images.[91] Weight bearing images may also demonstrate instability, most commonly L4–L5 degenerative spondylolisthesis, which would be occult on recumbent films.[92] Radiographs can be complementary to and provide further information than MRI. For instance, spondylolisthesis is often more pronounced on an upright radiograph than MRI, with the latter potentially underestimating the degree of listhesis and associated central spinal canal narrowing. In spinal deformity patients, the exacerbation of spinal curves with weight bearing can be dramatic. Flexion-extension radiographs in the lumbar or cervical spine are not indicated as part of an initial imaging investigation. There is no role for oblique radiographs of the spine. In the lumbar region, they double the gonadal dose and do not provide useful information that will affect clinical decision making.[92] Cervical spine oblique views similarly serve only to irradiate sensitive tissue (thyroid, lens of the eye) without clinical benefit.

Advanced Imaging Modalities

When patients who are deemed to be interventional candidates have low back pain lasting over six weeks despite conservative management, advanced imaging (CT, MRI, nuclear medicine) may be obtained. MRI is considered the first line in those with radiculopathic symptoms and in patients with severe or progressive neurologic deficits on presentation and red flag features raising suspicion for a serious underlying condition.[75] CT has undergone a revolution since the early 2000s with the advancement of multidetector technology. A data set for the lumbar spine can now be obtained in a few seconds, eliminating motion artifacts and dramatically improving patient tolerance. This data set can then be reconstructed in any plane without losing spatial resolution or additional radiation exposure. CT provides superior imaging of cortical and trabecular bone when compared with MRI. CT may be necessary to characterize primary bone tumors of the spine. This also helps explain why CT is typically the first line modality used in the acute trauma setting for fracture identification, especially in high energy trauma or other settings meeting the high-risk criteria for potential vertebral injury.[75] CT is also excellent at depicting osseous structural problems such as spondylolysis, pseudarthrosis, fracture, scoliosis, and stenosis, and in the postoperative evaluation of bone graft integrity, surgical fusion, and instrumentation.[75] In addition, CT provides reasonable contrast resolution and can identify root compressive lesions, such as disc herniations or characterize central spinal canal, lateral recess, and foraminal compromise, in most cases. CT cannot typically identify intrathecal pathology and is less sensitive than MRI in the detection of early inflammatory or infectious processes, neoplasm, or paraspinal soft tissue lesions. Radiation dose must always be considered when employing CT, particularly in young patients or in serial studies. One by-product of the rapid technologic advance of CT is that the literature contains no comparative studies between MRI and the latest generation of multidetector CT scanners in the detection and characterization of disc herniations. When advanced cross-sectional imaging of the spine is indicated, but the patient is not an MRI candidate, CT is an excellent alternative.

MRI has been the dominant spine imaging modality since the 1990s, despite modest technologic advancement in the realm of spine imaging in that time span. MRI has superior contrast resolution and thus the ability to distinguish between soft tissue types, allowing it to detect intrathecal pathology and identify subtle root compressive lesions. Therefore it is the first line modality for those suspected of having spinal cord compression, spinal cord injury, or cauda equina syndrome. MRI also has superior sensitivity in the detection of neoplasm and infection.

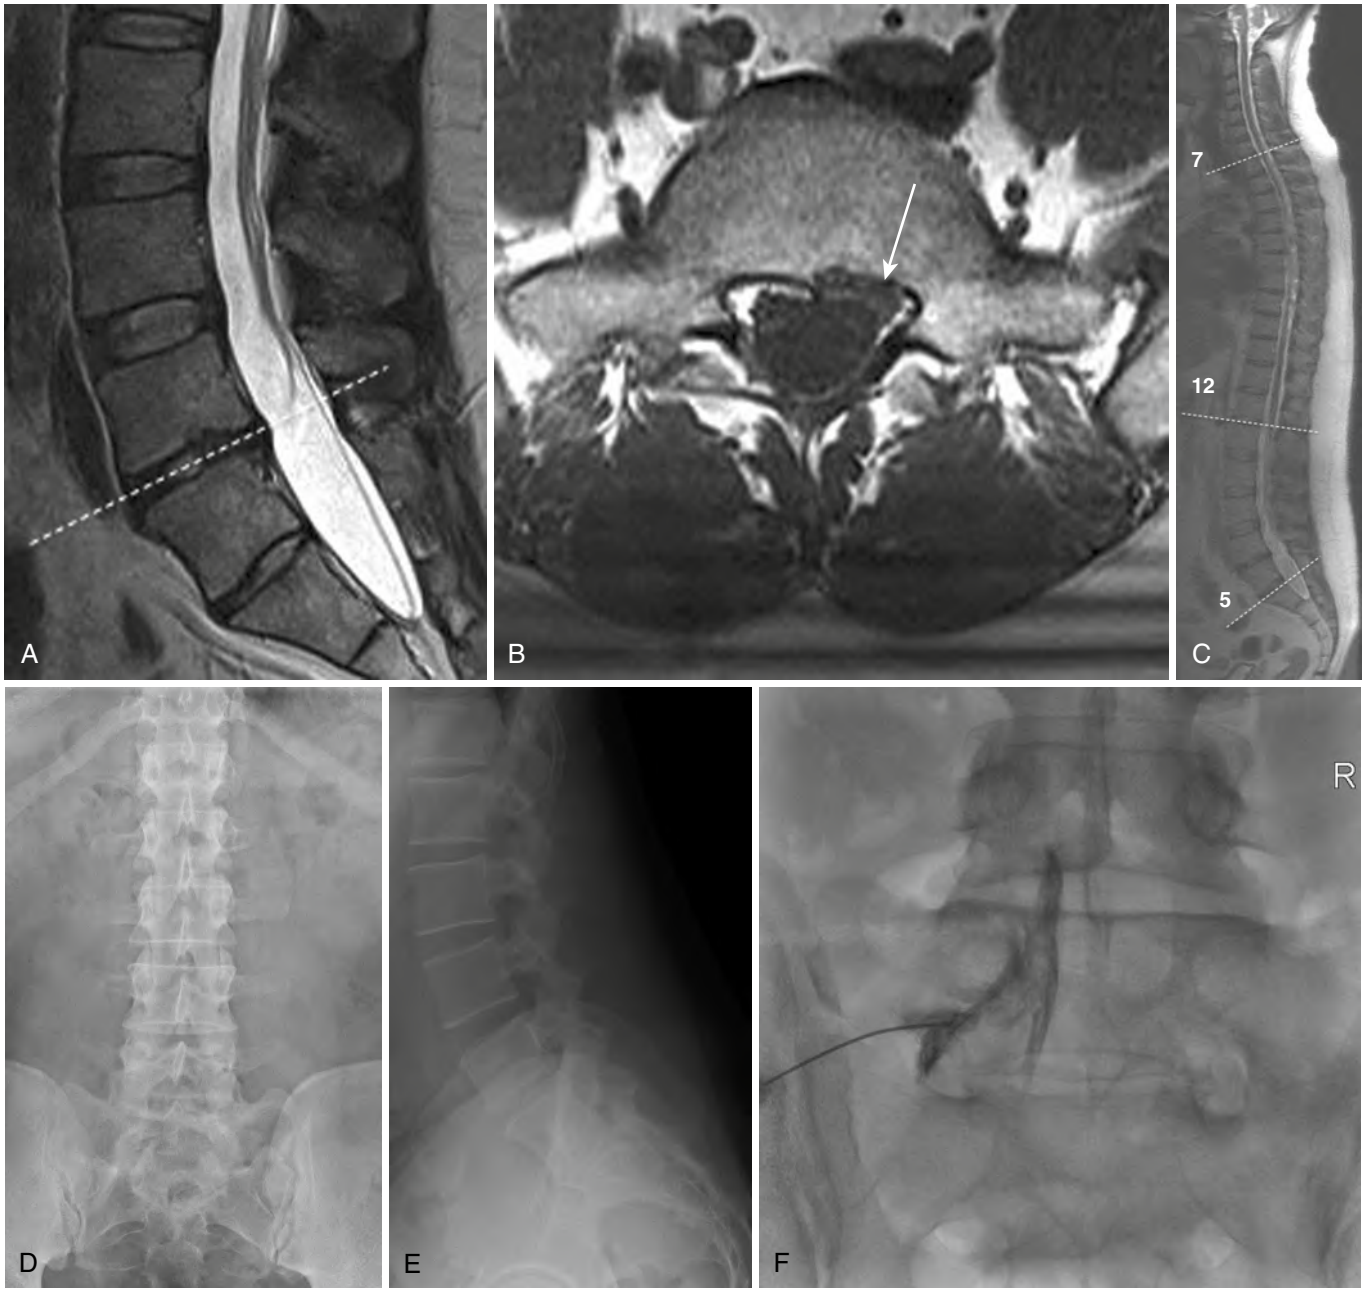
With the use of heavily T2-weighted imaging sequences (short tau inversion recovery [STIR] or fast spin-echo T2 sequences with fat saturation) or gadolinium-enhanced T1-weighted images with fat saturation, MRI can detect the physiologic parameters of edema, hyperemia, and inflammatory change. It

• **Figure 20.3** Transitional segments. Lateral radiograph **(A)** and sagittal T2 magnetic resonance image **(B)** demonstrate typical findings of a transitional segment interspace *(arrows):* a narrow disc space with parallel endplates and normal T2 signal intensity. Castellvi IIa transitional segment is demonstrated in frontal **(C)** and lateral **(D)** radiographs. Note right pseudoarticulation. In another patient, frontal radiograph **(E)** shows a left-sided pseudoarticulation, also seen on the axial computed tomography image (*arrows* in **[F]**). Narrow, parallel endplates are visible in the transitional interspace on the lateral radiograph **(G)**. This patient had axial pain attributed to the pseudoarticulation; this was injected **(H)** with relief of the index pain.

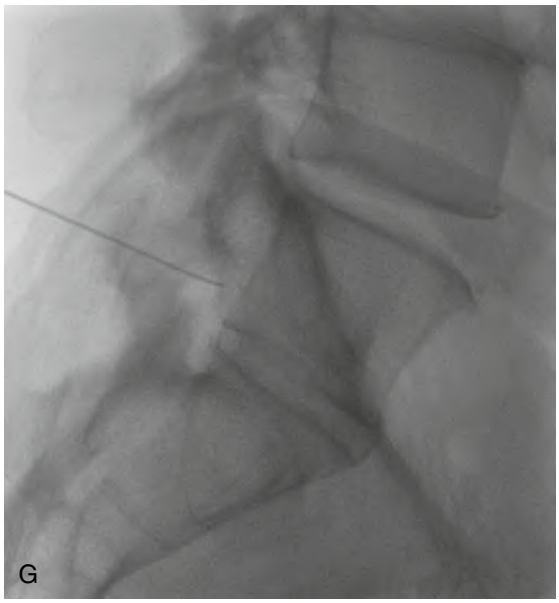
has greater specificity than CT in characterizing the age/acuity of fractures. With gadolinium enhancement, MRI can distinguish between recurrent disc herniation and scarring in the postoperative patient; in this setting, it should be performed without and with intravenous contrast. MRI does not evaluate the cortical bone well. Patient acceptance remains problematic because of prolonged imaging times and up to 10% examination failures caused by claustrophobia; this has decreased as imaging practices have increasingly incorporated both wide bore scanners[93] and/or sedation into a routine offering for MRI (typically with oral benzodiazepines). Open magnets also have improved patient acceptance but at the cost of image quality. Despite advances, including MRI-safe implanted devices becoming more commonplace, a small percentage of patients are MRI incompatible

because of some cardiac devices, spinal cord stimulators, or other implanted devices. MRI remains costly. The sensitivity challenges imposed by recumbent MRI imaging were discussed earlier; the hope is that the engineering challenges of high field strength, weight bearing MRI imaging will be met in the near future.

CT myelography retains a problem solving role in the lumbar spine; especially if a routine CT has not answered the clinical question, it will substitute for MRI in the MR-incompatible patient. CT myelography has superior spatial resolution when compared with MRI but lacks its soft tissue contrast resolution. It can provide an exquisite demonstration of root compressive lesions



• **Figure 20.4** The importance of segmental enumeration. This 36-year-old male who has failed conservative care presents with a left-sided L5 radicular pain pattern involving the lateral thigh, lateral calf, and dorsum of the foot. His magnetic resonance image (MRI) (sagittal T2 **[A]** and axial T1 **[B]** at level of *dotted line*) shows a subtle disc extrusion in the left lateral recess (*arrow* in **[B]**) at the second to last interspace. The lowest-most disc appears transitional. MRI scout **(C)** image demonstrates 24 presacral segments. Frontal and lateral radiographs (**D** and **E**) may suggest five lumbar vertebrae on cursory examination. Careful counting at fluoroscopy noted 11 rib-bearing vertebrae. T12 has no ribs, and L5 is transitional, Castellvi type 4. The transforaminal epidural steroid injection (**F** and **G**) was performed under the pedicle bearing the dysplastic left T5 transverse process and relieved the patient's pain.



• **Figure 20.4, cont'd** Note **(G)** the typical appearance of transitional disc space. Careful enumeration of every case is the only way to avoid wrong segment interventions.

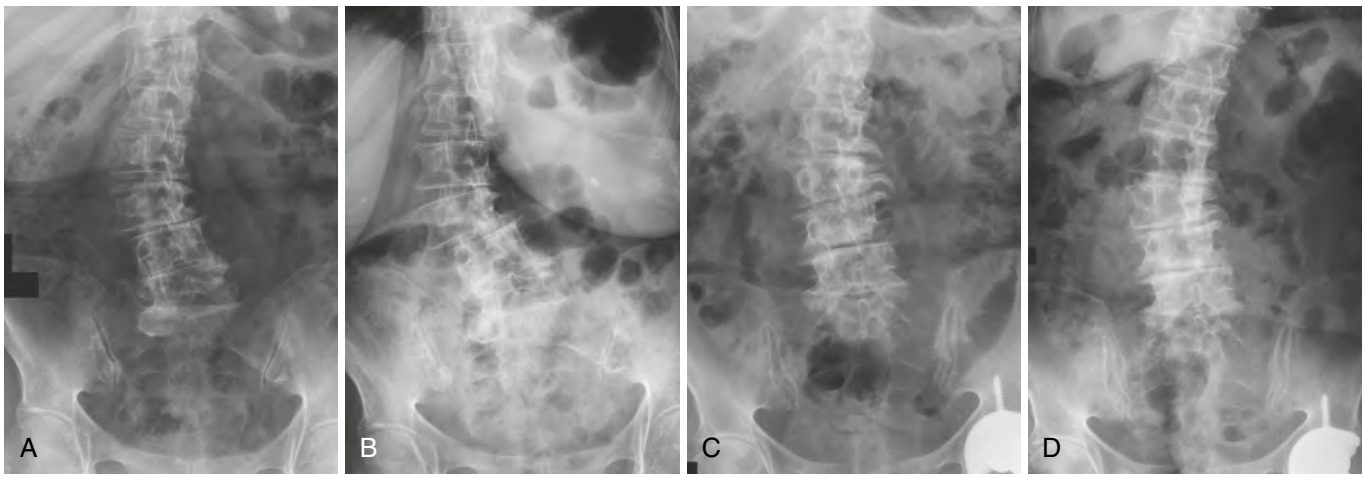
• Box 20.2 Spine Enumeration

- Approximately 11% of subjects will have anomalies of number or distribution of thoracolumbar vertebral bodies.
- Anomalous segmentation is predicted by the presence of transitional thoracolumbar or lumbosacral vertebral bodies.
- Ideally, vertebral numbering should occur from the skull base caudally.
- Practically, the human cervical spine is homologous and can be assumed to have seven segments.
- T1 is marked by the first upward inclined transverse process.
- Meticulous enumeration on every case will prevent wrong segment procedures.

and central spinal canal, lateral recess, and foraminal compromise. In the cervical spine, the superior spatial resolution of CT myelography and its ability to discriminate between bone and soft tissue compressive lesions give it a continuing role. CT myelography is minimally invasive, expensive, operator dependent to a degree, and also requires current CT technology to be maximally useful.

Cone-beam CT, weight bearing myelography holds promise for assessing position dependent pain syndromes, at least in part defeating the sensitivity fault of recumbent advanced imaging.[94] In this technology, arising from rotational angiography roots, the C-arm rapidly rotates about the standing patient who has had contrast introduced into the thecal sac. A flat panel fluoroscopy detector gathers a data set that can be reconstructed in any plane. Soft tissue contrast does not approach that of true CT, and the longitudinal field of view is limited to the length of the flat panel detector. Despite these limitations, the high inherent contrast among intrathecal contrast, the soft tissue structures of the spinal column, and bone allow for a very good depiction of the central spinal canal, lateral recess, and foraminal compromise. This technology will presumably only improve, but it is not in widespread clinical use even at institutions where it is available (Fig. 20.6). A lower-resolution version of this dynamic is multipositional conventional myelography. In a study of 100 patients, Merkle and colleagues showed that compared to supine MRI, 137 additional stenotic segments were diagnosed in 64 patients by standing myelography with extension, suggesting that routine MRI frequently underestimates spinal stenosis.[95]

Nuclear medicine studies are growing in importance in spine imaging. Technetium pyrophosphate bone scans detect increased blood flow and accelerated bone metabolic activity. With the addition of SPECT and SPECT/CT image fusion, significant additional spatial localization of hyperemia and increased metabolic activity are possible. This imaging is traditionally helpful in assessing the burden of metastatic disease but can also be valuable in assessing non-neoplastic inflammatory states such as spondylolysis. SPECT/CT can potentially identify inflammatory synovitis in the facet and sacroiliac joints, which might guide interventions.



• **Figure 20.5** The effect of upright weight bearing radiographs on balance and deformity. Recumbent radiograph **(A)** shows lumbar scoliosis with a rotatory component, which is significantly exacerbated in a subsequent upright radiograph **(B)**. In another patient, the recumbent radiograph **(C)** underestimates the true scoliotic curve seen on an upright radiograph **(D)**. Sagittal and coronal balance can only be assessed on upright, weight bearing imaging.

• **Figure 20.6** Ligamentum flavum redundancy (buckling) on upright myelography (cone-beam computed tomography [CT]). A 66-year-old man imaged for neurogenic intermittent claudication. Conventional myelogram in the lateral plane with the patient in the prone position **(A)** and postmyelogram sagittal **(B)** and axial CT at L4–5 interspace **(C)** with the patient in the prone position show minimal redundancy of the ligamentum flavum *(black arrows)* and mild central spinal canal compromise at the L4–5 level. Cone-beam CT myelography with the patient in an upright position demonstrates a marked increase in ligamentous buckling *(white arrow)* on the sagittal reconstruction **(D)** and complete effacement of the thecal sac on the axial reconstruction **(E)**. (Courtesy of Kent Thielen, MD, Mayo Clinic, Rochester, MN.)

However, validation studies of these techniques against accepted reference standards such as comparative blocks in the facet joints or intra-articular sacroiliac blocks have not yet been conducted. When MRI is not technically feasible, technetium bone scanning can be used to characterize the age of vertebral fractures in selecting patients for bone augmentation. The technetium bone scan, combined with gallium scan, offers sensitivity equal to MRI in the detection of spondylodiscitis. However, these techniques provide less anatomic information and a lesser ability to make a specific diagnosis; MRI may ultimately be necessary to characterize the degree of central spinal canal compromise that may influence surgical decision making. PET or PET/CT scans have an increasing role in assessing the burden of metastatic disease and in selecting lesions for percutaneous biopsy.

Imaging of Axial Pain Generators

Axial pain that may have an imaging correlate derives primarily from the stimulation of nociception of the spinal articulations: the intervertebral disc, the zygapophysial or facet joints, and the sacroiliac joint. More broadly, it may include pain originating from the muscular or ligamentous structures in the supporting architecture of the spine. Axial pain is clinically characterized as constant, dull, deep, poorly localized, and aching, located primarily in the paraspinous region with inconstant referral to the proximal extremities. This is in distinction to the neuropathic pain of radicular character, which is typically sharp, electric, lancinating, and experienced in a bandlike distribution into the more distal extremities. DePalma and Maus have well described the prevalence of axial spine pain generators (Table 20.4).[96,97] Intervertebral disc disruption (IDD) was the most common axial pain generator in this series, followed by the facet joint, the sacroiliac joint, and insufficiency fractures of the spine or pelvis. This work also emphasized the age dependence of these pain sources. Patients with discogenic pain (IDD) were significantly younger than patients with facet or sacroiliac joint pain. As the age increased, the probability of IDD as a pain source decreased, and the probability of facet or sacroiliac pain increased, up to approximately 70 years of age.[96] A later multivariable analysis also showed a gender relationship, with IDD more prevalent in young men.[98] This echoes the earlier work of Schwarzer, who demonstrated that lumbar facet-mediated pain was uncommon in a population of young workers (~15%) but more highly prevalent in an aged population (~32%).[99,100]

Imaging Correlates of Discogenic Pain

The imaging diagnosis of discogenic pain is made challenging by the lack of a pathoanatomic gold standard against which to assess imaging parameters. It is not possible to evaluate a disc, either at surgery or upon histologic examination, and deem it painful. The current most stringent reference standard for the diagnosis of discogenic pain is manometrically controlled provocation discography with normal control levels as documented in the practice guidelines of the Spine Intervention Society (SIS).[101]

However, it is important to observe that examination of the same body of evidence regarding the validity of discography as the reference standard has resulted in diametrically opposed recommendations regarding its use by different physician societies. The SIS,[101] the North American Spine Society,[102] and the American Society of Interventional Pain Physicians[103] accept discography as a useful diagnostic tool in back pain patients and recommend its use. The American Pain Society rejects discography as a diagnostically useful test.[104] A comprehensive review of discography in the journal of the American Society of Regional Anesthesia and Pain Medicine notes that whereas CT discography is the gold standard for the assessment of structural disc alteration, there is no convincing evidence that using discography as a selection tool improves surgical outcomes.[105] Any analysis of imaging findings in discogenic pain patients thus remains based on a reference standard (provocation discography) that is ultimately unproved against a pathoanatomic gold standard. This is further confounded by the evolution of the criteria for a positive discogram since the 1990s.

Although challenging, there is motivation to make the diagnosis of discogenic pain via noninvasive imaging. Discography has historically been considered a minimally invasive and nondestructive test. Recent *in vitro* and *in vivo* evidence has raised concern that disc puncture or discography may contribute to disc dysfunction. Korecki and colleagues[106] noted that in a bovine disc model, single punctures with a 25-gauge needle resulted in biomechanical degradation of disc function with cyclic loading. Carragee and coworkers demonstrated using a 10-year follow up that asymptomatic subjects who had undergone investigational discography showed more degenerative phenomena on imaging than did matched control subjects and incurred more spine related health care, including surgery.[107,108] Discography in these series allowed intradiscal pressures up to 100 per square inch (PSI) and were not performed on back pain patients. Another study, utilizing back pain patients with intradiscal pressures restricted to <50 PSI per SIS Guidelines, did not show any difference in degenerative imaging findings, including disc herniations, in punctured vs. unpunctured discs.[109] Although the clinical significance of these observations remains uncertain, a noninvasive diagnosis is desirable.

The specificity fault inherent in spine imaging was previously discussed: manifestations of disc "degeneration" including loss of T2 hyperintensity, loss of disc space height, and disc contour abnormalities (disc bulges and protrusions) are ubiquitous, often asymptomatic, and primarily represent normal age change (Fig. 20.7). However, in a population of symptomatic patients with suspected discogenic pain, are there imaging findings that correlate with positive provocation discography?

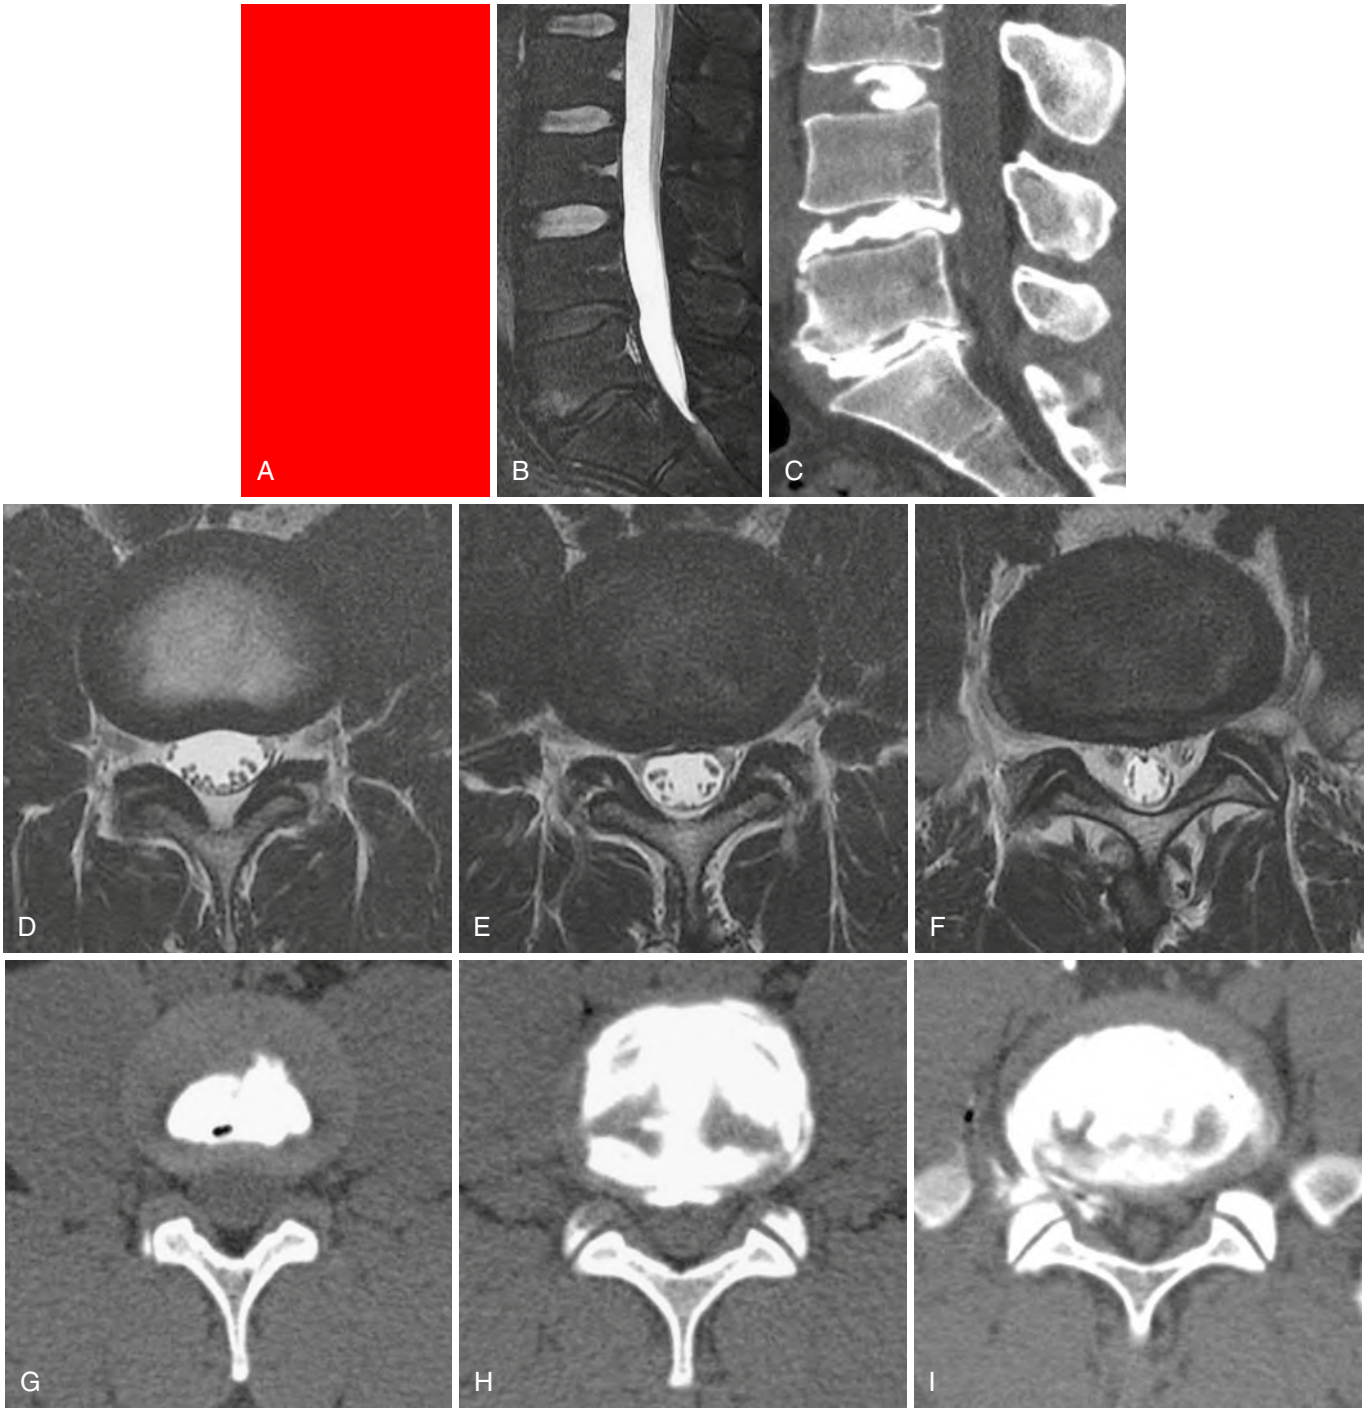
TABLE 20.4 Prevalence of Sources of Axial Low Back Pain, Age Correlation

Pain Source	Prevalence (%)	Mean Age (Std Dev)
Intervertebral disc disruption (IDD)	41.8	43.7 (10.3)
Facet joint	30.6	59.6 (13.1)
Sacroiliac joint	18.2	61.4 (17.7)
Vertebral insufficiency fracture	2.9	79 (11.8)
Pelvic insufficiency fracture	1.8	71.3 (11.7)
Baastrup's disease	1.8	75.3 (4.7)
Fusion hardware	2.9	59.6 (19.4)

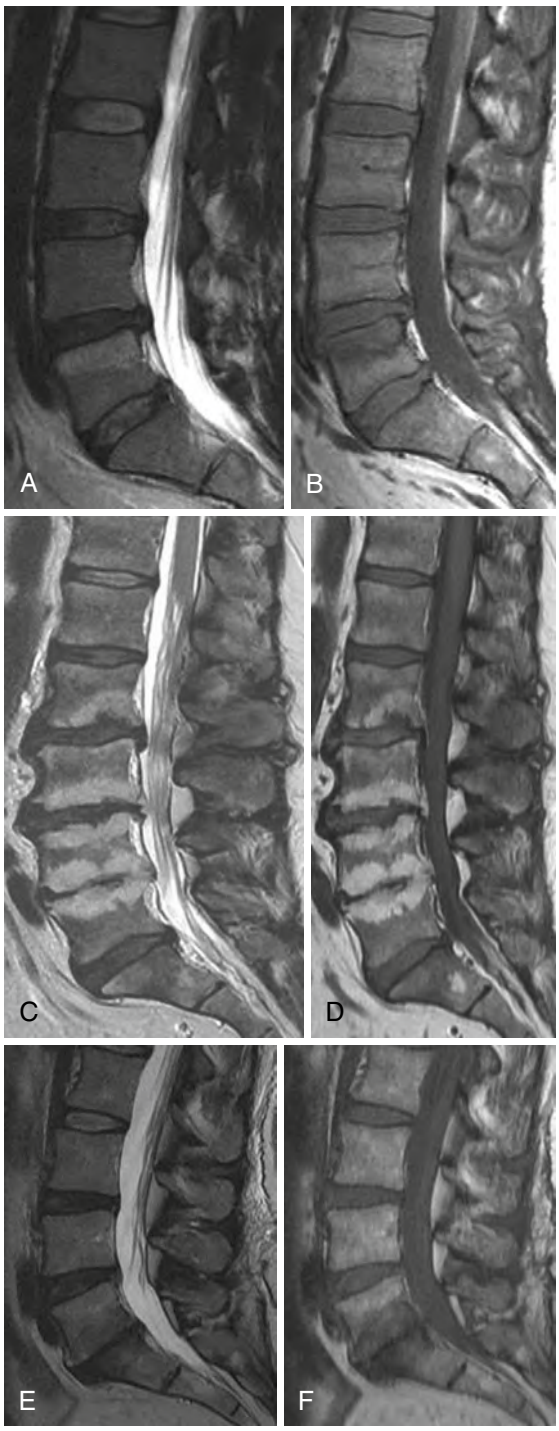
Data from DePalma MJ, Ketchum JM, Saullo T. What is the source of chronic low back pain and does age play a role? *Pain Med.* 2011;12:224–233.

Modic Endplate Changes

The functional unity of the disc and the cartilaginous endplate is manifested in signal changes within the endplate and adjacent subchondral marrow that accompany nuclear matrix degradation. Endplate marrow changes were originally classified by Modic in 1988 (Fig. 20.8).[110] Type I change represents ingrowth of vascularized granulation tissue into sub-endplate marrow; it exhibits a hypointense T1 and hyperintense T2 signal on MRI and may enhance with gadolinium. Type II change exhibits elevated T1 and T2 signals and reflects fatty infiltration of sub-endplate marrow. Type III change is hypointense on T1 and T2; it correlates with osseous sclerosis. Type I change is thought to represent an active inflammatory state, with type II more quiescent and type III post-inflammatory. Ohtori and colleagues[111] noted elevated levels of protein gene product 9.5-immunoreactive nerve fibers



• **Figure 20.7** Disc Height and Nuclear T2 Signal Loss. Lateral radiograph **(A)** of a 50-year-old male with intractable axial pain. Note the loss of height of the lumbosacral disc, which contains gas. There is slight retrolisthesis of L4 on L5 and L5 on S1. Sagittal fat-saturated T2-weighted MRI **(B)** shows loss of T2 signal in the L4–5 and L5–S1 discs; normal upper lumbar discs. Axial T2-weighted images at L3–4 **(C)**, L4–5 **(D)**, and L5–S1 **(E)** demonstrate normal L3–4 disc, loss of T2 signal in L4–5 with a small central herniation, and a broad bulge at L5–S1. Sagittal CT discogram **(F)** and axial images at L3–4 **(G)**, L4–5 (**H),** and L5–S1 **(I)** show normal L3–4 disc, Grade IV annular disruption at L4–5 and L5–S1 with a leak of contrast from the right posterolateral annulus at L5–S1. Patient had concordant axial pain at L4–5 and L5–S1 with a normal control disc at L3–4. (From Maus TP, Aprill CN. Lumbar discogenic pain, provocation discography, and imaging correlates. *Radiol Clin North Am.* 2012;50:681–704.)



• **Figure 20.8** Modic endplate changes. Modic I sagittal T2 **(A)** and T1 **(B)** images demonstrate elevated T2 and diminished T1 signals involving the superior half of the L5 vertebral body. The histologic correlate of Modic I is vascularized granulation tissue. There are disc herniations at the L3–4 and L4–5 discs. Modic II sagittal T2 **(C)** and T1 **(D)** images reveal elevated T1 and T2 signals in the sub-endplate marrow involving L2–L5. The histologic correlate of Modic II is fatty infiltration. Modic III sagittal T2 **(E)** and T1 **(F)** images show diminished T2 and T1 signals in the sub-endplate marrow about the L5 interspace. The histologic correlate of Modic III is sclerotic bone.

and tumor necrosis factor alpha (TNFα) immunoreactive cells in the cartilaginous endplates of patients with Modic changes. The immunoreactive nerve ingrowth was noted exclusively in patients with discogenic low back pain. TNFα immunoreactive cells were more common in type I endplate changes.

Modic endplate changes do carry an association with low back pain, particularly type I change. Albert and Manniche[112] reported low back pain in 60% of patients with Modic changes and in only 20% of those without Modic changes. Type I change was more strongly associated with low back pain than type II change. Thompson and colleagues examined nearly 2500 discs. Type I change had a positive predictive value (PPV) for positive provocation discography of 0.81, while type II change yielded a PPV of 0.64.[113] Weishaupt and colleagues,[114] with a threshold at 25% of vertebral body height for either type I or type II change, saw no false-positive results (100% specificity). Bogduk compiled the data of six studies examining Modic change of either Type I or II, revealing a specificity of 0.83 (sensitivity = 0.24) and a likelihood ratio of 3.4 as a predictor of positive discography.[115]

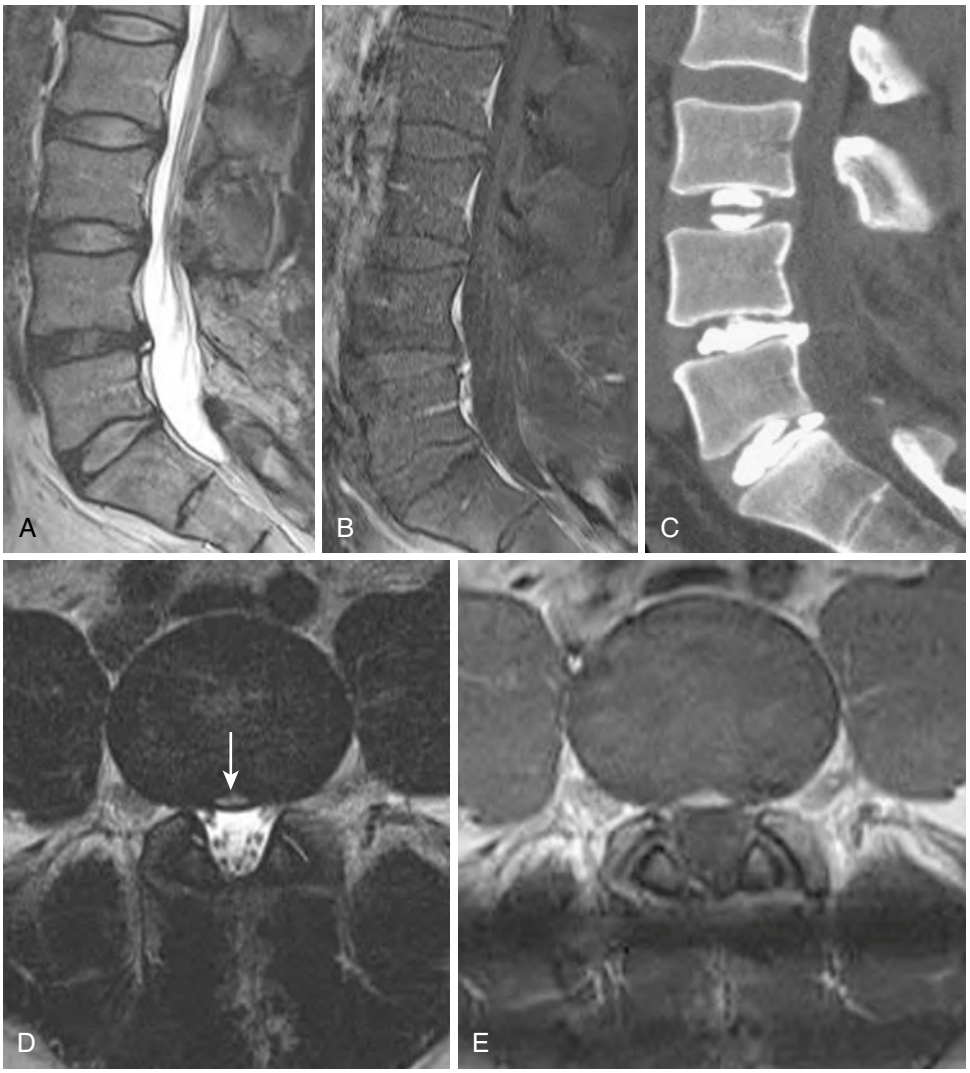
Modic type I change may also be associated with segmental instability. Persistent type I change after fusion surgery raises concern for pseudarthrosis. Patients with solid fusions are more likely to have either persistent type II change or resolution of all marrow abnormality. One caveat about Modic changes is that their detection and classification are heterogeneous across different studies. Among the multiple reasons are a lack of standardized reporting guidelines and technical factors such as magnetic field strength and pulse sequence parameters.[116] As in other disciplines, artificial intelligence will likely play an increasing role in the imaging evaluation of back pain, including the potential for automated detection/calculation of characteristics such as Modic changes and spinal stenosis grades.[117]

High Intensity Zone

In 1992, Aprill and Bogduk described the high intensity zone (HIZ) as an imaging marker of a painful disc at provocation discography (Fig. 20.9).[118] Their definition of the HIZ is a "*high intensity signal (bright white) located in the substance of the posterior annulus fibrosis, clearly dissociated from the signal of the nucleus pulposis in that it is surrounded superiorly, inferiorly, posteriorly and anteriorly by the low intensity (black) signal of the annulus fibrosis and is appreciably brighter than that of the nucleus pulposis" (Page 362).*[118]

This finding was identified on a midsagittal T2-weighted image; it may occur centrally in an otherwise normal annulus, in a bulging annulus, or be located superiorly or inferiorly behind the edge of the vertebral body in a severely bulging annulus. In a series of 500 consecutive patients, the per-patient prevalence was 29%; the per-disc prevalence of an HIZ was 6%. The majority of HIZs were present at the L4 and L5 disc levels, confirmed in later studies.

The relationship of the HIZ to pain production was evaluated in a subset of 41 patients selected for the presence of an HIZ on prediscography MR imaging.[118] Discography was performed with the requirement of a nonpainful control disc for a diagnosis of discogenic pain. Pain responses were tabulated both as "exact" reproduction of pain as well as "similar" pain. In all, 118 discs were tested in 41 patients; the per-disc prevalence of the HIZ was 34%, reflecting selection bias. In detecting exact pain, the HIZ had a sensitivity of 82% and specificity of 89%, a 70% PPV, and a positive likelihood ratio (+LR) of 7.3. When the discographic criteria were relaxed to exact or similar pain, the specificity rose



• **Figure 20.9** High intensity zone (HIZ). Middle-aged male has previously undergone L4–5 decompressive procedure, without discectomy, for back and leg pain. Axial back pain was unrelieved. **A,** Sagittal T2-weighted magnetic resonance image (MRI) shows loss of T2 signal in the L4 disc with an high intensity zone (HIZ) in the posterior annulus. **D,** Axial T2 MRI image at L4–5 interspace demonstrates the HIZ *(arrow)* in the posterior annulus. **E,** Axial-enhanced T1 MRI image showing enhancement in the HIZ, also demonstrated in the sagittal fat-saturated T1 image **(B)**. Sagittal postdiscogram computed tomography **(C)** demonstrates an annular fissure at L4–5 leading to HIZ. Pressurization of the L4–5 disc produced concordant axial pain at <20 pounds per square inch (PSI) above opening pressure. (From Maus TP, Aprill CN. Lumbar discogenic pain, provocation discography, and imaging correlates. *Radiol Clin North Am.* 2012;50:681–704.)

to 97% with a PPV of 95%; there were only two false-positive cases where a disc bearing an HIZ was nonpainful. The investigators postulated that the HIZ represents a complex grade 4 fissure where the nuclear material has been trapped within the lamellae of the annulus fibrosis and become inflamed, accounting for the T2 hyperintensity, brighter than that of the parent nucleus. They advanced the HIZ finding as pathognomonic of a symptomatic disc. The publication of these findings elicited considerable interest and many subsequent studies[114,119–128] attempting to verify or refute its conclusions. Bogduk compiled the results of 12 studies addressing the HIZ as a predictor of a positive discogram, revealing a pooled specificity of 88% (sensitivity 45%) and a likelihood ratio of 3.8 for this imaging finding.[115] A more recent retrospective analysis of nearly 2500 discs in patients who underwent discography showed that the presence of an HIZ had a PPV of 0.71.[129]

Disc contour abnormalities have been studied as predictors of positive discography, and although associations have been identified, there is considerable disparity among studies without a clear pattern.[120,121,129]

Quantitative/Functional Imaging

Conventional imaging techniques for assessment of the intervertebral disc and spinal pain are qualitative (not quantitative), unable to evaluate disc substructure, and unable to discriminate among early/subtle changes of disc degeneration. Although not in routine clinical use in most radiology practices, emerging advanced MRI techniques attempt to address these limitations. These include quantitating the degree of "degenerative" changes affecting the intervertebral disc, quantifying its biochemical composition,

discriminating among early degenerative changes, and identifying subtle changes in key pain generator phenotypes.[130] Such techniques include but are not limited to T2 mapping, T1 rho mapping, MR spectroscopy, and ultra-short time-to-echo (UTE) MRI.

T2 mapping (also known as T2 relaxometry) involves quantification of the content of water, proteoglycan, and collagen sequence breakdown. These different tissues can be objectively quantitated based on different relaxation times (T2 "values" or "times"), which is an intrinsic tissue property that reflects the disc's molecular environment.[131] These T2 relaxation times tend to decrease with age, and decreased T2 relaxation times correlate well with an increased grade of both disc and cartilaginous endplate degeneration.[132–135] Objective and continuous grading of disc generation may be possible by histogram analysis.[136] Some studies suggest that disc degeneration as quantified by T2 mapping may correlate with increasing low back pain, allowing differentiation of chronic low back pain patients from controls.[137] Others suggest that quantitative T2 mapping may be able to indicate discs at-risk for future herniation and correlate with patient's clinical status at longer term follow up.[138] One potential advantage of T2 mapping is the ability to indicate pathologic changes of the disc before it is evident subjectively to human readers. However, to date, normative values of T2 times are lacking, both within individual patients and across patient populations.[139] Thus T2 mapping is not yet able to supplant traditional visual assessment of MR images. Some data suggest that healthy discs in a given patient may provide the best definition of normal when available, to which abnormal levels could be compared.[139] There are many reasons why such quantitative imaging is not a panacea for the assessment of back pain. For instance, T2 calculations may be affected by unique subtle variations in the magnetic environment, such that different values may result from scan to scan, even when imaging equipment and scanning parameters are identical.[139] T2 times can also be affected by confounding variables such as specific lumbar levels among non-degenerated and degenerated discs,[140] time of the day,[141] and axial loading of the spine.[142] Precisely where to measure the quantitative features is an added complexity for quantitative imaging; for example, discs can be analyzed at the level of the anterior outer annulus, posterior outer annulus, or nucleus pulposus/inner annulus. The inherent limitation of not being to precisely delineate these different substructures further complicates matters.[139] In addition, the study methodology varies, including the use of either axial or sagittal imaging. Many publications in the quantitative imaging arena are also limited by relatively small sample sizes.

Meanwhile, mapping of the T1 rho time constant quantifies the degree of cartilaginous degeneration by assessing water molecule dispersion within the discal cartilage. T1 rho is an MRI relaxation time parameter that is sensitive to low frequency interactions between macromolecules and bulk water.[143] The dynamic range of T1 rho values is greater than that of T2 relaxation times.[131,143] Lower T1 rho values are found in degenerated discs and may correlate with discogenic pain.[144] In a high field strength (9.4 T) animal research, data from Paul and colleagues suggest that T1 rho mapping correlates better than T2 mapping with biochemical, histologic, and glycosaminoglycan characteristics of the disc.[143]

MR spectroscopy (MRS) can also evaluate the biochemical structure of tissues. After initial reports of the potential utility of this technique for assessing the intervertebral disc based on cadaveric and ex vivo data, in vivo studies began emerging. A recent study by Gornet and colleagues showed a correlation between discography results and MRS analysis of disc structure (proteoglycan and collagen) and acidity (lactate, alanine, propionate).[145] MRS showed the ability to discriminate discogram positive from negative discs and the potential for this information to affect surgical outcomes.[145] Some investigators have correlated multifidus muscle fatty atrophy with chronic low back pain and disc degeneration, with intramyocellular but not extramyocellular lipid accumulation as detected by MRS showing association.[146,147]

Quantitative imaging has also been applied to the cartilaginous endplate, such as with the use of UTE MRI. On conventional T2-weighted images, the endplate signal is hypointense and its integrity is difficult to assess.[130] UTE MRI results in the endplate as signaling hyperintense and affords the potential of assessing the morphology and biochemical structure of the endplate.[130] Quantitative measurements of endplate thickness on 3-dimensional UTE MRI appear to be associated with adjacent disc degeneration.[148] Some investigators have also used UTE MRI to assess the intervertebral disc. A hypo- or hyperintense band within the disc on UTE imaging may correlate well with disc degeneration, low back pain, and disability.[149]

In summary, quantitative high-resolution imaging techniques such as those described above show promise in evaluating degenerative findings involving the intervertebral disc. They offer the possibility of evaluating both structural and functional characteristics of the disc. The hope is that one or more such techniques could be implemented into routine or problem solving clinical practice to identify clinically meaningful and potentially actionable evidence of subtle/early disc degeneration.

Imaging Correlates: Conclusion

Imaging identification of discogenic pain is challenging for a variety of reasons. (1) There is no pathologic or surgical gold standard. (2) The existing standard of comparison, discography, is ultimately unproven, is subjective in its interpretation, and has evolved over time in its criteria for a positive test. None of the studies reviewed earlier use the most current and restrictive criteria, those of Spine Intervention Society (SIS). (3) The imaging findings likely have threshold effects, where only a significant expression of the finding (intensity of an HIZ, extent of marrow change) is a useful predictor of discogenic pain. Most studies do not account for this factor. (4) Imaging findings are likely technique dependent to an unknown degree, and imaging techniques are evolving.

The best available imaging predictors of discogenic pain, when applied to a select population of patients with axial back pain, in whom other pain generators have been excluded, are Modic endplate changes and the HIZ. Discography remains the reference standard for the diagnosis of discogenic pain. Quantitative imaging techniques have emerged and are evolving, but not in widespread clinical use.

Cervical Discogenic Pain: Imaging Correlates

This discussion has purposely focused on the lumbar spine. The lumbar spine segment is most commonly afflicted with discogenic pain, and the literature regarding its pathogenesis and evaluation with imaging and provocation discography, although challenging, is of greatest depth. The cervical intervertebral disc is structurally distinct from the lumbar disc. There is no posterior annulus, and the small nuclear compartment disappears early in life; the residual fibrocartilaginous plate normally develops fissures as mere age-related change.[101] There are no morphologic features at discography that contribute to a diagnosis of discogenic pain. Diagnosis

is reliant entirely on the provocation of concordant pain, with the requirement of nonpainful control discs.

As in the lumbar segment, structural age changes (loss of T2 signal, loss of disc space height, contour abnormality) are ubiquitous in cervical MRI studies. The Matsumoto study[33] cited earlier examined 2480 cervical discs in asymptomatic subjects and noted loss of T2 signal in 17% of males and 12% of females between ages 20–30, and 89% of males and 86% of females over 60 years old. A 10-year follow up of this study by Okada and colleagues demonstrated that progression of degenerative findings occurred in most patients (81%).[150] The only factor related to this progression was age. Clinical symptoms developed in a smaller proportion of subjects (34%). Daimon and colleagues then published a 20-year prospective longitudinal follow up of this study in 2018.[151] Progression of degenerative findings was essentially ubiquitous, seen in 95% of patients. The rate of progression of structural findings on MRI increased with age. Only the progression of foraminal stenosis had any association with the development of clinical symptoms (specifically, the onset of upper limb pain). In another study by Okada,[152] 89% of asymptomatic subjects (mean age 49 years) exhibited structural age changes on MRI; another group of patients (mean age 46 years) with symptomatic lumbar disc herniations but asymptomatic of neck pain showed cervical disc age-related change in 98% of the patients. There is a paucity of literature addressing the correlation of imaging findings with cervical discography. An early study by Parfenchuck (1994) showed only a modest ability of MRI findings of T2 signal loss or disc contour abnormality to predict a positive cervical discogram (sensitivity = 73%, specificity = 67%).[153] Schellhas' (1996) study suggested that MRI cannot reliably predict a positive cervical discogram.[154] A subsequent study by Zheng[155] again demonstrated only a modest predictive value of MRI using parameters of T2 signal loss and disc contour abnormality (sensitivity = 73%, specificity = 49%). The inflammatory disc parameters that proved to have such high specificity in the lumbar region are either unusual or little studied (Modic change) or have no anatomic existence (HIZ) in the cervical region. Occasionally foci of elevated T2 signal are observed in the posterior cervical disc, but in the absence of a posterior annulus, the anatomic correlate is unclear. Imaging identification of discogenic pain in the cervical spine remains elusive. Cervical discography remains the reference standard in the diagnosis of cervical discogenic pain. In patients with neck pain with or without neurologic symptoms, a study of 1059 patients revealed that the number of degenerated disc levels and the degree of cervical disc degeneration increases significantly with age.[156] C5–6 was the most common degenerated level, followed by C4–5 and C6–7. C5–6 and C6–7 were most common in those patients with two-level degeneration, followed by C4–5 and C5–6, and C3–4 and C-5. Degeneration was seen at contiguous levels, with skip level degeneration uncommon.

The imaging investigation of discogenic pain highlights a theme common to this chapter: physiologic parameters have greater significance in pain syndromes than purely structural alteration. To be ultimately valuable in the diagnosis of discogenic pain, imaging must move beyond macroscopic descriptions of morphology to the realm of biochemical imaging, quantifying the change in nuclear constituents over time. Besides characterizing biochemical nuclear matrix degradation, imaging will also need to identify inflammatory mediators in the disc and adjacent cartilaginous endplate more precisely. Perhaps then we will truly be capable of the noninvasive diagnosis of discogenic pain.

Vertebrogenic Pain

Recently, the so-called vertebrogenic model of pain has emerged as a potential alternative to the discogenic model. The vertebrogenic model is based on the hypothesis that nociceptors in the endplates can cause acute or chronic pain.[157] This theory, that low back pain may arise from the endplates rather than the disc, has been increasingly supported by a growing body of literature.[158,159]

At the root of the vertebrogenic model of pain is the concept that endplates are inherently prone to spondylotic changes. This is because of the conflicting functional roles held by endplates. Endplates must be strong enough to withstand the substantial physiologic stress put upon the spine. However, because discs lack a dedicated blood supply, endplates must also be porous enough to allow for passive transport from the vertebral body capillaries.[160] This porosity, in the setting of substantial tensile strains placed upon the vertebral bodies, frequently results in damage.[161] Some endplate regions are particularly susceptible to destructive changes, likely related to normal anatomic variations in endplate composition. For example, an endplate's center is thinner than its periphery, and superior endplates are thinner than their inferior counterparts.[162]

Once endplates are damaged, pro-inflammatory mediators can communicate between the disc and the vertebral body bone marrow.[159] This is typically followed by a cascade of spondylotic changes, in which cross-talk between the disc and bone marrow leads to progressively increasing inflammatory mediators.[163] Ultimately, such changes result in the degradation of endplates in regions often specific to the spinal level and location within the endplate.

On MRI, this spondylotic process typically appears as Modic changes. Modic changes, as discussed above, are associated with low back pain and are relatively specific imaging markers for predicting the reproduction of symptoms during provocative discography.[114] The association between Modic changes and provocative discography would seem to support the discogenic model. However, the closely related innervation between the annulus and endplates means that pain could be elicited from the endplate or disc. Some authors have opined that the correlation between MR findings and provocative discography presents some of the best evidence for the vertebrogenic model of low back pain.[161] Nevertheless, it remains impossible to distinguish between vertebrogenic and discogenic pain confidentially.

Anatomically, vertebrogenic pain is usually attributed to nociceptive innervation by branches of the basivertebral nerve (BVN). The BVN stems from the sinuvertebral nerve and enters the vertebral body via the posterior basivertebral foramen before branching along the endplates.[164, 165] The BVN has been shown to contain substance P, protein S-100, PGP 9.5, and calcitonin gene-related peptide, confirming its role in nociception.[163,166]

The innervation density of the vertebral body endplates is similar to the annulus and is greatest within the central endplate.[167] In healthy endplates, the innervation is modest in quantity.[167] However, damage to cartilage and subchondral bone induces proliferation of sensory nerve fibers, thought to be a chemotactic response to elements of disc breakdown.[111,168,169] Spondylotic changes may lead to a greater density of innervation by branches of the BVN, accounting for the localization of pain to the vertebral body endplates.

The vertebrogenic model has led to the recent development of novel therapeutic approaches to treat low pain back. Among these, BVN ablation using radiofrequency (RF) energy has gained the greatest interest.[170,171] Both single-arm studies[172,173] and randomized

control trials[170,171] have been completed. The results have overwhelmingly demonstrated the efficacy of BVN ablation. For example, Fischgrund et al. found that patients treated with intraosseous BVN ablation showed superior improvement in Oswestry Disability Index (ODI)—an outcome marker for patients with low back pain—and a greater rate of response compared to control patients treated with sham procedures.[170] Khalil et al. compared the efficacy of BVN RF ablation to standard care in patients with low back pain. The authors reported clear superiority of ODI-based outcome in the treatment group, with early statistical power resulting in termination of study enrollment and offering cross-over to the control group.[171] Laser ablation of the BVN, too, has been used with promising results.[174]

Despite the encouraging results demonstrated in these early trials, additional studies will have to determine the safety and long-term efficacy of BVN ablations. In addition, trials to date have been restricted to the lower spine (L3–S1), and patients with Modic I or II changes on MRI. Further investigation is needed to understand whether procedural success can be translated to other levels in the spinal column. Finally, it will be important to develop a reliable set of clinical, imaging, and/or testing (e.g. provocative discography) criteria by which vertebrogenic pain is diagnosed and whether such criteria can be used to differentiate vertebrogenic from discogenic pain.

Imaging of Axial Pain Generators

Zygapophysial Joint (Z-Joint, Facet Joint)

The supporting structure of the posterior column of the spine includes the paired facet joints with their associated capsules, the ligamentum flavum, the intraspinous and supraspinous ligaments joining the spinous processes, and the intertransverse ligaments. The inferior articular process of the facet joint faces anteriorly and is convex in configuration. On axial images, the inferior articular process is the more posterior component of the joint. The superior articular process (SAP) has a concave articular surface that faces posteriorly and medially. On axial images, it appears as the anterior component of the joint. In an erect standing position, the lumbar facet joints bear approximately 16% of the compressive load; they bear essentially no load in a flexed sitting position. With the loss of disc space height, the lumbar facet joints will bear proportionally more axial load. The fibrous joint capsule has been demonstrated to be richly innervated by nociceptors and proprioceptive fibers.[175] In a normal state, nociceptors such as those seen in the facet joint capsule have a high threshold and would not be expected to discharge unless loads are supraphysiologic. However, in the presence of pathologic joint inflammation, synovitis, chemical mediators may sensitize these nociceptors, and supraphysiologic levels of stress may no longer be required to stimulate pain. Such inflammatory mediators (substance P, bradykinin, phospholipase A2) have been detected in the facet joint capsule.[176]

There is thus a pathoanatomic basis for facet joint-mediated pain, particularly in the presence of facet synovitis. The imaging challenge in identifying a potentially painful joint lies in the well demonstrated specificity fault, that imaging changes of morphologic facet arthrosis (subchondral sclerosis, erosions, or cyst formation, osteophytes, joint space narrowing, vacuum phenomena) are age-related changes and do not correlate with pain. The reference standard for facet pain is positive comparative dual medial branch blocks, as there are no reliable physical exams or historical features allowing a confident diagnosis of Z-joint pain.[101] Schwarzer and colleagues semi-quantitatively scored CT finding of structural facet arthrosis and found no relationship to Z-joint pain as determined by placebo controlled medial branch blocks.[177] More recently, Cohen and associates showed no association between MRI findings of structural facet arthrosis and pain relief with dual medial branch blocks and subsequent radiofrequency rhizotomy.[178] These structural changes become universal by the sixth or seventh decade of life; they do not represent active inflammatory disease causal of pain.[179]

Instead, imaging must look to identify physiologic, not structural, markers of active facet synovitis. Imaging techniques that may be applicable include the technetium pyrophosphate bone scan (including its technologic evolution SPECT and SPECT/CT) and the MRI physiologic imaging parameters of T2 hyperintensity and gadolinium enhancement. Technetium pyrophosphate bone scans detect hyperemia and accelerated bone turnover, which may be considered manifestations of active inflammation. Dolan and associates[180] compared the response to intra-articular facet joint injection guided by clinical exam versus positive SPECT studies; there was a significantly greater short term (one- to three-month) clinical response in the SPECT-guided injections. A similar study by Holder and colleagues, using response to uncontrolled intra-articular injections as the reference standard, identified a 100% sensitivity and 71% specificity for SPECT scans in the detection of facet joint-mediated pain.[181] Pneumaticos and colleagues prospectively studied patients undergoing intra-articular injections in three groups: injections guided by positive SPECT scans, injections in patients with negative SPECT scan guided by clinical exam, and injections in patients without SPECT studies guided by clinical exam.[182] The patients whose injections were directed to SPECT-positive joints had significantly better clinical outcomes than the other two groups, as well as lower costs as fewer joints were injected. McDonald used SPECT/CT to identify joints for injection in 37 patients with clinical facet joint lumbar pain. The mean visual analog score dropped from 7.2–2.8, with an average duration of benefit of 2.2 months; only 1 in 37 patients did not report benefit. The fused SPECT/CT images were useful in distinguishing the L4–5 and L5–S1 facet joints.[183]

There is no correlation between the degree of morphologic facet arthrosis and the intensity of SPECT activity.[180] Rather, the phase of active synovitis correlating with pain production may occur relatively early in the progressive development of structural changes of facet arthrosis. Kim and colleagues correlated MRI findings in the facet joints with SPECT; they noted that the MRI appearance of T2 hyperintensity in the synovium, intrasynovial fluid, and cartilage disruption best correlated with a positive SPECT, here used as a reference standard for active facet synovitis.[184] More extensive structural manifestations of facet arthrosis did not demonstrate the physiologic finding of SPECT activity. Cervionke and colleagues have demonstrated an indirect association of T2 hyperintensity within and about the facet joint with axial pain.[185] T2 hyperintensity in the adjacent pedicle has also been associated with axial pain of facet origin; this finding can also be seen in pedicle or pars stress fractures. T2 hyperintensity accompanying facet synovitis may also be seen in the surrounding multifidus muscle, occasionally sufficiently extensive enough to raise concern of a sinister process. Gadolinium enhancement in and about the facet joint also suggests facet synovitis. Ultimately, the physiologic parameters of edema, hyperemia, and accelerated metabolic activity as detected by increased SPECT or SPECT/CT activity, and T2 hyperintensity and gadolinium enhancement on MRI must be evaluated as predictors of facet joint pain against the current reference standard, comparative medial branch blocks. Prevalence

studies of these parameters in populations asymptomatic of back pain are also needed for researchers to understand the specificity of these imaging observations. Despite the lack of absolute validation, if the patient is going to undergo an MRI for evaluation of axial pain, a fat-saturated or STIR sequence should be performed, as it represents the best chance of demonstrating physiologic findings (T2 hyperintensity), which may identify an axial pain generator (Fig. 20.10).

Various investigations have provided insight into the potential correlation of facetogenic pain with physiologic imaging findings of the facet joints. Lehman and colleagues retrospectively reviewed the utility of 212 SPECT/CT exams of the spine and sacrum over four years.[186] These exams were most commonly used in the diagnosis and management of pain, helping to identity pain generators and frequently resulting in a resultant change in clinical management. However, Lehman and his colleagues also studied 74 patients who underwent subsequent percutaneous facet joint steroid injection or comparative medial blanch blocks after a SPECT/CT scan.[187] Interestingly, the targeted facet joint treatment(s) was frequently discordant with the facet joint(s), demonstrating increased uptake on the nuclear medicine study. In approximately one-third of patients, the activity did not correlate with clinical findings. Similarly, when comparing facet joint activity on SPECT/CT with facet joint signal change on MRI with fat suppression, Lehman and colleagues found these two imaging findings did not always correlate and therefore should not be considered interchangeable.[188]

Besides SPECT/CT, other hybrid imaging modalities that are being used in at least the research setting to evaluate facet joint arthropathy are PET/CT and PET/MRI. PET/MRI is an alternative, emerging imaging modality that offers the possibility of evaluating facet joint inflammation with both radiotracer uptake and MRI findings of edema and/or enhancement. One of the elements for its appeal is the lack of ionizing radiation associated with the cross-sectional (MR) component, unlike the CT aspect of SPECT/CT and PET/CT. In a prospective study of 10 patients with clinically suspected facetogenic low back pain at specific levels, 18F-fluorodeoxyglucose (FDG) activity did show high concordance with MRI findings of considerable facet inflammation (prominent posterior element osseous or adjacent soft tissue edema/enhancement).[189] However, there was low concordance of both MRI findings of inflammation and FDG activity with the clinically implicated joints. Future research is needed to further elucidate the role of such hybrid imaging technologies, including ideally a comparison of imaging findings with the results of medial branch blocks.[190] One such prospective study by Freiermuth and colleagues included 29 patients; the sensitivity and specificity of SPECT/CT for a positive response after a medial branch block were 57% and 77%, respectively.[191] In addition to FDG-PET, some investigators are using sodium fluoride ([^{18}F]-NaF) PET (combined with either CT or MRI) to evaluate facet joint inflammation. This radiotracer can detect bone turnover. In one study of six patients with facetogenic low back pain who underwent [^{18}F]-NaF PET/MRI, a significant positive correlation was observed between maximum facet joint tracer uptake and clinical disability.[192] Such pilot data are promising but require further validation.

Space of Okada

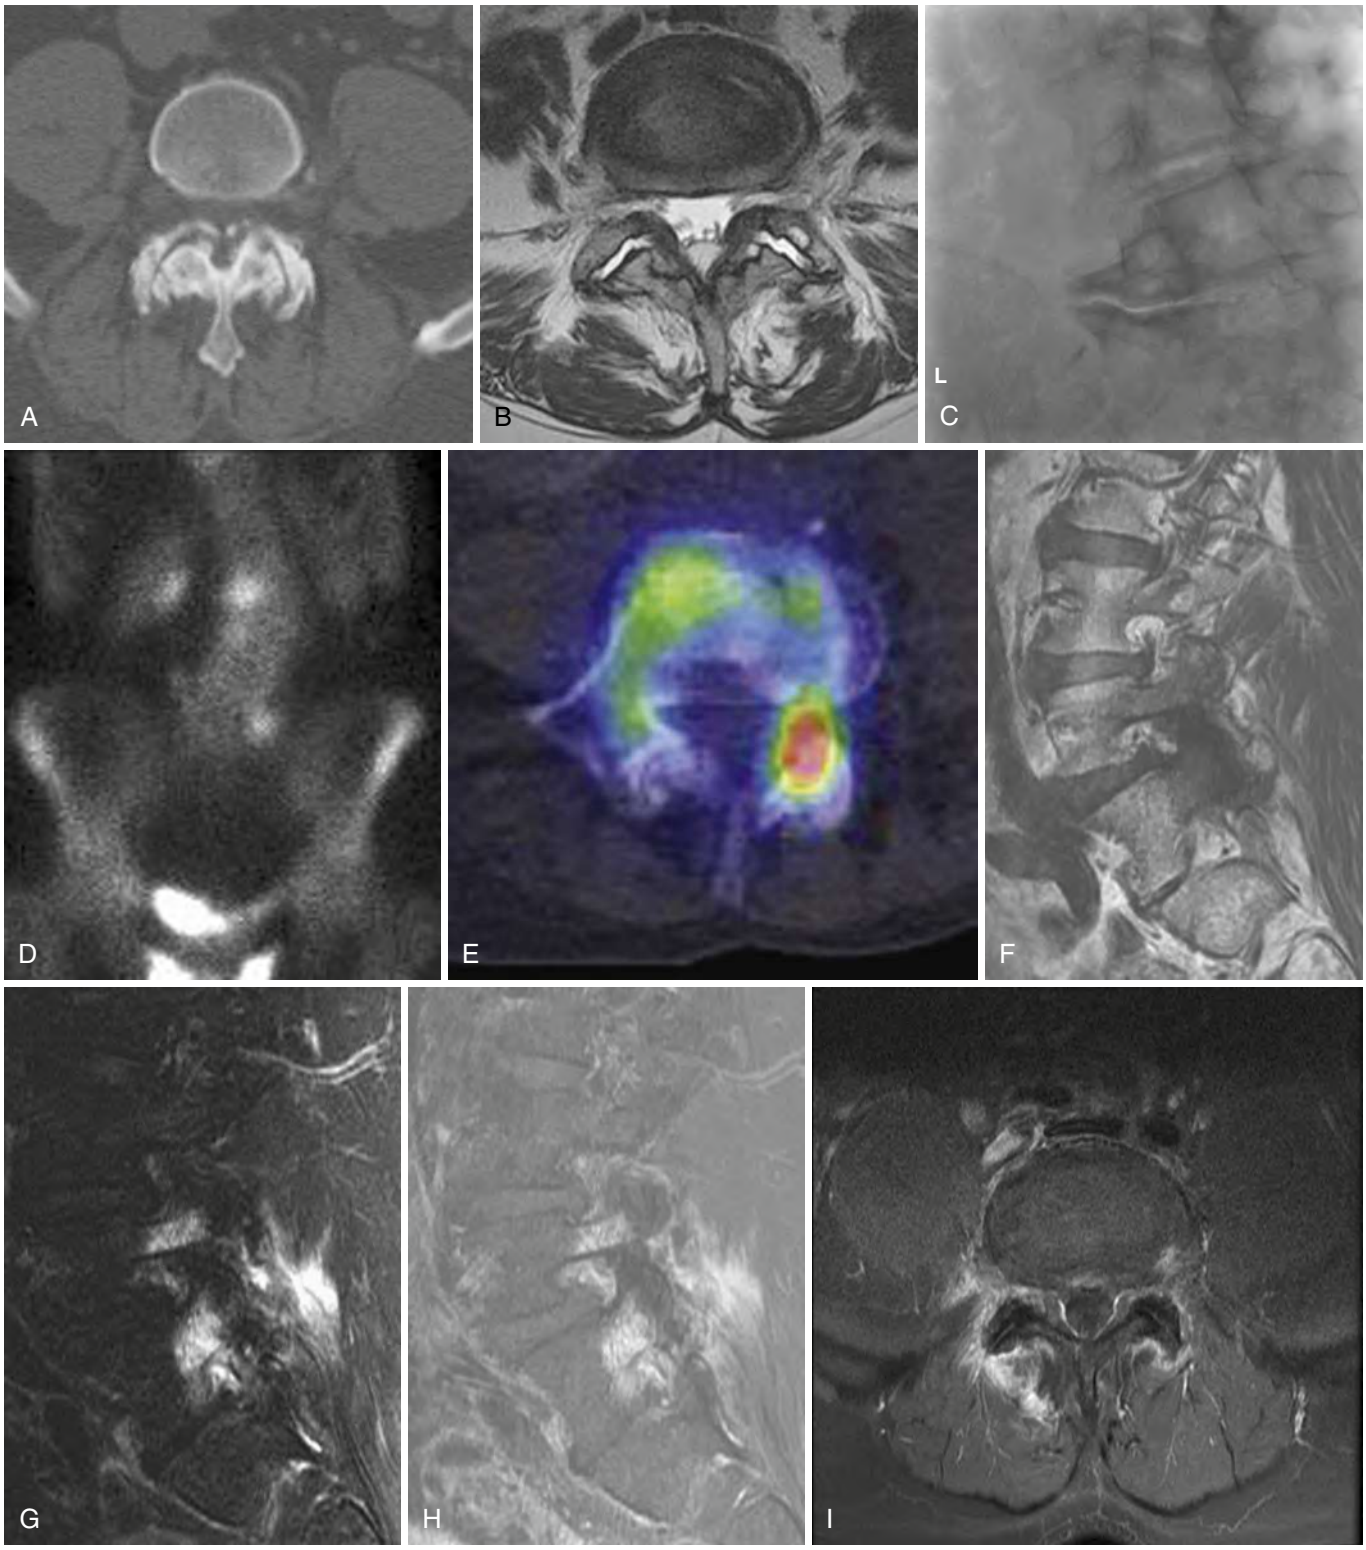
A tissue pathway between contralateral same segment facet joints was initially described in the cervical region by Dr. Kikuzo Okada in 1981; 80% of cervical facets demonstrated a communication between the joint capsules via a space situated dorsal to the ligamentum flavum in the axial plane and the interlaminar space in the coronal plane.[193] This communication is frequently observed in intra-articular injections of cervical facet joints that are structurally normal on imaging or exhibit only modest evidence of synovitis or structural arthrosis. In the lumbar region, this communicating pathway is commonly observed only in the face of advanced facet arthrosis; it may also be observed in the presence of defects in the pars interarticularis. This lumbar retroligamentous pathway also commonly communicates with an adventitial bursa within the interspinous ligament (i.e. Baastrup's disease).[194]

This pathway may serve as a means of transmission of infection or, more commonly, noninfectious inflammatory change between multiple joints and tissue compartments.[194] When the imaging findings of inflammation and/or fluid in the space of Okada are correlated with low back and/or radicular back pain, Lehman and colleagues in their pictorial review termed this clinical setting as the posterior ligamentous complex inflammatory syndrome.[195] In patients with lumbar axial pain and spondylolytic defects, this posterior element inflammatory complex may involve four facet joints, the bilateral pars defects, and the interspinous ligament. It may have a capacity of 4–6 cc of fluid in the author's experience. It is also a potential confounding space in epidural steroid injections. For example, this space may provide a false loss of resistance superficial to the dorsal epidural space during interlaminar injections; contrast injection may subsequently fill either facet joint at that segment level or the interspinous ligament (Fig. 20.11).[196] Similarly, during cervical and lumber transforaminal epidural steroid injections, in which the needle tip may be at least partially in or near the facet joint capsule, contrast injection will occasionally demonstrate flow from the ipsilateral facet joint to the space of Okada, simulating dorsal epidural flow.

Sacroiliac Joint

The sacroiliac joint is a large irregular synovial joint lined by thick hyaline cartilage on its sacral surface and thinner fibrocartilage on its iliac surface. The inferior and anterosuperior aspects of the radiographically perceived joint are synovial; its superior and posterior aspect is ligamentous. The posterior surface of the joint is covered by thick interosseous and dorsal sacroiliac ligaments. There is minimal movement of the joint, except under the hormonal influences of pregnancy. However, this modest mobility is vital for appropriate gait. The synovial portion of the joint is uniformly present in young adults, with a cartilage thickness of 2–5 mm; the synovial space may be attenuated in older adults by fibrous adhesions, but fusion across the joint is not a normal change of aging. Potential communications between the synovial space and the dorsal sacral foramina, the L5 epiradicular sheath, and the ventrally situated lumbosacral plexus have been observed.[197] These could explain radicular pain associated with sacroiliac joint dysfunction, as well as occasional lumbosacral temporary motor block after sacroiliac joint intra-articular injections, related to the spread of anesthetic. Although the surface area of the joint is large, its synovial space is of small volume, ranging from 1–2.5 cc.[198,199] Innervation of the sacroiliac joint is complex and remains controversial. Consensus suggests a dominant dorsal innervation from the L5 and S1–S4 dorsal rami.

Osteoarthrosis of the sacroiliac joints may be seen in pathologic specimens of young adults, but it is not generally appreciable radiographically until middle age. Changes in cartilage degeneration are more prominent on the iliac side of the joint. Beyond 40 years of age, many subjects have detectable narrowing of the

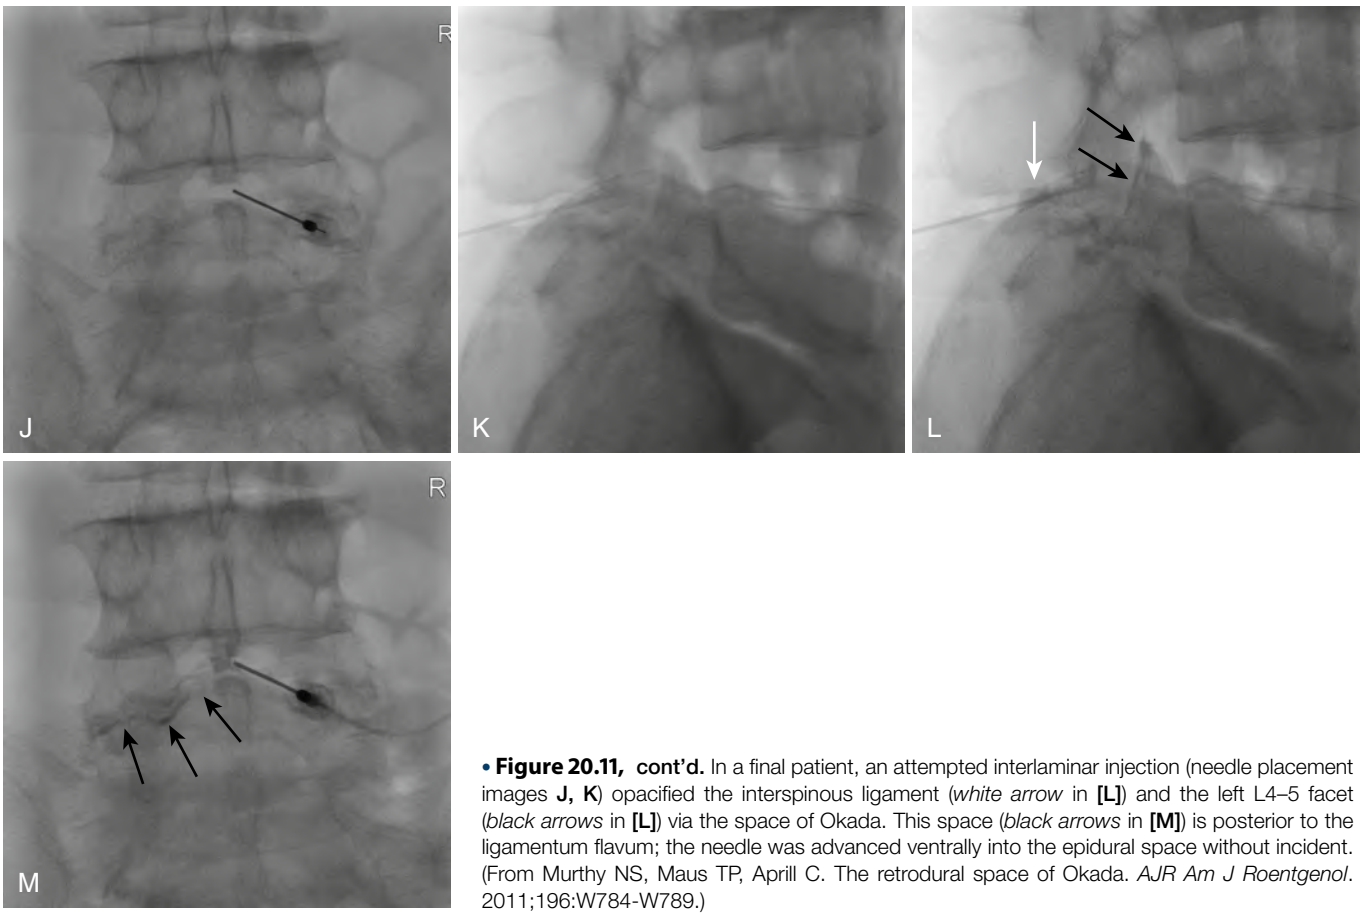


• **Figure 20.10** Imaging of facet arthrosis and synovitis. The changes of arthrosis (i.e. joint space narrowing, osteophytes, subchondral cysts, or sclerosis) as seen in the CT image **(A)**, the T2 MRI image **(B)**, or the radiographic image **(C)** do not correlate with pain. Planar bone scan image **(D)** of the same patient as **(C)** shows increased uptake near the lumbosacral junction on the left in this patient with left-sided axial pain. SPECT/CT image **(E)** provides better anatomic localization to the left L4–5 facet. In another patient with right-sided axial lumbar pain, T1 MRI image **(F)** shows a low signal in the right L5 pedicle and the right L4–5 facet. Fat-saturated T2 sagittal image **(G)** demonstrates T2 hyperintensity in L4 and L5 pedicles, L4–5 facet, and adjacent soft tissues. Enhanced T1 sagittal **(H)** and axial **(I)** images also demonstrate the extensive inflammatory response in this patient with active synovitis. T2 hyperintensity or enhancement in pedicles can occur in facet synovitis or stress fractures of the pars or pedicle. *CT*, Computed tomography; *MRI*, magnetic resonance image; *SPECT*, single-photon emission computed tomography.

sacroiliac joint, especially in its inferior portion. This may be accompanied by subchondral sclerosis and osteophyte formation, most prominent anteriorly and inferiorly. A vacuum phenomenon may be seen. As in the facet joint, changes of osteoarthrosis are a normal aging phenomenon and are not predictive of pain.

Evaluation of imaging features predictive of sacroiliac joint pain is yet again confounded by the lack of a pathoanatomic gold standard. Medical history and physical exam provocative maneuvers cannot consistently identify painful sacroiliac (SI) joints.[200] The reference standard for sacroiliac joint pain is the relief of

• **Figure 20.11** The space of Okada. Frontal fluoroscopic image **(A)** demonstrates the space of Okada providing communication between the bilateral C6–7 facets via the right-sided injection. In another patient **(B),** an attempted right L4 transforaminal injection opacified the superior recess of the L4–5 facet, traversed an L5 pars defect *(white arrow)* to the right L5–S1 facet, and opacified the space of Okada to a left L5 pars defect *(black arrow)* and the left L4 and L5 facets. Subsequent computed tomography **(C, D, E, F)** confirms the opacification of all these structures. The space of Okada is marked by the *white arrows* in **(D)**. The space of Okada may contain a small amount of fluid, which appears as T2 hyperintensity (*white arrows,* **G, H, I**). Note continuity with interspinous ligament (*arrow* in **[H]** and **[I]**).



• **Figure 20.11, cont'd.** In a final patient, an attempted interlaminar injection (needle placement images **J, K**) opacified the interspinous ligament (*white arrow* in **[L]**) and the left L4–5 facet (*black arrows* in **[L]**) via the space of Okada. This space (*black arrows* in **[M]**) is posterior to the ligamentum flavum; the needle was advanced ventrally into the epidural space without incident. (From Murthy NS, Maus TP, Aprill C. The retrodural space of Okada. *AJR Am J Roentgenol*. 2011;196:W784-W789.)

index pain with an intra-articular anesthetic block. This should ideally be either placebo controlled or a comparative block paradigm. Potential leakage from the joint capsule may complicate diagnostic specificity. Schwarzer[201] studied patients with chronic low back pain experienced below the lumbosacral junction. Using response to single blocks as the diagnostic criteria for sacroiliac pain yielded a prevalence of 30%. Requiring a positive block and a ventral capsular tear on postarthrographic CT yielded a prevalence of 21%; adding pain provocation with joint distension to the criteria lowered prevalence to 16%. The Maigne study using double blocks suggested a prevalence of 18.5%.[202] Subsequent work by DePalma[96] identified a prevalence of 18%; sacroiliac joint pain increased in prevalence with age up to approximately 70 years.

Structural changes of osteoarthrosis in the sacroiliac joint are poor predictors of pain. Elgafy and colleagues[203] scored CT features of arthrosis in SI joints and noted a sensitivity of 58% and a specificity of 69%. Physiologic imaging parameters suggesting the presence of hypervascularity, edema, or inflammation are more likely to predict pain. In the studies by Maigne[204] and Slipman,[205] technetium bone scans achieved specificities of 89.5% and 100%, although with low sensitivity, for sacroiliac pain as referenced by uncontrolled intra-articular injections. The MRI physiologic parameters of T2 hyperintensity and gadolinium enhancement have been studied primarily in the context of inflammatory spondyloarthropathies. MRI evidence of active inflammation (sacroiliitis) is intrinsic to the diagnoses of spondyloarthropathies and correlates well with clinical disease activity and therapeutic response to disease modifying agents (TNFα inhibitors) (Box 20.3).

Baastrup's Disease

Baastrup's disease, the apposition of the lumbar spinous processes resulting from hyperlordosis, segmental instability, or loss of disc space height, may degrade the interspinous ligament with the

• Box 20.3 Zygapophysial (Facet) and Sacroiliac Joint Pain

- Structural arthrosis, as seen by radiographs, computed tomography (CT) or magnetic resonance image does not predict pain.
- Physiologic parameters of hyperemia, edema, and increased metabolic activity may predict pain.
- These physiologic parameters may be assessed by T2 hyperintensity (STIR or fat-saturated T2 images), gadolinium enhancement, or increased uptake on single-photon emission computed tomography (SPECT) or SPECT/CT.
- There are no validation studies of physiologic parameters against accepted reference standards (dual, comparative blocks).
- There are no studies addressing specificity—that is, the prevalence of these findings in asymptomatic subjects.

formation of a pseudarthrosis or pseudobursa.[206] This may be a cause of focal midline lumbar pain. Such pseudobursa may have a synovial membrane and can communicate with facet joints or pars defects via the retroligamentous space of Okada.[193] The pseudobursa may extend anteriorly through a midline cleft in the ligamentum flavum and present on MRI or CT as a midline posterior epidural cyst, causing neural compression and contributing to radicular or claudicatory pain. It may be mistaken for a synovial cyst of facet origin but is distinguished by its posterior midline location, the relative absence of facet degeneration, and inflammatory change in the interspinous ligament.

Baastrup's disease may be identified on radiographs as contact between adjacent spinous processes with sclerosis, flattening, and enlargement. Not surprisingly, this structural change is commonly observed in asymptomatic individuals. In one study, it was present in 81% of individuals greater than 80 years old.[207] The authors also noted that "Baastrup's phenomenon" was observed in 41% of patients undergoing CT imaging for non-low back pain indications.[207] MRI findings of edema, inflammation (T2 hyperintensity, gadolinium enhancement), or a cystic fluid collection in the interspinous ligament are more likely to represent symptomatic disease, although this has not been well validated against anesthetic blocks. DePalma's study suggested that Baastrup's disease accounted for approximately 2% of axial low back pain.[96] In an MRI study by Maes and associates, imaging evidence of Baastrup's disease was present in 8.2% of subjects, most commonly at the L4–5 segment; nearly half of the patients had multiple-level involvement.[208] Baastrup's disease may also be identified as hyperemia and increased metabolic activity on technetium pyrophosphate SPECT or SPECT/CT studies as well as Fluorodeoxyglucose (FDG)-PET/CT scans. Focal uptake in the spinous processes is most likely to be inflammatory and should not be misinterpreted as metastatic disease. The distinction should be obvious when correlated with the simultaneously obtained CT images, which will show typical structural changes of arthrosis (Fig. 20.12).

Bertolotti's Syndrome

Bertolotti's syndrome describes the controversial association of transitional lumbosacral segments with mechanical back pain. It does not imply a specific mechanism of pain production. As discussed above, transitional anatomy is relatively common. In a large study of 4000 patients, Tini found no correlation between the presence of a transitional segment and low back pain.[209] The disc at the level of the transitional segment is often rudimentary, with little nuclear material; disc herniations seldom occur at this level.[89] Rather, stresses may be accentuated at the supra-adjacent disc level, where accelerated disc degeneration and an increased incidence of disc herniations have been reported (Fig. 20.12).

Axial low back pain in the presence of an asymmetric transitional segment has also been attributed to abnormal unbalanced motion at this level, with the neoarticulation of the transverse process with the sacral ala or the contralateral facet as the specific pain generator. Jönsson reported 11 cases of mechanical pain attributed to the neoarticulation despite normal bone scans.[210] Nine of 11 patients obtained pain relief with local anesthetic injection in the neoarticulation; a similar proportion of patients had improvement in pain with resection of the neoarticulation.[210] Physiologic imaging parameters (MRI T2 fat-saturated or STIR images, SPECT/CT) are more likely to be useful than structural changes, although no systematic studies have been performed. Brault reported a case of an adolescent athlete with focal mechanical pain consistently relieved by intra-articular injection of the facet contralateral to the neoarticulation. Interestingly, the bone scan showed increased uptake at the neoarticulation but not at the contralateral facet. Surgical resection of the neoarticulation resulted in complete relief of the contralateral pain at one year.[211] This may represent a case of pain generated by excessive facet capsular stresses caused by the asymmetric motion at this level, without detectable facet synovitis.

Transitional lumbosacral segments may thus be associated with axial pain, related to a neoarticulation, the contralateral facet at the level of an asymmetric neoarticulation, or IDD in the at-risk disc above a transitional segment. Radicular pain may be caused by a herniation in the adjacent segment disc or an extraforaminal entrapment at a neoarticulation. The presence of a transitional segment should always prompt meticulous attention to segmental enumeration because of both its intrinsic capacity for confusion and the seven-fold increased likelihood of an anomalous number of mobile presacral segments.[89]

Coccydynia

The radiographic evaluation of the sacrococcygeal region in patients with coccydynia remains controversial. This largely female pain syndrome is probably multifactorial in origin with contributions by somatic and neuropathic pain.[212] A single lateral view of the coccyx to evaluate for destructive osseous lesions is a reasonable screening study. Maigne has described a dynamic radiographic study to more fully evaluate the mobility of the coccyx.[213] This consists of a lateral radiograph with the patient standing for 10 minutes to visualize the coccyx without load, followed by a sitting lateral view, with the patient altering the pelvic position to that which stimulates the usual pain. Maigne and colleagues have studied coccygeal mobility and suggested that a normal coccyx may undergo from 5–25 degrees of angulation in moving from a standing to a sitting position. Flexion of the coccyx by more than 25 degrees with sitting as well as posterior subluxation of the coccyx with sitting and reduction with standing are considered pathologic and may be the anatomic basis of coccydynia.[213] Aggressive treatment decisions based on this evaluation are controversial. Advanced imaging has little role in this setting unless there is clinical suspicion of underlying systemic disease.

Pseudarthrosis, Postoperative Axial Pain

Patients with posterior fusion instrumentation may develop pain related to pseudarthrosis, infection, implant fracture or loosening, or the interface between the metal and the overlying soft tissue. Radiographs should be scrutinized for the integrity of the implant construct, loosening of pedicle screws (which will manifest as a halo of lucency surrounding the screws), or imaging evidence of pseudarthrosis. Anesthetic injection about prominent hardware may be useful in identifying this as a pain generator.

Despite advances in surgical technique and fixation hardware, fusion remains an imperfect procedure. Pseudarthrosis is defined as the failure to achieve a solid osseous fusion one year after attempted surgical fusion. It is manifested as persistent motion at the segment and absence of osseous trabeculae bridging the vertebrae. Approximately 15% of lumbar spinal fusions

• **Figure 20.12** Baastrup's disease and Bertolotti's syndrome as posterior element pain generators. An elderly male presents with neurogenic intermittent claudication. T2 fat-saturated sagittal image **(A)** and axial T2 image at the L4–5 interspace **(B)** demonstrate that the compressive lesion is a right paramedian dorsal cyst in continuity with the interspinous pseudobursae of Baastrup's disease. There are also facet joint effusions. In another patient with axial pain **(C),** a fat-saturated, enhanced T1-weighted image shows inflammatory enhancement in the interspinous ligaments of T12–L4. Sagittal T2 **(D)** and T1 **(E)** images of another patient demonstrate a large complex midline dorsal cyst emerging from an interspinous pseudobursae at the L3–4 interspace (axial T2 image **[F]**). A 17-year-old female (frontal lumbar spine radiograph **[G]**) presented with intractable left lumbosacral junction region pain. Note left pseudoarticulation (Bertolotti's syndrome). Single-photo emission computed tomography/computed tomography image **(H)** shows markedly increased uptake at the pseudoarticulation. Pain was relieved with injection into this site (fluoro image **[I]**; note that the patient is prone).

result in pseudarthrosis; the range of successful reported technical and clinical outcomes spans 16%–95%.[214] Rates of pseudarthrosis increased with the increasing number of fused levels and with risk factors including prior surgery, instability, deficient bone graft quality and quantity, and nicotine use (Fig. 20.13).

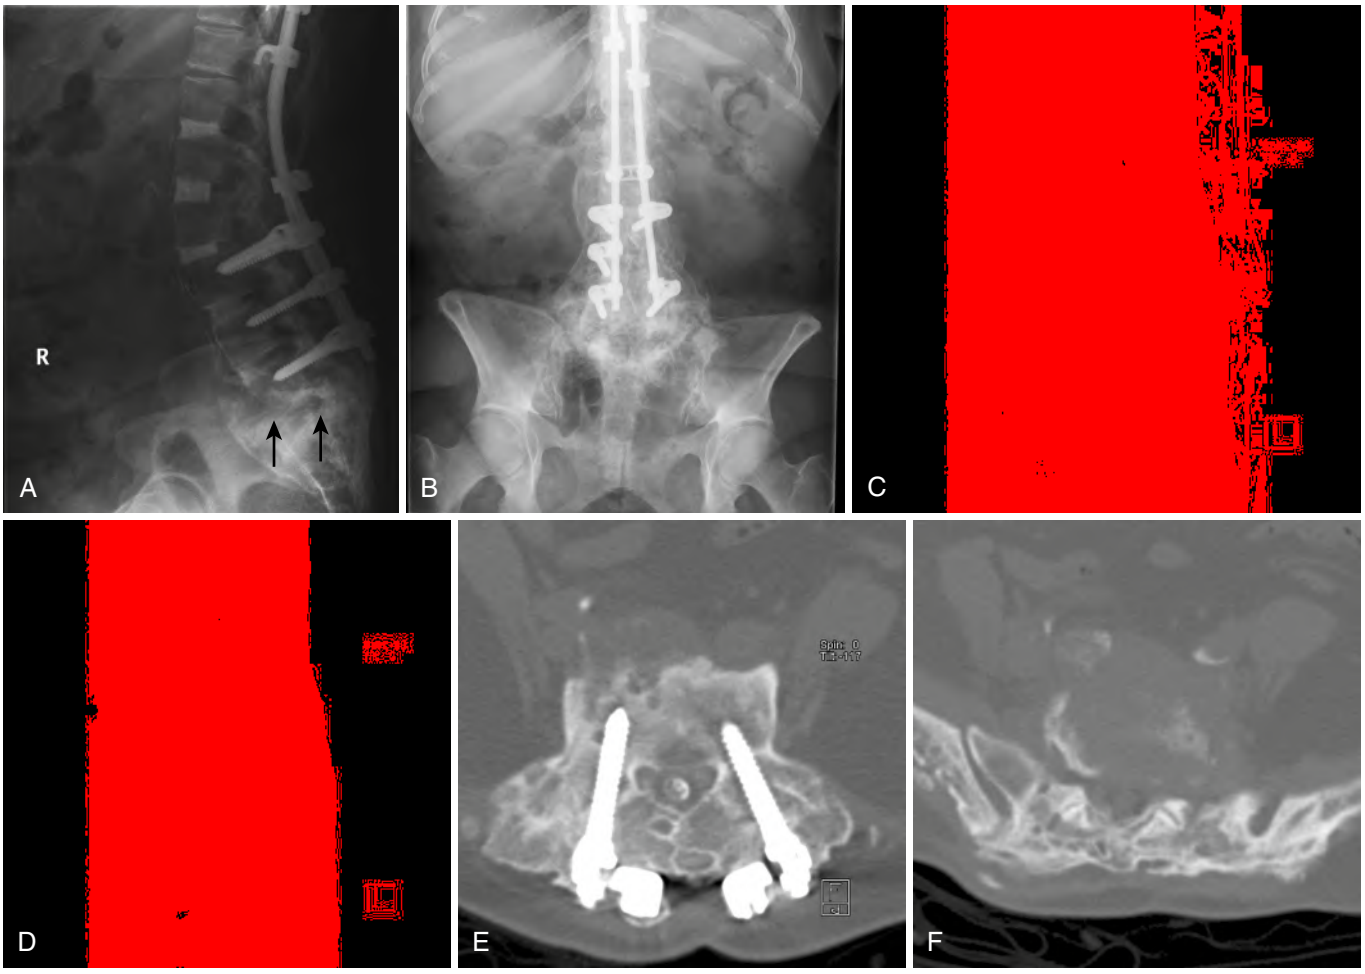
Detection of pseudarthrosis with imaging is of significance, as it is a cause of persistent or recurrent pain following surgery. The correlation is not exact; patients with radiographic pseudarthrosis may be pain free, and patients with solid fusions by all imaging techniques may have persistent pain arising from other factors. Therefore the clinical questions are two-fold: Is a pseudarthrosis present, and, if so, is it the cause of persistent or recurrent pain? The ultimate gold standard for fusion is surgical exploration; even this is not foolproof, as patients who have had hardware removal after intraoperative evaluation of stability have subsequently gone on to develop progressive deformity.[215]

Weight bearing radiographs are the primary tool in assessing stability and adequate fusion. In this setting, flexion-extension views likely add value. Radiographic evidence of instability includes the translation of 3 mm or more at L1–L4 or 5 mm at L5–S1. Radiographic fusion may take six to nine months, with ongoing remodeling for up to two years. The criteria for a radiographic solid interbody fusion are as follows:[216]

- No motion or less than three degrees of intersegment position change on lateral flexion and extension views
- Lack of a lucent area around the implant
- Minimal loss of disc height
- No fracture of the implant, bone graft, or vertebrae
- No sclerotic change in the bone graft or adjacent vertebrae
- Visible osseous formation in or around the cage

CT will provide greater sensitivity in the detection of pseudarthrosis, which manifests as lucent fracture lines with adjacent sclerosis or fragmentation of the bone graft, and fracture or lucency about implants. Ideally, to verify solid fusion, one wants to confirm the presence of continuous osseous trabeculae across the site of fusion. In patients with intervertebral cage devices, osseous trabeculae should be seen bridging the interspace through the cage and external to the cage.

Technetium bone scans with SPECT may be helpful. The fusion mass will be metabolically active for a prolonged period after surgery, and increased tracer uptake diffusely in the fusion mass is expected for several months. In normal healing, studies with serial



• **Figure 20.13** Pseudarthrosis on computed tomography (CT) myelography. This 71-year-old female is post multiple spine surgeries and has an instrumented fusion from the upper thoracic region to L5. She presents with bilateral leg pain in an L5 radicular distribution. Radiographs **(A, B)** show lucency with surrounding sclerosis at the L5 level. CT myelography sagittal reconstructions **(C, D)** reveal a pseudarthrosis at L5–S1 with Charcot or infectious features. Cultures were negative. Despite the instrumentation, the thecal sac is well demonstrated; it is patent at the L5 vertebral level **(E)** but obliterated at the L5–S1 disc level **(F)**. (From Thakkar RS, Malloy JP, Thakkar SC, et al. Imaging the postoperative spine. *Radiol Clin North Am.* 2012;50:731–747.)

bone scans have shown a steady decrease in tracer uptake after three months, with only minimal increased uptake at one year.[217] Increased uptake within the fusion mass beyond one year after surgery, or new increased uptake not present in prior studies, should raise concern for pseudarthrosis. On MRI, a solid bone graft should exhibit signal characteristics of normal marrow. Focal zones of T1 hypointensity, T2 hyperintensity, and gadolinium enhancement may indicate a site of pseudarthrosis with ongoing motion and inflammation. This requires careful inspection.

With disc arthroplasty, postoperative evaluation can occur by radiography or CT; radiography is more conservative of cost and radiation for serial follow up. The implant should be centered between the pedicles on AP images without penetration of the endplates. On lateral or sagittal images, the center of rotation should be in the posterior half of the disc space, but the implant should not extend beyond the posterior vertebral line.

The clinician and imager must also be aware of symptomatic adjacent segment disease as a cause of recurrent pain in the postfusion patient. Although controversial, this likely occurs at a rate of approximately 3% per year following lumbar fusion.[218] A similar rate has been associated with cervical fusion. The imaging findings will be those of discogenic pain. Radiographic evidence of adjacent segment disease may or may not be clinically symptomatic.

Pseudarthrosis and adjacent segment disease are two primary causes of pain in the postoperative patient, sometimes labeled the "failed back." Although conventionally considered a dread diagnosis, studies have shown that careful clinical evaluation, augmented by high quality imaging and provocation and anesthetic interventions, can identify the specific cause of pain in most cases. Waguespack and Slipman have each published reports on large series of patients with so-called failed back syndrome.[219,220] A specific diagnosis identifying the pain generator was achieved in over 90% of patients in both of these series. The most common diagnoses were foraminal stenosis (>20%), discogenic pain (20%), pseudarthroses (14%), neuropathic pain (10%), and recurrent disc herniation (7% to 12%), with lesser contributions from facet and SI joints. Each of these morphologic lesions has been individually addressed in the preceding sections. The imaging challenge is to systematically evaluate each segmental level for these potential pain generators despite the confusion of the surgically altered anatomy.

Imaging of Radicular Pain, Radiculopathy, and Myelopathy

Disc Herniation

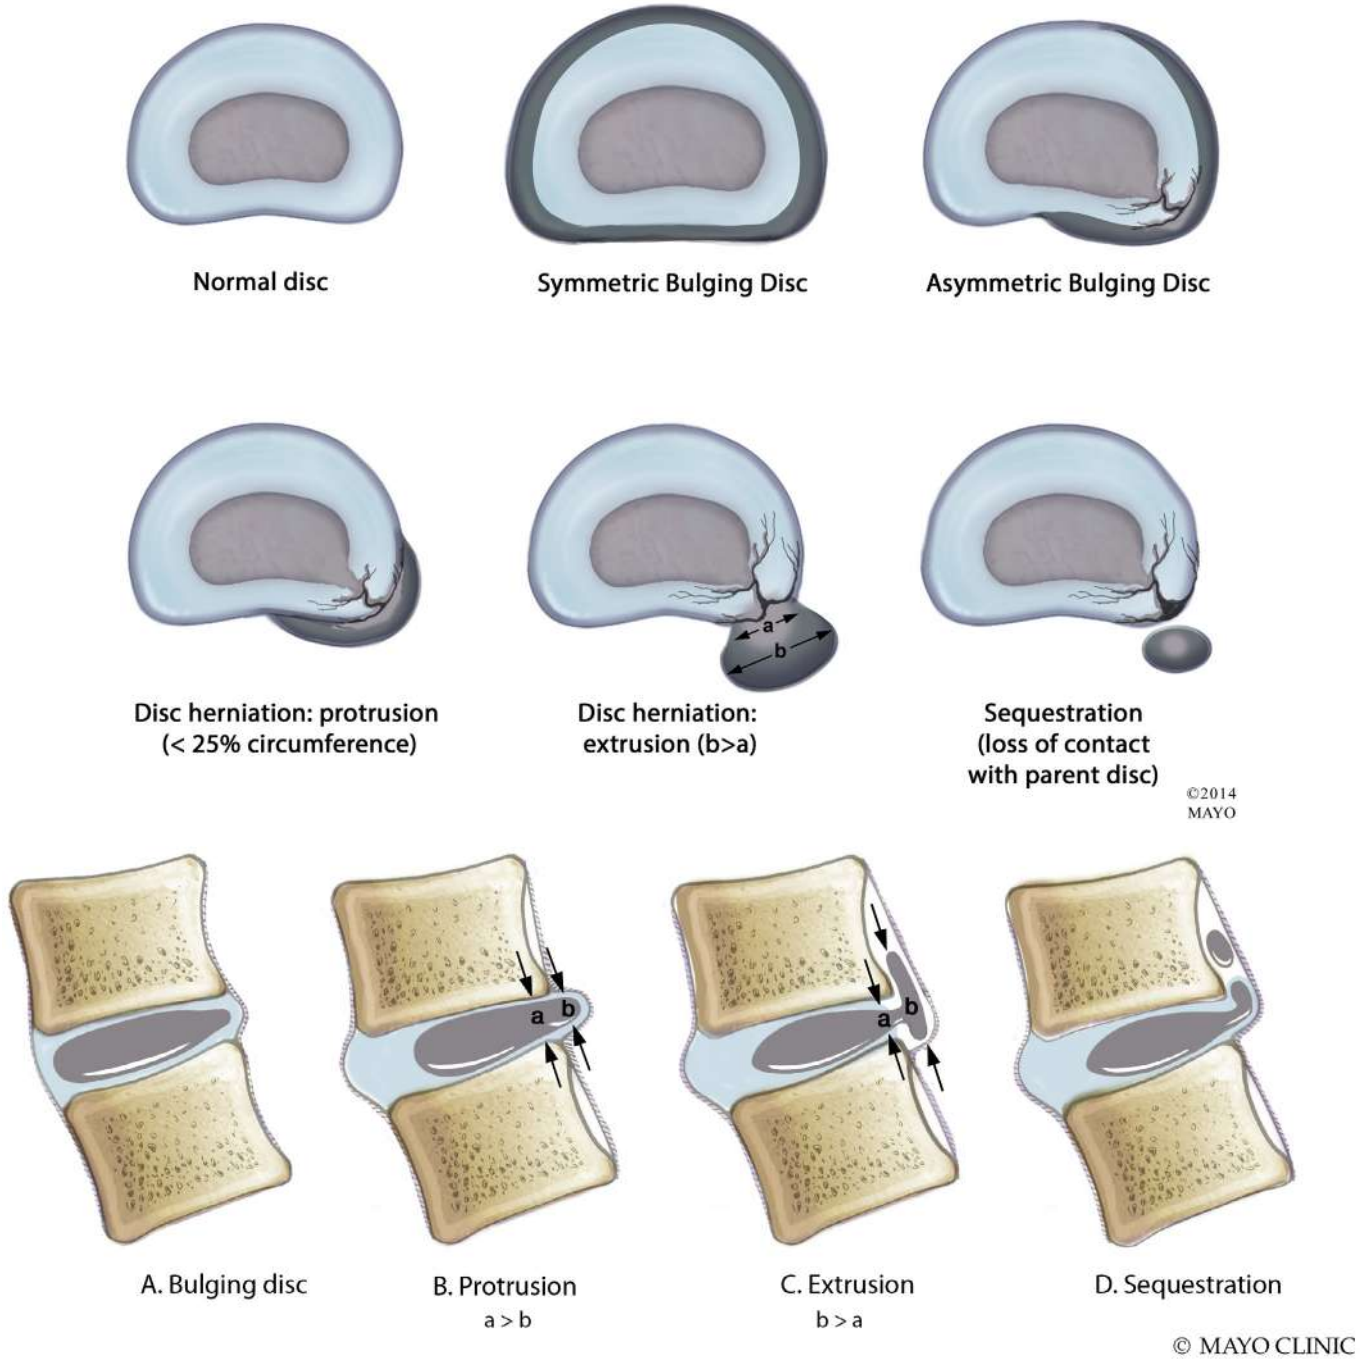
Radicular pain, or radiculopathy or myelopathy, has as its substrate neural compression and inflammation. Degradation of the nuclear matrix of the disc may occur in response to a variety of insults, including endplate infraction, genetically determined apoptotic chondrocyte cell death, diabetes mellitus, ochronosis, smoking, or infection. The nuclear compartment of the disc can no longer bear axial load, shifting its burden to the posterior annulus, which may undergo structural failure in the form of radial fissures, the anatomic basis of IDD. Besides potentially causing axial pain, these fissures may allow herniation of nuclear material into the outer annular lamellae as a contained protrusion or breach the annulus and pass into the epidural space as an extrusion. The mechanical compression of neural tissue and an induced inflammatory response conspire to provoke radicular pain or radiculopathy.

Mixter and Barr initially described the disc herniation as the cause of sciatica in 1934[221]; this observation, and the ability to relieve pain and neurologic dysfunction by surgical extirpation of the offending herniation, provided the basis for the first 70+ years of spine imaging. Myelography, CT, CT/myelography, and MRI were deemed useful in the patient with radicular pain or radiculopathy in the ability to first indirectly and later directly visualize the disc herniation and neural compression. The pathogenesis of radicular pain or radiculopathy is more complex than the simple compression of neural elements; an inflammatory response is also necessary to produce pain. The evidence supporting an inflammatory component in radicular pain was summarized by Mulleman and colleagues.[222,223] Neural compression in isolation produces nerve dysfunction, but not pain; exposure of compressed neural elements to the inflammatory response induced by disc nucleus pulposis results in radicular pain. This inflammatory response is mediated by phospholipase A2, interleukins 1 and 6, TNFα, and nitric oxide. The necessity of an induced inflammatory response for pain production provides a measure of understanding for the glaring specificity fault of disc herniation imaging: large disc herniations are often asymptomatic, and the severity of symptoms bears no relationship to herniation size.

The imaging description of disc herniations has historically been chaotic, with significant disparities among medical specialties and regions. Clarity was restored by a lexicon of lumbar spine nomenclature produced as a cooperative venture between multiple spine societies in 2001[224] and updated in 2014.[225] In this construct, spondylosis deformans describes those changes as thought to be because of normal aging. Degradation of the nuclear matrix may occur without structural failure of the annulus. Hence, there is relative preservation of disc space height and normal cartilaginous endplate and subchondral marrow. Anterior and lateral osteophytes are observed. MRI imaging shows loss of the normal intranuclear cleft and mild to moderately diminished T2 signal within the disc. Small concentric and transverse annular fissures may be seen in spondylosis; radial fissures are not considered a normal aging phenomenon. Small amounts of gas may be present within the disc that may be detected on plain films.

In this lexicon, pathologic discovertebral change is termed intervertebral osteochondrosis. This includes the changes of IDD, radial, and large circumferential fissures extending to the outer annulus. They may be accompanied by the development of posterior osteophytes that encroach on the central spinal canal. Besides posterior osteophytes, plain film manifestations of intervertebral osteochondrosis include large amounts of gas within the interspace, loss of disc space height, and endplate irregularity. On T2-weighted MRI images, the disc is of markedly diminished signal intensity. Disc herniations are common. Endplate cartilage erosion and reactive vertebral body marrow changes may also be present.[224]

Generalized disc displacement of over 25% of the circumference of the disc is a bulging disc. This can occur symmetrically throughout the circumference of the disc (symmetric bulging disc) or asymmetrically greater than 25% of the circumference of the disc (asymmetric bulging disc). The inclusive term for a localized or focal displacement of disc material is "herniation," which is defined as involving less than 25% (90°) of the disc circumference as viewed in the axial plane. Disc herniations can be either protrusions or extrusions, with the distinction between these two being one of shape (Fig. 20.14). In a protrusion, the width of displaced disc material in any plane does not exceed the width of its base at the outer margin of the disc space of origin. In an extrusion, the width of the displaced



• **Figure 20.14** Disc herniation definitions. Disc herniation definitions are depicted in the axial **(A)** and sagittal **(B)** planes. Note that the normal L1–L4 discs, shown here, are not round but an oblate structure whose dorsal margin is convex anteriorly. The L5 disc is normally oval in configuration, convex posteriorly. The definitions are elaborated in the accompanying text.

disc material exceeds its base in at least one plane. The presence of an extrusion shape suggests complete disruption of the outer annulus, and disc material has entered the epidural space. "Sequestration" is the term for loss of continuity of a disc extrusion with the parent disc from which it arose. Displacement of disc material away from the parent disc is termed "migration." Migration can occur caudally or cranially. A herniated disc can further be classified as contained or uncontained. A contained disc herniation is one in which the outer annulus fibrosis and/or the posterior longitudinal ligament is intact, whereas an uncontained herniation is one in which any such covering is absent. The shape definitions of protrusion and extrusion speak to this, but only by implication, not direct observation. While smooth posterior margins of disc protrusions on CT or MRI suggest containment and irregular margins suggest an uncontained herniation, CT or MRI can only rarely directly establish containment; post-CT discography can make this distinction.

Description of displaced disc material (Fig. 20.15) in the axial plane is defined by zones: the central canal zone defined by the medial margins of the facets (including the central and right/left central zones), the subarticular zone extending from the medial facet margin to the medial pedicle margin, the foraminal zone extending from the medial to lateral margins of the pedicle, and the extraforaminal (or far lateral) zone peripheral to the lateral pedicle margin. Therefore a right-sided disc herniation may be described as right central, right subarticular, right foraminal, or right extraforaminal. Similarly, the location in the sagittal plane (superior-inferior) is defined by levels in relationship to the vertebral endplate and pedicle margins. Extending from superior to inferior, the designations include the disc level, suprapedicular level, pedicle level, infrapedicular level, and the subsequent disc level. Although an element of subjectivity remains inherent in any usable system of terminology, careful adherence to these descriptors should allow a more coherent discussion of disc pathology.

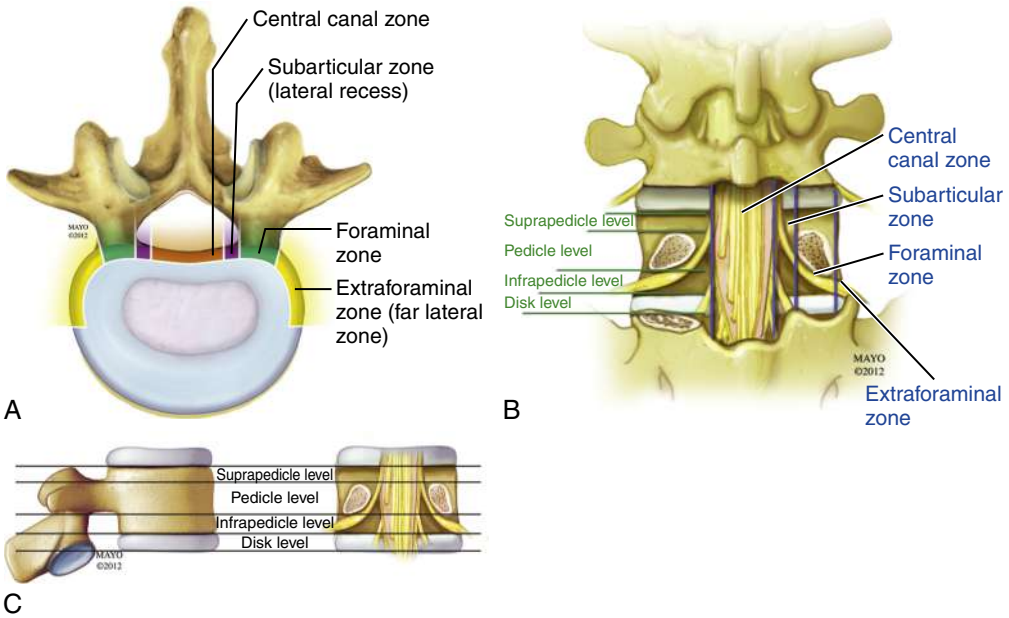
Imaging of patients with radicular pain or radiculopathy should begin with upright radiographs of the involved spine segment. This will establish the enumeration, assess balance and stability, and act as a low sensitivity screen for sinister disease. Advanced imaging may be needed in the setting of intractable radicular pain or progressive neurologic deficit. MRI has long been considered the primary imaging modality in the evaluation of disc herniations, but this has little basis in evidence. No studies compare the current generation CT with MRI technology in the detection and characterization of disc herniations. MRI remains the initial modality of choice largely because of its superior sensitivity and specificity in the detection of sinister disease causal of back or limb pain, which, it must be remembered, is the primary goal of imaging. CT myelography retains a problem solving role in the lumbar region, but it plays a more prominent role in the cervical spine, where its ability to distinguish disc from bone may affect surgical planning.

Imaging Reliability

MRI has shown good reliability in the assessment of disc herniations. Lurie and colleagues[226] analyzed MRI studies of patients with disc herniations from the Spine Patient Outcomes Research Trial (SPORT) trial; interobserver reliability was high ($\kappa = 0.81$) for disc morphology when classified as normal/bulge, protrusion, and extrusion/sequestration. There was moderate interobserver agreement for thecal sac ($\kappa = 0.54$) and nerve root compression ($\kappa = 0.47$). Pfirrmann and colleagues[227] proposed a grading system for nerve root compression. The authors divided the relationship of the herniated disc and the nerve root into four categories: no compromise, contact with the nerve root, deviation of the nerve root, and compression of the nerve root. The intra-observer ($\kappa = 0.62–0.67$) and intra-observer ($\kappa = 0.72–0.77$) reliability results were good. The correlation for a higher grade of nerve root involvement (compression) was better than for low-grade nerve root involvement.

Imaging Observations

MRI T2-weighted images can well display the interface between disc herniations and the thecal sac. The herniated material may be of low T2 signal intensity comparable to the parent disc that has undergone nuclear matrix degradation, but not uncommonly extruded disc material is of higher T2 signal than its parent disc. This may, in part, reflect inflammatory reaction surrounding the extruded material; it can make detection of extruded material in the lateral recesses or foramina challenging on fast spine echo, turbo spin-echo (FSE, TSE) T2-weighted images in which fat is also bright. Comparison with matched T1-weighted images will



• **Figure 20.15** Zones and levels of disc displacement. In the axial plane **(A)** the location of displaced disc material is described by zones. Moving from the midline laterally, these zones are the right or left central zone, demarcated by the medial margins of the facet joints; the subarticular zone (lateral recess), bounded by the medial aspect of the facet joint and the medial aspect of the pedicle; the foraminal zone, bounded by the medial and lateral aspects of the pedicle; and the extraforaminal or far lateral zone, peripheral to the lateral margin of the pedicle. These zones are also illustrated in the coronal plane **(B)**. The displacement of disc material in the cephalocaudal dimension is described by levels, as illustrated in **(B)** and **(C)**.

identify the now dark disc material against the bright fat in the lateral recess or foramina. Occasionally, disc herniations may be associated with a small amount of hemorrhage in the epidural space, which may manifest itself as an epidural process of high T1 and variable T2 signal intensity. This hemorrhage may be related to the pathogenesis of discal cysts, relatively rare cystic lesions in the epidural space, which may present with radicular pain and result from prior disc extrusion and hemorrhage with incomplete resorption.[228]

Ninety percent of lumbar disc herniations occur at the L4 or L5 interspace levels. The vector of disc displacement in most herniations is posterolateral. In the lumbar spine, the exiting nerve passes immediately inferior to the vertebral pedicle and exits the foramen above the interspace level. Therefore most disc herniations do not affect the exiting nerve but rather impinge on the traversing nerve, which exits under the next lower vertebral pedicle. For example, a posterolateral L4–L5 disc herniation results in an L5 radicular pain syndrome or radiculopathy. For a lumbar disc herniation to affect the like numbered nerve, it must be an extrusion with lateral and cephalad migration of disc material into the neural foramen. The greater spatial resolution of CT myelography may identify subtle lateral recess or foraminal lesions that are less clearly seen on MRI.

Contrast material is not typically used when MRI is undertaken to evaluate for causes of radicular pain or radiculopathy except in the presence of red flag features raising concern for infection of neoplasm or prior surgery. Unenhanced imaging can primarily detect the mechanical compression of a nerve, not the inflammatory response, which is also necessary to provoke radicular pain. T2 hyperintensity on STIR or fat-saturated images may identify this reaction. If gadolinium is given, it is often observed that the soft tissue seen on unenhanced images, thought to be herniated disc material, is largely enhancing inflammatory/granulation tissue about a small disc fragment. When confronted with a patient with clinically evident radicular pain or radiculopathy and no evidence of a neural compressive lesion on standard imaging, an enhanced exam may reveal an inflammatory process associated with a disc whose annulus is incompetent.[229] This is described as chemical radiculitis. The neural compressive component of the lesion may only be present on imaging with axial load and physiologic positioning (Fig. 20.16).

Postoperative Imaging

Gadolinium-enhanced MRI does have a well defined role in the evaluation of the postoperative patient. Plain films, CT, and CT myelography are relatively uninformative in the postoperative patient, as they cannot reliably distinguish recurrent disc herniation from epidural fibrosis/scar. Following discectomy, extensive anatomic changes evolve over time, confounding imaging interpretation. Great caution must be used in interpreting MRI within six weeks of surgery.[230] In this time frame, MRI is most useful in the evaluation for hemorrhage, pseudomeningocele, or discitis; evaluation for recurrent disc herniation is tenuous. The diagnosis of postoperative discitis is also complicated by the normal linear enhancement that may be observed in the postoperative disc.[230] As postoperative tissue disruption and edema stabilize, MRI with gadolinium enhancement has been reported to be 96%–100% accurate in distinguishing recurrent disc herniation from scars.[230] Scar or epidural fibrosis enhances rapidly and uniformly following gadolinium administration; disc material does not enhance for the first 20–30 minutes. Early post-gadolinium images in the postoperative patient will show recurrent disc herniation as a non-enhancing zone; enhancing epidural fibrosis may surround this. Extensive scar or epidural fibrosis is in and of itself a negative prognostic sign associated with an increased incidence of postoperative radiculopathy.[231] In the postoperative setting, the thecal sac should be examined for evidence of arachnoiditis. In this condition, the roots of the cauda equina are either clumped together or adherent to the dural tube. The dural tube may even appear empty of roots, which are smoothly scarred to its wall. Roots may exhibit enhancement in this condition.

Imaging Natural History

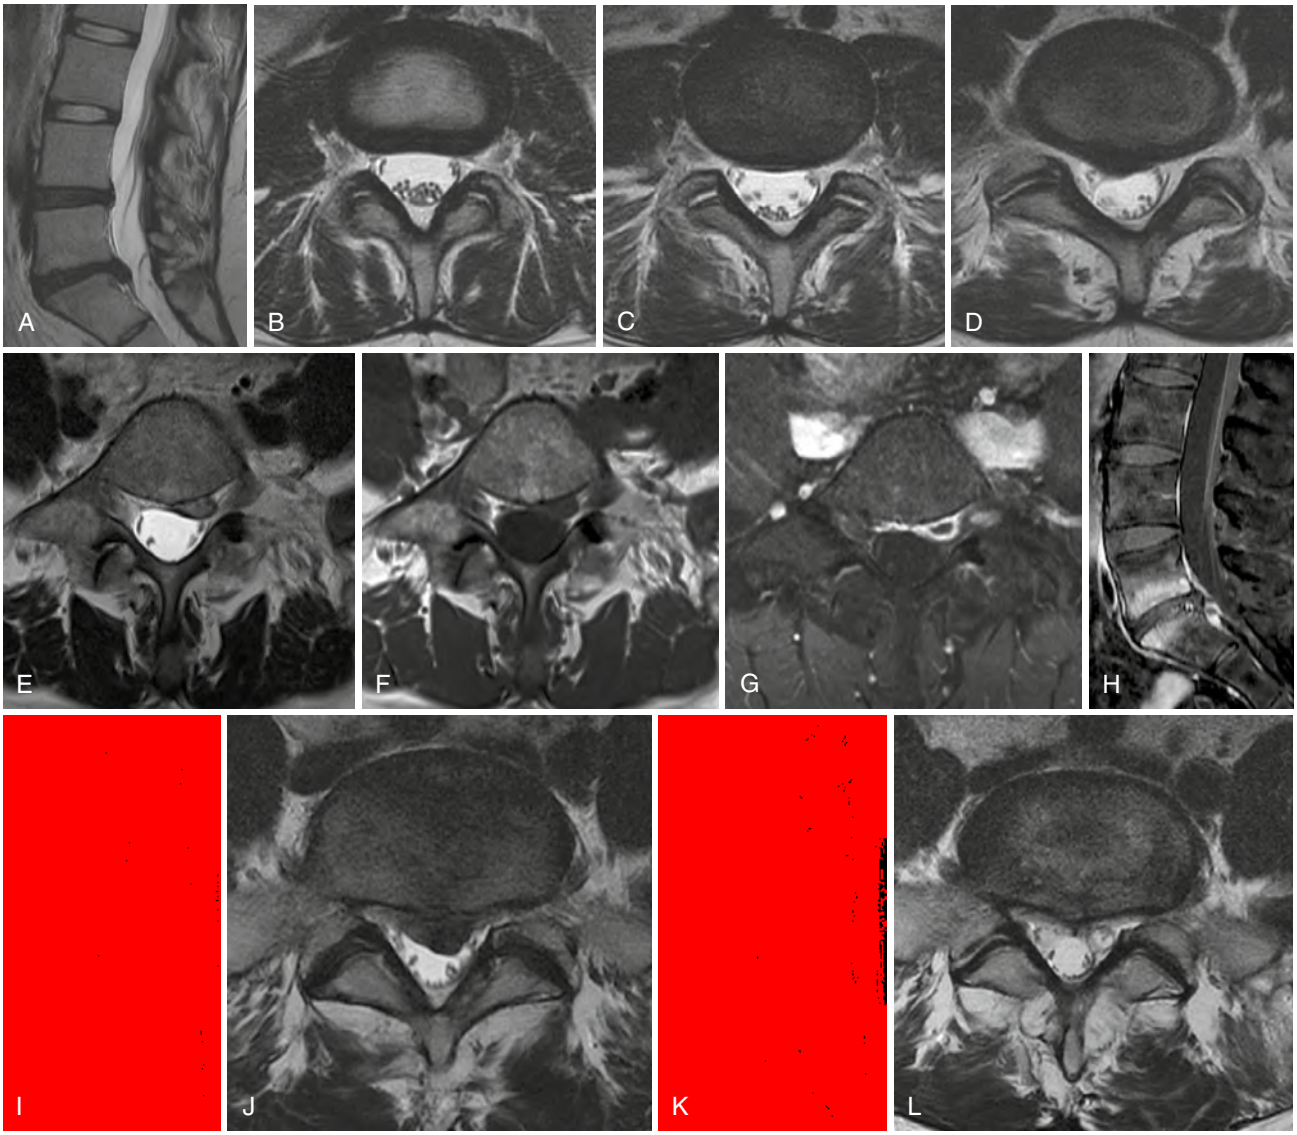
The imaging natural history of disc herniation is often resolution.[232] Large disc herniations, extrusions, and sequestrations, which have entered the highly vascular epidural space, are most likely to undergo resorption mediated by macrophage produced metalloproteases.[233–235] This inflammatory response is integral to the profound pain these patients feel, but it will ultimately resorb the extruded disc material. If the targeted administration of corticosteroids can attenuate the inflammatory response, thus allowing the patient to remain functional, over time, natural history will bear out with resolution of the herniated disc material and the radicular pain syndrome. Contained protrusions and bulges, with intact outer annulus shielding the herniation from the full fury of the immune system, tend not to change.

Validity of Disc Herniation Imaging: Correlation With Symptoms/Signs

The fundamental specificity fault of spine imaging is very evident in the imaging of disc herniations. Modic[61] demonstrated no relationship between herniation type, size, or change over time and patient outcome. Most of the imaging findings observed on an imaging study obtained at presentation with radicular pain will have been present at a time when the patient was asymptomatic.[60] In another study by Masui, disc herniations treated conservatively were followed over seven years.[236] Clinical outcomes were unrelated to the size of the herniation or age changes in the disc. To assign causality to a disc herniation, there must be concordance, a perfect match of the patient's pain or dysfunction syndrome, and the expected detriment caused by an observed herniation. The imager must know the nature of the pain syndrome to identify its likely cause among the distracters of asymptomatic findings. The sensitivity fault is also evident; disc herniations that do not appear to contact neural tissue on recumbent imaging may be compressive under axial load and physiologic posture. Willén and Danielson showed that significant additional information was demonstrated in 14% of sciatica patients on images obtained under extension and axial load, including accentuation of disc herniations, increasing lateral recess or foraminal stenosis, and distention of synovial cysts that contributed to root compression (Box 20.4).[237]

Unusual Manifestations of Disc Disease

Besides their common appearances, locations, and clinical features, intervertebral disc pathologic conditions can have a wide spectrum of manifestations; many of these entities were discussed in an extensive review published in the radiology literature.[238] These include disc herniations in relatively unusual locations, including the dorsal epidural space, the intradural compartment, and the extreme lateral or retroperitoneal zone. Disc herniations may develop cystic change (discal cysts), which may contain blood-fluid levels and even cause benign osseous erosion of adjacent vertebral bodies. On PET-CT, any disc herniations associated with



• **Figure 20.16** Disc herniations. Sagittal T2 magnetic resonance image (MRI) **(A)** and axial T2 images at L3–4 **(B)**, L4–5 **(C)**, and L5–S1 **(D)** discs demonstrate a normal L3–4 disc, a central protrusion at L4–5, and a right central extrusion with caudal migration at L5–S1. Axial T2 **(E)** and T1 **(F)** MRI images at the S1 endplate level demonstrate a left-sided sequestered disc fragment contacting the thecal sac. Fat-saturated T1 axial image **(G)** and sagittal image **(H)** show that much of the apparent disc herniation enhances and is an inflammatory reaction about a small disc fragment. Enhancing Modic I change is present. Another patient with left S1 radicular pain an L5–S1 disc extrusion **(I, J)** was treated with a transforaminal epidural steroid injection with the resolution of pain. He returned four years later with new L5 distribution pain and was reimaged **(K, L)**. Note that the L5–S1 extrusion has completely resolved; **([L]** is at the identical level as **[J])** and a new L4–5 extrusion has developed. The natural history of disc extrusion is resolution.

inflammatory response may manifest with increased uptake, simulating neoplasm. Clinically relevant disc pathology can range from extremely large in size, such as a massive disc herniation occupying over 50% of the central spinal canal, to very tiny, such as a minuscule spiculated/calcified disc that may cause spinal cerebrospinal fluid (CSF) leak and spontaneous intracranial hypotension. Clinical manifestations of the wide spectrum of disc pathology can range from transient with spontaneous resolution, such as acute calcific discitis, which is most common in the pediatric population, to permanently disabling, such as fibrocartilaginous embolism of disc material to the spinal cord with resulting cord infarct.

Radicular Pain

Lateral Recess, Foraminal Stenosis

As the nerve root exits the common dural sac into its root sleeve, it leaves the central spinal canal, passing caudally and laterally into the lateral recess or subarticular zone. Compromise of the lateral recess may be causal of radicular pain or radiculopathy. Lateral recess stenosis is primarily a product of facet joint arthrosis with overgrowth of the SAP. This encroaches on the posterior aspect of the lateral recess, impinging on the exiting nerve root. This

• Box 20.4 Disc Herniations and Radicular Pain

- Radicular pain requires both the compression of neural tissue and an inflammatory response, likely mediated by tumor necrosis factor α.
- Standard imaging can only detect nerve root displacement or compression, which are necessary but insufficient to cause symptoms.
- This is in part the basis of the specificity fault: many disc herniations are asymptomatic.
- Completing the causality of symptoms to a disc herniation requires concordance: there must be a key in lock match between the lesion and the syndrome of pain and neurologic dysfunction.
- The imager must know the nature of the radicular pain/radiculopathy syndrome to consider ascribing symptoms to a disc herniation.
- The natural history of disc herniations is resolution; larger herniations, extrusions, and sequestrations are more likely to resolve.
- There is no relationship between the size, type, or change in disc herniations over time and patient outcomes.
- Decisions regarding surgical intervention must be based on clinical grounds, not imaging appearance.

is best demonstrated on axial MRI or CT myelographic images (Fig. 20.17). These images should be scrutinized to ensure that the nerve root in question is indeed entrapped within the lateral recess rather than simply displaced medially into the central spinal canal. The minimum normal A-P dimensions of the lateral recess have been variably reported as 3 mm to 4 mm.[239] The lumbar level most commonly involved with lateral recess stenosis is the L4–5 interspace level.

As the exiting nerve root continues to progress caudally and laterally under its similarly numbered lumbar pedicle, it enters the foraminal zone. The intervertebral foramen is an inverted teardrop-shaped orifice; the exiting root is situated in the larger, superior aspect of the foramen. An annular bulge or lateral protrusion may intrude into the inferior portion of the neural foramen without causing neural compression. A disc extrusion with cranial migration of disc material into the foramen may contact, displace or compress the exiting root. Other spondylotic phenomena causing foraminal stenosis include osteophytes arising from the posterior margin of the vertebral body or SAP, synovial cysts, or abnormalities of vertebral alignment, including the concavity of a scoliotic curve or spondylolisthesis resulting from spondylolysis or facet arthropathy. Foraminal stenosis is best demonstrated on sagittal MRI images (see Fig. 20.17). The low signal nerve root and accompanying small veins should always be surrounded by high signal fat on T1- or T2-weighted sagittal MRI images. Axial MRI images may also demonstrate foraminal stenosis, although to less advantage.

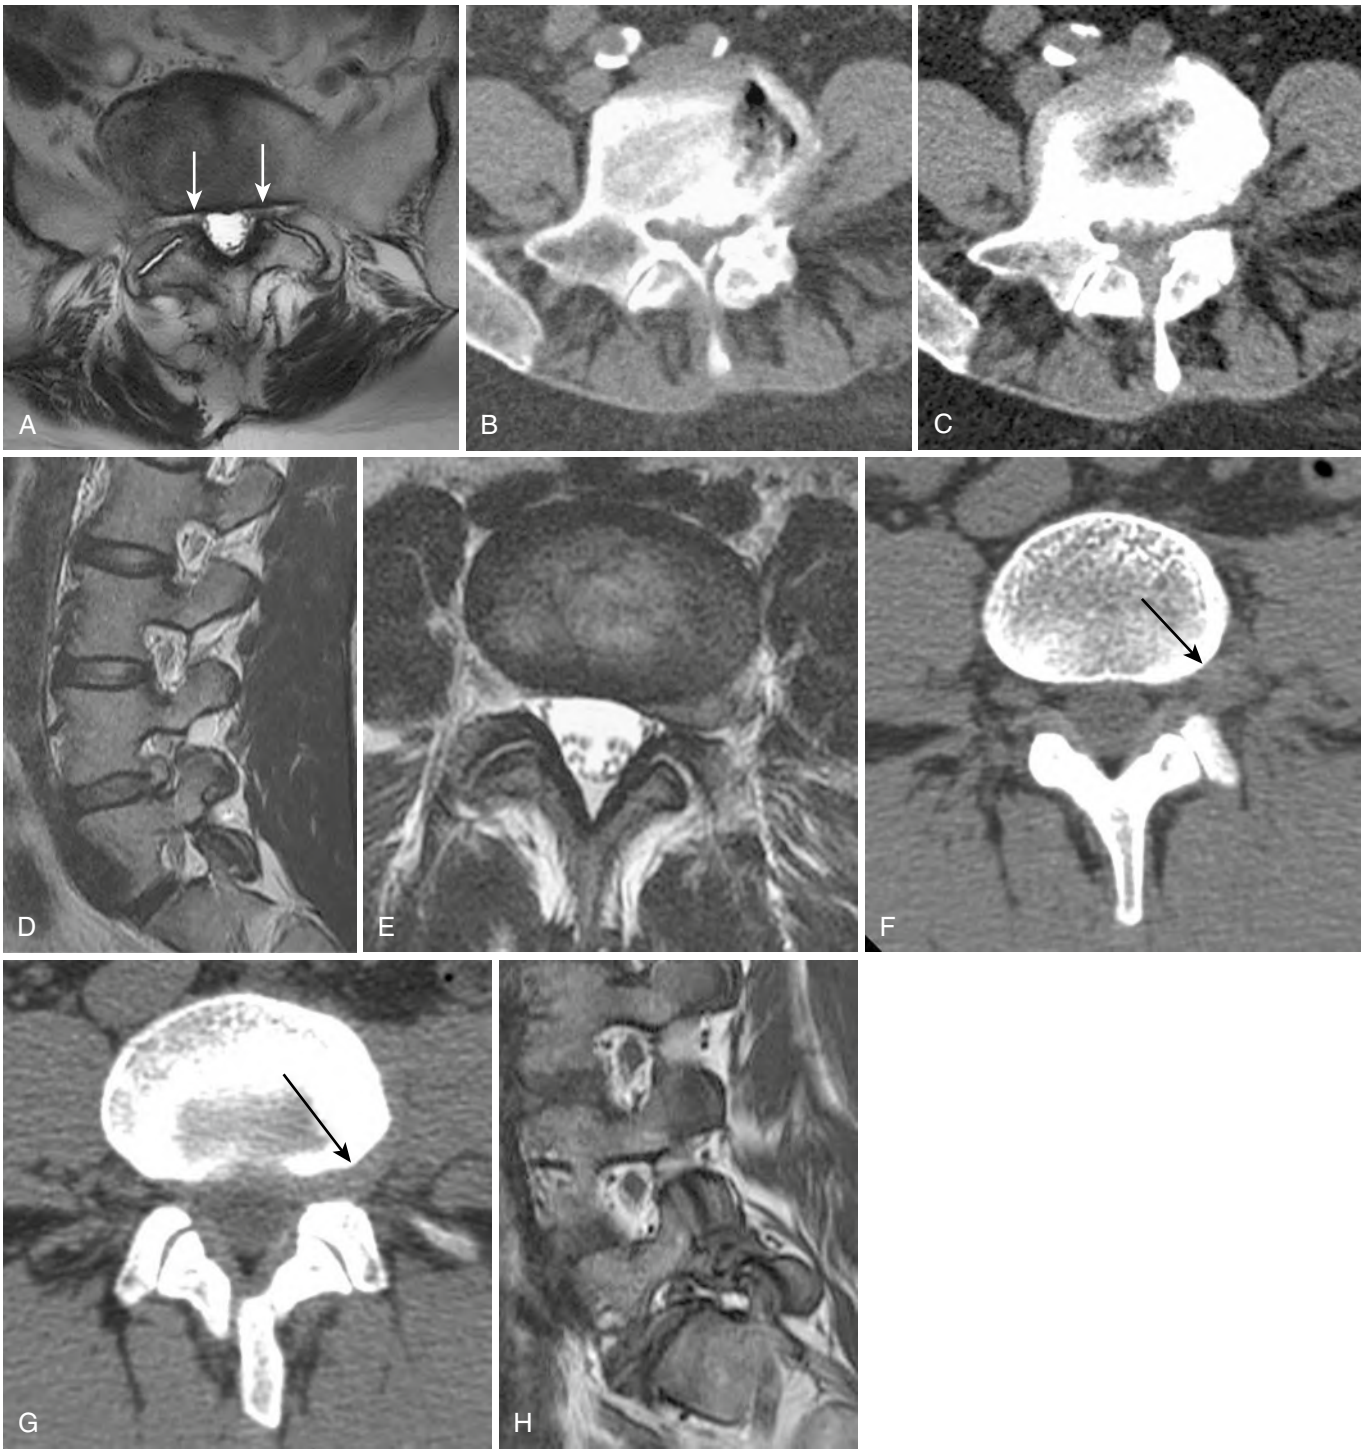
Synovial Cysts

Synovial cysts may accompany facet osteoarthrosis, may be a cause of radicular pain or neurogenic claudication, and may be associated with axial low back pain. Synovial cysts are thought to originate with a degenerative or traumatic defect in the fibrous facet joint capsule, with subsequent herniation of the synovial membrane through the defect. Expansion of the synovial outpouching, no longer constrained by the joint capsule, results in a cystic lesion, which may impinge on adjacent neural structures or simply serve as an imaging marker of capsular pathology. Synovial cysts may retain or potentially lose their communication with the facet joint. Ganglion cysts may have a similar gross appearance but histologically lack a synovial lining; they may be indistinguishable in imaging studies.

Although relatively unusual, synovial cysts are not rare: the series by Doyle and associates[240] demonstrated a prevalence of nearly 10% in a population of patients undergoing MRI for back or leg pain. In this series, anterior or intraspinal cysts, often arising from the superior recess, had a prevalence of 2.3%; posterior or extraspinal cysts were more common with a 7.3% prevalence. Synovial cysts are prevalent in the elderly population, with an average age of 63 years in Métellus' study,[241] 61 in Apostolaki's[242] study population, and 66 years in the large surgical series of Lyons.[243] Reported male-to-female ratios are inconsistent, varying from a 1:1 ratio in the Lyons series to 1.2:1 in the Métellus series and 1:2 in the Apostolaki study; Doyle noted a female predominance in posterior cysts only. Synovial cysts are far more common in the lumbar region than in the thoracic or cervical spine. The literature has consistently shown that 60%–70% of lumbar synovial cysts will be at the L4/5 level, followed in relative order by L5/S1, L3/4, and L2/3. Anterior or intraspinal synovial cysts most commonly occur posterolaterally to the thecal sac in close association to the facet joint. They may be embedded in the ligamentum flavum. Uncommonly, cysts may be located directly dorsal to the thecal sac, laterally within the neural foramen, or in a far lateral or extraforaminal site. Far lateral synovial cysts typically arise from the superior recess of the joint, which extends over the superior margin of the SAP; the communication with the joint will not be seen on an axial image but may be apparent on sagittal images.

Synovial cysts often arise from facet joints exhibiting significant arthrosis, with sclerosis, osteophytes, and increased joint fluid, although most joints with arthrosis do not produce cysts. Segmental hypermobility is postulated as an underlying cause of synovial cysts. This is supported by the strong association with the most mobile lumbar segment (L4/5) and the frequent (42%–65%) association with degenerative spondylolisthesis.[242] Disc age-related changes are commonly present at the level of the cyst. Metellus[241] also noted that most cysts arise from joints with a predominant sagittal orientation; this orientation is also associated with segmental instability.

Synovial cysts may be detected by CT, CT myelography, or MRI; MRI is thought to be the most sensitive (Fig. 20.18). Calcified cysts may rarely be seen on plain radiographs. Synovial cysts have great variation in their histology, with corresponding variation in their imaging appearance. Synovial cysts may be thin-walled collections of pure synovial fluid, or they may be complicated by varying degrees of chronic or acute hemorrhage and inflammation. Pure cysts have a high T2 signal, equal to or exceeding that of cerebrospinal fluid (CSF), with a corresponding low T1 signal and a thin, low signal wall. With chronic hemorrhage, cyst contents may develop a high T1 signal (methemoglobin) and a variable T2 signal; the wall often enhances with gadolinium. In the presence of chronic inflammation and calcification, the wall may become quite thick, with a very low T1 and T2 signal. On CT, calcification is variably observed, and cyst contents range from hypodense to slightly hyperdense relative to muscle. Changes in arthrosis in the adjacent facet joint are typical, including abnormal marrow signal (T2 hyperintensity, T1 hypointensity) in the articular processes and pedicle. Direct communication with the facet joint is not always demonstrable on either CT or MRI. Synovial cysts may not be evident on recumbent CT or MRI imaging, as the synovial fluid recedes into the joint space, collapsing the cyst; when the patient assumes axial load, the joint surfaces are opposed, driving the fluid into the cyst, which then exerts mass effect on neural



• **Figure 20.17** Subarticular Zone (Lateral Recess) and Foraminal Compromise. Axial T2 MRI image **(A)** at the S1 superior endplate demonstrates a widely patent central spinal canal but severe bilateral subarticular zone stenosis *(arrows)* resulting from facet hypertrophy. Consecutive CT images **(B, C)** at the L5 pedicle level in another patient show severe central spinal canal stenosis and severe subarticular zone stenosis primarily caused by endplate osteophytes. T2 sagittal and L4–5 disc axial images **(D, E)** in a patient with left anterior thigh pain reveal a left foraminal disc extrusion, displacing the dorsal root ganglion (DRG) superiorly and laterally. Axial CT images **(F, G)** in another patient with left L4 radicular pain also demonstrate a left L4 foraminal and extraforaminal extrusion *(arrows)* effacing the fat about the exiting L4 DRG and ventral ramus. A final patient with L5 spondylolysis **(H)** demonstrates the typical S-shaped foraminal stenosis at L5–S1 seen in this setting. Note normal foramina at L3–4 and L4–5 with abundant fat surrounding the DRG and small veins.

• **Figure 20.18** Synovial cysts. Typical bilateral L4 intraspinal synovial cysts **(A)** compress the thecal sac on a T2 axial image. A different patient **(B)** demonstrates a synovial cyst in the left L5–S1 neural foramen as well as a posterior extraspinal cyst. Another patient with right L5 radicular pain demonstrates an L4–5 synovial cyst on sagittal **(C)** and axial **(D)** T2 images. The patient underwent a right L5 transforaminal epidural steroid injection and an intra-articular injection of the facet joint/cyst. Her pain resolved. She presented four years later with axial pain. Magnetic resonance T2 sagittal **(E)** and axial **(F)** images show a new L5 compression fracture; the synovial cyst has resolved. A final patient demonstrates an irregular thick-walled cyst *(arrows)* arising from the left 3–4 facet **(G, H, I).** Note the T1 hyperintensity **(H).** Computed tomography **(J)** shows the cyst is calcified *(arrow).*

elements. Not infrequently, synovial cysts will fill when the joint is pressurized by intra-articular injection, despite no evidence of their existence on advanced recumbent imaging. The imaging differential diagnosis includes conjoined nerve root sleeves, sequestered disc fragments, cystic nerve sheath tumors, and degenerative cysts of other origins, such as pseudobursae in Baastrup's disease.

Anterior or intraspinal synovial cysts often present as lesions causing unilateral radicular pain or contributing to neurogenic claudication. Anterior synovial cysts may cause focal neural compression in the lateral recess, foramen, or extraforaminal space, or they may contribute to central spinal canal stenosis. Posterior cysts do not cause neural compression but may be associated with

axial pain and be an imaging sign of facet capsular disease. Synovial cysts may regress spontaneously. Radicular pain resulting from synovial cysts may be treated by an injection of corticosteroid into the facet joint bearing the cyst, with a transforaminal epidural steroid injection at the same procedural setting. This strategy successfully allowed 50% of patients to avoid surgical injections in a series by Sabers and colleagues.[244] Other non-operative therapies have included aspiration, fenestration, or rupture of cysts under CT or fluoroscopic guidance. A large case series (n = 101) of percutaneous cyst rupture showed surgical sparing in about 50% of cases.[245] A series of 85 CT-guided direct synovial cyst aspiration and fenestration procedures by Shah and colleagues similarly showed that 56% of patients had partial or complete long-term relief without the need for a subsequent operation.[246] A similarly sized (n=110) retrospective review of CT-guided cyst rupture demonstrated that cysts of high or intermediate T2-signal intensity were more likely to be successfully ruptured than T2-hypointense cysts; the high signal intensity cysts also had lower rates of subsequent surgery.[247] Surgical resection of synovial cysts generally has a favorable outcome, but it may require facetectomy, laminectomy, and possible fusion. Even after surgery, synovial cysts can recur.

Cervical Disc Herniations

The cervical intervertebral discs differ structurally from the lumbar disc. The cervical discs are thicker anteriorly than posteriorly and have a less well defined nuclear/annular structure. There is no discrete annulus at the posterior disc margin. The cervical discs function less to disburse axial load. They undergo maturational change with age; intradiscal T2 signal loss is a poor predictor of axial pain. Cervical radicular pain or radiculopathy is less common than lumbar symptomatology. Cervical radicular pain is most commonly caused by foraminal compromise of multifactorial origin: uncovertebral joint and facet hypertrophy, loss of disc space height, and less frequently disc herniation. In a population-based study in Rochester, Minnesota, disc herniations were causal of only 22% of cervical radiculopathies.[248] The C6 and C7 nerves were most commonly affected. As in the lumbar region, the vector of herniation is usually posterolateral, but as the cervical nerves exit low in the foramen, a herniation will likely affect the exiting nerve, not the traversing nerve. For instance, the C6 nerve exits low in the C5–6 neural foramen; a herniation at this segment is expected to impinge on the C6 nerve.

The natural history of cervical disc herniations parallels the lumbar region. Cervical disc herniations may undergo spontaneous regression. As in the lumbar region, extrusions, migrated disc material, and laterally situated disc herniations are more likely to undergo spontaneous regression. As most lesions causing cervical radicular pain are not purely soft disc but are, at least in part, osseous, overall regression of the root compressive lesion is less likely than in the lumbar region. MRI remains the primary advanced imaging modality, but CT myelography may play a larger role. It provides the best spatial resolution, critical in the narrow confines of the cervical region, and excels at discriminating bone from soft disc, which may alter the surgical approach (Fig. 20.19).

Thoracic Disc Herniations

Symptomatic thoracic disc herniations are rare; only 1%–2% of all disc surgeries are performed in the thoracic segment.[249] The expected specificity fault applies; age-related disc changes are ubiquitous, and herniations are often asymptomatic. The majority of disc herniations occur in the mid and lower thoracic region. In the surgical series by Stillerman,[250] the T8–T11 levels were most commonly affected. In this series, 76% of patients presented with pain, 61% with either motor or sensory dysfunction, and 24% with bladder dysfunction. Nearly two-thirds of the disc herniations showed evidence of calcification on CT imaging. At surgery, 7% showed intradural extension. Thoracic disc herniations involving the conus can mimic lumbar radicular pain; MRI studies of the lumbar spine should always extend to the conus on the sagittal sequences.

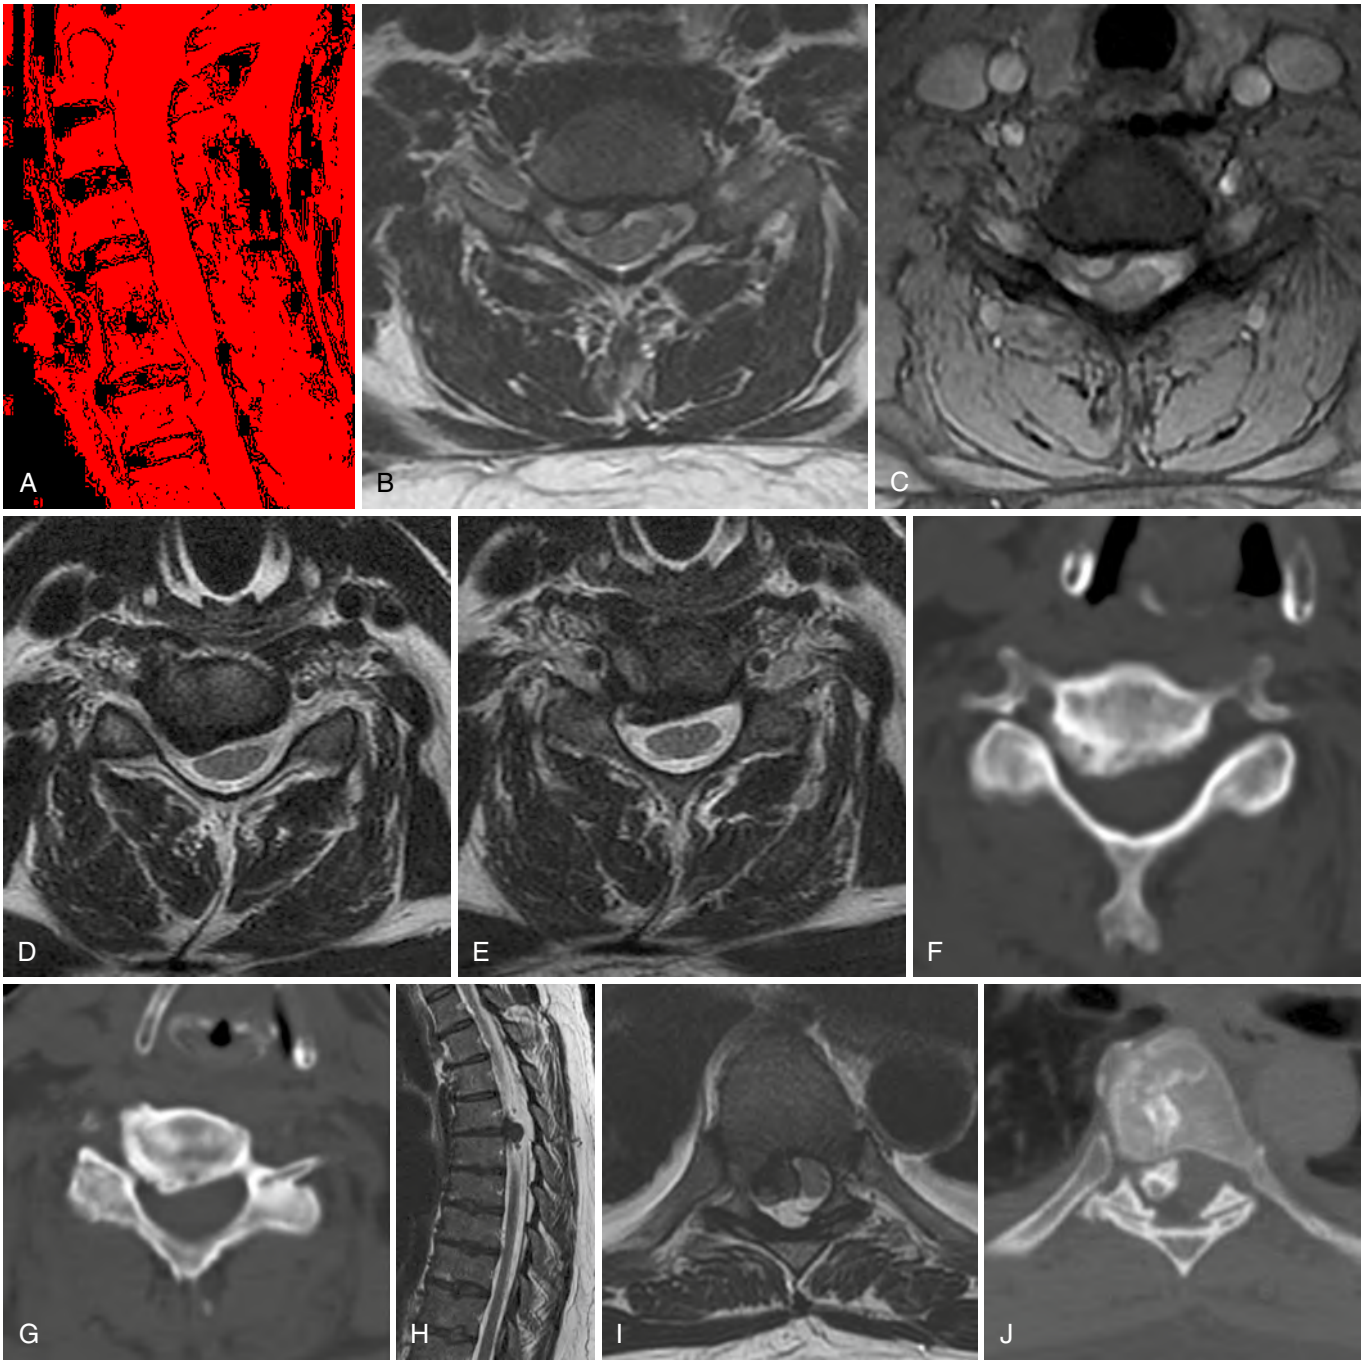
Imaging of thoracic radicular pain should involve MRI or CT myelography. CT myelography has the greatest spatial resolution and may better demonstrate the presence of calcification within thoracic discs. MRI can detect signal abnormality within the cord, which may identify cord edema or venous hypertension, verifying the physiologic significance of a disc herniation. All imaging evaluations for thoracic disc disease must include careful enumeration of the segmental level involved. If a lesion that may require surgical or percutaneous intervention is detected, the imaging study should be extended to include sagittal images from the sacrum to the skull base. Communication between radiologists, surgeons, and/or spine interventionalists is critical to avoid wrong segment interventions. Image guided marker (gold seed) placement is used by some centers to ensure correct level surgery.

Degenerative Spondylolisthesis

Spondylolisthesis refers to the abnormal anterior or posterior displacement of one vertebral body relative to another. Displacement caused by defects in the pars interarticularis (spondylolytic spondylolisthesis) will be discussed later. Degenerative anterolisthesis is the anterior displacement of a vertebral body relative to the body immediately caudal to it. The etiology of degenerative anterolisthesis is primarily facet joint arthrosis, often with a relative sagittal orientation of the facets. Disc structural failure is also necessary. Degenerative anterolisthesis may be present in 4%–14% of elderly patients.[251] Anterolisthesis is most frequent at the L4 level, with less common occurrence at L5, followed by L3. It is significantly more common in women than in men.[251] Radiographic findings of degenerative anterolisthesis include the obvious displacement itself, joint space narrowing and sclerosis in the associated facets, and findings of intervertebral osteochondrosis, including a loss of disc space height, gas within the disc, and subchondral sclerosis.

Degenerative retrolisthesis describes the posterior displacement of the index vertebral body relative to that below it; the primary causative process is intervertebral osteochondrosis. As there is a loss of disc space height, the oblique orientation of the facet results in the more superior vertebral body gliding posterior relative to its inferior counterpart. Degenerative retrolisthesis is most commonly seen at the L2 interspace level, with less common occurrence at L1, followed by L3. There is no significant gender difference.

Degenerative spondylolisthesis may be associated with axial low back pain. The Kauppila study showed that patients with degenerative spondylolisthesis had a higher prevalence of daily low back symptoms.[251] However, there was no increased disability in spondylolisthesis patients relative to controls. In this study, the overall incidence of degenerative spondylolisthesis approached 20%. Degenerative spondylolisthesis carries with it the risk of neural element compromise with secondary central spinal canal stenosis, lateral recess stenosis, or foraminal compromise.



• **Figure 20.19** Cervical and thoracic disc herniations. A patient with prior C5–6 anterior cervical discectomy and fusion presents with new right C7 distribution radicular pain. Sagittal T2 image **(A)** shows disc extrusion with caudal migration from the adjacent C6–7 segment. Note that the extruded material has a higher T2 signal than the parent disc, perhaps a reflection of the inflammatory response. Axial fast spine echo (FSE) T2 **(B)** and gradient echo **(C)** axial images at the C6–7 interspace well demonstrate the extrusion. In another patient with a right C6 radiculopathy, axial FSE T2 images **(D, E)** at the C5–6 interspace suggest a disc-osteophyte complex and uncovertebral joint osteophytes compromise the right C5–6 foramen. The primary osseous nature of the process is confirmed on computed tomography (CT) images **(F, G).** In the cervical spine, compressive lesions are more likely to be osseous than soft disc alone. Thoracic disc extrusion in a 51-year-old woman with progressive thoracic myelopathy is shown in images **H, I,** and **J**. Sagittal T2 magnetic resonance (MR) image **(H)** shows large T5–6 disc extrusion. Low T2 signal suggests calcification. The cord is displaced and compressed by the right-sided extrusion on the T2–weighted axial MR image **(I)**. Axial CT image **(J)** demonstrates coarse calcification in the disc extrusion. Note the linear defect with marginal sclerosis in the endplate, a finding often accompanying disc herniations.

Spinal Stenosis: Lumbar Neurogenic Intermittent Claudication

Lumbar spinal stenosis is an imaging observation; it may give rise to the clinical syndrome of neurogenic intermittent claudication (NIC). NIC is the most common reason for spine surgery in patients over 65 years of age.[252] The hallmark is the induction of gluteal and lower extremity pain with upright exercise or specific postural positions and palliation by forward flexion, sitting, or recumbency. The most common symptoms in patients with lumbar spinal stenosis are back pain (prevalence of 95%), claudication (91%), leg pain (71%), weakness (33%), and voiding disturbances (12%).[253] There may be a paucity of physical findings, even in the presence of symptoms.

Despite its significance, data on the natural history or prevalence of NIC are scarce. Kalichman and colleagues utilized data from the Framingham study to establish the prevalence of congenital and acquired lumbar central spinal canal stenosis in a community population.[254] Using the AP dimension of the central spinal canal derived from CT studies (12 mm = relative stenosis, 10 mm = absolute stenosis), they noted congenital central spinal canal narrowing of relative degree in 4.7% of the population and absolute stenosis in 2.6%. Acquired stenosis was identified in 22.5% (relative) and 7.3% (absolute) of individuals. Their literature review noted that the prevalence of acquired lumbar stenosis ranged from 1.7%–13.1%. The prevalence of acquired stenosis (absolute) increased from 4% in patients younger than 40 years old to 14.3% in patients older than 60 years. The North American Spine Society (NASS) 2011 evidence based guidelines on the diagnosis and treatment of spinal stenosis suggest, in the absence of reliable evidence, that the natural history of patients with clinically mild to moderately symptomatic degenerative stenosis is favorable in one-third to one-half of patients.[53] In patients with mild to moderately symptomatic stenosis, rapid or catastrophic neurologic decline is rare.

Pathophysiology

The pathogenesis of NIC in lumbar spinal stenosis has been a subject of investigation for half a century. Verbiest initially described mechanical compression of the nerve roots of the cauda equina as a cause of NIC in 1954.[255] Subsequent investigators have postulated that arterial and venous ischemia, perhaps exacerbated by restriction of CSF flow (which participates in nerve root nutrition), are contributors to the clinical syndrome. The current preponderance of evidence favors venous congestion secondary to mechanical compression. This hypothesis emphasizes the importance of multiple levels of compression and the physiologic effects of lumbar extension. Both of these observations have significant relevance to imaging.

The animal work of Takahashi and Olmarker demonstrated that two zones of modest compression in the cauda equina would dramatically reduce blood flow to the intervening nerve segment because of venous congestion; this venous congestion could precipitate neural dysfunction.[256,257] Kobayashi examined cauda equina histology after the application of modest stenosis (30% of the cross-sectional area) to the dural tube.[258] The cauda equina demonstrated congestion and dilatation of intraradicular veins and an inflammatory cellular infiltrate. There was disruption of the blood–nerve barrier, both at the compression site and in more distant sites of Wallerian degeneration. The necrotic debris created by Wallerian degeneration stimulated macrophage activity generating inflammatory molecules such as interleukin-1 and TNFα. Macrophages stimulate cytotoxic activity by the release of nitric oxide and proteases. They are considered the chief effector cells causing inflammatory neuritis that results in aberrant ectopic neural discharge and conduction disturbance, leading to the pain and neural dysfunction of NIC.[258]

Multiple sites of venous congestion are key to this model of NIC; it is supported by clinical studies. Sato demonstrated that patients with two-level central spinal canal stenosis were significantly more likely to exhibit NIC than were patients with a single level of canal compromise.[259] In two-level stenosis, the symptomatic expression most closely matched the radicular distribution of the more caudal of the two stenotic levels; in patients with compromise at the L3 and L4 disc levels, the pain pattern matched that of the traversing L5 roots.[259] Porter and Ward noted that the compression sites might be either in the central spinal canal or in the neural foramina.[260] In their cohort of 49 patients with NIC, 94% had either multilevel central spinal canal stenosis or central spinal canal plus neural foraminal stenosis. The work of Morishita emphasized the importance of the neural foramen as a potential zone of compression, particularly with dynamic changes in posture.[261] Even without demonstrable foraminal compromise by imaging in a neutral position, in lumbar extension, intraforaminal pressures exceeded venous pressure, and neural dysfunction was documented by electromyography (EMG). All levels of neural compromise, central, lateral recess, and foraminal are potentially significant and must be detected by imaging.

Congenital Central Spinal Canal Stenosis

A relatively small proportion of patients with clinical NIC will have developmental narrowing of the lumbar central spinal canal as a predisposing factor, with only modest spondylotic changes necessary to produce clinical symptoms. Singh and colleagues studied the morphologic characteristics of a cohort of surgically treated patients carrying the clinical diagnosis of congenital lumbar stenosis.[262] They noted that these patients had a significantly shorter pedicle length and a smaller cross-sectional central spinal canal area when compared with age- and sex-matched controls. The patients with a congenitally narrowed lumbar central spinal canal typically exhibit these morphologic characteristics over several vertebral segments, maximal at the L3 level. This contrasts with purely acquired stenosis, which is often more focal, particularly at the L4 disc level. Congenital central spinal canal stenosis patients tend to present at a younger age (40–50 years) and with less spondylotic change than typical.

Acquired Spinal Stenosis

Most patients presenting with NIC have acquired spondylotic change as their primary cause of central spinal canal, lateral recess, or foraminal compromise. The changes that result in compromise of the central spinal canal are rooted in the three-joint structure of the spine motion segment: the disc and the paired facet joints. In the anterior column, degradation of the disc nuclear matrix places an excessive load on the posterior annulus, and annular failure results in posterior endplate osteophytes and disc herniation. These changes encroach on the ventral aspect of the central spinal canal or lateral recesses. Loss of disc space height obligates narrowing of the neural foramina and contributes to increased facet load and ultimately arthrosis; facet capsular hypertrophy and

SAP osteophytes compromise the lateral recesses. Synovial cysts, particularly at the L4 level, may contribute to the central spinal canal, lateral recess, or foraminal compromise. The reduced height of the segment and the loss of elasticity of the ligamentum flavum result in its buckling centrally as a dominant cause of the loss of cross-sectional area of the central spinal canal. The ligamentum flavum may also thicken, although it is unclear if this represents true hypertrophy. These several anterior and posterior column phenomena conspire to narrow the central spinal canal, most commonly at the L4–5 disc level, followed by L3–4, L5–S1, and L1–2.[263]

Several measurable parameters could quantify the degree of stenosis depicted by radiography, myelography, CT, or MRI. Verbiest, in his early descriptions of the entity of spinal stenosis, suggested that a 10–12 mm AP diameter of the dural sac on conventional myelography constituted relative stenosis, with a measurement of <10 mm denoting absolute stenosis.[255] Steurer, in a 2011 review, surveyed the numerous measurements applied by various authors in the intervening decades in 25 unique studies and four systematic reviews.[239] The most common descriptors of central stenosis include the AP dimension of the osseous canal or the dural sac and the cross-sectional area of the dural sac. A dural sac AP dimension of <10 mm or a dural sac cross-sectional area of <100 mm^2 constitutes stenosis. Descriptors of LR or subarticular stenosis include the height and the lateral recess angle. Height is defined as the shortest distance between the most anterior point of the SAP and the posterior vertebral body, and the LR angle is the angle formed by the posterior vertebral body and the pars interarticularis. LR stenosis is typically defined as height <3 mm or angle <30 degrees. Descriptors of foraminal stenosis most commonly used suggest a diameter of ≤2–3 mm to indicate stenosis. In keeping with the prior discussion on specificity limitations of imaging findings, a recent investigation demonstrated that the severity of lumbar spinal stenosis as depicted by advanced imaging (CT or MRI) is not associated with differential responses after epidural steroid injections.[264]

The multiplicity of quantitative parameters suggests that no single measurement has proven satisfactory. The very notion of a readily quantifiable measure of stenosis may be flawed. There is a wide normal variation in the central spinal canal and dural tube diameters; an assessment of stenosis must address not simply diameter or cross-sectional area but the crowding or compression of neural tissue. The semiquantitative criteria advanced in 2001 by Fardon and Milette[224] simply defines reduction in the expected area by less than one-third as mild, by one-third to two-thirds as moderate, and by greater than two-thirds as severe. This allows a subjective judgment of neural compression at the potential cost of reliability. Lurie and associates studied the reliability of the subjective grading of stenosis of the central spinal canal, lateral recesses, and neural foramina and measurement of the central spinal canal and dural sac area aided by specific definitions and imaging examples of the criteria.[265] Stenosis was subjectively rated as none, mild, moderate, and severe using the Fardon and Milette definitions; nerve root compromise in the foramen was categorized as none, touching, displacing, or compressing. Inter-reader reliability in assessing the central spinal canal was substantial, with a $\kappa = 0.73$. There was moderate to substantial reliability for foraminal stenosis and nerve root impingement ($\kappa = 0.58$ and 0.51, respectively). Reliability for subarticular stenosis was only moderate at $\kappa = 0.49$. These results emphasize the importance of a clear definition of criteria for reliably grading stenosis by subjective scales.

Other imaging observations have been employed in an attempt to identify significant stenosis. The observation of nerve root redundancy as a qualitative marker of central spinal canal compromise dates from the original description of the entity of spinal stenosis by Verbiest.[255] This is presumed to originate from mechanical entrapment of the root at the site of compression, with subsequent elongation of the nerve above this site under the tensile stress of physiologic flexion and extension motion. Some of these prominent structures may also represent dilated veins. Although frequently observed, this sign has been subjected to little study. Redundant nerve roots are present in 34%–42% of surgical candidates with clinical NIC.[266] In a 2007 study by Min and colleagues, redundant nerve roots were more commonly observed in older patients, but there was no significant association with the duration of symptoms, diameter of the central spinal canal, preoperative symptom intensity, or surgical outcomes.[266] There was a nonsignificant trend toward poorer surgical outcomes in patients with redundant roots. The prevalence of redundant nerve roots in patients with lumbar spinal stenosis has been shown to be body position dependent; a study using an upright MRI scanner demonstrated the prevalence increased from 17% during flexed sitting to 80% during standing.[267]

A 2010 study by Barz first described the "nerve root sedimentation sign" (NRSS) as a marker of symptomatic NIC.[268] In patients without central spinal canal compromise, the roots of the cauda equina lie in the dorsal aspect of the dural sac on supine MRI imaging. A positive NRSS was defined as the absence of nerve root sedimentation to the dorsal dural sac on at least one axial MRI image at a level above or below the zone of compression; the two nerve roots leaving the dural sac at the next most caudal segment are exceptions. This retrospective study included 200 patients: 100 patients with low back pain but without clinical NIC, and a dural cross-sectional area (DCSA) of >120 mm^2 and a cohort of 100 patients with clinical NIC, a maximum walking distance of less than 200 m, and a DCSA of less than 80 mm^2 on at least one level. There was no correlation between the smallest DCSA and patient disability as measured by ODI. However, an NRSS was identified in 94 of the patients in the NIC cohort but none of the low back pain group.

Since then, multiple other studies have assessed the role of the NRSS as an imaging marker in patients with NIC.[269] Although some heterogeneity was noted in the results of these studies, two meta-analyses demonstrated NRSS to be an accurate imaging marker of spinal stenosis.[270,271] The latter, and more comprehensive, meta-analysis assessed the diagnostic capabilities of the NRSS in the diagnosis of spinal stenosis, based mainly on the presence of NIC. Using the results of 14 prior studies, the authors found that identification of an NRSS had high sensitivity (84%) and specificity (95%) for the diagnosis of clinical sequelae of spinal stenosis.[270] Piechota et al. recently found that 89% of patients with an NRSS presented with NIC.[272] In addition, patients with an NRSS have been shown to have higher intraoperative epidural pressure, adding evidence that the sign is related to tethering of nerve roots at the level of stenosis.[273] The prognostic usefulness of the NRSS in predicting surgical outcomes remains uncertain. Barz et al. found that the presence or absence of the sign did not impact the outcome (based on ODI) in surgically decompressed patients; nonoperative patients with an NRSS had more limited improvement than those without the sign.[274]

Given the specificity challenges of purely anatomic imaging, the more physiologic parameter of gadolinium enhancement may have a role. This is not a new observation; in 1993, Jinkins

observed abnormal intrathecal nerve root enhancement at the site of stenosis on enhanced MRI in patients with NIC.[275] He postulated this represented a breakdown of the blood-nerve barrier at sites of nerve root injury with subsequent Wallerian degeneration. This has been elegantly confirmed in a canine model by the work of Kobayashi.[258] Histologic examination demonstrated congestion and dilatation of intraradicular veins and inflammatory cellular infiltrate at sites of gadolinium enhancement. Gadolinium enhancement may provide added specificity in the correlation of imaging and the clinical symptomatology of NIC; this remains to be proven in clinical studies (Fig. 20.20).

Specificity of Imaging Findings

The ultimate challenge in establishing the utility of diagnostic imaging in the diagnosis of NIC is the lack of a gold standard against which to measure imaging parameters. Surgical findings may be subjective. Clinical outcomes depend highly on the technical success of the instituted surgical therapy and the outcome instruments used in any such measurement.

The specificity fault in imaging of central spinal canal stenosis can be seen in studies of asymptomatic volunteers. Boden and associates noted significant lumbar central spinal canal stenosis on MRI in 21% of asymptomatic subjects over the age of 60.[18] Jarvik and colleagues demonstrated that asymptomatic stenosis on MRI increases in prevalence with age: moderate to severe central spinal canal stenosis was observed in 7% of subjects aged <45 years; in 6% of subjects aged 45–55 years; in 11% of subjects aged 55–65 years, and in 21% of subjects aged >65 years.[19]

Against this background of asymptomatic central spinal canal narrowing, numerous conflicting studies have attempted to establish a relationship between imaging quantitation of central spinal canal or dural size and clinical expression of NIC. For example, Hamanishi and colleagues showed that a decrease in the DCSA to less than 100 mm² at more than two of three lumbar levels (L2–3, L3–4, L4–5) was highly associated with the presence of clinical NIC.[276] For each study showing such an association, several others refute it. Sirvanci examined patients undergoing decompressive surgery for NIC.[277] Morphologic stenosis was assessed by DCSA (>100 mm^2: normal; 76–100 mm^2: moderately stenotic; <76 mm^2: severely stenotic) and a four-point grading of subarticular and foraminal stenosis. There was no correlation between the measured parameters in any spine compartment and patient disability as measured by ODI. This applied both to patients with multilevel central stenosis and a subset with degenerative spondylolisthesis. The NASS guidelines[53] conclude there is insufficient evidence to recommend for or against a correlation between clinical symptoms or function and the presence of anatomic narrowing of the central spinal canal on cross-sectional imaging.

Sensitivity of Imaging Findings

There is also a basic sensitivity flaw in advanced imaging. NIC is by definition intermittent; most patients with NIC report exacerbation of symptoms with extension and weight bearing. It is well known that the cross-sectional area of the central spinal canal, subarticular zone or lateral recess, and neural foramina are maximized with flexion positioning; the dimensions of these structures diminish with extension and axial load. Intradiscal pressures are significantly lower when one is in a recumbent position than when sitting or standing. A 2009 study by Hansson and associates identified the ligamentum flavum as the greatest dynamic contributor to central spinal canal compromise with axial load and extension.[42] The average cross-sectional area of the central spinal canal diminished by 23 mm² at the L3 disc level and 14 mm² at the L4 level under load. The ligamentum flavum was responsible for 50% of the reduction at the L3 level and 85% of the reduction at the L4 level. Madsen and associates attempted to distinguish between the effects of axial load and extension. Their work suggested that lumbar spine extension is the dominant cause of reduction in DCSA in standing patients.[43] Mechanisms circumventing this flaw include upright axial loading devices, the technologically immature upright MRI, and cone-beam CT myelography (Box 20.5).

Thoracic Spinal Stenosis

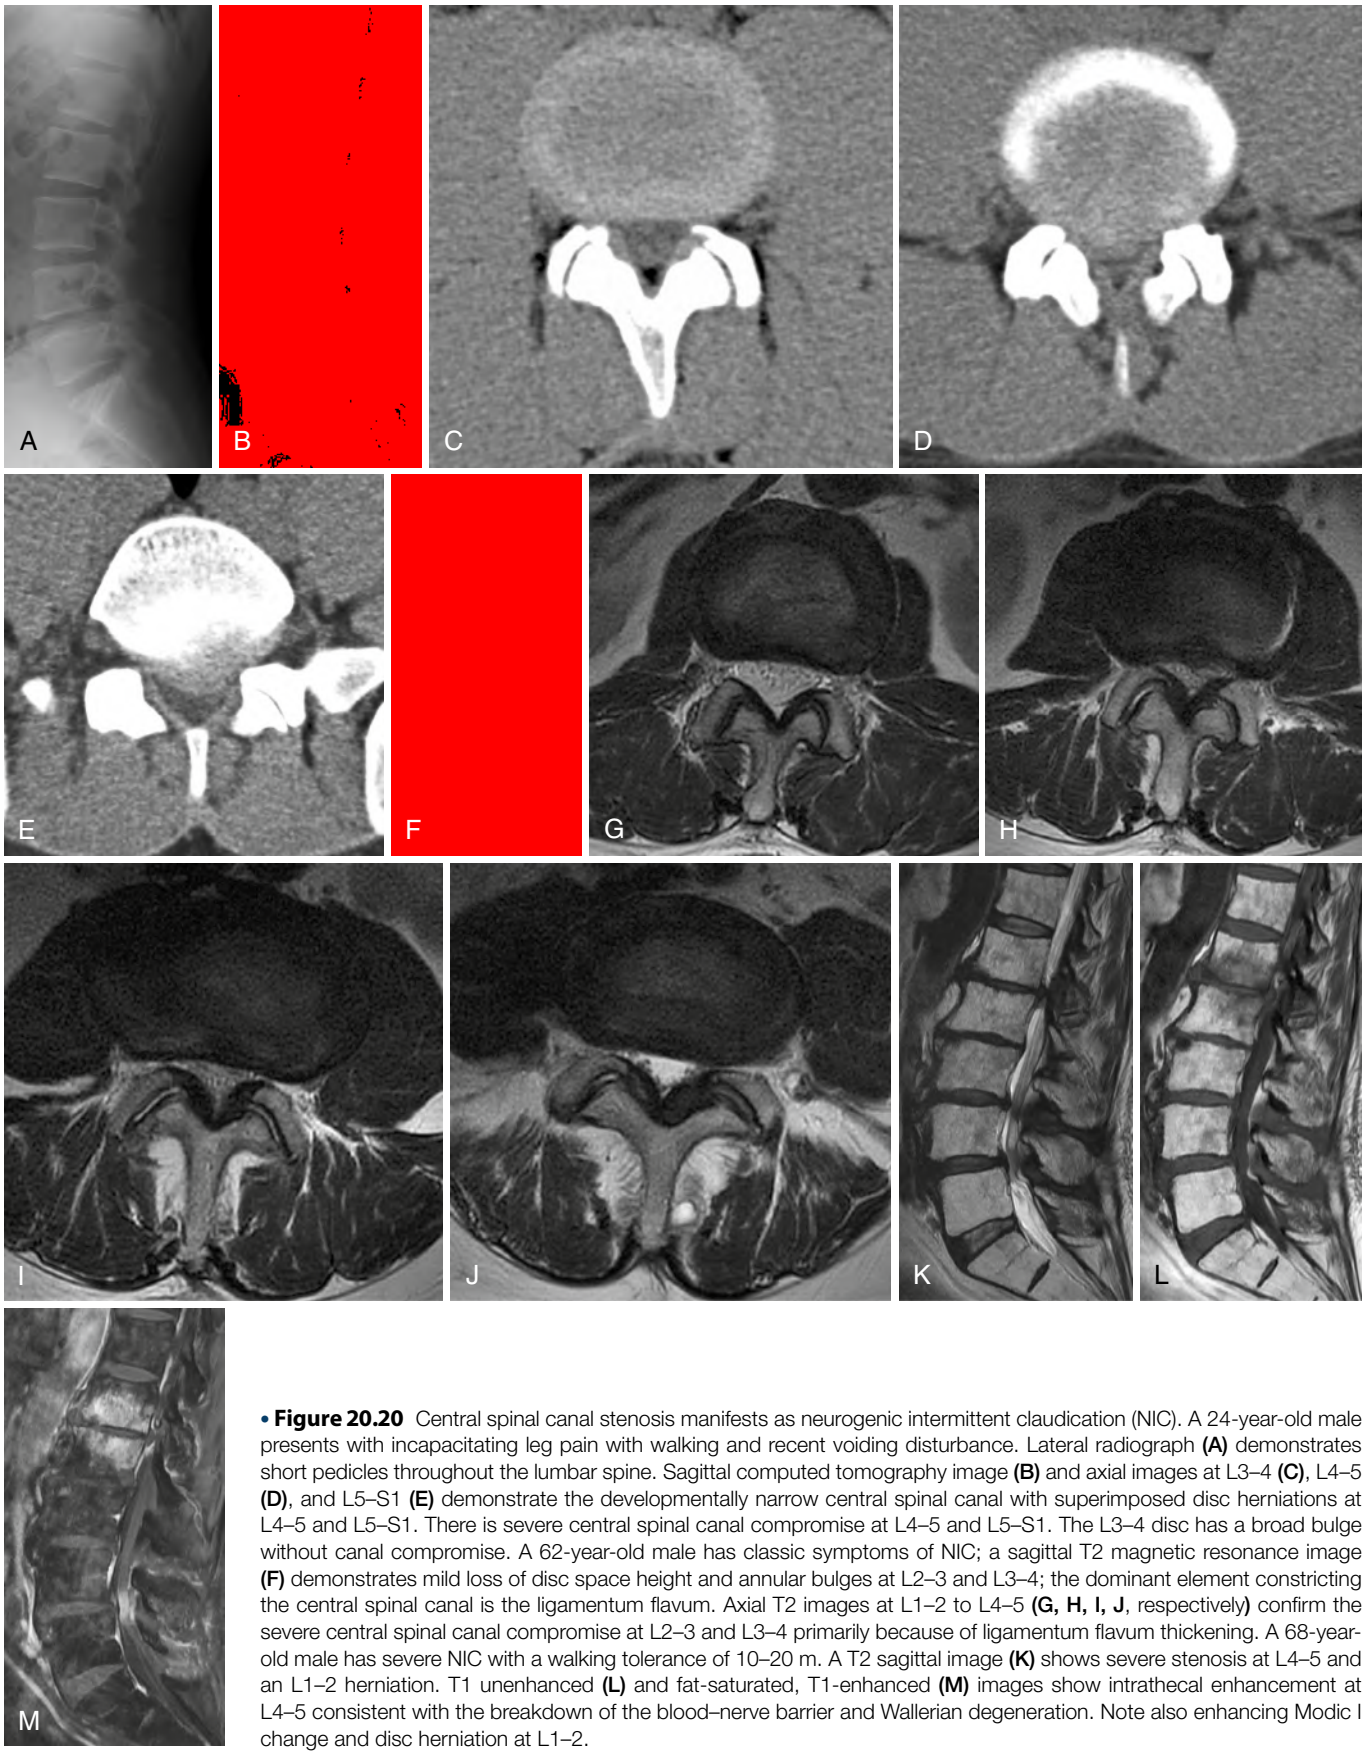
Symptomatic central spinal canal stenosis in the thoracic segment of the spine resulting from age-related change is far less common than in the cervical and lumbar regions, likely because of the added mechanical stability imparted by the rib cage. Systemic disease accounts for a correspondingly greater proportion of cases. Systemic processes leading to thoracic central spinal canal compromise include achondroplasia, osteochondrodystrophy, Scheuermann's disease, diffuse idiopathic skeletal hyperostosis (DISH), and Paget's disease.

Compromise of the thoracic central spinal canal may manifest clinically as myelopathy, radiculopathy, or a mixed presentation. The segmental level of canal compromise is most commonly reported to be in the lower thoracic region. Thoracic spine mobility, particularly flexion-extension motion, is the greatest near the thoracolumbar junction, and is likely the biomechanical mechanism underpinning this age-related pathology distribution. Posterior element age-related changes play a greater role than spine mobility in the genesis of thoracic central spinal canal compromise. This takes the form primarily of unilateral or bilateral facet joint hypertrophy. Thoracic disc herniations or disc-osteophyte complexes may also contribute. The ventral and dorsal contributions to thoracic central spinal canal compromise are visible on CT, CT/myelography, and MRI.

Other causes of thoracic central spinal canal stenosis include ossification of the thoracic ligamentum flavum (OLF), a well-recognized cause of thoracic stenosis in the Asian population but rare among Caucasian subjects. Epidural lipomatosis is a rare cause of central spinal canal compromise in the thoracic or lumbar spine. It may be idiopathic or secondary to endogenous or exogenous steroid excess. Obesity is a common factor in both groups. Excess epidural fat acts as a mass compressing the dural sac, most commonly from a dorsal vector in the thoracic region; it is more likely to be circumferential in the lumbar region.

Cervical Stenosis: Cervical Spondylotic Myelopathy (CSM)

CSM is the most common cause of spinal cord dysfunction in patients over 55 years old.[278] Stookey originally described cervical spondylotic myelopathy in 1928.[279] Although its pathophysiology remains incompletely understood, it is widely acknowledged to involve static factors causing stenosis of the cervical canal and dynamic factors causing repetitive cord injury.[278] These mechanical factors both directly injure neural tissue and initiate secondary ischemia, inflammation, and apoptosis. The histologic characteristics in the cord in CSM include cystic cavitation and gliosis of the central gray matter and demyelination of the medial portions of the white matter long tracks. There is Wallerian degeneration in



• **Figure 20.20** Central spinal canal stenosis manifests as neurogenic intermittent claudication (NIC). A 24-year-old male presents with incapacitating leg pain with walking and recent voiding disturbance. Lateral radiograph **(A)** demonstrates short pedicles throughout the lumbar spine. Sagittal computed tomography image **(B)** and axial images at L3–4 **(C)**, L4–5 **(D)**, and L5–S1 **(E)** demonstrate the developmentally narrow central spinal canal with superimposed disc herniations at L4–5 and L5–S1. There is severe central spinal canal compromise at L4–5 and L5–S1. The L3–4 disc has a broad bulge without canal compromise. A 62-year-old male has classic symptoms of NIC; a sagittal T2 magnetic resonance image **(F)** demonstrates mild loss of disc space height and annular bulges at L2–3 and L3–4; the dominant element constricting the central spinal canal is the ligamentum flavum. Axial T2 images at L1–2 to L4–5 **(G, H, I, J**, respectively**)** confirm the severe central spinal canal compromise at L2–3 and L3–4 primarily because of ligamentum flavum thickening. A 68-year-old male has severe NIC with a walking tolerance of 10–20 m. A T2 sagittal image **(K)** shows severe stenosis at L4–5 and an L1–2 herniation. T1 unenhanced **(L)** and fat-saturated, T1-enhanced **(M)** images show intrathecal enhancement at L4–5 consistent with the breakdown of the blood–nerve barrier and Wallerian degeneration. Note also enhancing Modic I change and disc herniation at L1–2.

• Box 20.5 Lumbar Spinal Stenosis: Neurogenic Intermittent Claudication

- Decompression procedures for lumbar spinal stenosis are the most common spine surgery in the elderly.
- Neurogenic intermittent claudication (NIC) is a clinical syndrome; spinal stenosis is an anatomic observation.
- The best evidence of NIC pathophysiology suggests venous congestion from multiple sites of compression initiates an inflammatory reaction and Wallerian degeneration with blood-nerve barrier disruption and intraradicular edema.
- Clinically, multiple sites of compression at different segment levels or different spine compartments (central, lateral, foraminal) are necessary for NIC.
- Beware the specificity fault: The correlation between quantitative measures of the central spinal canal or dural sac size and patient symptoms or function is poor.
- Beware the sensitivity fault: Dynamic lesions, presenting only with extension and axial load, may make recumbent imaging insensitive.

the posterior columns and posterolateral tracts cephalad to the site of compression. Loss of anterior horn cells and corticospinal tract degeneration are visible at and caudal to the site of compression.

The developmentally narrow central spinal canal is a more universal substrate for CSM than is the case with NIC in the lumbar region. The sagittal diameter of the adult spinal cord is nearly constant, measuring about 8 mm from C3–C7; the normal cervical cord enlargement occurs primarily in the transverse plane.[278] The normal cervical spinal canal sagittal diameter (posterior vertebral body to spinolaminar line) is 17–18 mm (C3–C7) in a Caucasian population; these subjects rarely develop sufficient age-related change to provoke CSM. Edwards and LaRocca observed that patients with developmentally narrowed midcervical sagittal diameters of <10 mm were often myelopathic, patients with canals of 10–13 mm were at-risk for CSM, canals of 13–17 mm were noted in patients with symptomatic spondylosis but rarely myelopathy, and subjects with canals >17 mm were not prone to develop spondylosis.[280] Morishita studied the kinematics of subjects with congenitally narrowed canals; there is hypermobility in the lower cervical region, providing a biomechanical explanation for the significantly greater age-related change seen in this setting.[281] Hence, an individual with a congenitally narrowed canal is at-risk because of the limited space available for the cord and a greater propensity to age-related spondylotic change.

Acquired cervical central spinal canal stenosis encompasses age-related spondylotic change (most common), ossification of the posterior longitudinal ligament (OPLL), and OLF. Disc degradation results in a loss of disc space height, excess loading of the uncovertebral joints with osteophyte formation, excess facet loading causing hypertrophy, and central buckling of the ligamentum flavum. These processes circumferentially narrow the canal and directly compress the cord, exiting nerves and the anterior spinal artery. The most common levels of compromise were C3–4 (27%), C4–5 (37%), and C5–6 (29%) in a surgical series.[282] This series included patients with spondylosis only and those with OPLL. It is also known that the cross-sectional area of the cervical canal diminishes in both extension and flexion, with greater effects during extension.[47,48] Ventral compression of the cord compromises flow through the arterioles arising from the anterior spinal artery in the ventral sulcus of the cervical cord; dorsal compression reduces perfusion to the central gray matter. Oligodendrocytes are extremely sensitive to ischemic injury; resultant apoptotic cell death may cause the demyelination characteristically observed in CSM.[278] Animal evidence further supports the role of an inflammatory cascade in apoptotic cell death.[283]

Imaging

Historically, radiographic assessment of cervical anatomic stenosis relied on the AP dimension of the central spinal canal as measured from the posterior vertebral body to the spinolaminar line. The normal sagittal diameter from C3 through C7 is considered 17–18 mm. Edwards and LaRocca noted that a cervical canal with a sagittal diameter of less than 13 mm was at-risk for myelopathy; absolute stenosis was defined as being less than 10 mm.[280] The advent of cross-sectional imaging has allowed us to directly measure the diameters and cross-sectional areas of the cervical central spinal canal and the cervical cord. MRI has also given us the ability to evaluate physiologic parameters of the spinal cord: T2 hyperintensity, T1 hypointensity, gadolinium enhancement, and, with diffusion tensor imaging (DTI), fractional anisotropy (FA), and apparent diffusion coefficient (ADC).

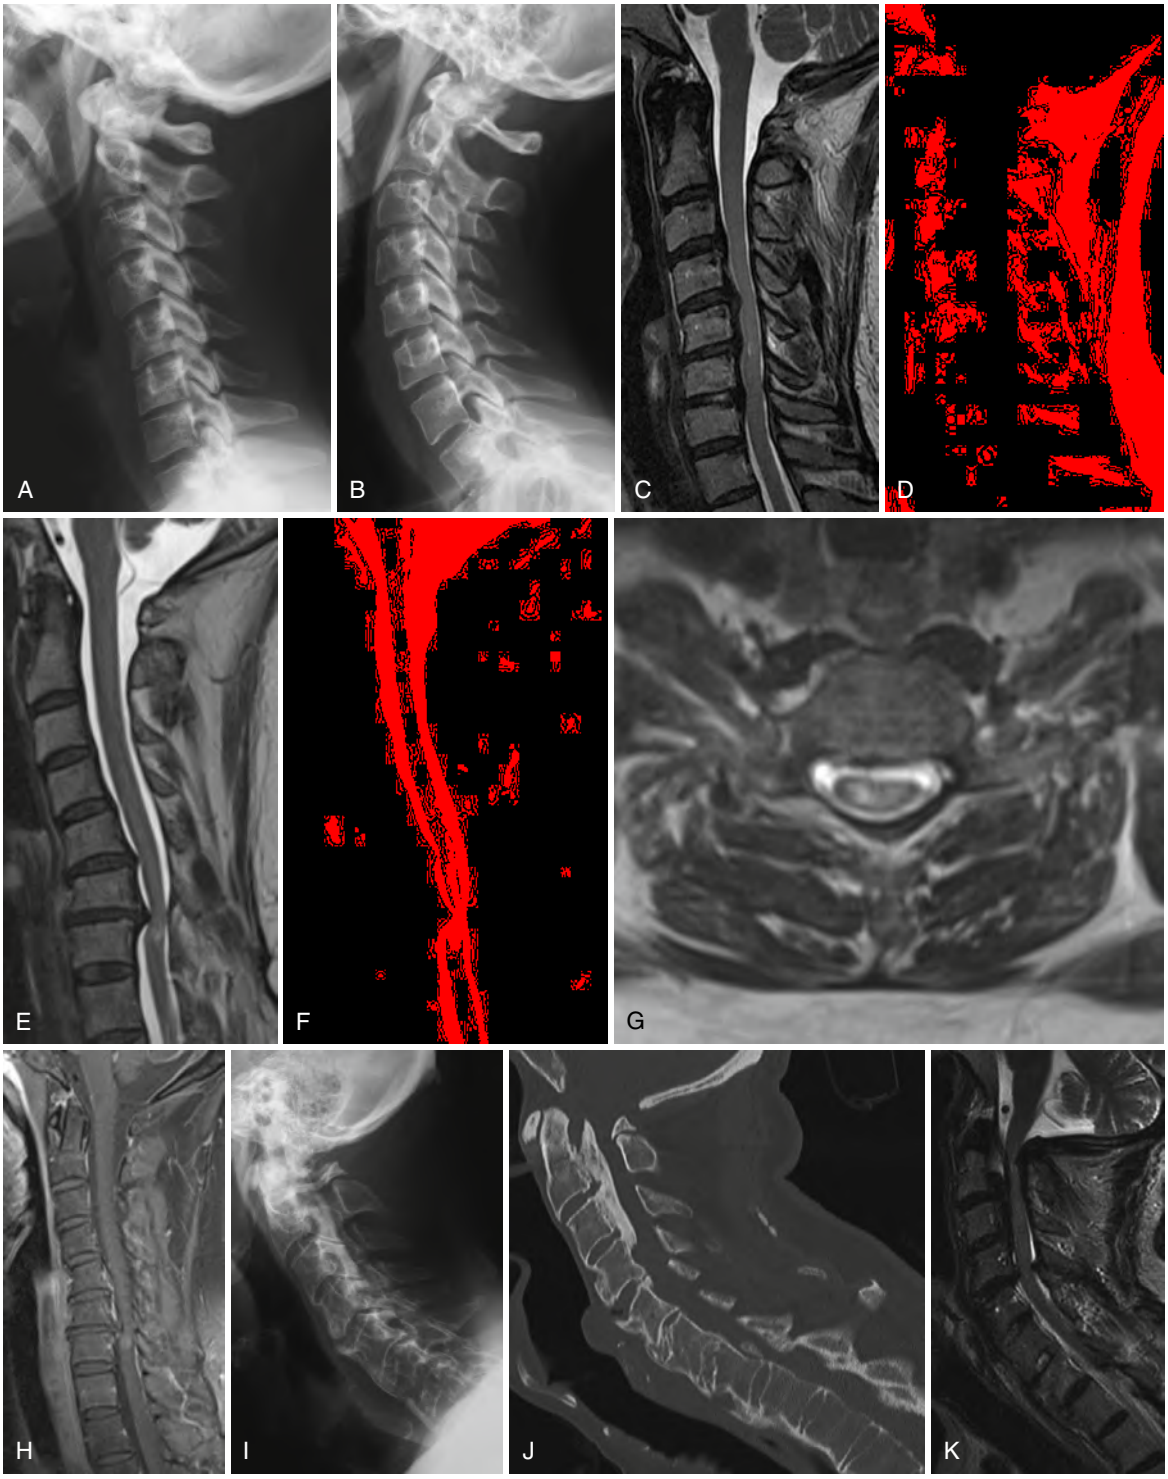
A 2010 study by Naganawa and associates demonstrated good intra- and interobserver reliability in the evaluation of the cross sections of the cervical canal and spinal cord with both CT/myelography and MRI.[284] They noted that dural sac diameter and cross-sectional area measurements were slightly but significantly larger with CT/myelography than fast spin-echo T2-weighted MRI; conversely, the diameters and cross-sectional areas of the spinal cord were slightly but significantly larger with MRI. MRI graded the stenosis as slightly but significantly more severe than CT/myelography. A 2009 study by Song and associates found no significant difference in interobserver or intra-observer reliability between CT/myelography and MRI.[285] With its superior spatial resolution, CT/myelography was somewhat better in assessing foraminal stenosis and much better in discriminating osseous versus soft tissue lesions. MRI was more reliable in identifying direct nerve root compression (Fig. 20.21).

Imaging Specificity

The significant prevalence of asymptomatic cervical central spinal canal stenosis was noted earlier in this chapter. When a population of patients with a clinical diagnosis of CSM is studied, the correlations appear more favorable. The transverse area of the spinal cord as measured by MRI correlates well with the severity of myelopathy and the pathologic changes observed in the cord in CSM.[286] The physiologic parameters of T2 hyperintensity or T1 hypointensity have provided further insight into the evolution of CSM. The several studies addressing these correlates are explored in a review.[287] From these studies, we can conclude the following:

1. Intramedullary T2 hyperintensity represents a range of reversible (edema) and irreversible (demyelination, gliosis, cystic necrosis) pathology.
2. Faint and indistinct T2 hyperintensity is more likely to reflect reversible edema.
3. Very intense and well defined T2 hyperintensity more likely represents fixed gliosis or cystic necrotic change.
4. Intramedullary T1 hypointensity represents irreversible necrosis and myelomalacia.

Gadolinium enhancement of the affected spinal cord in CSM was first reported in 2004.[288] A 2010 study by Ozawa[289] and a 2011 study by Cho[290] compared CSM patients who exhibited



• **Figure 20.21** Cervical central spinal canal compromise manifests as cervical spondylotic myelography (CSM). A 36-year-old female presents with very subtle bilateral hand incoordination, neck pain, and left arm symptoms. Her lateral radiograph **(A)** shows no lamina posterior to the articular pillar. Compare to a normal lateral radiograph **(B)**. Sagittal T2 **(C)** and T1 **(D)** images show effacement of cerebrospinal fluid and cord compression from the C4–C6 interspaces with subtle T2 hyperintensity in the cord at the C5–6 interspace level. Note that no dorsal epidural fat is visible above the C7–T1 level, a typical finding. A 48-year-old female had intractable upper extremity pain and dysesthesia involving the right lateral forearm. There were also long tract signs. Sagittal T2 **(E)** and T2 with fat saturation **(F)** demonstrate cord deformity at the C6–C7 interspace level, with focal T2 hyperintensity in the right side of the cord, as seen on the axial fast spine echo image **(G)**. Post-gadolinium sagittal T1-weighted image with fat saturation **(H)** shows enhancement at the site of T2 hyperintensity, a negative prognostic sign. A 77-year-old Caucasian male has slowly progressive myelopathy on clinical examination. Lateral radiograph **(I)** demonstrates ossification of the posterior longitudinal ligament in the upper cervical spine; note the coexistent manifestations of diffuse idiopathic skeletal hyperostosis. Computed tomography sagittal reconstruction **(J)** and sagittal T2 **(K)** images better depict the severe cord deformity at C2.

gadolinium enhancement with a non-enhancing control group. There was no correlation of enhancement with preoperative clinical symptoms. Enhancement disappeared in most patients within one year of surgical decompression; patients who exhibited preoperative enhancement had a poorer postoperative prognosis than those who did not. Of note, as further elucidated by other investigators, the cord enhancement in CSM often has a characteristic morphology.[291,292] On sagittal images, the enhancement typically appears as a narrow transverse band (pancake-like), located at or slightly caudal to the maximal level spinal stenosis. The degree of cross-sectional involvement of this intramedullary enhancement is variable on axial images, but it is commonly peripherally located and limited to the white matter, uni- or bilaterally. The abnormal cord T2 hyperintensity within which the enhancement occurs is typically much greater in longitudinal extent. The enhancement can persist for a variable duration after decompressive surgery. Awareness of the enhancement pattern can prevent diagnostic delay, expedite treatment, and avoid unnecessary biopsies.[291]

Floeth studied 20 CSM patients with FDG-PET in a single level stenosis setting at C3/C4 or C4/C5.[293] All the CSM patients showed a significant decrease in 18F-FDG uptake in the lower cord below the stenosis, relative to normal controls. A cohort of these patients also exhibited increased uptake at the level of stenosis. The patients with increased 18F-FDG uptake at the stenosis had a significantly shorter duration of symptoms, a more precipitous decline in function in the three months prior to decompression, and ultimately exhibited significant improvement after decompression. Patients without increased uptake at the stenotic zone did not recover neurologic function after decompression.

Early reports suggest that DTI may offer greater accuracy in the identification of symptomatic cord compromise than T2 hyperintensity or T1 hypointensity. The measured parameters are FA, mean diffusivity (MD), or ADC. The ADC or MD values reflect overall diffusivity in the tissue despite directional dependence. Anisotropy (directional dependence) of diffusion in white matter tracts results from oriented membrane structure (i.e. axons and myelin). Diminished FA values may reflect the loss of directionally oriented membrane structures, increased extracellular edema, or both. Several studies[287] suggest that diminished FA is more sensitive in the detection of early cord injury than intramedullary T2 hyperintensity and is better correlated with symptoms. This may help to select patients for surgical decompression, although additional work remains to be done. DTI has not been widely implemented in clinical practice for patients with CSM. The interested reader is referred to an excellent review on the role of DTI in the diagnosis and management of CSM.[294]

Imaging Correlates With Decompression Prognosis

The ultimate goal of imaging must be to improve the clinical outcomes of patients. In the CSM population, this currently implies the timely and appropriate selection of patients for therapeutic interventions, primarily surgical decompression. There is a large body of literature[287] that has examined the role of imaging in predicting clinical response to surgical decompression; imaging parameters under consideration include the cross-sectional area of the cord, intramedullary T2 hyperintensity, including its degree of intensity and multifocality, intramedullary T1 hypointensity, change or stability of intramedullary signal after decompression, recovery of cord cross-sectional area after decompression, and intramedullary gadolinium enhancement. These are summarized in Box 20.6. Utilization of these findings should assist in the selection and counseling of CSM patients regarding surgical decompression.

• Box 20.6 Cervical Spondylotic Myelopathy: Prognostic Factors for Surgical Decompression

1. Intramedullary T2 hyperintensity diminishes prognosis relative to the normal signal.
   a. Intense, focal T2 hyperintensity is a more negative prognostic sign than ill-defined hyperintensity.
   b. Multilevel T2 hyperintensity is a more negative prognostic sign than single level change.
   c. Resolution of T2 hyperintensity postoperatively improves prognosis.
   d. Expansion of T2 hyperintensity postoperatively diminishes prognosis.
2. Intramedullary T1 hypointensity greatly diminishes prognosis.
   a. Evolution of T1 hypointensity postoperatively diminishes prognosis.
3. Intramedullary gadolinium enhancement greatly diminishes prognosis.
4. Increased metabolic activity at the site of compression on 18F-fluorodeoxyglucose positron emission tomography improves prognosis over no increased activity.
5. Postoperative residual compression and failure of re-expansion of the cord cross-section are negative prognostic signs.

Ossification of the Posterior Longitudinal Ligament

Ossification of the posterior longitudinal ligament (OPLL) is a multifactorial disease whose genetic basis is a defect in the nucleotide pyrophosphatase (NPPS) gene.[278] The prevalence is 1.9%–4.3% of the Japanese population and approximately 3% of the populations of Korea and Taiwan. It is implicated in up to 25% of North American and Japanese cases of CSM. It has a significant association (up to 50%) with DISH, and some consider it a subtype of DISH (Fig. 20.21). Like age-related causes of structural central spinal canal narrowing, it is often asymptomatic. The ossification is most common in the cervical region, where it causes static narrowing of the canal. The repeated impact of the ventral cord on the osseous mass contributes to myelopathic injury. Patients may present in their 40s and 50s with pain, chronic myelopathy, or acute neurologic injury after modest trauma. The natural history of ossification is progression. Close clinical follow up is warranted.

The ligamentous ossification may be identified on radiographs, CT, and MRI. On lateral radiographs, reduction of the sagittal canal diameter available for the cord by >60% correlates strongly with myelopathy.[293] The ossification is located from C2–4 in 70% of cases, T1–4 in 15%, and L1–3 in 15%.[295] On CT, the ossification may be classified as segmental (posterior to individual vertebrae, 39%), continuous (bridging across vertebra, 27%), mixed type (29%), and other (ossification posterior to discs, variable sagittal extension, 5%).[296] In addition to documenting the degree of central spinal canal compromise, the CT characteristics of OPLL can suggest dural penetration. CSF leaks are a significant risk in anterior decompression surgery, mainly when the dura is ossified or inseparable from the osseous ligamentous mass. On MRI, mature ligamentous ossification is of diminished signal intensity

on all sequences. Early OPLL may have an inhomogeneous signal and exhibit slight enhancement.[296] When mature, there is no enhancement, allowing differentiation from epidural fibrosis. The secondary signal alterations in the cord were described earlier in the chapter.

Systemic Disease Causal of Spine/Limb Pain

In the context of the very low prevalence of systemic disease as causal of spine or limb pain, this chapter has focused on the mechanical and inflammatory processes involving the articulations of the spine that most commonly provoke axial or radicular pain syndromes and syndromes of neurologic dysfunction. However, it must be remembered that detection of undiagnosed systemic disease—including stress fractures, infection, spondyloarthropathy, neoplasm, and dural fistula—is the primary role of spine imaging.

Stress Fractures

Stress fractures encompass fatigue fractures, in which normal osseous architecture is subjected to sustained supraphysiologic loads, and insufficiency fractures, in which deficient osseous structure fails under normal load conditions. Insufficiency (osteoporotic) fractures are the most common manifestation of systemic disease to present as back pain. In 2005, an estimated 2 million osteoporotic fractures occurred in the United States in patients aged >50 years; 27% were vertebral body fractures.[297] This is an underestimated prevalence, as many vertebral fractures remain asymptomatic. Each vertebral wedge configuration fracture accentuates load on the anterior aspect or adjacent vertebra and increases the annual risk of additional fractures five-fold.[298] Although many vertebral compression fractures are clinically important, it should be noted that a common, typically asymptomatic and clinically insignificant imaging observation is mild anterior wedging of the lower thoracic and/or upper lumbar vertebral bodies. This chronic appearance may sometimes be because of remote trauma, but it is probably most often simply a chronic developmental/physiologic finding. Aside from the emergent traumatic setting, in which CT reigns supreme, imaging of vertebral compression fractures begins with weight bearing radiographs, which provide a low cost means of assessing change over time with serial images but are relatively insensitive in fracture detection. Radiographic findings include a wedge deformity, most commonly of the superior endplate, which may be accompanied by increased density in the involved endplate in the acute or subacute phase. Chronic deformities often demonstrate remodeled osteophytes. MRI or bone scans are much more sensitive in fracture detection and can better assess acuity. The presence and extent of a marrow edema pattern (T1 hypointense, T2 hyperintense, most conspicuous on STIR or fat-saturated images) can provide an estimate of acuity. The signal abnormality in the marrow tends to be bandlike, paralleling the involved endplate; it may be traversed by a low signal line, adding further confidence to the diagnosis of fracture.

A primary role of imaging in this setting is the characterization of a vertebral fracture as benign or malignant. Carr and colleagues recently reviewed the differentiating imaging features of these two types of compression fractures.[299] Malignant lesions are much more likely to exhibit diminished T1 signal throughout the vertebral body, while benign lesions may demonstrate at least partial preservation of normal marrow signal. Extension of diminished T1 signal to the vertebral pedicles or posterior elements is relatively specific for malignancy. Discrete lesions in the bone, especially if destructive, are also strongly predictive of malignancy. A paravertebral or epidural non-hematomatous mass associated with a fracture is more common in and even more specific for malignant lesions but can also be seen in spinal infection. Posterior bowing (expansion) of the vertebral body strongly suggests malignancy. Gadolinium enhancement to a level greater than that noted in normal marrow suggests a malignant lesion. Associated disc rupture and retropulsion of the cortex without bowing of the posterior margin of the vertebral body suggest a benign lesion. Discrete linear zones of T2 hyperintensity similar to CSF adjacent to the fractured endplate (the fluid sign) are visible in 40% of osteoporotic compression fractures and are a finding of high specificity for a benign fracture.[300] Advanced MRI techniques, such as diffusion sequences or chemical shift imaging, may play a problem solving role.[299,301]

In the non-MRI compatible patient, CT can aid in the characterization of fractures but is less sensitive to marrow abnormality than MRI. Trabecular preservation within the vertebral body outside the fracture zone suggests a benign process. The ability of CT to display cortical or trabecular destruction or an adjacent soft tissue mass can aid in the diagnosis of a malignant or otherwise aggressive lesion. The fluid sign noted earlier is occasionally visible as a vacuum cleft containing gas under the fractured endplate, marking a benign osteoporotic compression. Bone scans are highly sensitive in fracture detection, but they are of poor specificity in characterization.

Pelvic insufficiency fractures are increasingly recognized as a cause of axial and somatic referred pain experienced in the low back, pelvis, groin, and proximal lower extremities. Postmenopausal osteoporosis is the dominant risk factor, along with pelvic radiation, corticosteroid use, rheumatoid arthritis, and osteomalacia. The role of osteoporosis is emphasized by the marked female predominance of these lesions, with a reported female-to-male ratio of 9:1.[302] Patients are typically in their sixth decade or older. There is often significant morbidity associated with insufficiency fractures. Taillandier and colleagues[302] noted that 50% of their patients did not recover their former level of independence, and in 25%, the insufficiency fracture precipitated institutionalization in their elderly study population. Sacral insufficiency fractures are the most common expression of this condition; pubic ramus fractures, parasymphyseal fractures, and para-acetabular fractures have also been described.

Lourie first described sacral insufficiency fractures in 1982.[303] Plain radiographs of the pelvis are relatively insensitive. The most common radiographic finding is a vertical sclerotic band in the sacral ala paralleling the SI joint, representing trabecular compression and callous formation.

Less commonly, one may see cortical disruption at the superior or inferior margins of the sacrum or directly visualize a fracture line. These are difficult findings to appreciate in the setting of osteoporotic bone and overlying bowel gas. In Grangier's[304] series, only 25% of patients had typical plain film findings. CT is more sensitive in detecting cortical disruption and the sclerotic margins of the fracture. Axial CT demonstrates the vertical component of the fracture. There is often a horizontal fracture line extending through the sacral body. This may be missed on axial images and better identified on coronal CT images. A vacuum phenomenon may also be observed within the fracture.

Technetium bone scan also represents a sensitive means of insufficiency fracture detection. The classic finding is the so-called Honda sign. Increased metabolic activity in bilateral vertical sacral

ala fracture lines are bridged by a horizontal line representing a fracture through the sacral body, resulting in a representation of the letter H. In Fujii's[305] series, 63% of patients with sacral insufficiency fractures exhibited this sign in toto, with 35% showing a variant thereof such as two vertical lines without a crossbar or a single vertical and horizontal line. The Honda sign taken with its variants had a 96% sensitivity and 92% PPV for sacral insufficiency fracture in this series.

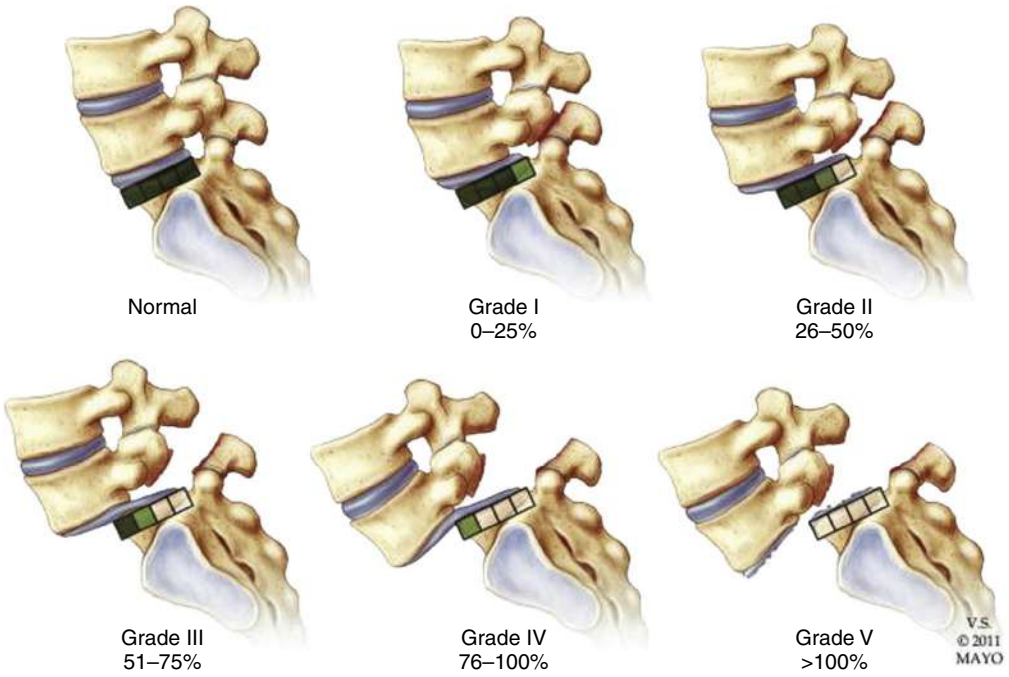
MRI is more sensitive than CT in the early detection of insufficiency fractures; it will reveal marrow edema (low T1, high T2 signal with gadolinium enhancement) in a pattern typical of insufficiency fracture (Honda sign) before sclerosis or a fracture line can be visualized with CT.[301] Imaging in the coronal plane is preferred; fat-saturated or STIR sequences are mandatory. In Grangier's series, marrow edema was observed in all cases as early as 18 days after symptom onset.[304] Over time, the fracture line will become visible within the zone of marrow edema as a line of diminished signal. Fluid (very high, homogeneous T2 and corresponding low T1 signal) may be detected within insufficiency fractures. The confidence in the diagnosis of sacral insufficiency fracture will be increased by the presence of similar bone lesions in the pubic rami, immediately about the pubic symphysis, and in the para-acetabular region, also typical sites of insufficiency fracture.

Spondylolysis

Spondylolysis, or isthmic spondylolisthesis, describes a defect in the pars interarticularis, which may be unilateral or bilateral. It is considered a fatigue fracture occurring within a vulnerable pars. The vulnerability may be related to the distribution of ossification centers within the posterior neural arch, not a deficit in bone quality. Spondylolysis has a familial predisposition. There is a 2–4:1 male-to-female predominance. The incidence of spondylolysis has been estimated at 7% in the United States population.[306] Spondylolysis is frequently asymptomatic, but it is a particular clinical issue in adolescent athletes. A retrospective study of lumbar radiographs in over 4000 athletes demonstrated a 13.9% rate of spondylolysis with concomitant spondylolisthesis in 47%.[306] Spondylolysis occurs most commonly at the L5 level (67%), followed by the L4 (15%–20%) and L3 levels (1%–2%). It is unusual in the cervical region, where it most often occurs at the C6 level. Spondylolysis is extremely rare in the infant population but appears to develop in childhood or adolescence, with no significant change in its incidence beyond age 20.

Although considered a fatigue fracture, it is unusual in that there is seldom an effective healing response, and the osseous defect is persistent. The pars defect is frequently a synovial-lined pseudoarthrosis. Shipley demonstrated that injection of the facet immediately superior to a pars defect showed communication with the pars defect cavity in 30 of 32 facets, with communication to the next most inferior facet in 20 of 32 facets.[307] The presence of synovial fluid in the defect likely contributes to its diminished capacity to heal.

Radiographic findings of spondylolysis are often evident on lateral plain films where a radiolucent band can be directly visualized across the pars interarticularis, with or without a sclerotic margin; there is no role for oblique radiographs. Spondylolisthesis refers to the anterior translation of the vertebral body bearing the spondylolytic defects in relation to the vertebral body below (Fig. 20.22). Spondylolisthesis is graded from I to V based on the percentage of anterior translation relative to the AP dimension of the vertebrae: grade I, 0%–25%; grade II, 26%–50%; grade III, 51%–75%; grade IV, 76%–100%; and grade V, >100% (spondyloptosis).[301] Most cases of spondylolisthesis are of grade I. A trapezoidal appearance of L5 with a dome-shaped superior endplate of S1 can be observed in chronic spondylolysis with spondylolisthesis.



• **Figure 20.22** Spondylolisthesis, modified Meyerding classification. Modified Meyerding classification of spondylolisthesis: grade I, 0%–25%; grade II, 26%–50%; grade III, 51%–75%; grade IV, 76%–100%; grade V, greater than 100% (spondyloptosis [falling off]). (From Murthy NS. Imaging of stress fractures of the spine. *Radiol Clin North Am.* 2012;50:799–821.)

CT allows direct visualization of the pars defect interposed between the adjacent facet joints on axial images. Sagittal reconstructions make the defect more obvious. Care must be taken to distinguish between a true pars defect and severe facet arthrosis. CT will also help distinguish between a stress response (sclerosis, hypertrophy) in the contralateral pedicle or pars in a unilateral spondylolysis and an osteoid osteoma. CT allows characterization of the process as a stress response (sclerosis), an incomplete fracture, or a completed fracture. Fujii and colleagues categorized these types as early, progressive, and terminal.[308] The early stage consists of a narrow fissure with sharp margins; the progressive stage consists of a narrow fissure with less well defined, rounder margins; and the terminal stage consists of a wide defect with rounded, sclerotic margins. Early stage lesions healed with conservative care, including bracing, more frequently than progressive lesions; no terminal stage lesions healed (see Fig. 20.23).[308]

The defect in the pars interarticularis can be directly visualized on multiplanar MR imaging, especially if thin sections and specific oblique axial plane images are acquired.[309,310] A systematic review by Dhouib and colleagues concluded that MR imaging has high diagnostic performance for detecting pars defects in young adults and that it can be considered a first line imaging test since it avoids exposure to ionizing radiation unlike radiographs, CTs, and bone scans.[311] Several ancillary signs have been described on MRI, including (1) an increase in the sagittal diameter of the central spinal canal at the level of the pars defect, (2) reactive marrow changes (hypointense T1, hyperintense T2) within the adjacent pedicle, and (3) wedging of the posterior aspect of the associated vertebral body, usually L5.[312] Reactive marrow changes in a vertebral pedicle are not specific for the presence of spondylolysis and may be observed in the presence of adjacent facet arthrosis or synovitis. Hollenberg and colleagues developed an MRI classification of spondylolysis (Table 20.5).[313] A subsequent study comparing CT staging and MRI findings noted that CT-defined early stage lesions all exhibited T2 hyperintensity in the ipsilateral pedicle; terminal stage lesions never exhibited T2 hyperintensity in the pedicle.[313] Nearly 80% of lesions with T2 hyperintensity in the pedicle healed with conservative care.[314]

TABLE 20.5 MRI Classification of Spondylolysis

Grade	Description	MRI Features
0	Normal	Normal bone marrow signal No cortical disruption
1	Stress reaction	Bone marrow edema No cortical disruption
2	Incomplete fracture	Bone marrow edema Incomplete fracture through the pars interarticularis
3	Acute complete	Bone marrow edema Complete fracture through the pars interarticularis
4	Chronic complete	No bone marrow edema Complete fracture through the pars interarticularis

From Murthy NS. Imaging of stress fractures of the spine. *Radiol Clin North Am.* 2012;50: 799–821, Table 1.

MRI, Magnetic resonance imaging.

Spondylolysis has also been assessed with SPECT/CT, although at the cost of radiation dose to a typically young population. Gregory and colleagues assessed the diagnostic value of combining SPECT with CT in the evaluation of spondylolysis.[315] They described four categories of patients: group A: (+) SPECT and (+) CT findings for spondylolysis; group B: (+) SPECT and (–) CT findings for spondylolysis +/– sclerosis of the pars; group C: (–) SPECT and (+) CT findings for spondylolysis; and group D: (–) SPECT and (–) CT findings for spondylolysis. Group A and B patients were felt to have a healing potential with early fatigue fractures or stress responses; group C patients had terminal lesions without healing potential, and group D patients had other pain generators, often the disc.[315] Although adult spondylolysis is often asymptomatic, there is a tendency to develop significant disc failure at the level of the pars defect, which may cause late progression of the degree of vertebral displacement (spondylolisthesis) and associated neural element compromise resulting from foraminal stenosis, which is well demonstrated on sagittal MRI. Spondylolysis patients may then experience axial pain caused by the inflammatory change about the pars defect, discogenic pain from the failed disc, and radicular pain from secondary foraminal compromise.

Characterization of pars defects sufficient for therapeutic planning requires assessment of both morphologic and physiologic parameters. A stress response in the pars or an incomplete fracture may respond to conservative therapy with healing; completed chronic fractures seldom heal and are often asymptomatic. Persistent symptoms in the face of a chronic completed fracture may reflect secondary phenomena of discogenic pain or radicular pain from foraminal stenosis. The combined morphologic and physiologic characterization can be performed with SPECT/CT or MRI. The interested reader is referred to a far more complete review by Murthy.[301]

Spine Infection

Extradural spinal infections are primarily the result of arterial seeding. In children, the disc and endplate have a rich blood supply; infection occurs initially in the disc itself. In adults, the disc is avascular; an infection develops in the anterior subchondral vertebral body with secondary spread to the disc, adjacent vertebrae, and subligamentous (deep to the anterior longitudinal ligament) space. Most disc space infections involve two adjacent lumbar vertebrae. Spread from contiguous infection or direct disc inoculation (surgery, injections, discography) is much less common.

Pyogenic disc space infection involves men much more commonly than women (2–3:1) in the fifth to seventh decades of life.[316] Infection is usually unimicrobial, *Staphylococcus aureus* is the most common pathogen, and urinary tract infections are the most common source of seeding.[317] Clinical symptoms may precede radiographic findings by 1–8 weeks. Clinical signs of elevated erythrocyte sedimentation rate, white blood cell count, and C-reactive protein are usually present. The C-reactive protein and erythrocyte sedimentation rate are both sensitive but not specific, while generally, the white blood cell count is the least helpful inflammatory marker. Plain films may reveal early rarefaction of anterior subchondral bone, followed by a loss of disc space height (at 1–3 weeks) with subsequent destructive changes in the vertebral endplates. Late changes include variable amounts of sclerosis, kyphotic deformity from vertebral collapse, and ankylosis. CT in pyogenic discitis shows early hypodensity in the disc, moth-eaten destruction of the vertebral endplates, and inflammatory changes and/or a mass in the paravertebral soft tissues and/or epidural space. Scattered gas formation may be observed. Extensive gas formation in the central

portion of the disc is typical of noninfectious disc degeneration. The disappearance of such a vacuum disc sign may herald infection. This is particularly true if there are associated endplate erosive changes, even if subtle. Note that the disappearance of vacuum phenomenon (as best seen on CT) may also occur in uninfected discs because of replacement by fluid (as best seen on MRI), which is likely a dynamic, time- and position-dependent process.[318]

MRI is the preferred imaging modality for the evaluation of discitis, with a greater than 90% sensitivity and specificity in disease detection.[316,317] It also provides critical anatomic information. Early marrow changes are elevated T2 signal (best observed with fat saturation or STIR), diminished T1 signal, and gadolinium enhancement (Fig. 20.24). There is a loss of the crisp dark cortical line of the vertebral endplate. The intranuclear cleft is lost within

• **Figure 20.23** Stress fractures, including spondylolysis. Spondylolysis at L5 is visible on flexion **(A)** and extension **(B)** radiographs. Although there is no translation of L5 on S1, the degree of rotation (12 degrees) qualifies this as unstable. In unilateral spondylolysis, the contralateral pars often show hypertrophy and sclerosis **(C)**. Computed tomograph (CT) can be used to stage pars fractures as early stage **(D)** with a narrow, sharply marginated fissure; progressive stage **(E)** with a narrow fissure having slightly rounded margins; and terminal stage **(F)** with a wide fissure with rounded margins and sclerosis. Typical sacral stress fracture *(arrows)* demonstrates a low signal fracture line on a coronal T1 image **(G)**, a linear zone of T2 hyperintensity on a STIR image **(H)**, whereas CT demonstrates a linear zone of sclerosis **(I)**. The integrity of the neural foramina is better defined on CT. (From Murthy NS. Imaging of stress fractures of the spine. *Radiol Clin North Am.* 2012;50:799–821.)

the disc, and foci of elevated T2 signal and gadolinium enhancement develop. The paravertebral and epidural soft tissues show diffuse enhancement (phlegmon) or frank abscess formation, with zones of hypo-enhancement and increased T2 signal where liquid purulent material is present, surrounded by peripheral enhancement. The imaging differential diagnosis consists of a Modic type I degenerative change, atypical cartilaginous (Schmorl's) nodes, adjacent metastatic lesions, osteomalacia secondary to osteodystrophy, and pseudoarthroses in patients with AS or a Charcot spine. Discrimination from a Modic type I endplate change can be particularly vexing; differential points are presented in Table 20.6. Although not as commonly applied in spinal imaging as in the brain, diffusion-weighted imaging (DWI) can be helpful when attempting to distinguish infectious spondylodiscitis from Modic type I endplate changes. Patel and colleagues demonstrated that the presence of a "claw" sign on DWI strongly suggests Modic I, while its absence strongly suggests infection.[319] This sign refers to "well-marginated, linear, typically paired regions of high signal situated within the adjoining vertebral bodies at the boundaries between the normal bone marrow and vascularized bone marrow that lies close to the affected disc."[319] An additional helpful discriminating feature for lumbar spinal infection is the "imaging psoas" sign.[320] This sign refers to T2 hyperintensity in the psoas musculature, which in a study of 51 biopsy-proven or clinically diagnosed patients with osteomyelitis-discitis compared to 50 age-matched control patients was highly correlated with spinal infection (sensitivity and specificity were both 92%). Despite these additional and more conventional imaging findings, imaging cannot always confidently diagnose spinal infection versus sterile inflammatory changes. In challenging cases, image guided biopsy and culture are appropriate.

MRI abnormalities lag behind the clinical syndrome. Imaging may be minimally abnormal early in the disease process but then remain quite dramatic even after a gratifying clinical response to antibiotics. Following the short term efficacy of antibiotic therapy, erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and white cell count will be more useful than repeated imaging. Follow up imaging should be reserved for patients with a clinical concern for continued infection with central spinal canal compromise. Persistently elevated or increasing ESR or CRP at week 4 of antibiotic therapy predicts treatment failure.[321]

Nuclear medicine scans using gallium-67 citrate and technetium-99m diphosphonate are complementary in the evaluation for suspected spondylodiscitis. A series by Hadjipavlou and colleagues demonstrated 100% sensitivity, specificity, and accuracy for the combination of gallium and technetium scans when compared with surgical biopsy results.[322] Gallium may be helpful in following the resolution of the infection. All nuclear medicine techniques lack anatomic information; they cannot define the extent of epidural or paraspinal disease or central spinal canal compromise.

Pyogenic epidural abscesses may arise from the contiguous spread of adjacent spondylodiscitis or facet joint infection, but they are most commonly primary because of the hematogenous dissemination or direct inoculation of the epidural space. *S. aureus* is the most common pathogen; immune compromise, especially diabetes, is common.[316] Emergent MRI is the imaging modality of choice. This will demonstrate a T1 hypointense, T2 hyperintense epidural process with peripheral or heterogenous enhancement, depending on the physical state of abscess versus phlegmon. The midline ventral epidural septum may be violated; most neoplasms respect this structure. Compression of the dural sac is common;

TABLE 20.6 Differentiating Spondylodiscitis From Modic Type I Endplate Changes

	Favoring Spondylodiscitis	Favoring Modic Type I Endplate Changes	Pitfall/Comments
Disc Space Signal	T2 hyperintensity	T2 hypointensity or lack of T2 hyperintensity	Severely degenerated discs rarely can be T2 hyperintense (even fluid signal)
Disc Space Enhancement	Present	Absent	Rarely absent in infection; rarely present in Modic I
Disc Space Vacuum Sign	Absent, or only scattered	Often present; a large amount of confluent gas on radiographs virtually exclude infection	Gas may be present early in infection, in rare gas-forming bacterial infections, or in rare fistulas with the gastrointestinal tract
Vertebral Body Endplates	Endplate destruction	Lack of endplate destruction	Modic I can have endplate irregularity; *computed tomography is very useful here*
Paraspinal, Epidural Spaces	Inflammation or abscess	Absent	Peripherally enhancing disc herniation can be confused for abscess
Location	Anteriorly eccentric	Laterally eccentric: at point of biomechanical stress (e.g. inner aspect of the curve)	Both spondylodiscitis and Modic I are often along the entire endplate
Fever, Elevated Inflammatory Markers	Present	Absent	Fever is only variably present in spondylodiscitis; inflammatory markers are nonspecific
Short Term Follow Up	Progression	Stability	If *remote* comparison images are available, even Modic I can show significant progression

From Diehn FE. Imaging of spine infection. *Radiol Clin North Am.* 2012;50:777–798.

severe compromise with neurologic deficit precipitates emergent decompression. Imaging resolution of an epidural abscess more closely parallels the clinical state than in spondylodiscitis. Spinal subdural abscesses are less common but can be very long segments and also constitute an emergency.

Pyogenic facet joint infection is uncommon; it usually results from hematogenous dissemination, although direct inoculation caused by invasive procedures is reported. Clinical presentation may resemble spondylodiscitis, although most commonly with lateralizing symptoms; the lumbar spine segment is most frequently affected. Bilateral involvement may occur via the space of Okada.[193] CT will demonstrate an erosive process centered on the joint with inflammatory change in the adjacent multifidus muscle. MRI will demonstrate marrow edema in the articular processes, a joint effusion, and edematous changes in the multifidus; enhancement in the joint with peripheral enhancement about an adjacent paraspinal or epidural abscess or uniform heterogeneous enhancement within a phlegmon may be noted.

Tuberculosis (TB) remains the most common cause of spinal infection worldwide, and it is of increasing incidence in industrialized societies. Clinical symptoms are usually insidious. Whereas 90%–100% of patients will have back pain, only 50% will have constitutional symptoms or fever. Tuberculous spondylitis (Pott's disease) arises from hematogenous (arterial) spread of tuberculous bacilli, usually from a pulmonary source. This initially lodges in the anterior subchondral bone. There is early anterior subligamentous extension and then spread to adjacent vertebrae, often multiple, as well as spread across the disc. Neurologic deficit occurs in a moderate number of patients because of epidural extension. Posterior elements tend to be spared. Extensive anterior column destruction with gibbus deformity is characteristic.

Tuberculous spondylitis with discitis shows disc space narrowing, vertebral osteolysis with collapse, and gibbus deformity on plain films. The thoracolumbar junction is most frequently affected, with less frequent involvement as one ascends the thoracic or descends the lumbar spine.[316] Plain films may not be abnormal until two to five months after the onset of infection. Paraspinal soft tissue masses caused by subligamentous spread, particularly with calcification, are characteristic. CT will demonstrate the osteolytic changes of spinal tuberculosis earlier than plain films will. It more readily demonstrates epidural involvement, particularly when calcification or bone fragments are visible in the epidural space. Paraspinal involvement is also well demonstrated.

MRI is the primary imaging procedure for the detection of spinal TB. Early changes of tuberculous spondylitis with discitis are very similar to pyogenic disc space infection, with marrow and disc inflammatory changes consisting of elevated T2 signal, diminished T1 signal, and enhancement. Extensive subligamentous spread of disease suggests TB, especially when the disc spaces are relatively spared. Paraspinal abscesses, granulomas, and epidural involvement are common. Epidural involvement may be observed in 60%–80% of cases.[316] A potential differentiating feature favoring tuberculous over pyogenic spondylitis when the ventral epidural space is affected in the perseveration of the midline central septum (anterior meningovertebral ligament).[323] When preserved, the tuberculous lesion in the ventral epidural spaces takes on the configuration of a draped curtain.[323] In contrast to indolent infection or neoplasm, more rapidly aggressive epidural disease processes, such as pyogenic epidural infection (phlegmon, abscess) or hematoma, tend to lack this draped curtain sign this sign because of violation of the midline ligament.[324]A second pattern of tuberculous infection is spondylitis without discitis (see Fig. 20.24).[325] This describes lytic lesions in the central portions of the vertebral bodies, often multiple, without disc involvement. This pattern of involvement was present in approximately 50% of patients in one large series.[322] Imaging findings consist of discrete, destructive vertebral body lesions. Plain films show well defined lytic lesions, often multifocal, and with more frequent posterior element and cervical involvement than is observed in tuberculous discitis. Lytic lesions may exhibit marginal sclerosis on CT, indicating a more indolent lesion than a typical metastatic deposit. These lesions typically enhance peripherally on MRI, often with a cystic central cavity. There may be cortical destruction with an adjacent paravertebral abscess. Because of the greater frequency of multiple lesions, this entity must be distinguished from metastasis, myeloma, or lymphoma.

MRI has significantly advanced the diagnosis of spinal infection, allowing this to be suggested as a likely diagnosis before destructive changes have evolved. However, the MRI findings remain unspecific, and accurate diagnosis and therapy require tissue sampling for histology and culture. Image guided percutaneous aspiration/biopsy with large caliber bone cutting needles can provide minimally invasive tissue sampling. However, the yield of this procedure is relatively low, especially, but not only, in patients in whom antibiotics have been initiated.[326]

Inflammatory Spondyloarthropathy

Noninfectious inflammatory disease of the spine includes rheumatoid arthritis (RA) and the seronegative spondyloarthropathies (SpA), of which AS is the prototype. These diverse entities have spine involvement in common and may present with axial spine pain.

Rheumatoid arthritis is most common in the cervical spine, sometimes called the fifth limb in RA patients. Symptoms and signs of cervical spine involvement are present in 60%–80% of RA patients.[327] Spinal involvement by RA is unlikely in the absence of hand involvement. The most frequent site of involvement is the atlanto-axial articulation. Inflammatory pannus may be seen on MRI as a low T1, high T2 signal-enhancing mass posterior to the dens. This may cause compression of the cervicomedullary junction. The inflammatory change may destroy the transverse and alar ligaments, resulting in atlanto-axial instability in 20%–25% of RA patients. A distance of greater than 4 mm between the posterior arch of C1 and the cortical surface of the dens on radiographs is abnormal and is most evident in flexion views. The destruction of supporting structures at the craniocervical junction may also result in cranial settling, vertical migration of the dens into the foramen magnum, with possible compression of the C1 and C2 cranial nerves, the medulla, and vertebral arteries.

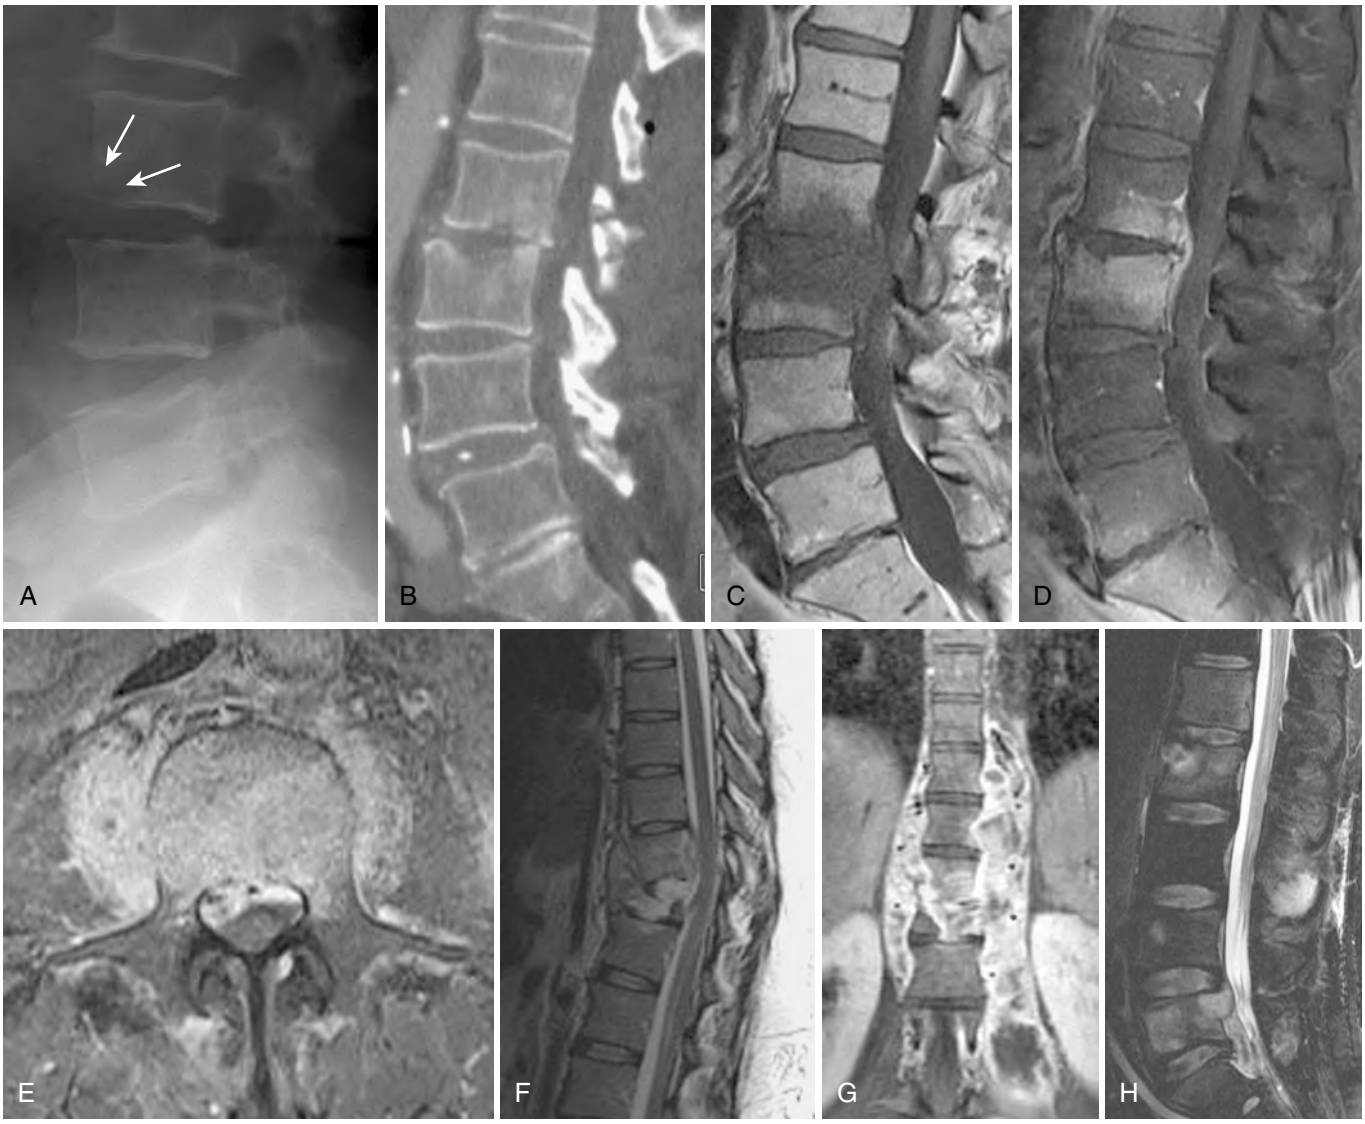
The cervical spine below the C1–2 articulations demonstrates erosive arthritis in the uncovertebral and facet joints in RA patients. The inflammatory change can be demonstrated on MRI as increased T2 signal on STIR sequences and gadolinium enhancement on fat-saturated T1 sequences. This results in multilevel instability, with anterior subluxation of successive vertebral bodies in flexion, the so-called step ladder cervical spine, noted in up to 30% of RA patients.[327] Disc space narrowing and endplate sclerosis are common, but this may be a secondary phenomenon to the posterior element instability.

Involvement of the thoracic and lumbar spine in RA is uncommon. Synovitis and erosive change may be present in the facet and costovertebral joints, but these findings are inconstant and not well demonstrated. Discovertebral changes may be present, but it is again unclear if these are primary inflammatory lesions

or a response to facet instability. The sacroiliac joints may show inflammatory change but with much less frequency and severity than in AS patients.

The seronegative spondyloarthropathies are a group of rheumatoid factor negative inflammatory disease processes affecting the spine and sacroiliac joints, with a unique predilection for entheses. Historically these have included AS, psoriatic arthritis, reactive arthritis (formerly known as Reiter's syndrome), and arthritis associated with inflammatory bowel disease. The categorization of these diseases has evolved, most recently in 2009, with the designation of axial spondylarthritis for the spectrum of disease with axial, as opposed to peripheral, dominance.[328] Axial spondylarthritis requires active sacroiliitis on MRI plus one or more features of spondylarthritis or human leukocyte antigen B27 (HLA-B27) positivity with two or more features of spondylarthritis. This discussion only encompasses the axial imaging features of the classically defined processes (Fig. 20.25).

MRI is the necessary imaging modality for the assessment of disease activity in the SI joints and spine articulations. MRI or CT can demonstrate the aftermath of disease: joint space narrowing, subchondral erosions, reactive sclerosis, or periarticular fat deposition (a Modic II analog); only MRI can assess active inflammation with T2 hyperintensity (STIR or fat-saturated images) and gadolinium enhancement on fat-saturated T1 images.



• **Figure 20.24** Spondylodiscitis. A lateral radiograph **(A)** demonstrates early pyogenic spondylodiscitis manifest as subtle destruction of the anterior inferior aspect of the L3 vertebrae (*arrows*). In another patient, a sagittal computed tomography reconstruction **(B)**, sagittal T1-unenhanced **(C)** and enhanced **(D)** and axial T1-enhanced magnetic resonance images (MRIs) **(E)** of a patient with L2–3 pyogenic discitis. Note the loss of disc space height, endplate destruction, low T1 signal, and extensive vertebral, epidural, and paraspinal enhancement. Sagittal T2-weighted MRI **(F)** of a back pain patient without myelopathy demonstrates vertebral destruction with kyphotic deformity; this is tuberculous spondylodiscitis. Coronal T1-enhanced MRI **(G)** in the same patient demonstrates the extensive paraspinal disease typical of Pott's disease. A sagittal T2-weighted MRI **(H)** in another patient with tuberculous spondylodiscitis; note the multiple vertebral lesions with sparing of the discs. This can be confused with metastatic disease. Tissue sampling is essential. (From Maus T. Imaging the back pain patient. *Phys Med Rehabil Clin N Am*. 2010;21:725–766.)

AS is the prototypical seronegative spondyloarthropathy; active disease in the SI joints by MRI criteria is integral to its diagnosis. AS has a prevalence of up to 0.1% in the general population; a very high percentage will be HLA-B27 positive. Males dominate by a ratio of 4:1. The disease involves synovial and cartilaginous joints and entheses (ligament and tendon insertions on the bone) with a strong predilection for the axial skeleton. The most common presentation is low back pain with inflammatory features (Calin criteria, four out of five of insidious onset, age <40 years, three months persistence, morning stiffness, and pain improved by exercise).[329] Radiating pain mimicking sciatica may be observed in up to 50% of patients.

Imaging findings in AS include sacroiliitis, ultimately bilaterally symmetric, and multiple manifestations of spondylitis (see Fig. 20.25). Sacroiliitis is the uniform initial imaging finding. Early plain film findings of sacroiliitis are blurring of the subchondral cortex by small erosions, predominantly on the iliac side of the joint. As the erosions coalesce, the joint space appears widened and ill-defined; sclerotic reaction develops in the trabecular bone about both sides of the joint. Over time the joint undergoes ankylosis via direct osseous bridging; the joint space is no longer visible, and the sclerosis resolves.[330] MRI can detect inflammation in the SI joint in symptomatic patients with normal plain films. Inflammation can be reliably identified with low interobserver variability as high T2 signal on STIR sequences or gadolinium enhancement on fat-saturated T1 images.[331] In patients with recent onset axial low back pain with inflammatory clinical characteristics, SI joint inflammation may be detected by MRI in one-third of patients and structural changes in one-sixth of patients.[331] Inflammation is initially observed in the iliac side of the joint at its caudal and dorsal aspects, and in the adjacent dorsal entheses.

Spine findings in AS are present in 50% of patients and include osteitis, syndesmophyte formation, discovertebral lesions, and inflammation leading to ankylosis of facet and costovertebral joints.[330] Osteitis is observed at the anterior margins of the discovertebral junction, termed the "Romanus lesion." On plain films, sclerosis at these sites leads to increased density of the anterior corners of the vertebra, termed the "shiny corners sign."[330] Remodeling of the anterior margin of the vertebral body as a result of osteitis straightens the normally concave anterior vertebral margin, referred to as "squaring" of the vertebra. These findings are most evident in the lumbar region. MRI is more sensitive to the early detection of osteitis, recognized as diminished T1 and increased T2 signal and enhancement at the anterior vertebral corners.[330] Osteitis at the margins of the discovertebral junctions leads to reactive bone formation in the outer annulus fibrosis, which ultimately bridges the margins of adjacent vertebrae. These vertically oriented osseous struts are syndesmophytes. They are distinguished from osteophytes by their vertical orientation and gracile nature; osteophytes are oriented in the horizontal plane and are bulkier. Syndesmophytes are most common at the anterior and lateral aspects of the vertebral body; when long standing, the ossification may involve the anterior longitudinal ligament.

Erosions at the discovertebral junction are termed "Andersson lesions"; this inflammatory destruction of the vertebral endplate with intravertebral disc displacement can progress to pseudarthrosis. The imaging findings can be challenging to differentiate from those of infectious spondylodiscitis. Endplate destruction is visible on plain films; MRI demonstrates structural and inflammatory change. The inflammatory change will undergo evolution reminiscent of the progression from Modic type 1 to Modic type 2. Over time, sclerosis and transdiscal ossification are leading to ankylosis. The facet and costovertebral joints show similar findings, with initial periarticular erosions followed by sclerosis and ankylosis. Enthesitis of the posterior interspinous and supraspinous ligament attachments ultimately leads to ossification of these structures, visible as a vertical midline osseous band on frontal radiographs, the so-called dagger sign. The most common inflammatory spinal lesions in the midthoracic spine (T7–T8) and the midlumbar region (L2–3).

AS may also produce changes at the atlanto-axial articulation. Synovitis may cause erosive changes in the dens, although the extent of inflammatory change seldom reaches that noted in RA. Atlanto-axial subluxation may be present. The extensive ankylosis observed in patients with long standing AS leads to flattening of the lumbar lordosis and exaggeration of the thoracic kyphosis. The rigidity places these patients at-risk for catastrophic fracture-dislocations with modest trauma, most commonly with a hyperextension mechanism. The cervical spine is most frequently involved; neurologic deficits are common. Plain film evaluation is difficult because of the osteopenia typical of these patients; the three-column nature of these fractures is best appreciated with CT or MRI. The threshold for the use of advanced imaging in the AS patient with trauma should be low. Three-column fractures that do not cause acute neurologic injury or go undetected may be a cause of chronic focal pain as pseudarthrosis. MRI will show a linear zone of inflammatory change, often through a disc space with extension through the posterior elements. The cortical disruption may be best appreciated on CT. Finally, some AS patients will have findings of dural ectasia (see Fig. 20.25). The thecal sac will be abnormally capacious with diverticular-like outpouchings; there is associated osseous erosion in the posterior elements, medial margins of the pedicles, and the posterior vertebral body. These patients may present with a cauda equina syndrome, perhaps related to arachnoiditis.

Psoriatic arthritis (PA) is far less common than AS, affecting approximately 7% of patients with cutaneous psoriasis.[330] Approximately 10%–25% of patients with moderate to severe skin disease will have abnormal SI joint radiographs. Spondylitis is present in a roughly similar proportion but may or may not coexist with sacroiliitis. Males and females are equally affected.[330] The sacroiliitis is usually bilateral but asymmetric, with a lesser tendency to progress to osseous ankylosis. Erosions and foci of reactive sclerosis tend to be larger and more discrete than in AS. The spondylitis in PA is characterized by asymmetric, coarse paravertebral ossification, more strongly resembling osteophytes than syndesmophytes. Vertebral squaring and shiny corners are absent. Facet involvement is infrequent.

Reactive spondylarthritis (RS) describes an inflammatory arthropathy, preferentially affecting the heel and large peripheral joints.[330] Sacroiliitis is very common, affecting up to 45% of patients. It is more commonly unilateral or asymmetric than in AS; ankylosis is rare. Spine involvement may be identical to that of PA but more common; the lumbar spine is involved in 30% of RS patients.[330] In the setting of a triggering infection (often chlamydia) and the triad of urethritis, uveitis, and arthritis, the term "Reiter's syndrome" may be applied.

Enteropathic arthritis may also be observed in association with ulcerative colitis or Crohn's disease. The initial presentation of back pain may precede symptoms of gastrointestinal disease. The spondylitis and sacroiliitis noted in association with these conditions are indistinguishable from classic AS. Sacroiliitis is usually bilaterally symmetric, progressing to ankylosis. Spondylitic findings of vertebral squaring, discovertebral lesions, syndesmophytes, and involvement of the facet joints are typical.

Spine Neoplasm

Spinal neoplasms are classified by the anatomic compartment from which they arise: extradural, intradural-extramedullary, or intramedullary. Extradural neoplasms arise from the vertebral bodies, within the paravertebral soft tissues, or within the epidural space. These include metastatic lesions, hematologic malignancies, and primary osseous or cartilaginous tumors. Intradural-extramedullary lesions arise within the dural tube but are extrinsic to the spinal cord itself. Lesions in this category include meningiomas, schwannomas, neurofibromas, and leptomeningeal metastatic disease. Intramedullary lesions are those that arise primarily from the spinal cord or filum terminale. Primary cord tumors (most commonly ependymomas, astrocytomas, and hemangioblastomas) make up most of these lesions, while metastases are less common. Because of space constraints, only a few comments on spinal tumors are included here; for a more robust review of the wide variety of diseases in this category and their imaging appearances, the reader is referred to several excellent reviews from the radiology literature.[332–334]

Extradural neoplasms are common. MRI provides the best combination of lesion detection, morphologic characterization, and assessment of neural compromise. Nuclear medicine techniques such as technetium bone scan and PET scanning provide high sensitivity to lesion detection and excellent body wide assessment of tumor burden (Fig. 20.26). Nuclear medicine studies will not provide precise anatomic information regarding the compression of neural elements. CT is less sensitive than MRI in lesion detection; plain films are far less sensitive.

Extradural neoplasms may narrow the subarachnoid space (cerebrospinal fluid) as they extrinsically intrude into the central spinal canal. They exhibit diminished T1 signal, elevated T2 signal, and gadolinium enhancement on MRI. The unenhanced T1 image is the mainstay of lesion detection; normal adult marrow should be brighter than the intervertebral discs because of normal fatty marrow. Fat-saturated T2-weighted images and STIR images provide high sensitivity to lesion detection. Fat-saturated post-gadolinium images will also display extradural neoplasm with high sensitivity. On axial images, compression of the thecal sac or exiting nerve roots can be directly displayed. CT and plain films play a role in characterizing primary bone and cartilaginous tumors, including malignant lesions such as osteosarcoma, chondrosarcoma, chordoma, and benign tumors, including hemangioma, osteoid osteoma, giant cell tumor, and aneurysmal bone cyst.

Metastases are the most common extradural spine tumor, and the spinal column is the most common site of osseous metastases. An overwhelming majority of spine metastases are because of prostate, lung, and breast cancer. The thoracic spine is most commonly involved (70%), followed by the lumbar and cervical segments. Involvement of the vertebral body is the most common (85%), with less frequent spread to the paravertebral tissues or epidural space. The discs, dura, and the anterior longitudinal ligament are resistant to invasion by metastatic tumors. The posterior longitudinal ligament is more readily involved, as numerous venous channels penetrate it. Vertebral body metastases may be blastic (bone forming), lytic (destructive), or mixed. Blastic lesions are observed as ill-defined areas of increased density on plain films or CT; on MRI, blastic lesions will have low T1 and T2 signals with enhancement. Common primary tumors are prostate, carcinoid, or bladder cancer. Lytic metastases show destruction on plain films and CT, and low T1 and variable T2 signal with enhancement on MRI. Lytic metastases are most commonly produced by breast, lung, renal, and thyroid neoplasms. Mixed lytic and blastic lesions are visible in lung, breast, cervical, and ovarian primaries.

Hemangiomas are the most common spine tumor, present in 10%–12% of adults. They are frequently multiple. Typical hemangiomas are benign and of no clinical significance; they are identified by their fatty content on MRI (high T1 and T2 signal) and a corduroy appearance on plain films or CT. This is because of sparse, thickened trabeculae surrounded by fat. On axial images, this results in a polka dot appearance.

Osteoid osteomas occur in patients under the age of 30 years, and they typically present with pain, often nocturnal. Aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) can usually relieve pain. The lesion consists of a small nidus, less than 1.5 cm in diameter, surrounded by a larger zone of sclerotic reaction or soft tissue inflammation, visible on plain films or CT. The nidus is intensely enhancing on CT, MRI, or bone scan. Ten percent of osteoid osteomas occur in the spine, almost exclusively in the posterior neural arch. The lumbar spine is involved in 59% of spinal osteoid osteomas, the cervical region in 27%, and the thoracic spine in 12%. Lesions larger than 1.5 cm are considered osteoblastoma.

Myeloma is the most common malignant primary tumor of bone; it presents with bone pain in 75% of patients. It is often widespread at presentation. Its imaging appearance can range from discrete destructive lesions to diffuse loss of bone density indistinguishable from osteoporosis on plain films. CT is better able to resolve the discrete destructive lesions in trabecular or cortical bone. The MRI appearance is variable, with diminished T1 marrow signal and gadolinium enhancement in a multifocal or diffuse pattern. Compression fractures are common, and they may be indistinguishable from benign osteoporotic fractures. Single focal lesions (plasmacytomas) are expansile and lytic on imaging.

Leukemia may present with spine pain in the setting of diffuse marrow involvement and associated compression fractures. The most common imaging finding is that of diffuse marrow replacement, with osteopenia on plain films and CT, and generalized loss of the normal T1 marrow signal. Normal marrow should always be brighter than disc signal on T1 images. Focal extra-osseous soft tissue masses of leukemic tissue may be present and are termed "chloromas."

Lymphoma is a great impersonator. It can present in the spine as vertebral lesions indistinguishable from metastases, epidural soft tissue mass without bone involvement, diffuse leptomeningeal process, and primary intramedullary lesion.

Intradural-extramedullary neoplasms are situated within the dural sac, widening the subarachnoid space as they displace the cord or cauda equina; these lesions are typically benign.[94] Meningiomas typically exhibit a broad base against the dural surface and enhance uniformly. Schwannomas and neurofibromas are generally indistinguishable on imaging. They may enhance uniformly or show central zones of cystic degeneration. The classic "dumb-bell" neurofibroma may issue through and widen a neural foramen. They may also occur entirely within the dural sac or in a paravertebral location. Leptomeningeal metastatic disease is most typically seen as an enhancement on the surface of the cord or within the roots of the cauda equina. Sometimes more discrete small masses may be observed within the cauda equina. CSF cytology remains more sensitive than MRI in the detection of leptomeningeal metastatic disease.

Intramedullary neoplasms are rare entities, but they may present with pain or dysfunction that can mimic degenerative disease. Ependymomas arise from the ependymal cells lining the central

• **Figure 20.25** Spondyloarthropathy. Changes of sacroiliitis are detectable on radiographs **(A)** as irregularity, erosions, and sclerosis, dominant on the iliac side of the joint. In the end stage of ankylosing spondylitis (AS), the sacroiliac joints are fused, and sclerosis resolves **(B)**; this radiograph also depicts the dagger sign, as the fused spinous processes make a continuous sclerotic structure in the midline. Computed tomography (CT) **(C)** is more sensitive in the detection of erosions and early sclerotic reaction in AS; this structural change may simply reflect prior disease. Only magnetic resonance imaging (MRI) can detect disease activity **(D)** as demonstrated by the T2 hyperintensity in and about both sacroiliac joints in this AS patient. The gracile vertical syndesmophytes bridging lumbar vertebrae and the fused posterior elements are well seen on CT **(E)**; the spine in AS is rendered vulnerable to three-column unstable fractures with modest trauma **(F)**. These situations deserve CT imaging. The spondyloarthropathy of inflammatory bowel disease may present as back pain (T2 sagittal **[G]** and enhanced T1 fat-saturated sagittal **[H]**) with evidence of multifocal inflammatory spondyloarthropathy. The differential diagnosis here is multilevel spondylodiscitis, especially Pott's disease (tuberculosis). Changes of sacroiliitis in inflammatory bowel disease **(I)** may be indistinguishable from AS. Asymmetric sacroiliitis (T1-enhanced, fat-saturated coronal MRI **[J]**) is typical of reactive spondylarthritis (formerly Reiter's syndrome).

spinal canal of the cord. Ependymomas are the most common intramedullary tumor in adults. A specific subtype of ependymoma, the myxopapillary ependymoma, occurs in the conus medullaris and filum terminale. Because of their slow growth, they may cause osseous erosion and scalloped enlargement of the central spinal canal. MRI demonstrates an enlarged cord or filum terminale with an elevated T2 signal and heterogenous enhancement. Small cysts or hemorrhage are frequent. Astrocytomas are typically low-grade neoplasms, more commonly noted in young patients and the cervical region. They typically extend over multiple vertebral segments within the cord with poorly defined margins. The cord is enlarged with heterogenous enhancement. The entire cross-section of the cord is typically involved. Considerable edema within the white matter of the cord extends cephalad and caudal to the enhancing neoplasm itself. Peritumoral cysts may be present. Hemangioblastomas are rare lesions that typically occur in the cervical and thoracic spine. An intensely enhancing vascular nodule adjacent to the pial surface, often associated with an intramedullary cyst and relatively extensive cord edema, is typical. About one-third of patients with hemangioblastomas will have Von Hippel Lindau syndrome.

Intramedullary spinal cord metastases are less common than primary cord tumors. However, these are being increasingly diagnosed, and several enhancement features on post-gadolinium MRI have high specificity for these lesions compared to primary cord tumors: the rim, flame, and central dot signs.[335,336] Indeed, specific enhancement patterns such as these can be extremely helpful differentiating features when assessing both neoplastic and non-neoplastic causes of myelopathy.[94] Spinal cord metastases also often demonstrate considerable spinal cord edema, even if the size of the metastasis is relatively small.[337] Evidence of the primary malignancy and/or other metastatic disease may be evident, and the spinal cord metastases themselves may be multiple.[337]

Spinal Dural Arteriovenous Fistula

Spinal dural arteriovenous fistulas (AVFs) are the most common form of vascular malformation involving the spine. This lesion merits description in that it may present with pain and progressive neurologic deficit, mimicking NIC; it frequently remains misdiagnosed or undiagnosed for prolonged periods despite characteristic imaging features.[338] In Atkinson's series, the mean delay from symptom onset to diagnosis was 23 months.[339] Patients are frequently subjected to misdirected interventions, including decompressive surgery. When diagnosed, it is treatable with the arrest of the progressive neurologic deficit.

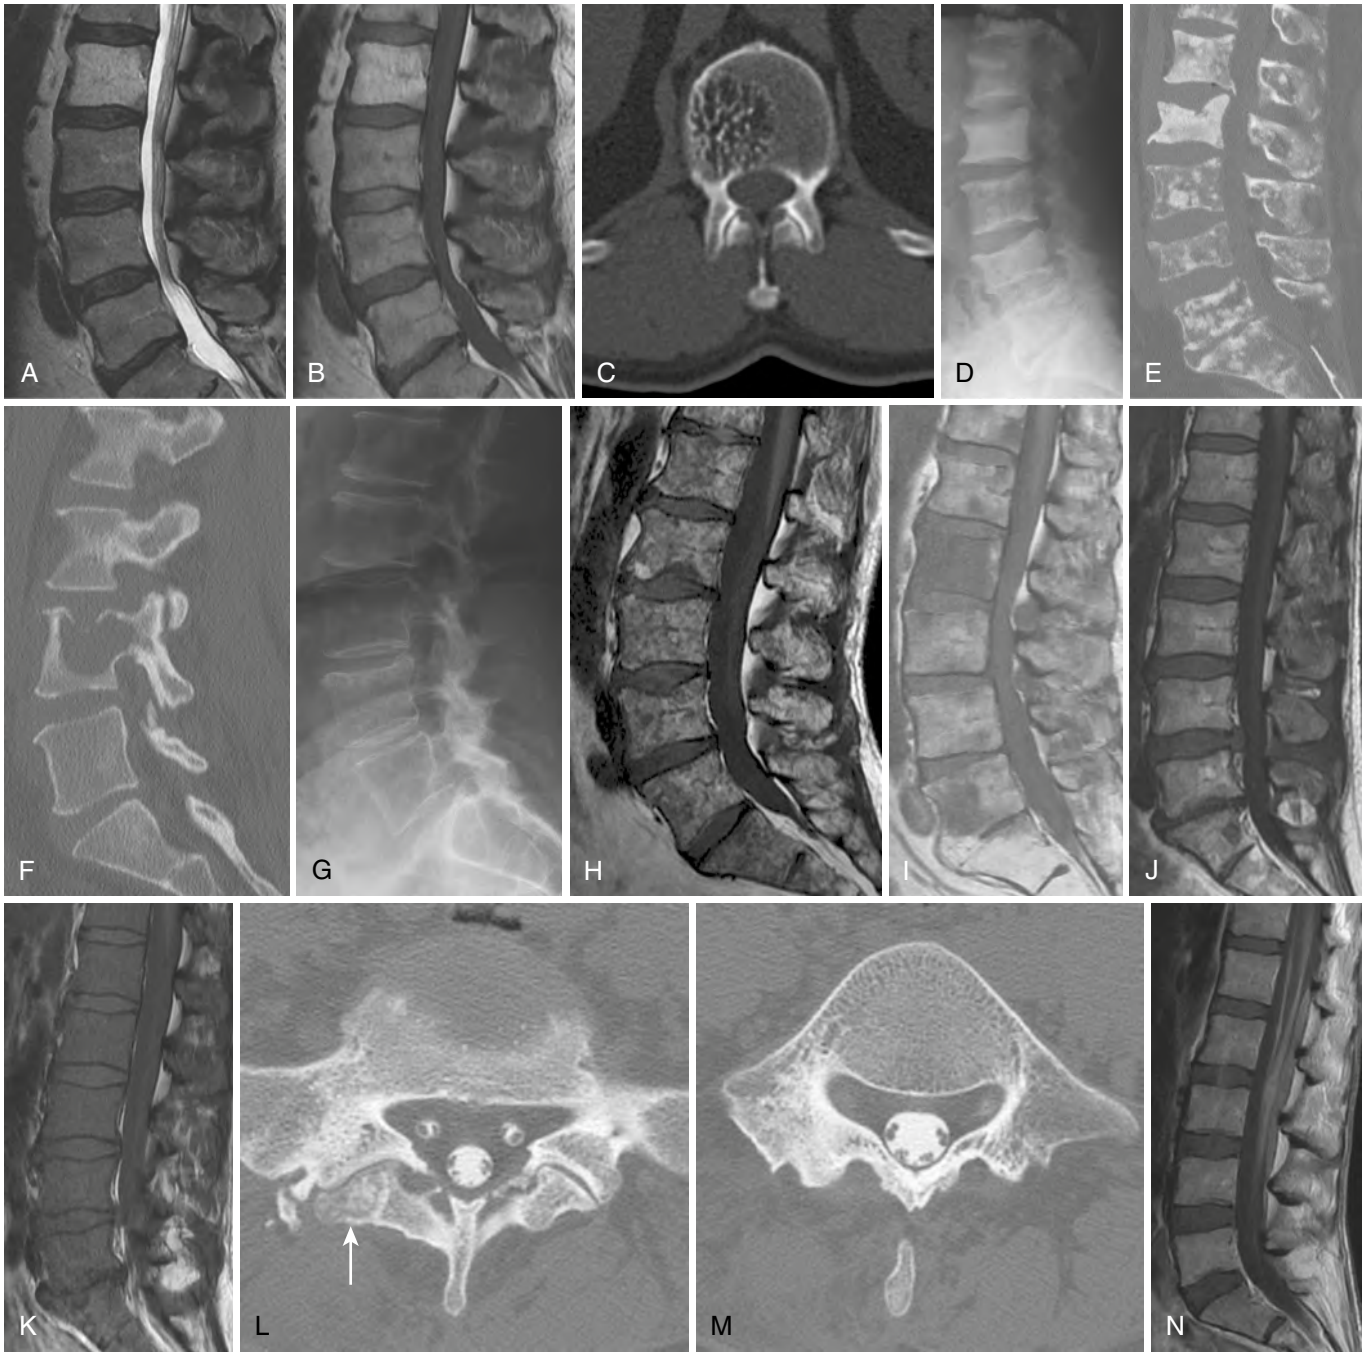
Spinal dural AVFs are an acquired lesion, with a fistulous communication within the dura of a root sleeve and intrathecal venous drainage to the venous plexus surrounding the cord. This results in venous hypertension within the cord and ultimately cord dysfunction. The fistula is most common in the low thoracic or lumbar spine. It is a lesion observed in elderly males. Gilbertson's series[340] included patients with a mean age of 62 years (range 37–81 years). Atkinson's series[339] reported a 4:1 male predominance. Pain was a reported symptom in 53% of patients. Many of these patients described a burning, dysesthetic pain in the lower extremities; 15% had low back pain when erect, which worsened with use of the lower extremities. This is typically accompanied by a slowly progressive or stepwise worsening myelopathy, manifest as lower extremity fatigue and weakness. Atkinson's series[339] reported that 69% of patients had upper and lower motor neuron signs; 30% had only lower motor neuron signs.

Imaging findings of dural AVFs have been well described.[341] On CT myelography, abnormally prominent tortuous vessels are present in 100% of cases; this may give the cauda equina a beaded appearance. There will be T2 hyperintensity in the cord on MRI in nearly 100% of cases (Fig. 20.27). This typically extends over multiple vertebral segments and may be accompanied by cord enlargement in 45% of cases. There may be patchy cord enhancement ("missing-piece" sign[342]); these findings may raise a concern for tumor. A differentiating finding is the presence of prominent T2-hypointense flow voids or intravascular enhancement caused by the dilated veins, particularly on the dorsal surface of the cord. The T2 hyperintensity in the cord usually involves the low thoracic cord and conus; this does not predict the site of the fistula, though if the conus is spared, the fistula is likely thoracic in location.[343] Magnetic resonance angiography is useful in predicting the site of the fistula (Fig. 20.27)[341] and reducing the scope of spinal angiography, which provides a definite diagnosis. For patients whose spinal dural AVF had been identified with spinal angiography, a 2014 study by Cao and colleagues demonstrated four independent predictors compared to angiography negative patients with suspected vascular diseases: age ≥50 years, length of intramedullary cord lesion ≥5 vertical segments, perimedullary dilated vessels, and sub-cervical lesion location.[344] The presence of three or more of these criteria predicted a spinal dural AVF with a sensitivity of 85% and a specificity of 97%. Once diagnosed by angiography, the fistula then may be disconnected surgically or by an endovascular approach. After treatment, progression of findings, especially worsening of parenchymal T2 hyperintensity, suggests either incomplete treatment or recurrence.[345]

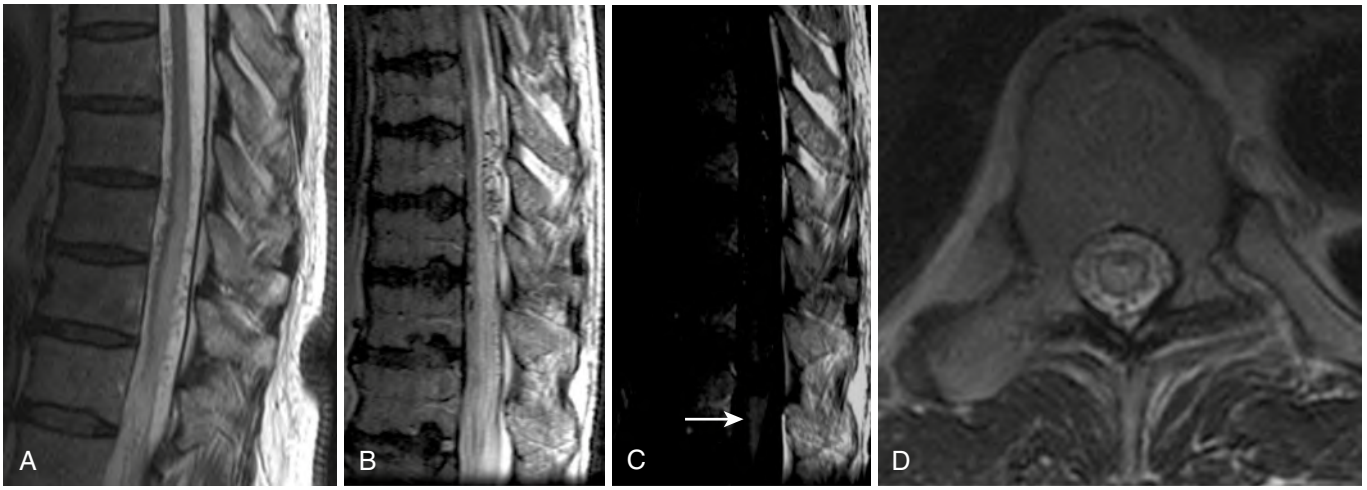
The goal of diagnosis and therapy is primarily to arrest the progression of the neurologic deficit and possibly improve the current disability. After successful occlusion of the fistula, either surgically or by endovascular embolic techniques, gait improvement was noted in 67%–80% of patients.[341] Bowel/bladder dysfunction or pain is relieved in only a minority of patients. Worsening of motor symptoms should prompt an imaging investigation for recanalization of the fistula.[341] After successful fistula occlusion, cord enlargement, enhancement, and T2 hyperintensity and the prominent veins about the conus will slowly resolve; T2 hyperintensity and enhancement may persist for up to a year. Progression of the findings should prompt a search for residual/recurrent fistula. A rare counterpart to the conventional spinal dural AVF is the spinal epidural AVF. While this uncommon condition can also present with congestive myelopathy, symptoms may rarely occur to compression from epidural venous engorgement. Based on a series of 24 patients over a ten-year period, Nasr and colleagues that the imaging findings on MRI are essentially identical to the more common spinal dural AVF, including intramedullary T2 hyperintensity and enhancement and associated intradural flow voids.[346] Meanwhile, a key differentiating factor from traditional dural AVF on angiography is the presence of a venous pouch in the epidural venous plexus.

Conclusion

As a synopsis of the imaging assessment of the patient with spine or limb pain, this chapter has ranged widely over large swaths of pathology and imaging technology. There are enduring themes. The primary role of imaging is to detect systemic disease causal of the patient's pain or neurologic dysfunction; such disease is uncommon. Currently, imaging is currently overutilized to the



• **Figure 20.26** Spine neoplasm. Sagittal T2 **(A)** and T1 **(B)** images show a lesion in the L2 vertebral body characterized by increased signal intensity on both sequences, typical of hemangioma, the most common benign spinal extradural neoplasm. A computed tomography (CT) image in another patient **(C)** demonstrates the classic CT features of hemangioma: thickened trabeculae surrounding increased marrow fat, resulting in a polka dot appearance. Blastic metastases **(D)** have increased bone density; CT is more sensitive than radiographs **(E)**, particularly in the detection of lytic metastases **(F)**. Myeloma can be challenging to detect on radiographs, mimicking osteoporosis **(G)**; magnetic resonance imaging (MRI) in the same patient **(H)** identifies the myriad of tiny destructive lesions. The MRI T1 sagittal sequence **(I)** typically reveals metastatic disease as focal hypointense lesions, as in this patient with prostate cancer, as the bright signal of normal marrow fat is replaced. When marrow replacement is diffuse, this can be difficult to detect. Normal marrow should always be brighter than adjacent discs. Note that normal marrow in **(J)** is completely replaced two years later by leukemia **(K)** when this patient presented with back pain. Osteoid osteoma is a posterior element benign neoplasm causal of pain, often nocturnal and relieved by salicylates. It is visible as a small nidus (*arrow* in **[L]**) with a surrounding sclerotic reaction **(M)**. Leptomeningeal metastases or lymphoma may be imaged as diffuse enhancing tissue coating the cord and cauda equina **(N)**.



• **Figure 20.27** Dural arteriovenous fistulae. T2 sagittal magnetic resonance images (MRIs) in two patients, **(A)** and **(B)**, both demonstrate enlargement of the conus with multisegmental T2 hyperintensity. Post-gadolinium T1 sagittal MRI (**[C]**, same patient as **[B]**) shows intravascular enhancement in the enlarged perimedullary veins and patchy parenchymal enhancement in the conus *(arrow)*. Axial T2 image through the lower thoracic cord **(D)** demonstrates increased T2 signal throughout the substance of the cord, with a dark border of diminished T2 signal at the periphery of the cord. (From Morris JM. Imaging of dural arteriovenous fistula. *Radiol Clin North Am.* 2012;50:823–839.)

detriment of patients and society. It has no value in the patient's initial presentation in the absence of red flag features suggesting systemic disease. The decision to begin imaging should be reasoned, considering the benefits of improved outcomes versus real risks and harms. The ACR and the ACP have promulgated evidence based guidelines for imaging use; they should be respected. When imaging occurs, it must be done with full appreciation of its inherent specificity and sensitivity faults. There is a high prevalence of asymptomatic, age-related change evident on all types of spine imaging; loss of T2 signal in the disc nucleus, anterior and lateral vertebral osteophytes, disc protrusions, and facet and sacroiliac joint arthrosis do not correlate with pain. Imaging performed without axial load, and physiologic posture may be insensitive to dynamic lesions. Structural alterations detected by imaging are of less significance than physiologic parameters of edema, hyperemia, disruption of blood-nerve barrier, or accelerated metabolism noted with T2 hyperintensity (STIR or fat-saturated images), gadolinium enhancement, or nuclear medicine techniques. Always treat the patient, not the images.

Acknowledgments

The authors sincerely thank Dr. Sonia Watson, Ph.D., for her assistance in reference citation management.

Key Points

- The primary role of imaging is to identify systemic disease; no imaging is indicated in the acute presentation of back or limb pain without "red flag" features.
- All spine imaging has a significant specificity fault: a high prevalence of asymptomatic age-related findings, including disc "degeneration" and facet arthrosis.
- Spine imaging performed without physiologic positioning, and axial load may be insensitive to dynamic lesions.
- Imaging correlates poorly with clinical presentation and course.
- Meticulous enumeration of spine segmentation from the skull base caudally is necessary to avoid wrong segment procedures.
- MRI findings can reasonably predict positive lumbar discography; the HIZ and significant expression of the Modic endplate change have high specificity but low sensitivity.
- Imaging cannot identify cervical discogenic pain.
- Findings of structural arthrosis of the facet or sacroiliac joints (osteophytes, joint space narrowing, sclerosis) have no relationship to pain; physiologic findings (positive bone scan, MRI T2 hyperintensity) may predict pain but have not been tested against an appropriate reference standard.
- Radicular pain requires both neural compression and an inflammatory response; standard imaging detects only the neural compression.
- There is no relationship between the size, type, or change in disc herniations over time and patient outcomes.
- The imaging natural history of disc herniation is resolution.
- NIC requires compression at multiple segmental levels or in multiple compartments (central, lateral recess, foraminal) for clinical expression.
- MRI signal changes in the cervical cord can provide prognostic guidance for decompression in the CSM patient.

Biomarkers of Pain: Quantitative Sensory Testing, Conditioned Pain Modulation, Punch Skin Biopsy

JULIANE SACHAU, RALF BARON

Introduction

Identification of potential biomarkers for chronic pain is essential for correct diagnosis, prediction, and evaluation of treatment response. A biomarker is defined as a "characteristic objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention."[1] The establishment of a new biomarker should follow a standardized process and requires the definition of the exact objective, i.e. what should be measured.[2] The United States Food and Drug Administration (FDA) has defined seven types of biomarkers that can be used to assess different categories: susceptibility/risk, diagnostic, monitoring, prognostic, predictive, pharmacodynamic/response, safety (Table 21.1).[3]

The correct diagnosis is a prerequisite prior to starting a suitable pain therapy. It is, for example, important to distinguish between chronic neuropathic and chronic nociceptive pain,[4] as the treatment of these entities would be approached differently. While nociceptive pain, i.e. pain that arises from damage to non-neuronal tissue with activation of nociceptors, is likely to respond to non-steroidal anti-inflammatory drugs such as naproxen or ibuprofen, or in more severe cases opioids, treatment of neuropathic pain, i.e. pain as a direct consequence of a lesion or disease of the somatosensory system, is more challenging and requires the use of different co-analgesics, e.g. anti-convulsants, anti-depressants.

Many patients with chronic pain do not achieve adequate pain relief with available drugs. With regard to chronic neuropathic pain, the number needed to treat for a 50% pain reduction for recommended first-line agents, i.e. tricyclic anti-depressants, selective serotonin-norepinephrine reuptake inhibitors, and calcium alpha two delta agonist anti-convulsants, ranges from 3.5 to 7.7.[5] In addition, many clinical trials involving newer agents have failed to show any treatment effect. Both inadequate pain relief with already available drugs and the failure of clinical trials involving newer agents might be explained by the heterogeneous clinical picture and the numerous underlying pathophysiologic pain mechanisms. *A priori* stratification of patients using a valid predictive biomarker could help identify patients who would benefit the most from a specific drug. In addition, to modify current treatment and/or initiate further measures, it is important to forecast disease progression.

To date, no valid biomarker has been identified for use in the assessment and treatment of chronic pain. However, the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) has recently considered three promising biomarkers for use in the development of analgesic treatments, i.e. sensory testing, skin punch biopsy, and brain imaging.[6]

In this chapter, we will focus on sensory testing, including "static" quantitative sensory testing (QST) and "dynamic" conditioned pain modulation (CPM), as well as skin punch biopsy and their role as susceptibility, diagnostic, prognostic, predictive, and pharmacodynamic biomarkers. Although sensory testing does not completely correspond to the definition of a biomarker as an objective measurement because of its psychophysical nature, it is discussed here as there are promising hints for its use as a biomarker, and at least for QST, there exists a standardized protocol with reference values.

Quantitative Sensory Testing

Sensory testing of chronic pain patients has become more relevant recently, as the heterogeneous clinical presentation of pain patients has become increasingly recognized.

Concerning neuropathic pain, patients with the same pain etiology can present with various symptoms and signs, for example, the simultaneous presence of mechanical allodynia and thermal hypesthesia in the same patient with postherpetic neuralgia. In contrast, different pain etiologies can share similar somatosensory abnormalities. The different somatosensory abnormalities are thought to reflect the underlying pathophysiologic mechanisms in chronic pain patients. For example, mechanical hyperalgesia, i.e. enhanced pain to punctate stimuli and dynamic allodynia, are thought to reflect central sensitization mechanisms, whereas increased sensitivity to heat can be related to primary hyperalgesia, i.e. peripheral sensitization of nociceptive afferents.[7]

Up to now, treatment of chronic pain has been based on the underlying etiology. However, current recognition of the heterogeneous clinical presentations of chronic pain has led to the concept of a mechanism-based therapy with stratification and treatment of patients according to the underlying pathophysiologic mechanisms.[8] An exact classification of patients according

TABLE 21.1 Categories Of Biomarkers According to the Biomarkers, EndpointS and other Tools (BEST) Glossary of the United States Food and Drug Administration (FDA)[3]

Category	Definition
Susceptibility/risk	potential for developing a disease in an individual without clinically apparent disease
Diagnostic	detect/confirm the presence of a disease or condition of interest or identify individuals with a subtype of the disease
Monitoring	assess the status of a disease or medical condition or for evidence of exposure to (or effect of) a medical product or an environmental agent
Prognostic	identify the likelihood of a clinical event, disease recurrence, or progression in patients who have the disease of interest
Predictive	identify individuals who are more likely than similar individuals without the biomarker to experience a favorable or unfavorable effect from exposure to a medical product or an environmental agent
Pharmacodynamic/ response	show that a biologic response has occurred in an individual who has been exposed to a medical product or an environmental agent
Safety	measured before or after an exposure to a medical product or an environmental agent to indicate the likelihood, presence, or extent of toxicity as an adverse effect

to their somatosensory profile is necessary to realize this concept and might lead to improved treatment response.

Diagnostic

QST allows for the quantification of the somatosensory function of the peripheral and central nervous system, including non-nociceptive (Aβ-) and nociceptive fibers (Aδ- and C-fibers) by applying calibrated mechanical (e.g. graded von Frey hairs) and thermal stimuli to the skin, whose intensity or painfulness are evaluated by the patient.

Many different QST procedures, mainly thermal testing procedures, have been used in the past to assess sensory function, especially in patients with neuropathic pain. One advantage of QST is the ability to assess the entire somatosensory system, including both large and small nerve fibers, in contrast to conventional electrophysiology (electromyogram/nerve conduction studies), which primarily assess large nerve fibers. Therefore QST has been used for the early diagnosis of diabetic polyneuropathy showing abnormal vibration and thermal detection thresholds. Compared to clinical examination or nerve conduction studies, the sensitivity of QST ranges from 27%–98% for cold or 58%–84% for vibration in diabetic neuropathies.[9] Pure small fiber neuropathies are characterized by an isolated lesion of thin myelinated Aδ-fibers or unmyelinated C-fibers. Affected patients complain about burning or electric shock-like pain, tingling, pins and needles as well as impaired thermal perception. While nerve conduction studies are per definition normal in these entities, QST shows abnormal thermal thresholds indicative of small nerve fiber damage.[10] Therefore QST has been recommended as a diagnostic tool to screen for cold and warm deficits in patients with suspected neuropathy with small fiber involvement, e.g. early diagnosis of diabetic neuropathy or diagnosis of small fiber neuropathy.[9]

In addition, altered sensory function was shown to be present in different neuropathic pain etiologies such as postherpetic neuralgia (PHN) or central pain. Compared to reference data of 162 healthy controls, almost half of patients with PHN are characterized by dynamic mechanical allodynia.[11] In addition, patients frequently exhibit abnormal loss to thermal or mechanical detection parameters. QST abnormalities were also found in pain conditions other than neuropathic pain, such as fibromyalgia, chronic low back pain, osteoarthritis, and migraine. A meta-analysis of 41 studies using QST for phenotyping patients with osteoarthritis showed that decreased pressure pain thresholds at both affected and unaffected sites could differentiate between patients and healthy controls.[12] Many studies used sensory testing in fibromyalgia patients. Affected patients were shown to be characterized by altered thermal thresholds for heat and cold pain.[13,14] In addition, increased sensitivity to pressure pain is a common sign in fibromyalgia patients.[15]
