mechanically ventilated infants, maintenance of thermal stability and oxygen saturation, increased feeding ability and tolerance, and maintenance of organized state (Conde-Agudelo & Díaz-Rossello, 2016). In term and preterm newborns, skin-to-skin contact has a strong analgesic effect during painful procedures such as heel lance (Johnston et al., 2017). LBW newborns receiving skin-to-skin contact maintain higher oxygen saturation and are less likely to have desaturations below 90%. In addition, their mothers are more likely to continue breastfeeding both in the hospital and for 1 month after discharge. Kangaroo care of preterm infants fosters neurobehavioural development by promoting stability of cardiac and respiratory function, minimizing purposeless movements, offering maternal proximity, improving the infant's behavioural state, and permitting self-regulating behaviours (Johnston et al., 2017).

Co-bedding of twins (or multiples) is another developmental intervention that involves placing twins or other multiples together in the same crib or isolette while in the NICU, in an effort to enhance newborn growth and development. Co-bedding twins in NICU has been noted to contribute to improved self-regulation and sleep patterns without negatively affecting the incidence of sepsis or caregiver error (Hayward et al., 2015). However, there is insufficient evidence to fully endorse co-bedding of hospitalized multiple-birth infants.

Studies have confirmed the beneficial effects of developmental care with preterm infants. In addition to requiring fewer days of mechanical ventilation, preterm infants who received individualized developmental care had shorter hospital stays, a significant decrease in complications (i.e., intraventricular hemorrhage [IVH] and BPD), less need for sedation when critically ill, improved neurodevelopmental scores at 9, 18, and 36 months of life, and a decrease in feeding intolerance (Westrup et al., 2007).

Developmental care for preterm infants has expanded to a wide variety of interventions, such as infant massage, playing of soothing soft music, recordings of parents reading stories, positioning to enhance self-regulatory abilities, and enhancement of hand-to-mouth activities. Active participation in providing a developmentally supportive environment for their infant involves the parents in daily caregiving activities when the newborn is critically ill and may not be fed or held.

As preterm infants mature, their environment plays a critical role in recovery while optimizing growth and development. Health care team members and parents can enhance the newborn's neurobehavioural development by becoming adept at reading the infant's behavioural cues and supplying appropriate interventions (Table 28.3).

Family Support and Involvement. Health care workers often are so absorbed in the life-saving physical aspects of care that they ignore the emotional needs of infants and their families. The significance of early parent–child interaction and infant stimulation has been documented by reliable research. Nurses must be aware of these infant and family needs and incorporate activities that facilitate family interaction into the nursing care plan.

TABLE 28.3 Signs of Stress or Fatigue in Newborns

Subsystem	Signs of Stress
Respiratory	Tachypnea, pauses, gasping, sighing
Colour	Mottled, flushed, dusky, pale or grey
Visceral	Hiccups, gagging, choking, spitting up, grunting and straining as if having a bowel movement, coughing, sneezing, yawning
Autonomic	Tremors, startles, twitches
Motor	Fluctuating tone; lack of control over movement, activity, and posture; increased motor activity; progressively frantic diffuse activity if stimulation continues
Flaccidity	Low tone in trunk; limp, floppy upper and lower extremities; limp, drooping jaw (gape face)
Hypertonicity	Arm or leg extensions, arm(s) outstretched with fingers splayed in salute gesture, fingers stiffly outstretched, trunk arching, neck hyperextended
Hyperflexion	Trunk, extremities, fisting
Activity	Squirming; frantic, diffuse activity or little or no activity or responsiveness
State	Disorganized quality to state behaviours, including available states, maintenance of state control, and transition from one state to another; Roving eyes; gaze averting; glazed, unfocused look or worried, panicked expression; weak cry; cry-face; irritability
	Closed eyes and sleeplike withdrawal
	Abrupt state changes
	Signs of stress when presented with more than one type of stimulus at a time
Sleep	Whimpering sounds, facial twitching, irregular respirations, fussing, grimacing, restless appearance
Awake	Glazed, unfocused look; staring; worried or pained expression; hyperalert or panicked appearance; eye roving; crying; cry-face; actively averting gaze or closing eyes; irritability; prolonged awake periods; inconsolability; frenzy
	Abrupt or rapid state changes
Other state-related behaviours and attention interaction	Efforts to attend to and interact with environmental stimulation eliciting signs of stress and disorganized subsystem functioning
Autonomic	Physiological instability of varying degrees with autonomic, respiratory, colour, and visceral responses

Data from Alvarez-Garcia, A., Fornieles-Deu, A., Costas-Moragas, C., & Botet-Mussons, F. (2014). Maturational changes associated with neonatal stress in preterm infants hospitalized in the NICU. *Journal of Reproductive and Infant Psychology, 32*(4), 412–422; Lin, H. C., Huang, L. C., Li, T. C., et al. (2014). Relationship between energy expenditure and stress behaviors of preterm infants in the neonatal intensive care unit. *Journal for Specialists in Pediatric Nursing, 19*(4), 331–338; Sweeney, J., & Blackburn, S. (2013). Neonatal physiological and behavioral stress during neurological assessment. *Journal of Perinatal and Neonatal Nursing, 27*(3), 242–252.

The birth of a preterm infant is an unexpected and stressful event for which families are often emotionally unprepared. They find themselves simultaneously coping with their own needs, the needs of their newborn, and the needs of their family (especially when they have other children). To compound the situation, their newborn's precarious condition engenders an atmosphere of apprehension and uncertainty. Parents are often faced with multiple crises and overwhelming feelings of responsibility, helplessness, and frustration.

All parents have some anxieties about the outcome of a pregnancy, but after a preterm birth the concern is heightened for both the viability and normalcy of their infant. Mothers may see their newborn only briefly before the newborn is removed to the NICU or even to another hospital, leaving them with just the recollection of the newborn's very small size and unusual appearance. They often feel alone or lost on the mother–baby unit, belonging neither with mothers who have lost their infants nor with those who have given birth to healthy, full-term newborns. The staff and physicians are often guarded in discussing the infant's condition; mothers may be expecting to hear that their newborn has died, and they are sensitive to the anxieties of other mothers and staff members. Going home without their baby only compounds their feelings of disappointment, failure, and deprivation. See Transport to a Regional Centre later in the chapter for care of the family when their newborn is transferred to another hospital.

Parents need to be informed of their newborn's progress and reassured that the baby is receiving proper care. They need to understand the smallest aspects of the newborn's condition and treatment. Parents need a realistic, honest, and direct assessment of the situation. Using nonmedical terminology, moving at a pace that is comfortable for parents to assimilate the information, and avoiding lengthy technical explanations all facilitate communication with family members. Psychological tasks that must be accomplished by parents during their infant's care are presented in Box 28.4. See Family-Centred Care box: Preterm Infant.

FAMILY-CENTRED CARE

Preterm Infant

A multiparous, single woman had a preterm infant born at 28 weeks' gestation and the newborn was subsequently transported to an NICU in a city 125 kilometres away from her home town. The mother is to be discharged tomorrow. The newborn will likely require a stay in the NICU for at least 6 to 8 weeks. What information should the transport team provide the mother? What methods of assistance will this mother need now? Identify resources in the community that have services of potential benefit to the woman. Use your community or town as a guide to such resources.

BOX 28.4 Psychological Tasks of Parents of a High-Risk Infant

- Work through the events surrounding labour and birth.
- Acknowledge that the newborn's life is endangered and begin the anticipatory grieving process.
- Confront and recognize feelings of inadequacy and guilt in not giving birth to a healthy child.
- Adapt to the neonatal intensive care environment.
- Resume parental relationships with the sick infant and initiate the caregiving role.
- Prepare to take the infant home.

Modified from Gardner, S. L., & Voos, K. (2021). Families in crisis: Theoretical and practical considerations. In S. L. Gardner, B. S. Carter, M. Enzman-Hines, et al. (Eds.), *Merenstein and Gardner's handbook of neonatal intensive care: An interprofessional approach* (9th ed.). Elsevier.

Facilitating parent–infant relationships. Because of their physiological instability, newborns are separated from their mothers immediately and surrounded by barriers including isolette walls, mechanical equipment, and special caregivers. There is some evidence indicating that the emotional separation that accompanies the physical separation of mothers and newborns may interfere with the normal mother–infant attachment process, discussed in Chapter 23. Maternal attachment is a cumulative process that begins before conception, strengthens with significant events during pregnancy, and matures through mother–infant contact during the newborn period and infancy.

When a newborn is sick, the necessary physical separation appears to be accompanied by an emotional estrangement by the parents, which may seriously damage the capacity for parenting their infant. This detachment is further hampered by the tenuous nature of the newborn's condition. When survival is in doubt, parents may be reluctant to establish a relationship with their infant. They prepare themselves for the infant's death while continuing to hope for recovery. This **anticipatory grief** and hesitancy to embark on a relationship are evidenced by behaviours such as delay in giving the newborn a name, reluctance in visiting the nursery (or when they do visit, focusing on equipment and treatments rather than on their newborn), and hesitancy to touch or handle the newborn when given the opportunity.

Preparing parents to see their newborn for the first time is an important nursing responsibility. The nurse needs to prepare them for their newborn's appearance, the equipment attached to the child, and the general atmosphere of the unit. The initial encounter with the NICU is a stressful experience; and the frightening array of people, equipment, and activity is likely to be overwhelming. A book of photographs or pamphlets describing the NICU environment (infants in isolettes or under radiant warmers, monitors, mechanical ventilators, and IV equipment) provides a useful and nonthreatening introduction to the NICU. At the bedside the nurse should explain the function of each piece of equipment and the role it plays in facilitating recovery. Explanations may often need to be patiently repeated because parents' anxiety over the newborn's condition and the surroundings may prevent them from really "hearing" what is being said. When possible, some items related to therapy can be removed (e.g., phototherapy can be discontinued temporarily, and eye patches removed to permit eye-to-eye contact).

Parents vary greatly in the degree to which they are able to interact with their newborn. Some may wish to touch or hold their newborn during the first visit, but others may not feel comfortable enough to even enter the nursery. These reactions depend on a variety of prenatal and postnatal factors, such as the parity of the mother and their preparation before birth; the newborn's size, condition, and physical appearance; and the type of treatment the newborn is receiving. It is essential to recognize that the individualized pacing and quality of the interactions are more important than an early onset of these interactions. Parents may not be receptive to early and extended newborn contact because they need time to adjust to the impact of an infant with health issues at birth and may need to grieve the loss of their anticipated birth of a healthy newborn before they can begin the process of attachment.

Research indicates that approximately one third of fathers experience depressive symptoms and 7% of new fathers are diagnosed with depression (Noergaard et al., 2018). Creating a father-friendly culture within the NICU setting may aid in reducing paternal stress. Guiding principles that contribute to a father-friendly neonatal unit can include encouraging paternal skin-to-skin contact with their newborn as soon as feasible, ensuring that fathers receive information updates directly from health care providers and not only through the mothers, and providing opportunities for fathers to participate in early milestone events, including first baths or movement from isolette to open bed (Noergaard et al., 2018).

The parents' inability to focus on their newborn is a clue for the nurse to help them express and deal with feelings of guilt, anxiety, helplessness, inadequacy, anger, and ambivalence. Nurses can help them recognize that these are normal responses shared by other parents. It is important to point out and reinforce the positive aspects of parents' behaviour and interactions with their newborn.

Parents of preterm infants follow the same acquaintance process as that of parents of term newborns. They begin by touching their newborn's extremities with their fingertips and stroking the newborn tenderly and then proceed to caresses and fondling (Figure 28.8). Touching is the first act of communication between parents and child. Parents need to be prepared for their newborn's exaggerated and generalized startle responses to touch so they do not interpret these as negative reactions to their overtures. It may be necessary to limit tactile stimuli when the newborn is critically ill and labile, but the nurse can offer other options, such as speaking softly or reading stories to their newborn while at the bedside.

Eventually, parents begin to endow their newborn with an identity—as part of the family. When a newborn no longer appears as a foreign object and begins to take on features of family members, such as the father's chin or a sibling's nose, nurses can facilitate this incorporation. Parents are encouraged to bring in clothes or a family snapshot for their infant; and the nurse can help them set goals for themselves and the child. Parents can be taught to recognize their newborn's cues for stimulation, handling, and other interaction, especially aversive behaviours that indicate a need for rest. Some families record the parents' voices telling or reading stories and play the recordings when the infant is able to cope with such stimuli.

Above all, nurses and other members of the interprofessional care team must encourage and reinforce parents during their caregiving activities and interactions with their newborn to promote healthy parent–child relationships. It is also helpful for the parents to have contact and communication with a consistent group of nurses. This decreases the amount of different information given to them and often instills confidence that, although they cannot be at their infant's bedside 24 hours a day, there are competent and caring nurses whom they may call to inquire about the newborn's status. Periodic parent conferences involving the staff caring for the child serve to clarify misunderstandings or issues related to the infant's condition.

Support groups for parents of infants in intensive care nurseries are often a source of comfort and support for parents who may feel isolated from peers because of the birth of the preterm infant. Groups can encourage parents experiencing anxiety and grief to share their feelings. A parent with NICU experience may make contact with a new member and provide additional support. These parents can support the new NICU parent through hospital visits, phone contact, email or video conference, and home visits.

Some high-risk infants may be discharged earlier than expected. Criteria for early discharge require the infant to be physiologically stable, receive and ingest adequate nutrition, consistently gain weight, and maintain a stable body temperature in an open bassinet. In addition, screening for hyperbilirubinemia, newborn metabolic and hematological conditions, safe transportation, and hearing should occur before the preterm infant's discharge. An evaluation of the home environment and family resources, and arrangements for appropriate medical follow-up are essential. The parents or other caregivers must exhibit physical, emotional, and educational readiness to assume care of the infant. The parents need to show that they know how to take the infant's temperature, recognize signs and symptoms of illness, and understand the infant's dietary needs (Jefferies & Canadian Paediatric Society [CPS] Fetus and Newborn Committee, 2014/2020).

Parent Education. Sudden infant death syndrome (SIDS) is more likely to occur in preterm infants than in term infants. Infants discharged from an NICU are almost twice as likely to die unexpectedly during the first year of life as infants in the general population. Instruction in **cardiopulmonary resuscitation (CPR)** is essential for parents of all infants but especially for parents of infants at risk for life-threatening events. Risk factors for SIDS include preterm birth, apnea or bradycardia spells, neurological immaturity, and the tendency to choke. All parents should be encouraged to obtain instruction in CPR at the hospital, local Red Cross, or other community agency. It should be emphasized that CPR knowledge does not preclude the need for proper positioning of the infant in the crib (i.e., supine, unless otherwise directed by the primary care provider) when put to sleep. In addition, the bed should have a firm mattress and be free of extra blankets and stuffed animals or toys, which may cause the infant to become entangled and subsequently smothered.

Complications of Prematurity

Respiratory Distress Syndrome. *Respiratory distress, respiratory failure,* and *respiratory distress syndrome (RDS)* are terms that are used interchangeably but mean different things. The first two terms represent symptoms whereas RDS represents a lung disorder usually affecting preterm infants. Primary RDS is caused by surfactant deficiency, as the preterm infant does not have full lung maturity to produce adequate

Fig. 28.8 **A:** Mother interacts with her preterm infant by touch. **B:** Father interacts with his newborn by talking to his infant. (*A,* iStock.com/metinkiyak. *B,* BSIP/Science Source.)

amounts of surfactant. Surfactant reduces surface tension and helps to maintain lung alveoli open. The incidence and severity of RDS increase as gestational age decreases. Lack of exposure to antenatal corticosteroids, maternal diabetes, perinatal infection, Caesarean birth without labour, **hydrops fetalis**, and third-trimester bleeding are factors that also place an infant at increased risk for RDS (Gardner, Enzman-Hines, et al., 2021). Alternatively, conditions associated with a decrease in the incidence and severity of RDS include female gender, **intrauterine growth restriction (IUGR)**, and stressors such as maternal hypertension (gestational), maternal substance use, chronic placental abruption, and prolonged rupture of membranes.

The diagnosis of RDS is made on the basis of clinical manifestations (Box 28.5) and radiographic studies. Radiographic findings characteristic of RDS include (1) a diffuse granular pattern over both lung fields that closely resembles ground glass and represents alveolar atelectasis, (2) dark streaks, or bronchograms, within the ground-glass areas that represent dilated, air-filled bronchioles, and (3) low lung volumes (Jensen et al., 2017). RDS can be difficult to distinguish from pneumonia and other causes of respiratory failure. The extent of respiratory function and acid–base balance is determined by blood gas analysis. Pulse oximetry, carbon dioxide monitoring, and pulmonary function studies help to differentiate pulmonary and extrapulmonary illness.

The treatment of RDS involves immediate establishment of adequate oxygenation and ventilation, supportive care and measures required for any preterm infant, and those instituted to prevent further complications associated with preterm birth (see Evolve for Nursing Care Plan).

The supportive measures most crucial to a favourable outcome in RDS are to:

- Maintain adequate ventilation and oxygenation.
- Maintain acid–base balance.
- Maintain an NTE.
- Maintain adequate tissue perfusion and oxygenation.
- Prevent hypotension.
- Maintain adequate hydration and electrolyte status.

Surfactant replacement therapy. **Surfactant** is a surface-active phospholipid secreted by the alveolar epithelium, typically occurring between 26 and 34 weeks' gestation, and results in expansion and maintenance of lung expansion at low intra-alveolar pressure. Deficient surfactant production causes unequal inflation of alveoli on inspiration and the collapse of alveoli on expiration. Without surfactant, newborns are unable to keep their lungs inflated and thus exert a great deal of effort to re-expand the alveoli with each breath. As infants tire, they open fewer and fewer alveoli, leading to widespread atelectasis.

BOX 28.5 Clinical Manifestations of Respiratory Distress Syndrome

- Tachypnea (≥60 breaths/min) initially*
- Dyspnea
- Pronounced intercostal or substernal retractions
- Fine inspiratory crackles
- Audible expiratory grunt
- Flaring of the external nares
- Cyanosis or pallor
- Apnea
- With progression of condition, deteriorating vital signs, including blood pressure, apnea, body temperature instability

*Not all infants born with respiratory distress syndrome manifest these characteristics; very-low-birth-weight and extremely-low-birth-weight infants may have respiratory failure and shock at birth because of physiological immaturity.

Criteria for surfactant replacement have been explored in numerous trials, with extensive consideration given to prophylactic versus rescue therapy, timing of administration, as well as method of administration for preterm infants (Davis et al., 2005/2017). Current practice is to administer early rescue therapy for infants born prior to 30 weeks' gestation who require ventilation because of RDS (Polin et al., 2014). A course of one or two doses is given through an endotracheal tube (Figure 28.9). Close monitoring for potential adverse effects (apnea, bradycardia, desaturation, plugging of the endotracheal tube, pulmonary hemorrhage, pneumothorax) is essential. As noninvasive respiratory support increasingly becomes a primary method of respiratory support, minimally invasive surfactant therapy (MIST) administration has followed (Niemarkt et al., 2017). Four methods of MIST administration include intrapharyngeal, aerosolization, via laryngeal mask, and via tracheal catheterization, although additional research is required to determine the optimal route and eligibility criteria.

Inhaled nitric oxide (iNO). Distinguishing hypoxemic respiratory failure from severe RDS creates challenges for neonatal clinicians. **Persistent pulmonary hypertension** of the newborn (PPHN) occurs in infants of all gestational ages, including LBW infants. In preterm infants with significant primary lung disease caused by surfactant deficiency, progressive atelectasis may occur and lead to increased pulmonary vascular resistance with the inherent sequelae of reduced pulmonary blood flow and hypoperfusion of the lung. The increase in peripheral vascular resistance contributes to right-to-left shunting of blood through fetal communications, the ductus arteriosus and foramen ovale, as demonstrated through echocardiography studies and results in further hypoxemia. Inhaled nitric oxide (iNO), a colourless gas administered through the ventilator circuit, provides pulmonary vasodilation and reduces the pulmonary vascular resistance, leading to improved oxygenation. Surfactant replacement therapy and alveolar recruitment strategies remain first-line treatment modalities. A trial of iNO therapy may be clinically indicated in preterm infants with echocardiography confirmed pulmonary hypertension (Giesinger et al., 2017). Nursing care of the preterm infant receiving iNO therapy for pulmonary hypertension includes judicious monitoring of oxygen

Fig. 28.9 Exogenous surfactant administration via endotracheal tube. (Courtesy E. Jacobs, Texas Children's Hospital.)

saturation levels, which are typically targeted at >95% with titration of oxygen as indicated.

Extracorporeal membrane oxygenation (ECMO). High-frequency ventilation known as ECMO is not typically used in infants less than 34 weeks' gestation because the anticoagulant therapy required in the pump and circuits may increase the potential for IVH. Additionally, the size of the cannulae required are not suitable for preterm infants. However, institutional approaches and individual circumstances of the newborn may give rise to variations in ECMO utilization.

Patent Ductus Arteriosus. The ductus arteriosus is a muscular contractile structure in the fetus connecting the left pulmonary artery and the dorsal aorta. The ductus constricts after birth as oxygenation increases. Other factors that promote ductal closure include catecholamines, low pH, bradykinin, and acetylcholine. When the fetal ductus arteriosus fails to close after birth, a patent ductus arteriosus (PDA) exists. Ductal closure usually occurs within hours or days in the term newborn but may be delayed in preterm infants as a result of reduced oxygenation and circulating **hormones** (prostaglandins).

The clinical presentation of an infant with a PDA includes systolic murmur, active precordium, bounding peripheral pulses, tachycardia, tachypnea, crackles on auscultation of air entry, and hepatomegaly. The systolic murmur is heard best at the second or third intercostal space at the upper left sternal border. An active precordium is caused by an increased left ventricular stroke volume. A widened pulse pressure may result in bounding peripheral pulses.

Radiographic studies of infants with a large PDA typically show cardiac enlargement and pulmonary edema; with a smaller PDA, the radiograph may appear normal for the infant's age (Swanson & Erickson, 2021). Blood gas analysis reveals hypercarbia and metabolic acidosis. A colour flow Doppler echocardiograph can demonstrate a PDA and be used to identify the direction of the shunting (left to right, right to left, or both) and quantify the amount of blood shunting across the PDA.

A PDA can be managed medically or surgically. Medical management consists of ventilatory support aimed to reduce ductal shunt volume, fluid restriction, diuretics, and medications, such as indomethacin, ibuprofen, or acetaminophen. Indomethacin is a prostaglandin synthetase inhibitor that blocks the effect of the arachidonic acid products on the ductus and causes the PDA to constrict. Ibuprofen has a similar pharmacological action profile and reportedly has fewer adverse effects than indomethacin, yet a recent Cochrane review reported that they are equally effective (Ohlsson et al., 2020). Acetaminophen provided for 3 to 7 days has demonstrated a positive impact on ductal closure and is currently used as a second-line medication option (Oncel et al., 2014).

Surgical ligation has been performed when a PDA is clinically significant and medical management has failed. Postligation cardiac syndrome has sometimes contributed to a period of postoperative instability requiring anticipatory management to offset hypoxia and hypoperfusion (Giesinger et al., 2019). Percutaneous PDA occlusion is an evolving alternative intervention for VLBW infants with symptomatic PDAs; comparative evidence evaluating percutaneous occlusion versus other therapies is not available (Backes et al., 2019). Nursing interventions for the newborn with a PDA focus on supportive care. The newborn requires an NTE, adequate oxygenation, and meticulous fluid balance.

Periventricular-Intraventricular Hemorrhage. **Periventricular-intraventricular hemorrhage (PV-IVH)** is one of the more common types of neurological injuries that occurs in newborns and is among the most severe in both short- and long-term outcomes. While the true incidence of PV-IVH is unknown, a general estimate is 15% in newborns less than 32 weeks of gestation or under 1 500 g (Volpe, 2017). Research has shown that contributing events may occur antenatally and postnatally (Merhar & Thomas, 2020).

The pathogenesis of PV-IVH includes intravascular factors (e.g., fluctuating or increasing cerebral blood flow, increased cerebral venous pressure, and coagulopathy), vascular factors, extravascular factors (hypoglycemia, acidosis), and routine medical care (rapid volume expansion, blood transfusion). The developing preterm infant's brain has highly vascularized areas with fragile blood vessels that are prone to bleeding when homeostasis is not maintained; the most commonly affected area is in and around the subependymal germinal matrix. PV-IVH events typically occur within the first 72 hours of birth; PV-IVH is classified according to severity, which informs long-term neurodevelopmental outcomes. Posthemorrhagic ventricular dilatation progresses in approximately 30 to 50% of infants with serious IVH, and without timely intervention, further damage of the white matter may occur (Leijser et al., 2018). Ventriculoperitoneal shunt insertion may also be necessary to relieve ensuing hydrocephalus.

Nursing care focuses on recognition of factors that increase the risk for PV-IVH, interventions to decrease the risk of bleeding, and supportive care to infants who have bleeding episodes. The newborn is positioned with their head in midline and the head of the bed elevated to 30° to prevent or minimize fluctuations in intracranial blood pressure during the first 72 hours of life. An NTE is maintained, as well as oxygenation to target saturation levels. Rapid infusions of fluids should be avoided. Blood pressure should be monitored closely for fluctuations.

Necrotizing Enterocolitis. Necrotizing enterocolitis (NEC) is an acute inflammatory disease of the bowel with increased incidence in preterm infants. The precise cause of NEC is still uncertain, but it appears to occur in newborns whose gastrointestinal tracts have experienced vascular compromise. Intestinal ischemia of unknown etiology, immature gastrointestinal host defenses, bacterial proliferation, and feeding practices play a multifactorial role in the etiology of NEC. Preterm birth remains the most prominent risk factor for development of NEC (Brown, 2020). However, NEC does occur in term newborns, although rare.

The damage to mucosal cells lining the bowel wall may be significant. Diminished blood supply causes cell death and a reduction in secreting protective, lubricating mucus. The thin, unprotected bowel wall is attacked by proteolytic enzymes; the bowel wall continues to swell and break down and is unable to synthesize protective IgM. Gas-forming bacteria invade the damaged areas to produce **pneumatosis intestinalis**, the presence of gas in the submucosal or subserosal surfaces of the bowel.

A consistent relationship has been observed between the development of NEC and enteric feeding of hypertonic substances (e.g., formula, hyperosmolar medications). It is unclear whether this connection is a result of the formula imposing a stress on an ischemic bowel or serving as a substrate for bacterial growth or possibly a combination of these factors.

Breast milk is the preferred enteral nutrient because it confers some passive immunity (IgA), macrophages, and lysozymes. Donated breast milk for eligible preterm infants may help to decrease the risk of NEC (see Chapter 27, Milk Banking).

The early clinical signs of NEC are subtle and nonspecific and may often be overlooked for other conditions and may include decreased activity, hypotonia, pallor, recurrent apnea and bradycardia, respiratory distress, metabolic acidosis, **oliguria**, hypotension, decreased perfusion, temperature instability, and cyanosis. Clinical manifestations include abdominal distension, bilious vomiting, bloody stools,

abdominal tenderness, and erythema of the abdominal wall (Gallagher et al., 2021).

Diagnosis of NEC is confirmed by radiographic examination that reveals bowel loop distension, pneumatosis intestinalis, pneumoperitoneum, portal air, or a combination of these findings. Laboratory evaluation includes a complete blood count (CBC) with differential, blood culture, coagulation studies, arterial blood gas analysis, and serum electrolyte levels. The white blood cell count may be either increased or decreased. The platelet count and coagulation studies may be abnormal, with thrombocytopenia and evidence of disseminated intravascular coagulation. Electrolyte levels may be abnormal, related to leaking capillary beds and fluid shifts seen with inflammatory illnesses.

Treatment is with bowel rest and broad-spectrum antibiotic therapy, typically for 7 to 10 days, depending on severity and progression of illness. A nasogastric tube is inserted and placed to low intermittent suction to provide gastric decompression; parenteral therapy is commenced.

If there is progressive deterioration or evidence of perforation, surgical intervention may be indicated. Resection and primary anastomosis may be performed; extensive bowel involvement may require establishment of an ileostomy, jejunostomy, or colostomy. Recovery may be delayed; sequelae may include short-bowel syndrome, stricture with obstruction, malabsorption, and failure to thrive secondary to intestinal dysfunction. Post-NEC intestinal failure–associated liver disease, clinically manifested as an elevated conjugated bilirubin greater than 100 mcmol/L, may be linked to parenteral lipids and septic events and requires consideration for lipid restriction or alternative lipid products, including omega-3 lipid emulsions (Mutanen & Wales, 2018). Bowel adaptation and bowel-lengthening procedures have reduced but not eliminated indications for pediatric intestinal transplantation secondary to intestinal failure (King et al., 2013).

The Post-Term Infant

Post-term (or postmature) infants are those whose gestation is prolonged beyond 42 weeks, regardless of birth weight. These infants may be large or small for gestational age, but most often their weight is appropriate for gestational age. The rate of infants born post-term has been declining and was 0.3 in 2014 (Public Health Agency of Canada [PHAC], 2017). The cause of prolonged pregnancy is unknown. **Postmaturity** can be associated with placental insufficiency, resulting in a newborn that has a thin, emaciated appearance at birth because of loss of subcutaneous fat and muscle mass. Not all post-term infants demonstrate features of postmaturity. There may be dry, loose, peeling skin; meconium staining of the fingernails; the hair and nails may be long; and vernix may be absent.

During labour and birth, increased oxygen demands of the post-term fetus may not be met. Insufficient gas exchange in the post-term placenta increases the likelihood of intrauterine hypoxia. This may result in the passage of meconium in utero and the risk for meconium aspiration syndrome. In one study, post-term infants were found to have a mortality rate almost three times higher than that of a control group of term infants (Brady & Poindexter, 2020).

Meconium Aspiration Syndrome

Meconium staining of the amniotic fluid (MSAF) may be present with atypical or abnormal fetal heart rate patterns and may be indicative of stress in utero. Globally, MSAF appears in 10 to 15% of all live births, primarily in term and post-term births, with 5% being at risk of developing meconium aspiration syndrome (MAS) (Paudel et al., 2020). Many infants with meconium staining exhibit no signs of concerns at birth; however, the presence of meconium in the amniotic fluid necessitates careful supervision of labour and close monitoring of fetal well-being. The presence of a team skilled in neonatal resuscitation is required at the birth of any infant with MSAF (Figure 28.10). Current resuscitation guidelines assert that there is not enough evidence to suggest routine tracheal intubation and suctioning of meconium below the cords for nonvigorous infants who present with MSAF (Perlman et al., 2015). Instead, gentle oropharyngeal suctioning of the mouth and nose, as required, is indicated. Presence of thick meconium that appears to obstruct the newborn's airway may require intubation for suctioning and establishing airway clearance (Perlman et al., 2015).

Fig. 28.10 Infant being resuscitated at birth. Note presence of meconium on abdomen and umbilical cord. (Courtesy Shannon Perry.)

If meconium is not removed from the airway at birth it can migrate down to the terminal airways, causing mechanical obstruction and lead to MAS. Diagnosis is premised on symptoms of respiratory distress and chest X-ray findings demonstrating hyperinflation with atelectasis. Chemical pneumonitis and pulmonary hypertension may further complicate management. Meconium inhibits surfactant function. Ventilation, exogenous surfactant, iNO, or ECMO may be used for treatment.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN) is a term applied to the combined findings of pulmonary hypertension and right-to-left shunting through fetal heart communications, in the context of a structurally normal heart. PPHN may manifest either as a single entity or a sequela of MAS, congenital heart disease, RDS, hyperviscosity syndrome, neonatal pneumonia, or sepsis. PPHN may be referred to as *persistent fetal circulation* because the disease involves reversion to fetal pathways of blood flow.

A brief review of fetal blood flow can help with visualizing the concerns with PPHN (see Figure 9.15). In utero, oxygen-rich blood leaves the placenta via the umbilical vein, goes through the ductus venosus, and enters the inferior vena cava. From there it empties into the right atrium and is mostly shunted across the foramen ovale to the left atrium, effectively bypassing the lungs. This blood enters the left ventricle, leaves through the aorta, and preferentially perfuses the carotid and coronary arteries—the heart and brain receive the most oxygenated blood. Blood drains from the brain into the superior vena cava, reenters the right atrium, proceeds to the right ventricle, and exits through the main pulmonary artery. The lungs, a high-pressure circuit, need only enough perfusion for growth and nutrition. The ductus arteriosus (connecting the main pulmonary artery and the aorta) provides a

path of least resistance for the blood leaving the right side of the fetal heart and shunts most of the cardiac output away from the lungs and toward the systemic system.

After birth, both the foramen ovale and the ductus arteriosus close in response to biochemical processes, pressure changes within the heart, and dilation of the pulmonary vessels. The reduction in pulmonary vascular resistance allows virtually all of the cardiac output to enter the lungs, become oxygenated, and provide oxygen-rich blood to the tissues. Any process that interferes with transition from fetal to newborn circulation may precipitate PPHN. PPHN characteristically proceeds into a downward spiral of increasing hypoxia, pulmonary vasoconstriction, and oxygenation failure.

Infants with PPHN are often critically ill; prompt recognition and aggressive intervention are required to reverse the process. Management depends on the underlying cause of the persistent pulmonary hypertension. Optimizing ventilation support for underlying lung disease, provision of sedation and muscle relaxation, and treatment with pulmonary vasodilators, including iNO and cardiotropic medications, to support right ventricular dysfunction aid in management. ECMO therapy may be indicated in the management of term newborns with acute severe oxygenation failure that is unresponsive to other treatment modalities.

OTHER CONCERNS RELATED TO GESTATION

Small-for-Gestational-Age Infants and Intrauterine Growth Restriction

Newborns who are SGA or have IUGR are considered high risk, with a perimortality rate 5 to 20 times greater than that for term newborns (Kliegman, 2014). While related, SGA and IUGR are not synonymous terms. IUGR represents a reduction in fetal growth pattern as a result of a perinatal pathophysiological process, whereas SGA refers to birthweight below population growth curves, which may be familial or ethnicity related.

Conditions occurring in the first trimester (e.g., infections, **teratogens**, chromosomal abnormalities) can affect all aspects of fetal growth and result in symmetrical IUGR (i.e., head circumference, length, and weight are all less than the tenth percentile). Infants with symmetrical growth restriction have a smaller head circumference and concomitant reduced brain growth. Growth restriction during later stages of pregnancy, due to maternal or placental factors, typically results in asymmetrical growth restriction—weight will be less than the tenth percentile, whereas length and head circumference will be greater than the tenth percentile, possibly within normal limits. Newborns with asymmetrical IUGR, referred to as *head sparing*, have the potential for normal growth and development.

Care of the SGA newborn is guided by the accompanying clinical concerns and is comparable to the care provided to preterm infants with similar conditions. Common difficulties that affect SGA or IUGR infants are perinatal asphyxia, meconium aspiration, immunodeficiency, hypoglycemia, **polycythemia**, and temperature instability. Gas exchange is supported by maintaining a clear airway and preventing cold stress. Hypoglycemia is treated with oral feedings (e.g., breast milk, formula) or IV dextrose as the newborn's condition warrants. Consideration of donor breast milk when the mother's own milk supply is not established is warranted, in an effort to protect the newborn from NEC (Jackson & Harrington, 2018). An external heat source (radiant warmer or isolette) may be required until the newborn is able to maintain an adequate body temperature.

Hypoglycemia and Hyperglycemia. All high-risk newborns are at risk for hypoglycemia. Newborns who experience physiological stress may experience hypoglycemia as a result of a decreased glycogen supply, inadequate gluconeogenesis, or overutilization of glycogen stored during fetal and postnatal life. Preterm infants may also become hypoglycemic as a result of inadequate intake and increased metabolic demands due to illness (see Chapter 26, Hypoglycemia). The SGA newborn, not unlike the preterm infant, is at higher risk for hypoglycemia as a result of decreased fetal stores and decreased rate of gluconeogenesis.

Hyperglycemia is defined as a blood glucose level greater than 6.9 mmol/L (whole blood) or plasma glucose of 8.0 to 8.3 mmol/L (Blackburn, 2018). Adverse outcomes associated with hyperglycemia include higher rates of sepsis, white matter brain injury, and increased mortality (Hay & Rozance, 2018). Increased circulating levels of glucose may lead to osmotic changes, increased urine output, and fluid shifts in the already compromised CNS of the preterm infant. The net result of hyperglycemia may be cellular dehydration and IVH. Physiological stress associated with surgical procedures also generates periods of hyperglycemia with increased catecholamine release, which inhibits insulin release and glucose utilization (Blackburn, 2018). Reducing glucose intake in perioperative fluid management may dampen the hyperglycemic surge.

Heat Loss. SGA newborns are particularly susceptible to temperature instability as a result of decreased **brown fat** deposit, decreased adipose tissue, large body surface exposure, inability to accomplish flexed position due to poor muscle tone, and decreased glycogen storage in major organs such as the liver and heart. Close attention must be given to maintenance of an NTE.

Large-for-Gestational-Age Infants

A newborn is considered large for gestational age (LGA) when the birth weight is above the ninetieth percentile on growth charts or 2 standard deviations above the mean weight for gestational age. The LGA newborn has a higher incidence of birth injuries, asphyxia, and congenital anomalies such as heart defects. In Canada the rate of newborns who were LGA was 9.9% in 2017 (PHAC, 2021).

LGA newborns may be preterm, term, or post-term; they may be infants of diabetic mothers. Each of these categories carries special concerns. Regardless of coexisting potential health issues, the LGA infant is at risk by virtue of size alone.

The nurse needs to assess the LGA newborn for hypoglycemia and trauma resulting from vaginal or Caesarean birth. Any specific birth injuries should be identified and treated appropriately.

Infants of Diabetic Mothers

The morbidity and mortality of **infants of diabetic mothers (IDMs)** have been reduced significantly as a result of effective control of maternal diabetes and an increased understanding of fetal disorders. Because infants born to a parent with gestational diabetes mellitus (GDM) are at risk for the same complications as IDMs, the following discussion of IDMs also includes infants born to patients with GDM.

The severity of maternal diabetes is determined by the duration of the disease before pregnancy; age of onset; extent of vascular complications; and abnormalities of the current pregnancy, such as pyelonephritis, diabetic ketoacidosis, pregnancy-induced hypertension, and inability to follow treatment regimen. Stable metabolic control that begins before conception and continues during the first weeks of pregnancy may prevent malformation in an IDM. Elevated levels of hemoglobin A1c during the periconception period appear to be associated with a higher incidence of congenital malformations (see Chapter 15, Diabetes Mellitus). In the case of gestational diabetes, macrosomia is the most common finding; serious complications are rare (Feig et al., 2018).

Transition-related hypoglycemia, that which occurs in the first 72 hours of life, is defined as a blood glucose level less than 2.6 mmol/L

(Narvey & Marks, 2019). Monitoring for symptoms of hypoglycemia in an IDM include jitteriness or tremors, cyanotic episodes, seizures, intermittent apneic episodes, and difficulties feeding; informed and educated parents may also be able to provide important observations. Symptomatic hypoglycemia may contribute to neuronal injury; national practice guidelines recommend maintaining glucose levels greater than 2.6 in at-risk infants, which includes IDMs (Narvey & Marks, 2019).

Hypoglycemia in IDMs is related to hypertrophy and hyperplasia of the pancreatic islet cells and thus is a transient state of hyperinsulinism. High maternal blood glucose levels during fetal life provide a continual stimulus to the fetal islet cells for insulin production (glucose easily passes the placental barrier from maternal to fetal side; however, insulin does not cross the placental barrier). When the newborn's glucose supply is removed abruptly at the time of birth, the continued production of insulin soon depletes the blood of circulating glucose, creating a state of hyperinsulinism and hypoglycemia within 0.5 to 4 hours, especially in newborns of mothers with poorly controlled diabetes. Precipitous drops in blood glucose levels can cause serious neurological damage or death. Congenital hyperinsulinism may contribute to persistent hypoglycemia; however, this condition is usually not associated with maternal DM.

IDMs have a characteristic appearance (Box 28.6 and Figure 28.11). Infants of mothers with advanced diabetes may be SGA, have IUGR, or be the appropriate size for gestational age because of the maternal vascular (placental) involvement. There is an increase in congenital anomalies in IDMs in addition to a high susceptibility for hypoglycemia, hypocalcemia, hypomagnesemia, polycythemia, hyperbilirubinemia, cardiomyopathy, and RDS (Landon et al., 2017). CNS anomalies such as anencephaly, spina bifida, and holoprosencephaly occur at rates 10 times higher in IDMs than in infants from any other population of mothers. Cardiac anomalies such as ventricular septal defects and coarctation of the aorta are increased five-fold in IDMs, and sacral agenesis and caudal regression occur almost exclusively in IDMs (Landon et al., 2017). IDMs are more likely to have disproportionately large abdominal circumferences and shoulders, leading to an increased risk of shoulder dystocia and birth injury.

Hyperinsulinemia and hyperglycemia in the diabetic mother may be factors in reducing fetal surfactant synthesis, thus contributing to the development of RDS. Although large, these infants may be born before term as a result of maternal complications or increased fetal size.

Some IDMs are also at increased risk for deep vein thrombosis, with renal vein thrombosis and hematuria being the most common presentation. Additional health concerns in IDMs include perinatal iron deficiency and neurological impairments (seizures, lethargy, jitteriness, and changes in tone) (Hay, 2012).

Important management of IDMs includes careful monitoring of serum glucose levels and observation for accompanying complications such as RDS and cardiac anomalies. Newborns are examined for the presence of any anomalies or birth injuries, and blood studies for determination of glucose, calcium, hematocrit, and bilirubin are obtained on a regular basis.

Because the hypertrophied pancreas is sensitive to blood glucose concentrations, the administration of glucose may trigger an insulin surge, resulting in rebound hypoglycemia. Feedings of breast milk or formula may begin within the first hour after birth, provided that the infant's cardiorespiratory condition is stable. Newborns born to mothers with poorly controlled diabetes may require IV dextrose infusions to prevent serious neurological sequelae (Narvey & Marks, 2019). The Canadian Paediatric Society recommends that symptomatic, hypoglycemic newborns (and asymptomatic newborns who have failed to respond to enteral supplementation) be treated with IV dextrose solution (Narvey & Marks, 2019).

Symptomatic IDMs who are unable to feed should be started on a continuous IV infusion of 10% dextrose at 4 to 6 mg/min/kg unless blood glucose is below 1.8 mmol/L. In such cases a one-time bolus infusion of 10% dextrose (200 mg/kg) should be given over 2 to 4 minutes, followed by a continuous IV infusion of 10% dextrose and water as noted previously (Narvey & Marks, 2019). Evaluation of serum glucose 30 minutes after intervention is required to determine if further stepwise increases in glucose infusion are needed. Additional pharmacological agents that may be required include glucagon and diazoxide, typically after consultation with pediatric endocrinology services.

Nursing Care. The nursing care of IDMs involves early examination for congenital anomalies, signs of possible respiratory or cardiac issues, maintenance of adequate thermoregulation, early introduction of carbohydrate feedings as appropriate, and monitoring of serum blood glucose levels. Testing blood taken from the newborn's heel with calibrated portable reflectance meters (e.g., glucometers) is a simple and effective screening evaluation that can then be confirmed by laboratory examination (see Chapter 26, Heel Stick). IV glucose infusion requires careful monitoring of the site and the newborn's reaction to therapy; high glucose concentrations ($\geq$12.5%) should be infused via a central line instead of a peripheral site. IDMs also need to be monitored for hypocalcemia and hypomagnesemia. Signs of hypocalcemia are similar to those of hypoglycemia and occur typically within the first 24 hours of age. Newborns also need to be monitored closely for hyperbilirubinemia. Because macrosomic newborns are at risk for complications associated with a difficult birth, they are monitored for birth injuries such as brachial plexus injury and palsy, fractured clavicle, and phrenic nerve palsy.

See the Nursing Care Plan, The Infant of a Mother With Diabetes Mellitus on the Evolve site.

BOX 28.6 Clinical Manifestations of Infants of Diabetic Mothers

- Large for gestational age
- Very plump and full faced
- Abundant vernix caseosa
- Plethora
- Listless and lethargic
- Possibly meconium stained at birth
- Hypotonia

Fig. 28.11 Large-for-gestational-age infant. This infant of a diabetic mother weighed 5 kg (11 lb) at birth and exhibits the typical round facies. (From Zitelli, B. J., & Davis, H. W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed.]. Mosby.)

DISCHARGE PLANNING AND TRANSPORT

Discharge Planning

Discharge planning for the high-risk newborn begins early in the hospitalization. Throughout the infant's hospitalization, the nurse must gather information from the health care team members and the family. This information is used to determine the infant's and family's readiness for discharge.

As the nurse assesses the discharge needs of the infant's parents, steps can be taken to eliminate any knowledge deficits. Discharge teaching for the high-risk newborn's family is extensive, requires time and planning, and cannot be accomplished on the day of discharge alone. Information should be provided about infant care, especially as it pertains to the infant's particular needs (e.g., supplemental oxygen, gastrostomy feedings, follow-up medical visits). Parent education includes having them give return demonstrations of their infant care skills to show whether they are becoming increasingly independent in providing care for their infant. Parents of a preterm infant or one with special needs should be given the opportunity to room-in and spend a night or two providing care for their infant away from the NICU. This affords them the opportunity to become more aware of the necessary care and to have transition time during which to ask questions regarding home care. Additional parent teaching should include bathing and skin care; requirements for meeting nutritional needs after discharge; safety in the home, including supine sleep position and prevention of infection (e.g., respiratory syncytial virus); and medication administration.

Medical equipment and supplies required for care of the infant in the home should be delivered to the home before discharge; parents and care providers should have education and ample practice in its use. Parents of an infant being discharged with special needs (i.e., gavage or gastrostomy feedings, oxygen, tracheostomy, or colostomy) should receive several days of carefully planned education in the various procedures before discharge.

Car seat safety is an essential aspect of discharge planning. Parents should obtain an age-appropriate car seat before discharge and demonstrate its use with the infant. Current national practice guideline recommendations note that while it is clear that infants placed in a car seat are more likely to experience oxygen desaturation or bradycardia than when they are supine, this does not predict an adverse neurodevelopmental outcome or mortality postdischarge. The infant car seat challenge that had been routinely used as a screening tool is no longer recommended (Narvey & CPS Fetus and Newborn Committee, 2016).

Preterm infants have a high rate of readmission to the hospital and of emergency department visits. It is imperative that the family have a health care provider they can contact for questions regarding infant care and behaviour once they are home.

Before discharge, all high-risk or preterm infants should receive the appropriate immunizations, metabolic screening, hematology assessment (bilirubin risk as appropriate), and evaluation of hearing and for retinopathy of prematurity (Jefferies & CPS Fetus and Newborn Committee, 2014/2020). Successful discharge of a high-risk infant requires an interprofessional and family-centred approach. Medical, nursing, social services, and other professionals (physiotherapy, occupational therapy, developmental follow-up specialist) are crucial to the smooth transition of these infants and their families to the community and home. If the infant is retrotransferred to a facility providing less acute care, interfacility communication is essential to continuity of care.

Discharge to home for high-risk infants requires timely follow-up by a practitioner familiar with the issues common to the high-risk newborn. Further follow-up of specific complications by qualified specialists and referral to centres for developmental interventions can help ensure the best outcome possible for these infants.

Referrals for appropriate community resources are also encouraged for infants with developmental delays or those at risk for further challenges (e.g., preterm infants). Social-service support may be indicated for young or high-risk parents (e.g., parents with a history of substance use or previous child maltreatment).

For the family of the child who is technology dependent, special education needs should be discussed before discharge. For further discussion of home care, see Chapter 41.

Transport to a Regional Centre

If a hospital is not equipped to care for a high-risk mother and fetus or a high-risk newborn, transfer to a specialized perinatal or regional tertiary care centre is arranged. Maternal transport that occurs with the fetus in utero has two distinct advantages: (1) newborn morbidity and mortality are decreased, and (2) the mother and newborn are not separated at birth.

For a variety of reasons, it is not always possible to transport the mother before the birth. Therefore, facilities must have the personnel and equipment necessary for making an accurate diagnosis and implementing emergency interventions to stabilize the newborn's condition until transport can occur. The goal of these interventions is to maintain the newborn's condition within the normal physiological range. Specific attention should be given to vital signs, oxygenation and ventilation, thermoregulation, acid–base balance, fluid and electrolyte status, blood glucose, and developmental interventions.

Arrangements for transport to a tertiary centre should be made as soon as the high-risk infant is identified (see Community Focus box: Newborn Transport) and best done by a specially trained neonatal transport team. The infant must be kept warm and adequately oxygenated (including intubation and surfactant replacement as indicated), have vital signs and oxygen saturation monitored, and, when indicated, receive an IV infusion. The infant must be transported in a specially designed isolette containing a complete life support system and other emergency equipment that can be carried by ambulance, helicopter, or a fixed-wing aircraft (Figure 28.12).

COMMUNITY FOCUS

Newborn Transport

During a scheduled clinical experience in the nursery at a community hospital, inquire about how newborns are transferred to other units. How are referrals made? What communication links exist between the community hospitals and the tertiary centre's NICU? Observe a neonatal transport team working to stabilize a newborn before transport to the tertiary centre if possible. Who are the transport team members? What are their roles and responsibilities? What equipment have they brought with them? What communication links exist between the NICU and the transport team when they are stabilizing and transporting the sick newborn? To whom does the transport team report? How are the parents kept informed of the newborn's condition during the stabilization?

The transport team may consist of physicians, nurse practitioners, nurses, respiratory therapists and paramedics. The team must have experience in resuscitation, stabilization, and provision of critical care during the transport. When a newborn is to be transported from the hospital, the parents need a description of the facility where the newborn is going. They need to know the location and nature of the facility and the care that the newborn requires at the alternative facility. The name of the newborn's primary health care provider and the telephone number of the nursery can be given to them, and unfamiliar terms such as *neonatologist*, *ventilator*, *infusion*, and *isolette* can be explained. Providing simple explanations and opportunities to ask questions promotes family-centred care. If booklets and a website are available that describe the facility, they should be given to the family.

Perhaps most important, providing parents some contact time with the newborn before the transport is vital. Being able to see, touch, and (if possible) hold their newborn may help decrease parents' anxiety. Often a photograph or even a video recording of their newborn can serve as tangible evidence of the newborn's existence until the parents are able to travel to the regional facility. When possible, it is often advisable to transfer the mother to the same institution as their newborn.

KEY POINTS

- Preterm infants are at risk for conditions related to the immaturity of their organ systems.
- Late preterm infants are at higher risk for feeding difficulties, respiratory distress, jaundice, neurodevelopmental delay, hypoglycemia, infection, and thermoregulation than their term counterparts.
- RDS, retinopathy of prematurity, and chronic lung disease (BPD) are associated with preterm birth.
- High-risk infants must be observed for respiratory distress and other early signs of physiological distress.
- The adaptation of parents to preterm or high-risk infants differs from that of parents of term newborns.
- SGA infants are considered to be at risk because of fetal growth restriction.
- Health concerns of post-term infants are related to the progressive placental insufficiency that can occur in a post-term pregnancy.
- Infants born to diabetic mothers (gestational or otherwise) are at risk for hypoglycemia, RDS, and birth asphyxia and trauma.
- Metabolic abnormalities of diabetes mellitus in pregnancy adversely affect embryonic and fetal development.
- Parents need special instruction (e.g., CPR, oxygen therapy, suctioning, developmental care) before they take a high-risk infant home.
- Specially trained nurses may transport high-risk newborns to and from special care units.

The Newborn at Risk: Acquired and Congenital Conditions

Jennifer Young
Originating US Chapter by *Debbie Fraser*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Summarize assessment and care of the newborn that has soft-tissue, skeletal, and neurological injuries due to birth trauma.
2. Identify maternal conditions that place the newborn at risk for infection.
3. Identify clinical signs of infection in the newborn.
4. Describe the nurse's role in the diagnosis and care of congenital infections and newborn sepsis.
5. Identify the effects of maternal use of tobacco, alcohol, cannabis, methamphetamine, opioids, and cocaine on the fetus and newborn.
6. Describe the assessment of a newborn exposed to substances in utero.
7. Compare characteristics of neonatal Rh and ABO incompatibility.
8. Describe inborn errors of metabolism (IEMs) and identify nursing care for infants with an IEM.

The birth of an at-risk or high-risk newborn presents challenges for health care providers as transition to extrauterine life may be complicated by additional conditions or circumstances. The newborn may be considered high risk because of antenatal, intrapartum, or newborn conditions such as macrosomia, maternal cephalopelvic disproportion, birth injury, in utero substance exposure, infection, or congenital anomalies.

At times, the nurse can anticipate a newborn's health challenges, such as when a patient is admitted in preterm labour or a congenital anomaly is diagnosed in the antenatal period. At other times, the birth of a high-risk newborn is unanticipated. In either case, the personnel and equipment necessary for immediate care of the newborn must be available.

INJURIES ASSOCIATED WITH BIRTH

Birth trauma is a physical injury sustained by a newborn during labour and birth; it represents an important source of neonatal morbidity. Careful assessment for risk factors and anticipatory planning for birth may assist in reducing injuries sustained during birth. The use of fetal ultrasonography allows antepartum diagnosis of certain fetal conditions that may be treated in utero or shortly after birth. Elective Caesarean birth may be chosen for some pregnancies to prevent significant birth injury but will not completely eliminate their occurrences. Some significant birth injuries caused by prolonged labour or an abnormal fetal presentation may be unavoidable even when the labouring patient is receiving skilled and competent obstetrical care.

Many injuries resolve without treatment in the newborn period. Others require some degree of intervention; few are serious enough to be fatal. The nurse's contributions to the newborn's welfare begin with early observation of the newborn's transition to extrauterine life. Prompt recognition and reporting of signs that indicate deviations from normal or healthy birth facilitate early initiation of appropriate therapy. Table 29.1 provides an overview of birth injuries and the sites in which they occur. Soft-tissue injuries that commonly occur at birth (i.e., caput succedaneum and cephalohematoma) are discussed in Chapter 25.

When the infant is born, the nurse performs a rapid inspection and physical assessment to determine whether there are any life-threatening conditions requiring immediate medical or surgical attention. A comprehensive physical assessment of the newborn is performed after the parents have had the opportunity to interact with their new baby. Because some birth injuries may not be immediately apparent, ongoing assessment is necessary and should occur during each interaction with the newborn.

Skeletal Injuries

The skull bones of a newborn are held together by fibrous material referred to as *sutures*. Skull sutures function like an expansion joint and allow the skull bones to be mobile during the birthing process. Skull fractures may occur in association with a forceps-assisted birth or after

TABLE 29.1 Types of Birth Injuries

Site of Injury	Type of Injury
Scalp	Subgaleal hemorrhage (see Figure 25.12, *C*)
Skull	Linear fracture Depressed fracture Occipital osteodiastasis (abnormal separation of adjacent bones)
Intracranial	Epidural hematoma Subdural hematoma (laceration of falx, tentorium, or superficial veins) Subarachnoid hemorrhage Cerebral contusion Cerebellar contusion Intracerebellar hematoma
Spinal cord (cervical)	Vertebral artery injury Intraspinal hemorrhage Spinal cord transection or injury
Plexus	Erb palsy Klumpke paralysis Total (mixed) brachial plexus injury Horner syndrome Diaphragmatic (phrenic nerve) paralysis Lumbosacral plexus injury
Cranial and peripheral nerve	Radial nerve palsy Medial nerve palsy Sciatic nerve palsy Laryngeal nerve palsy Diaphragmatic paralysis Facial nerve palsy

From Parsons, J. A., Seay, A. R., & Jacobson, M. (2016). Neurologic disorders. In S. L. Gardner, B. S. Carter, M. Enzman-Hines, & J. A Hernandez (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care* (8th ed.). Elsevier.

a prolonged difficult labour whereby the fetal skull experiences repeated forceful contact against the maternal symphysis pubis or other maternal bony anatomy. Two types of skull fractures typically occur: linear fractures and depressed fractures. The location of the fracture and involvement of underlying structures determine its significance.

The newborn's skull may become indented without laceration of either the skin or the dural membrane. Depressed fractures, or ping-pong ball indentations, may occur during a difficult birth from pressure of the head on the bony pelvis. If an artery lying in a groove on the undersurface of the skull is torn as a result of the fracture, increased intracranial pressure (ICP) will result. Fractures at the base of the skull may lead to severe hemorrhage and require blood replacement and other stabilization measures. Uncomplicated linear skull fractures often heal without special treatment. Large fractures associated with neurological symptoms require urgent assessment to ensure cortical injury does not ensue (Prazad et al., 2020).

The clavicle is the bone most often fractured during birth as a result of shoulder dystocia or from the forces of labour. Generally, the break is in the middle third of the bone (Figure 29.1). Limited arm motion, crepitus over the bone, and absence of the Moro reflex on the affected side are often present. Gentle handling to reduce pain and containment of the limb against the chest may be employed for 7 to 10 days or until evidence of pain subsides; the prognosis is good with minimal risk of sequelae. The humerus and femur are other bones that may be fractured during a difficult birth.

Fig. 29.1 Fractured clavicle after shoulder dystocia. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn*. Hoffman-La Roche. Used with permission of F. Hoffmann-La Roche Ltd.)

Fractures in newborns generally heal rapidly. Immobilization can be accomplished with slings, splints, swaddling, and other immobilization devices. Nurses need to support parents while they learn to handle, change, and feed their newborn with a skeletal injury, as they may be fearful of hurting the baby.

Peripheral Nervous System Injuries

Brachial plexus injury results from trauma to the spinal roots of the fifth cervical nerve to the first thoracic nerve and alter the normal position and relationship of the arm, shoulder, and neck. Erb palsy (Erb-Duchenne paralysis) is caused by damage to the upper brachial plexus and usually results from lateral traction of the head and neck away from the shoulder as the fetus goes through the birthing process. Erb palsy may occur with shoulder dystocia or with a difficult vertex or breech birth. Klumpke palsy, a less common lower plexus palsy, results from severe stretching of the upper extremity while the trunk is relatively less mobile. Macrosomia and shoulder dystocia are associated with brachial plexus injury.

The clinical manifestations of Erb palsy are related to the paralysis of the affected extremity and muscles. The arm hangs limply alongside the body. The shoulder and arm are adducted and internally rotated; the elbow is extended, and the forearm is pronated, with the wrist and fingers flexed. In newborns with very severe deficits, the arm may be cooler because of the sympathetic nervous system outflow at T1. Torticollis is commonly present and almost always with the face turned away from the involved arm (Nelson, 2020). In lower brachial plexus palsy, the muscles of the hand are paralyzed, with resultant wrist drop and relaxed fingers. In a third and more severe form of brachial palsy, the entire arm is paralyzed and hangs limply and motionless at the infant's side. The Moro reflex is absent on the affected side in all forms of brachial palsy (Figure 29.2).

The goal of treatment for any of the palsies described above is two-fold: prevention of contractures, and maintenance of correct placement of the humeral head within the glenoid fossa of the scapula. Complete recovery from stretched nerves usually takes 3 to 6 months. However, avulsion (disconnection) of the nerves of the ganglia from the spinal cord results in permanent damage. For those injuries that do not improve by 3 to 6 months, surgical intervention may be needed to relieve pressure on the nerves or to repair the nerves with grafting (Nelson, 2020).

Fig. 29.2 Erb-Duchenne paralysis in newborn infant. Moro reflex is absent in right upper extremity. Recovery was complete. (From Chung, K. C., Yang, L. J.-S., & McGillicuddy, J. E. [2012]. *Practical management of pediatric and adult brachial plexus palsies*. Saunders.)

Fig. 29.3 Facial paralysis (palsy). Absence of movement on the affected side is especially noticeable when the infant cries. (Courtesy Facial Palsy UK.)

Care of the newborn with brachial palsy focuses on positioning of the affected arm through 90-degree abduction with external shoulder rotation, forearm supination, and extension at the wrist with the palm facing the newborn's face. Occupational therapy or physiotherapy, initiated in the second week, involves passive range-of-motion exercises of the shoulder, wrist, elbow, and fingers. Wrist flexion contractures may be prevented with the use of a wrist splint with padding in the fist. In dressing the newborn, preference is given to the affected arm. Undressing begins with the unaffected arm, and re-dressing begins with the affected arm to prevent unnecessary manipulation and stress on the paralyzed muscles. Parent education includes newborn positioning in the football position and avoiding picking up the baby from under the axillae or by pulling on the arms.

Pressure on the facial nerve (cranial nerve VII) during birth may result in injury. Facial palsy or paralysis is most noticeable when the newborn cries. The primary clinical manifestations are loss of movement on the affected side, such as an inability to completely close the eye, drooping of the mouth, and absence of wrinkling of the forehead and nasolabial fold (Figure 29.3). The mouth is drawn to the unaffected side, wrinkles are deeper on the normal side, and the eye on the involved side remains open. Often the condition is temporary, resolving within hours or days of birth. Permanent paralysis is rare.

Nursing care of the newborn with facial nerve paralysis involves assisting the newborn to suck and helping the parent with feeding techniques. The newborn may require gavage feeding to prevent aspiration. Breastfeeding is not contraindicated, but the breastfeeding parent may need additional assistance to help the newborn latch on to the breast. If the eyelid on the affected side does not close completely, artificial tears can be instilled daily to prevent drying of the conjunctiva, sclera, and cornea. The lid may be taped shut to prevent accidental injury. If eye care is needed at home, parents require education regarding administration of eye drops before the newborn and family are discharged home.

Phrenic nerve paralysis results in diaphragmatic paralysis as found on ultrasonography, which shows paradoxical chest movement and an elevated diaphragm. An elevated diaphragm may not be obvious if the newborn is receiving positive-pressure ventilation. Diaphragmatic paralysis often occurs in conjunction with brachial palsy. Cyanosis and respiratory distress are common and important signs of possible diaphragm injury. Phrenic nerve injury is usually unilateral; the lung on the affected side does not expand and respiratory efforts are ineffective. The newborn requires positioning on the affected side to facilitate maximum expansion of the uninvolved lung. Pneumonia and atelectasis on the affected side may also occur.

The newborn with phrenic nerve paralysis requires the same nursing care as that for any infant with respiratory distress (see Chapter 28). Follow-up is essential because of the extended length of recovery.

Central Nervous System Injuries

Birth injuries to the spine and spinal cord rarely occur. Spinal cord injury may be associated with excessive traction or torsion placed on the spine during a complicated or instrument-assisted birth. Cervical spinal cord injuries may result in paralysis of all extremities and severe respiratory depression; death may also occur. Infants who survive with cervical spinal cord injuries require an interprofessional team including nursing, occupational therapy and physiotherapy, neurology, urology, and pediatric medicine to meet their complex care needs.

Neurological injury in newborns is common with the increased survival of premature low-birth-weight (LBW) and very-low-birth-weight (VLBW) infants. Preterm infants, with a fragile cerebrovascular network, are at risk for periventricular or intraventricular hemorrhage. Fragility and increased permeability of capillaries and prolonged prothrombin time predispose preterm infants to certain forms of brain injury. The more common cerebral complications and associated nursing care are outlined in Table 29.2.

The highest incidence of abnormal neurological findings occurs in VLBW infants and those with intracranial hemorrhage (ICH).

TABLE 29.2 Neurological Complications

Description	Clinical Manifestations	Therapeutic Management	Care Management
Hypoxic-Ischemic Brain Injury			
Nonprogressive neurological (brain) impairment caused by intrauterine or postnatal asphyxia resulting in hypoxemia or cerebral ischemia Hypoxic-ischemic encephalopathy—the resultant cellular damage that causes the clinical manifestations	Appears within first 6–12 hours after hypoxic episode Seizures Abnormal muscle tone (usually hypotonia) Disturbance of sucking and swallowing Apneic episodes Stupor or coma Muscular weakness in hips and shoulders (full term), lower-limb weakness (preterm)	Prevent hypoxia. Provide supportive care. Provide adequate ventilation. Maintain cerebral perfusion. Prevent cerebral edema. Treat underlying cause. Administer antiseizure medications. Initiate therapeutic hypothermia if criteria met.	Observe for signs that indicate cerebral hypoxia. Monitor ventilatory and intravenous therapy. Observe for and manage seizures. Support family. Provide guidelines for family management of potential mild-to-severe neurological damage.
Germinal Matrix or Intraventricular Hemorrhage			
Hemorrhage into and around ventricles caused by ruptured vessels as a result of an event that increases cerebral blood flow to area	Most bleeds are initially asymptomatic. Sudden deterioration in condition if bleed is large: • Oxygen desaturation • Bradycardia • Hypotonia • Metabolic acidosis • Shock • Significant drop in hematocrit • Tense anterior fontanel Signs of worsening hemorrhage: • Twitching • Decreased level of consciousness, stupor • Apnea • Seizures • Full, tense fontanels Evident on cranial ultrasonography or magnetic resonance imaging	Provide supportive care. Provide ventilatory support. Maintain oxygenation. Regulate fluid, electrolytes, acid–base balance. Suppress or prevent seizures. Provide ventricular shunting or drainage of cerebrospinal fluid.	Prevent increased cerebral blood pressure. Avoid events that may increase or decrease cerebral blood flow (e.g., pain, unnecessary stimulation, endotracheal suctioning, hypoxia, hyperosmolar medications, rapid volume expansion). Elevate head of bed 20–30 degrees; keep head in midline. Support family. Monitor for posthemorrhagic ventricular dilatation after diagnosis. Provide developmental care and enhancement.
Intracranial Hemorrhage			
Subdural Subarachnoid Intracerebellar	Sudden decrease in hematocrit Change in sensorium Poor feeding See Chapter 50.	See Chapter 50.	Same as for germinal matrix or intraventricular hemorrhage

Additionally, deep white matter injury occurs when there is inadequate arterial blood supply, which leads to hypoxia and ischemia to associated regions (Young, 2017). Major neurological conditions such as cerebral palsy, cognitive or sensory impairment, seizures, and hydrocephalus are diagnosed typically in the first 2 years of life during neurodevelopmental follow-up. Learning disorders, attention-deficit/hyperactivity disorder (ADHD), and fine- and gross-motor incoordination may not be diagnosed until preschool or even school age. Cerebral palsy is one of the most common neurological deficits in survivors of preterm birth (see Chapter 54).

Many types of ICH occur in newborns. ICH as a result of birth trauma is more likely to occur in the full-term macrosomic newborn. In the newborn, more than one type of hemorrhage can and does commonly occur (see Table 29.2). The nursing care of a newborn with ICH

is supportive and includes monitoring of neurological signs, observation and management of seizures, prevention of increased ICP, and intravenous (IV) therapy.

Hypoxic Ischemic Encephalopathy. Newborn hypoxic ischemic encephalopathy (HIE) is considered a form of brain injury stemming from perinatal complications and occurs in 1 to 6 per 1 000 live births (Lemyre et al., 2018). Acute placental bleeding or maternal conditions that contribute to placental insufficiency, umbilical cord accidents, abnormal fetal presentation, or prolonged late stages of labour are several factors that may be associated with a reduction in oxygen delivery to the fetus. Sentinel events including maternal amniotic fluid embolism or uterine rupture are related to moderate or severe HIE. Total body therapeutic hypothermia provides a mechanism for neuroprotection and reduces the severity of the brain injury in HIE, leading to improved neurological outcomes for many newborns. Initiation of total body cooling needs to occur in the early stages of injury (first 6 hours after birth) for infants who meet all eligibility criteria (Lemyre et al., 2018):

- Gestational age greater than 35 weeks
- Less than 6 hours postnatal age
- Cord or postnatal gas within 1 hour of birth with pH less than 7.0 OR base deficit greater than –16 OR
- APGAR score of 5 or less at 10 minutes and continued need for ventilation or resuscitation at 10 minutes
- Signs of moderate or severe encephalopathy

NEWBORN INFECTIONS

Sepsis

Sepsis (the presence of microorganisms or their toxins in the blood or other tissues) continues to be a significant cause of newborn morbidity and mortality. *Septicemia* refers to a generalized infection in the bloodstream. Perinatally acquired infections may cause miscarriage, stillbirth, intrauterine infection, congenital malformations, and acute neonatal disease.

Newborns are at risk for sepsis for a number of reasons. Maternal immunoglobulin M (IgM), the largest antibody, does not cross the placenta. IgG levels in term newborns, which contains antibodies to maternal infections previously encountered, are equal to maternal levels. However, for preterm infants little IgG transports across the placenta from maternal circulation before 32 weeks. Neonatal neutrophils are present in term newborns but have decreased functional capabilities; response to infections is diminished. Phagocytosis is less efficient. Serum complement levels are low in term newborns and even lower in the preterm infant; serum complement (C1 through C6) is involved in immunological reactions, some of which kill or lyse bacteria and enhance phagocytosis.

Exposure to the maternal vaginal microbiome during birth stimulates healthy development and provides the primary source for normal gut colonization, initiating host immune maturation and metabolism (Jašarević et al., 2015). Development of the infant microbiome can be altered by Caesarean birth, perinatal antibiotics, and formula feeding (Neu, 2016).

Newborn bacterial infection is classified into two categories according to the time of presentation, early onset and late onset. While definitions can vary slightly, early-onset (congenital) sepsis usually manifests within 72 hours of birth—and often within the first 24 hours of life—whereas late-onset sepsis occurs after 72 hours. Early-onset sepsis is acquired by vertical transmission through amniotic fluid infection or from bacterial flora within the mother's anogenital tract during vaginal birth (Esper, 2020).

The most common bacterial organism in preterm infants is *Escherichia coli*; in term newborns, the most common organism is group B streptococci (GBS), although screening and intrapartum prophylaxis has decreased the incidence of GBS early-onset disease (Jefferies & Canadian Paediatric Society [CPS] Fetus & Newborn Committee, 2017). *E. coli*, which may be present in the vagina, accounts for approximately half of all cases of sepsis caused by Gram-negative organisms. Other bacteria noted to cause early-onset bacterial infection include *Staphylococcus aureus*, enterococci, *Klebsiella*, *Citrobacter*, *Enterobacter,* and *Streptococcus viridans*. Other pathogens that are harboured in the vagina and may infect the infant include gonococci, *Candida albicans*, herpes simplex virus (HSV type 2), and chlamydia. Early-onset sepsis is associated with a history of obstetrical events such as preterm labour, prolonged rupture of membranes (more than 18 hours), maternal fever during labour, and chorioamnionitis (Jefferies & CPS Fetus & Newborn Committee, 2017; Pammi et al., 2021).

Late-onset sepsis, occurring after 72 hours of age, is considered to be primarily an infection acquired through the infant's environment. The offending organisms include coagulase-negative staphylococci, *Staphylococcus aureus, Klebsiella* organisms, enterococci, *Pseudomonas,* and *Candida* species (Haslam, 2020). GBS and *E. coli,* also frequently identified in late-onset sepsis, are commonly found to be the cause of septicemia in extremely-low-birth-weight (ELBW) and VLBW infants residing in the neonatal intensive care unit (NICU). Additional infections of concern include methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), and multidrug-resistant Gram-negative pathogens. Bacterial invasion can occur through the umbilical stump, the skin, mucous membranes of the eye, nose, pharynx, and ear as well as the respiratory, nervous, urinary, and gastrointestinal systems. Table 29.3 outlines risk factors for newborn sepsis.

Viral infections such as respiratory syncytial virus (RSV), rotavirus, herpes, influenza, and varicella may occur in newborns. It is important to recognize the manifestations of infections in the newborn period so that the acute infection can be treated, health care–acquired infections

TABLE 29.3 Risk Factors for Newborn Sepsis

Source	Risk Factors
Maternal	Low socioeconomic status Inadequate prenatal care Malnutrition Substance use Sexually transmitted infections
Intrapartum	Premature rupture of fetal membranes Maternal fever Chorioamnionitis Prolonged labour Rupture of membranes >18 hours Premature labour Maternal urinary tract infection
Newborn	Twin or multiple gestation Male infant Meconium aspiration Congenital anomalies of skin or mucous membranes Galactosemia Absent spleen Low birth weight or prematurity Malnourishment Prolonged hospitalization Multiple interventions

in other infants are prevented, and effects on the infant's subsequent growth and development can be anticipated.

Invasive fungal infections have become an increasing concern for preterm infants. Predisposing factors include a prolonged course of antibiotics and altered skin integrity. *Candida* and *Malassezia* species are pathogens most frequently implicated in fungal infections. Infection by any pathogen continues to be a significant factor in fetal and neonatal morbidity and mortality in Canada.

Nursing Care

The antenatal record should be reviewed for risk factors associated with infection and the signs and symptoms suggestive of infection. Maternal vaginal or perineal infection may be transmitted directly to the newborn during passage through the birth canal. Psychosocial history and history of sexually transmitted infections (STIs) may indicate possible human immunodeficiency virus (HIV), hepatitis B virus (HBV), or herpes (type 2).

Perinatal events should also be reviewed. Premature rupture of membranes (PROM) may be caused by maternal or intrauterine infection. Ascending infection may occur after prolonged PROM, prolonged labour, or intrauterine fetal monitoring. In some cases infection may contribute to early rupture or occur with intact membranes. A maternal history of fever during labour or the presence of foul-smelling amniotic fluid may also indicate chorioamnionitis. Antibiotic therapy initiated during labour should be noted. The newborn's gestational age and birth weight affect the incidence and severity of infection. The newborn needs to be assessed for respiratory distress, temperature instability, skin abscesses, petechial rashes, and other indications of infection.

The earliest clinical signs of newborn sepsis are characterized by a lack of specificity. The nonspecific signs include lethargy, poor feeding, poor weight gain, and irritability. The nurse or parent may simply note that the newborn is not doing as well as before. Differential diagnosis may be difficult because signs of sepsis are similar to signs of noninfectious newborn conditions such as hypoglycemia and respiratory distress. Additional clinical and laboratory information, including cultures, will substantiate the findings described. Table 29.4 outlines the clinical signs associated with newborn sepsis.

Laboratory studies are important in assessing for newborn infection. Specimens for cultures include blood, cerebrospinal fluid (CSF), and urine. A complete blood cell count (CBC) with differential should be performed to assess for increased or decreased white blood cell count, both of which may signal sepsis. The total neutrophil count, immature to total neutrophil (I/T) ratio, absolute neutrophil count (ANC), and C-reactive protein may be also be used in determining the possibility of sepsis. It is important to note that these tests are often adjuncts for the confirmation of newborn sepsis; a combination of these tests and clinical signs often alert the practitioner to the need for treatment. Additional diagnostic tests that may be used to identify or exclude newborn sepsis include sedimentation rate, interleukins (IL-8, IL-2, IL-6, and IL-1β), and nucleic acid amplification testing (NAAT).

Antepartum viral infection can now be treated successfully with a number of antiviral medications to decrease viral replication and fetal transmission of disease; newborns may also be treated with antiviral medications such as acyclovir and ganciclovir. In high-risk newborns with significant illness, antiviral or antibiotic treatment may begin once cultures are obtained. When the pathogen is identified, antibiotic, antiviral, or antifungal therapy may be narrowed to target the specific organism. Principles of antibiotic stewardship contribute to the future health and well-being of newborns; ensuring the right antibiotic is used to eradicate the identified organism without undue prolongation is essential. Culture-negative sepsis continues to present uncertainty and creates treatment dilemmas for neonatal health care providers.

TABLE 29.4 Clinical Signs of Newborn Sepsis*

System	Signs
Respiratory	Apnea, bradypnea Tachypnea Grunting, nasal flaring Retractions Decreased oxygen saturation
Cardiovascular	Bradycardia or tachycardia Hypotension Decreased perfusion Metabolic acidosis
Central nervous	Temperature instability Lethargy, reduced spontaneous movements Hypotonia Irritability, seizures
Gastrointestinal	Feeding intolerance Abdominal distension Vomiting, diarrhea Hematochezia
Integumentary	Jaundice Pallor Petechiae Mottling

*Laboratory findings include neutropenia, increased immature white cells, hypoglycemia or hyperglycemia, metabolic acidosis, and thrombocytopenia.

Modified from Askin, D. F. (1995). Bacterial and fungal sepsis in the neonate. *Journal of Obstetric, Gynecologic, and Neonatal Nursing, 24*(7), 635–643.

The newborn requires continuous assessment for sequelae to septicemia, which include meningitis, disseminated intravascular coagulation (DIC), pneumonia, and septic shock. Septic shock results from the toxins released into the bloodstream. The most common signs of septic shock include decreasing oxygen saturation, respiratory distress, tachycardia, and evolving features of hemodynamic instability with reduced cardiac output (prolonged capillary refill, cool extremities, mottling, reduced urine output).

Monitoring an IV infusion and administering antibiotics are important nursing responsibilities. It is important to administer the prescribed dose of antibiotic within 1 hour after it is prepared in order to avoid loss of medication stability. If the IV fluid that the infant is receiving contains electrolytes, vitamins, or other medications, the nurse should ensure compatibility with the antibiotic prior to administration. The antibiotic (or other medication) may be deactivated or may form a precipitate when combined with other medications.

Care must be taken in suctioning secretions from any newborn's oropharynx or trachea. Routine suctioning is not recommended and may further compromise the infant's immune status, cause hypoxia, and increase ICP. Efforts should also be made to prevent ventilator-associated pneumonia in infants on mechanical ventilation. Isolation procedures are implemented as indicated according to hospital practices, based on method of pathogen spread.

Prevention. As key members of the interprofessional team, nurses are responsible for minimizing or eliminating environmental sources of infectious agents in the nursery. Hand hygiene remains the single most effective measure to reduce infection. Additional measures to be taken

include routine practices, careful and thorough cleaning of contaminated equipment, frequent replacement of used equipment (e.g., changing IV and nasogastric tubing per hospital protocol; cleaning resuscitation and ventilation equipment, IV pumps, and isolettes), and appropriate disposal of contaminated linens and diapers. Overcrowding must be avoided in nurseries. Guidelines regarding infection control, space, and visitation in areas where newborns receive care have been established and should be followed.

The newborn's skin, its secretions, and normal flora are natural defenses that protect against invading pathogens, thus care practices that preserve this protection should be used. Warm water may be used to remove blood and meconium from the newborn's face, head, and body. A mild nonmedicated soap (in single-use container) can be used with careful water rinsing. Vernix caseosa should not be scrubbed vigorously for removal, since this further disrupts the skin barrier properties.

Breastfeeding (for medically stable infants) or feeding expressed breast milk is encouraged. Breast milk provides protective mechanisms against infection. Colostrum contains IgA, which offers protection against infection in the gastrointestinal tract. Human milk contains iron-binding protein that exerts a bacteriostatic effect on *E. coli*. Human milk also contains macrophages and lymphocytes. The vulnerability of infants to common mucosal pathogens such as respiratory syncytial virus (RSV) may be reduced by passive transfer of maternal immunity in the colostrum and breast milk. There is evidence that early enteral feedings with human milk are beneficial in establishing a natural barrier to infection in ELBW and VLBW infants. Human milk is also thought to provide some degree of protection from necrotizing enterocolitis (NEC) (Rodriguez & Caplan, 2015) (See Necrotizing Enterocolitis, Chapter 28).

Probiotics are nutritional supplements comprised of live microorganisms that, when administered in adequate amounts, may provide benefit to healthy gut flora. Different strains of probiotics lead to different biological activities; administration of certain probiotics in infants can lead to an enhanced gut barrier and contribute to inhibition of gut colonization by pathogens (Marchand & CPS Nutrition and Gastroenterology Committee, 2012/2019). Evidence supports the use of probiotics in preterm infants for prevention of late-onset sepsis and NEC (Dermyshi et al., 2017).

! NURSING ALERT

Artificial and natural long fingernails worn by nurses have been associated with serious newborn infection and morbidity from *Pseudomonas aeruginosa* and *Klebsiella* organisms in the NICU. Therefore, nurses caring for newborns should keep their fingernails short.

CONGENITAL INFECTIONS

The range of pathological conditions produced by infectious agents is large, and the difference between the maternal and fetal effects caused by any one agent is also great. Some maternal infections, especially during early gestation, can result in fetal loss or malformations because the fetus's ability to handle infectious organisms is limited and the fetal immunological system is unable to prevent the dissemination of infectious organisms to various tissues.

Not all prenatal infections produce teratogenic effects. Some viral agents can cause remarkably similar manifestations, and it is common to test for all of them when a prenatal infection is suspected. The acronym TORCH stands for a group of infectious diseases that may contribute to newborn illness and negative long-term sequelae:

T—Toxoplasmosis
O—Other (e.g., HBV, parvovirus, HIV, West Nile)
R—Rubella
C—CMV infection
H—Herpes simplex

To determine the causative agent in a symptomatic newborn, tests are performed to rule out each of these infections. The *O* category may involve testing for several viral infections (e.g., HBV, varicella zoster, measles, mumps, HIV, syphilis, and human parvovirus). Bacterial infections are not included in the TORCH workup because they are usually identified by clinical manifestations and readily available laboratory tests. Several maternal infections, their possible effects, and specific nursing considerations are outlined in Table 29.5.

Chlamydia Infection

Chlamydia trachomatis is an intracellular bacterium that causes ophthalmia neonatorum and pneumonia. Symptoms of ophthalmia neonatorum include eye discharge, pain and tenderness in the eye, and swollen eyelids; complications may include corneal scarring, ocular perforation, and permanent vision loss (Public Health Agency of Canada [PHAC], 2017). The organism may spread to the lungs from nasal secretions if left untreated, causing chlamydia pneumonia in about 33% of infected newborns (see Clinical Reasoning Case Study: Newborn With Chlamydia).

Administration of prophylactic antibiotic eye drops to newborns within 1 to 2 hours after birth is presently recommended for newborns and is mandatory by law in most provinces and territories, although the practice is not supported by the Canadian Paediatric Society (CPS, 2019; Moore et al., 2015/2018) (see Chapter 26, Eye Prophylaxis).

CLINICAL REASONING CASE STUDY

Newborn With Chlamydia

An 8-day-old male infant with eye drainage for 2 days is brought to the pediatric urgent care centre by Savannah, his 22-year-old mother. Savannah is breastfeeding and states that she was diagnosed and partially treated for sexually transmitted infections in late pregnancy; she does not remember the name but says one started with a "C." The medications made her stomach sick, so she quit taking them after 2 days. The practitioner examines the newborn, who has a purulent yellowish discharge from both eyes but otherwise appears healthy; they suspect chlamydial conjunctivitis and orders cultures of the eye drainage. The retrieved medical record from the newborn's birth indicates that eye prophylaxis with erythromycin ophthalmic ointment was administered.

Questions

1. Evidence: Is there sufficient evidence to draw conclusions about the cause of the infant's eye drainage?
2. List the treatments that might be ordered for the newborn and for Savannah.
3. What are the sequelae of inadequate chlamydia infection?
4. What is the evidence related to prophylaxis at birth?
5. What nursing intervention(s) should be implemented? Identify which have the highest priority.
6. Identify important patient-centred outcomes with reference to your nursing interventions.

Cytomegalovirus Infection

Congenital cytomegalovirus (CMV) infection is a leading infectious cause of hearing impairment and cognitive delay in infants and children; there is no effective and safe immunization against CMV (Yinon et al., 2018). Transmission to the fetus may occur through primary or secondary infection; probability of intrauterine transmission following primary maternal infection is 30 to 40%, while the

TABLE 29.5 Infections Acquired From the Mother Before, During, or After Birth*

Fetal or Newborn Effect	Transmission	Nursing Considerations†
Human Immunodeficiency Virus (HIV)		
No significant difference between infected and uninfected newborns at birth in some instances	Transplacental; during vaginal birth; potentially in breast milk	Administer combination antiretroviral prophylaxis to HIV-positive mother; prophylaxis to prevent perinatal transmission may begin after first trimester. Choice of regimens is determined by examining a number of factors, including mother's current treatment. Detailed recommendations can be obtained from the SOGC (Loutfy et al., 2018). HIV-exposed newborns should commence antiretroviral prophylaxis within 48 hours of birth (Moore et al., 2019). Vaginal birth may be considered according to maternal viral load; discussion with health care provider is required. HIV-positive mothers in developed countries should avoid breastfeeding (see Chapter 27, Contraindications to Breastfeeding).
Chickenpox (Varicella-Zoster Virus [VZV])		
Intrauterine exposure—congenital varicella syndrome: limb dysplasia, microcephaly, cortical atrophy, chorioretinitis, cataracts, cutaneous scars, other anomalies, auditory nerve palsy, motor and cognitive delays Severe symptoms (rash, fever) and higher mortality in newborn whose mother develops varicella 5 days before to 2 days after birth	First trimester (fetal varicella syndrome); perinatal period (infection)	Provide varicella zoster immunoglobulin or IVIG to newborns born to mothers with onset of disease within 5 days before or 2 days after birth; antiviral therapy may also be indicated. Healthy term newborns exposed postnatally to varicella are protected by maternal IgG antibody; VZIG prophylaxis is not indicated (Kett, 2013). Institute isolation precautions in infant born to mother with varicella up to 21–28 days (latter time if newborn received varicella zoster immune globulin or IVIG after birth [if hospitalized]).† Prevention: Immunize all children with varicella vaccine.
Chlamydia Infection (*Chlamydia trachomatis*)		
Conjunctivitis, pneumonia	Last trimester or postpartum period	Treat with oral erythromycin or oral sulfonamide for 14 days; a second course of erythromycin may be required, and follow-up of exposed infant is recommended.
Coxsackievirus (Group B Enterovirus [Nonpolio], Parechovirus)		
Poor feeding, vomiting, diarrhea, fever; cardiac enlargement, arrhythmias, heart failure; lethargy, seizures, meningoencephalitis, pneumonitis Mimics bacterial sepsis	Peripartum	Treatment is supportive. Provide IVIG in newborn infections.
Cytomegalovirus (CMV)		
Variable manifestation from asymptomatic to severe Microcephaly, cerebral calcifications, chorioretinitis Jaundice, hepatosplenomegaly Petechial or purpuric rash (Figure 29.4) Neurological sequelae—seizure disorders, sensorineural hearing loss, cognitive impairment	Perinatal period	Infection acquired at birth, shortly thereafter, or via human milk is not associated with clinical illness in term newborns. Exposed preterm infants may have systemic infection, including interstitial pneumonia. Affected individuals excrete virus. Pregnant patients should avoid close contact with known cases. Infected newborns may require antiviral treatment for several weeks.
Parvovirus B19 (Erythema Infectiosum)		
Fetal hydrops and death from anemia and heart failure with early exposure Anemia with later exposure No teratogenic effects established Ordinarily low risk of adverse effect to fetus	Transplacental	In pregnant patients with diagnosed infection serial ultrasonography to assess for fetal hydrops or anemia. Conduct cordocentesis to determine need for intrauterine transfusion if hydrops is present (Crane & SOGC Maternal Fetal Medicine and Infectious Diseases Committees, 2014). Aggressive cardiovascular and respiratory support is required in newborns with hydrops. Pregnant health care workers should not care for patients who might be highly contagious (e.g., child with sickle cell anemia, aplastic crisis). Occupational exposure should be minimized in pregnant patients without immunity.

TABLE 29.5 Infections Acquired From the Mother Before, During, or After Birth—cont'd

Fetal or Newborn Effect	Transmission	Nursing Considerations
Gonorrhea (*Neisseria gonorrhoeae*) Ophthalmitis Neonatal gonococcal arthritis, septicemia, meningitis	Last trimester or postpartum period	Healthy newborns exposed to *N. gonorrhoeae* require conjunctival culture and a single dose of IV/IM antibiotic; newborns with confirmed ophthalmia, scalp abscess, or disseminated infection should be hospitalized and cultures obtained to determine antimicrobial treatment (Moore et al., 2015/2018). Consider testing newborn for *Chlamydia*, HIV, and syphilis. Irrigate newborn's eyes with saline until discharge is eliminated.
Hepatitis B Virus (HBV) May be asymptomatic at birth; more than 90% of infants infected perinatally develop chronic HBV infection Clinical hepatitis, jaundice, changes in liver function; possible fulminant hepatitis (mortality rate of 75%) Increased risk for preterm birth	Transplacental; contaminated maternal fluids or secretions during birth	Administer HBIG to all newborns of HBsAG-positive mothers within 12 hours of birth; in addition, administer HepB vaccine at separate site. Prevention—Screen all pregnant patients. Infants born to HBsAG-positive mothers and weighing <2 000 g (4 lb 7 oz) should receive three-dose vaccine series *in addition* to birth dose.
Listeriosis (*Listeria monocytogenes*) Maternal infection associated with spontaneous abortion, preterm birth, and fetal death Preterm birth, sepsis, and pneumonia seen in early-onset disease; late-onset disease usually manifests as meningitis.	Transplacental by ascending infection or exposure at birth	Hand hygiene is essential to prevent health care–associated infection. Infected newborns will receive 2 to 3 weeks of IV antibiotics for bacteremia/meningitis.
Rubella, Congenital (Rubella Virus) Congenital rubella syndrome Eyes—retinopathy, cataracts (unilateral or bilateral), microphthalmia, retinitis, glaucoma CNS signs—microcephaly, seizures, severe cognitive impairment Congenital heart defects—patent ductus arteriosus Auditory defects—sensorineural hearing impairment Dermal erythropoiesis—blueberry muffin lesions IUGR, hyperbilirubinemia, meningitis, thrombocytopenia, hepatomegaly	First trimester; early second trimester	Pregnant patients should avoid contact with all affected persons, including infants with rubella syndrome. Emphasize vaccination of all unimmunized prepubertal children, susceptible adolescents, and patients of childbearing age (nonpregnant). Caution childbearing patients against becoming pregnant for at least 28 days after vaccination.
Syphilis, Congenital *(Treponema pallidum)* Stillbirth, prematurity, hydrops fetalis May be asymptomatic at birth and in first few weeks of life or may have multisystem manifestations: hepatosplenomegaly, lymphadenopathy, hemolytic anemia, pneumonia, and thrombocytopenia Copper-coloured maculopapular cutaneous lesions (Figure 29.5) (usually after first few weeks of life), mucous membrane patches, hair loss, nail exfoliation, snuffles (syphilitic rhinitis), profound anemia, poor feeding, pseudoparalysis of one or more limbs, dysmorphic teeth (older child)	Transplacental; can be anytime during pregnancy or at birth	This is the most severe form of syphilis. Prevention—routine screening of all pregnant patients. Treatment consists of IV or IM antibiotics for a minimum of 1 week. Diagnostic evaluation depends on maternal serology testing, maternal therapy and response, maternal and newborn serology titres, results of nontreponemal newborn tests, and newborn physical examination (including ophthalmological examinations and long-bone radiographs) and laboratory examination results (e.g., LFTs, CBC, platelets, CSF protein and cell count). Monitor closely for development of complications of disease during first year of life.
Toxoplasmosis, Congenital *(Toxoplasma gondii)* May be asymptomatic at birth (70–90% of cases) or have maculopapular rash, lymphadenopathy, hepatosplenomegaly, jaundice, thrombocytopenia In some cases severely infected fetus may die in utero or shortly after birth (10–15%). Preterm birth is common. Later developments— hydrocephaly, cerebral calcifications, chorioretinitis (classic triad), microcephaly, seizures, cognitive impairment, deafness, encephalitis, myocarditis, hepatosplenomegaly, anemia, jaundice, diarrhea, vomiting, purpura	Throughout pregnancy, although first-trimester exposure is more serious Predominant host for organism is cats. May be transmitted through cat feces or poorly cooked or raw infected meats	Caution pregnant patients to avoid contact with cat feces (e.g., emptying cat litter boxes). Administer sulphadiazine (with folinic acid) and pyrimethamine (Daraprim). Spiramycin and cotrimaxazole may be administered to infected pregnant patient to reduce transmission to fetus but have no effect if fetal infection has occurred (Valentini et al., 2015).

Continued

TABLE 29.5 Infections Acquired From the Mother Before, During, or After Birth—cont'd

Fetal or Newborn Effect	Transmission	Nursing Considerations
Herpes Simplex Virus (HSV)		
Neonatal herpes manifests in one of three ways: (1) with SEM involvement; (2) as localized CNS disease; or (3) as disseminated disease involving multiple organs. In skin and eye disease rash appears as vesicles or pustules on erythematous base. Clusters of lesions are common. Lesions ulcerate and crust over rapidly (Figure 29.6). Ophthalmological clinical findings include chorioretinitis and microphthalmia; neurological involvement such as microcephaly and encephalomalacia may also develop. Disseminated infections may involve virtually every organ system, but liver, adrenal glands, and lungs are most commonly affected. In HSV meningitis, infants develop multiple lesions of cortical hemorrhagic necrosis. It can occur alone or with SEM lesions. Presenting symptoms, which may occur in second to fourth weeks of life, include lethargy, poor feeding, irritability, and local or generalized seizures. Neonatal HSV has high mortality rate.	Transplacental, although >85% of cases transmitted at birth (Money & Steben, 2017) Direct transmission from infected personnel or family	Absence of skin lesions in newborn exposed to maternal HSV does not indicate absence of disease. Contact precautions (in addition to routine precautions) should be instituted. It is recommended that swabs of mouth, nasopharynx, conjunctivae, rectum, and any skin vesicles be obtained from exposed newborn; in addition, urine, stool, blood, and CSF specimens should be obtained for culture. Therapy with IV antiviral is initiated if culture results are positive or if there is strong suspicion of herpes virus infection. Treatment is for 14 days if limited to SEM and 21 days if CNS involvement; ophthalmic treatment is required for ocular involvement in addition to IV antiviral. Therapy with oral agents for 6 months is recommended for infants with HSV CNS disease (Money & Steben, 2017). Breastfeeding is encouraged if there are no lesions on the mother's breast.
Group B Streptococcus (GBS)		
Early-onset infection (first 7 days of life)—pneumonia, respiratory distress, shock, apnea, and meningitis Late-onset infection (7 days to 3 months of age)—bacteremia or meningitis; may occur later in LBW infants Significant mortality rate	Acquired perinatally; intrapartum antibiotics decrease early-onset but not late-onset disease.	Broad-spectrum IV antibiotics are recommended for newborns with presumptive GBS infection; in newborns who are positive for GBS, antibiotic choice will be tailored to organism sensitivity.

CBC, Complete blood count; *CNS,* central nervous system; *CSF,* cerebrospinal fluid; *HBIG,* hepatitis B immunoglobulin; *HBsAG,* hepatitis B surface antigen; *IM,* intramuscular; *IUGR,* intrauterine growth restriction; *IV,* intravenous; *IVIG,* intravenous immunoglobulin; *LBW,* low-birth-weight; *LFT,* liver function test; *SEM,* skin, eye, and mouth; *SOGC,* Society of Obstetricians and Gynaecologists of Canada; *VZIG,* varicella zoster immunoglobulin.
*This table is not an exhaustive representation of all perinatally transmitted infections. For further information regarding specific diseases or treatment not listed here, refer to American Academy of Pediatrics (AAP) Committee on Infectious Diseases, Pickering, L. (Ed.). (2018). *2018 Red book: Report of the Committee on Infectious Diseases* (31st ed.). AAP.
†Isolation precautions depend on institutional policy.

Fig. 29.4 Neonatal cytomegalovirus infection. Shown here is a typical rash in a severely affected infant.

Fig. 29.5 Neonatal syphilis lesions on hands and feet.

transmission rate substantially decreases to approximately 1% after a secondary infection (Yinon et al., 2018). Routine screening in pregnancy does not occur. Newborns with congenital CMV may experience intrauterine growth restriction, microcephaly, hepatosplenomegaly, thrombocytopenia, and/or jaundice at birth. Hearing impairment may not be apparent until after the first year of life (Goderis et al., 2014). Approximately 20 to 30% of symptomatic infants will die of DIC and liver dysfunction (Yinon et al., 2018). See Table 29.5 for further discussion of CMV.

Fig. 29.6 Herpes simplex virus oral lesions. (Courtesy David A. Clarke.)

Gonorrhea

In Canada, the overall rate of reported cases of gonorrhea increased by more than 109% between 2008 and 2017; 63% of gonorrhea cases are resistant to at least one antibiotic (PHAC, 2019). The incidence of gonococcal infection in pregnant patients ranges from 2.5 to 7.3%. After rupture of membranes, ascending *Neisseria gonorrhoeae* infection can be transmitted to the fetus or be transmitted during vaginal birth. The organism may invade mucosal surfaces such as the conjunctiva (ophthalmia neonatorum), rectal mucosa, and pharynx. Legislation exists in many parts of Canada that mandates ocular prophylaxis administered shortly after birth; however, routine provision may no longer be useful (Moore et al., 2015/2018).

Group B Streptococcus

Group B streptococci (GBS) are Gram-positive organisms that can lead to newborn GBS disease as bacteremia, meningitis, or pneumonia. Universal antepartum maternal screening and administration of penicillin have significantly decreased the incidence of GBS; however, it remains a significant cause of newborn mortality in North America. Approximately one in four pregnant patients are colonized in the lower urogenital tract with GBS; routine screening with a vaginorectal swab at 35 to 37 weeks of gestation is recommended for all pregnant patients, even for those with planned Caesarean births (Money & Allen, 2018). Intrapartum antibiotics should be provided for any labouring patient positive for GBS on vaginorectal culture, any patient with a newborn previously infected with GBS, or any patient who experienced a confirmed GBS bacteriuria in the current pregnancy (Money & Allen, 2018).

GBS remains the leading cause of sepsis in term newborns; approximately 80% of cases present within 24 hours of birth. Risk factors for newborn GBS infection include less than 37 completed weeks of gestation at birth, prolonged rupture of membranes greater than 18 hours, and maternal fever during labour (Money & Allen, 2018). In the newborn with presumed or confirmed GBS infection, ampicillin or penicillin and an aminoglycoside are the therapy of choice (Jefferies & CPS Fetus & Newborn Committee, 2017).

Hepatitis B Virus (HBV)

Transmission of HBV occurs more often at birth or in the immediate postpartum period rather than transplacentally. However, risk of infection increases to 50 to 70% with maternal hepatitis occurring late in pregnancy. Hepatitis B surface antigen (HBsAg) is produced and detected in acute and chronic hepatitis B infections. Screening for HBsAg occurs for pregnant patients during routine antenatal care. Antiviral therapy may be warranted, pending viral load of the pregnant patient. Infants born to mothers who are HBsAg positive or of unknown status should be passively immunized with hepatitis B immunoglobulin (HBIG) and also receive hepatitis B vaccine within 12 hours of birth (Baley & Gonzalez, 2020) (see Chapter 26, Immunizations). Completion of the vaccination schedule should occur by 6 months. Infants born to mothers who received treatment for HBV during pregnancy still require passive and active vaccinations at birth. Vaccination for newborns not exposed to maternal HBV is provided in some provinces before discharge from the hospital. Breastfeeding may be initiated prior to receiving the vaccine; the risk of mother-to-child transmission through breastfeeding is negligible if newborns receive vaccinations at birth (Centers for Disease Control and Prevention [CDC], 2020b).

Herpes

Herpes simplex virus (HSV) infection in the pregnant patient causes a high risk of morbidity and mortality in the newborn. Pregnant patients who experienced HSV infection prior to pregnancy will have developed antibodies that will be passed to the fetus across the placenta; it is less common for newborns to develop herpes infection from a parent with recurrent disease. However, newborn infection remains possible if a recurrence of a genital HSV lesion is present at the time of a vaginal birth. Primary infections occurring in the first or second trimester may lead to spontaneous abortion or cause fetal growth restriction. Newborn herpes infections are typically acquired at or near birth from a parent experiencing primary genital infection, of which two-thirds of patients may be asymptomatic. Elective Caesarean birth is recommended for pregnant patients who experience recognizable HSV as a primary occurrence in the third trimester (Money & Steben, 2017). Breastfeeding is contraindicated if the postpartum patient has an active lesion on their breast.

Human Immunodeficiency Virus (Type 1)

Vertical transmission of HIV occurs in less than 2% of pregnancies in Canada (Moore & Allen, 2019). Some transmissions occur in utero but most occur at the time of birth. If there have been no interventions undertaken during pregnancy, at birth, or during the newborn period, HIV transmission may occur in up to 25% of cases (Moore et al., 2019). Documented routine HIV education and routine testing with consent are recommended for all pregnant patients in Canada (Keenan-Lindsay & Yudin, 2017). Labouring patients with undocumented HIV status undergo rapid HIV testing; if maternal screening is not achievable, newborns should undergo rapid HIV antibody testing. Commencing antiretroviral prophylaxis in the newborn requires thoughtful consideration and evaluation of risk while awaiting test results; initiation of prophylaxis should occur no later than 72 hours after birth. See Table 29.5 for further discussion of HIV infection in the newborn.

Although it is rare for an infant to be born with symptoms of HIV infection, all newborns born to seropositive mothers should be presumed to be HIV positive until proven otherwise. Newborn HIV antibody testing is required; breastfeeding should be deferred until antibody test results are confirmed negative. Nursing care begins by implementing routine practices. Measures should also be taken to protect the newborn from further exposure to maternal blood and body fluids.

Parvovirus B19

Parvovirus B19 is well known in older children as fifth disease or "slapped cheek illness" because of the characteristic facial appearance of the affected child. Transmission typically occurs through respiratory droplet contact; vertical transmission may occur in persons without established immunity prior to pregnancy. The most common adverse fetal outcome associated with infected fetuses is hydrops fetalis (Baley & Gonzalez, 2020). The estimated risk of transplacental transmission is approximately 30%, and fetal death may occur in about 9% of those affected (see Table 29.5).

Rubella Infection

A pregnant patient infected with rubella has a 90% chance of transmitting the disease to the fetus (Government of Canada, 2015). Vaccination failures, failure to complete recommended vaccination schedule, and the immigration of unimmunized persons result in periodic outbreaks of rubella, also known as German measles. Congenital rubella is rare; most cases occur after primary maternal infection that causes viremia and intrauterine transmission (Baley & Gonzalez, 2020).

The risk for congenital anomalies varies with the fetus's gestational age at the time maternal infection occurs. Abnormalities are most severe if the mother contracts the virus during the first trimester, with occurrence of congenital defects as high as 85% in the first 12 weeks of gestation; infection during this time may also result in miscarriage or stillbirth (Baley & Gonzalez, 2020).

Hearing impairment, a common finding, appears to be progressive after birth. Defects of the eyes, central nervous system (CNS), and heart are also associated with congenital rubella. Microcephaly, significant cognitive and behavioural challenges, and learning issues are prevalent for children with a history of congenital rubella. Screening for rubella immunity in pregnant patients occurs during routine antenatal care. Passive and active immunization do not provide benefit to the newborn at birth as the effects of congenital rubella have already transpired. See Table 29.5 for further discussion.

Syphilis

Rates of reported syphilis infections in Canada have increased by 167% from 2008 to 2017 (PHAC, 2019). It is estimated that for every 100 pregnant patients diagnosed with primary or secondary disease, 2 to 5 newborns will contract congenital syphilis. Vertical transmission of syphilis can occur; if syphilis (primary or secondary) during pregnancy is left untreated, 70 to 100% of newborns born to these patients will have symptomatic congenital syphilis. In approximately 40% of pregnancies, fetal demise may occur (Robinson & CPS Infectious Diseases and Immunization Committee, 2009/2018). The most severely affected infants are born to untreated mothers. Breastfeeding in persons with syphilis is not contraindicated unless open lesions are present on the breast, including the nipple and areola. See Table 29.5 for further discussion.

! NURSING ALERT

The newborn with congenital syphilis may be entirely asymptomatic until after discharge from the hospital. It is therefore imperative that caregivers use routine precautions with all newborns.

Tuberculosis

Congenital tuberculosis (TB) is rare. Caused by an in utero infection with *Mycobacterium tuberculosis*, the fetus may become infected transplacentally or by aspiration of amniotic fluid (Li et al., 2019). Canada has approximately 4.9 cases of TB per 100 000 people; however, a disproportionate increase in incidence of 21.5 cases per 100 000 people has occurred among Canadian-born Indigenous people (Government of Canada, 2019). Additionally, adult refugees newly immigrated to Canada from global locations with a high incidence of the disease who have latent TB are at increased risk of developing active TB disease. Poverty, inadequate housing, and overcrowding are significant risk factors for TB. Clinical features of congenital TB can be nonspecific: respiratory distress, lethargy, persistent fever, hepatosplenomegaly, and poor feeding (Esper, 2020). After birth, exposed newborns contract TB through inhalation of infected droplets expelled by infected individuals, which results in pneumonia and necrosis of lung tissue. Treatment consists of a combination of antituberculosis agents and may be required for several months. Maternal–infant separation may be indicated if the mother tests positive for TB and has symptoms of active TB disease (Esper, 2020). Expressed breast milk may be administered, as the tubercle bacillus is passed through respiratory droplets, not breast milk (Gardner et al., 2021).

Varicella Zoster

The varicella zoster virus responsible for chickenpox and shingles is a member of the herpes family. About 90% of persons in their childbearing years are immune; therefore, the risk of infection in pregnancy is low (Shrim et al., 2018). Maternal varicella infection in early pregnancy may cause congenital malformations including cerebral atrophy, hydronephrosis, and limb anomalies in the fetus. Newborn infection is more likely to occur when maternal infection occurs less than 5 days prior to birth; 30 to 40% of newborns will develop infections even if varicella zoster immune globulin is administered to the mother (Shrim et al., 2018). Optimal newborn care includes varicella zoster immunoglobulin and immunization. See Table 29.5 for more information.

Zika

Zika virus is a mosquito-borne flavivirus; outbreaks of Zika virus disease have occurred worldwide since 2007 (World Health Organization [WHO], 2018). The bite of an infected mosquito, found mainly in tropical and subtropical regions, functions as the vector for infectious pathogen transmission to humans. Zika virus is also transmitted from the pregnant parent to the fetus in utero and can cause severe microcephaly, limb contractures, ocular abnormalities, and other neurological findings. Zika virus has also been found in breast milk, although transmission has not been confirmed. Zika virus can also be transmitted through sexual intercourse. There is no vaccine to prevent or treatment available for Zika virus disease. Sexually active men and women living in regions with active Zika virus require counselling regarding risk of transmission and contraceptive methods to prevent adverse fetal outcomes (WHO, 2018).

Candidiasis

Candidiasis is a fungal infection most commonly caused by *Candida albicans*, a species of *Candida* (CDC, 2020a). Candidiasis is not a congenital infection but rather an infection that occurs after birth. Oral candidiasis, also known as *oral thrush*, may develop even in the first week of life and presents as creamy-white patches on the tongue or buccal mucosa. The white patches are easily differentiated from milk curds; the patches cannot be removed and may bleed when touched. In most cases the infant does not seem to be in discomfort from the infection; however, some will pull away from the breast or bottle and cry.

Topical application of nystatin suspension over the surfaces of the oral cavity is usually sufficient to prevent spread of the disease and limit its course. Several other topical antifungal agents may be used, including miconazole or clotrimazole. To prevent relapse, therapy should be continued for at least 2 days after the lesions disappear (Lawrence & Lawrence, 2016). Infants who are breastfed may acquire thrush from the

breastfeeding parent. *Candida* may be present on the nipples of breastfeeding parents; if the parent is colonized, antifungal treatment for the parent is recommended to prevent reinfection in the infant. Cessation of breastfeeding is not necessary, even if the breastfeeding parent is receiving systemic antifungal medications (Lawrence & Lawrence, 2016).

! NURSING ALERT

Nystatin is best absorbed when given 1 hour after a feeding. Using a needleless syringe or medicine dropper, apply the medication to each side of the infant's mouth for optimal absorption.

Diaper dermatitis caused by *Candida* organisms manifests as a moist, erythematous eruption with a sharply demarcated edge and small white or yellow pebbly pustules; satellite lesions may extend beyond the larger lesion. Small areas of skin erosion may also be seen. *Candida* diaper dermatitis appears on the perianal area and inguinal folds and may include the lower portion of the abdomen. When possible, exposing the perineal area to dry air is recommended. Topical antifungal ointments assist in coating the skin and repelling moisture while treating the fungal ailment (see Chapter 52, Diaper Dermatitis).

Nursing Care

Trends in emerging infections command exemplary nursing practices. Careful hand hygiene remains the single most important nursing intervention in reducing the spread of any infection.

Astute recognition of risk factors and subtle changes in clinical condition assists the health care team in initiating processes to identify causative organisms of infectious processes. Implementing isolation precautions to further minimize transmission of disease may be required. Cohorting colonized patients with dedicated staff can also assist in containing infection outbreaks. Antimicrobial stewardship is pivotal in combatting antibiotic resistance; nursing staff play a pivotal role in educating families regarding the importance of optimal selection of medication and adherence to the full course of medication that is ordered, in order to lead to optimal clinical outcomes for newborns experiencing infections.

ADVERSE EXPOSURES AFFECTING NEWBORNS

Adverse exposures during pregnancy include environmental toxicants that may influence critical periods of fetal development and lead to adverse health outcomes. For example, maternal exposure to teratogens, including radiation and chemotherapy, can contribute to congenital malformations, depending on timing and duration. Paternal occupations, including exposure to solvents and pesticides, have also been linked to an increased prevalence of congenital anomalies (Falck et al., 2020). Many medications and other substances easily cross the placenta and affect fetal brain development, as well as impact the pregnant patient's circulation through the uterus and placenta. Additionally, a medication may affect the pregnant patient's metabolic physiology, resulting in stress hormone secretion that may also affect the fetus (Ross et al., 2015). As a result, in utero substance exposure may elicit a spectrum of responses. For example, the long-reaching effects of fetal alcohol spectrum disorder (FASD) may extend to the next generation through ethanol-related changes to gene expression (Liyanage et al., 2017).

The global phenomenon of opioid use has led to an increasing population of newborns that develop a passive dependence driven by prenatal exposure and resulting in withdrawal symptoms after birth. In utero substance exposure does not always lead to signs of withdrawal, nor do all newborns respond in a similar manner. Term newborns experience withdrawal more significantly than preterm infants, likely because of CNS developmental immaturity in the preterm baby; males may be more affected than females (Bagwell, 2020). Data from across Canada reflect a rise in newborn withdrawal. Between 2013 and 2017, there was an increase in incidence of neonatal abstinence syndrome (NAS) by 21% (Canadian Institute for Health Information, 2018).

Nurses are well positioned to observe and identify signs of withdrawal in a newborn's early days of life, as well as provide support and education to families. Maternal substance use may be difficult to determine, as guilt and fear may drive inaccurate responses at the time of screening. Information can be garnered by asking questions privately in a nonjudgemental manner. Drug dependence in pregnancy does not sit within a homogeneous profile; persons of all ages, ethnicities, and socioeconomic backgrounds experience drug dependence. Polydrug use occurs frequently; thus nurses need to ask questions specific to the use of prescription medications, over-the-counter drugs, nutritional supplements, legal substances including alcohol, tobacco, and marijuana, and illicit or other recreational drugs.

Newborn toxicology screens can be completed on urine and meconium, although both present benefits and challenges to their use. Newborn urine toxicology screens will reflect recent substance exposure only; infrequent maternal substance use or use prior to 1 week before birth may not be detected. Meconium toxicology screening helps in detecting substance exposure in the last trimester. However, specimen collection proves to be challenging and may yield false negatives, particularly when newborn substance exposure is not initially considered during the newborn's first day or two of life. Hair testing for clinical indications of substance exposure is rarely used. Legal requirements for the drug testing of newborns vary by province; thus health care providers must be aware of the regulations in their location (Ordean et al., 2017).

Neonatal Abstinence Syndrome

Initially developed by Dr. Finnegan, the term **neonatal abstinence syndrome (NAS)** is used to describe the set of behaviours exhibited by newborns exposed primarily to opioids; other substances in utero may also elicit features of withdrawal (Bagwell, 2020). The initial presenting symptoms of withdrawal may be seen at variable times, depending on the amount of in utero substance exposure and the associated principles of pharmacokinetics for the substance. Clinical manifestations may fall into any one or all of the following categories: CNS, and gastrointestinal, respiratory, and autonomic nervous systems. The manifestations become most pronounced between 24 and 72 hours of age and may last from 6 days to 8 weeks, depending on the severity of the withdrawal (Box 29.1).

Some effects may not be identified until after the newborn period, possibly not until school age, and can include cognitive and motor delay as well as behavioural issues. Table 29.6 summarizes the effects of commonly used substances on the fetus and newborn.

Several assessment tools exist to objectively evaluate symptoms associated with withdrawal and the infant's response to interventions. The Finnegan Neonatal Abstinence Scoring System tool, or simply referred to as "the Finnegan" (see Figure 29.7), was established in 1975 and remains the mainstay for assessment and management of NAS. Several other scoring tools exist but are not as widely used and therefore will not be explored in this text. Grossman and colleagues (2018) have outlined an alternative approach to assessment for withdrawal that focuses on infant performance related to three parameters: eating, sleeping, and consolability (ESC). Infants exposed to substances in the prenatal period are cared for in the hospital within a setting that facilitates family rooming-in and control over the surrounding environment while being observed for specific outcomes: (1) feed more

BOX 29.1 Signs of Withdrawal in Newborns

Neurological	Autonomic	Gastrointestinal	Miscellaneous
• Irritability	• Diaphoresis	• Poor feeding	• Disrupted sleep patterns
• Seizures	• Fever	• Loose stools	• Excoriations (knees, face)
• Hyperactivity	• Mottled skin	• Dehydration	• Temperature instability
• High-pitched cry	• Nasal stuffiness	• Vomiting	
• Tremors	• Tachypnea (>60 breaths/min)	• Frantic, uncoordinated sucking	
• Exaggerated Moro reflex			
• Hypertonicity of muscles			

TABLE 29.6 Summary of Effects of Commonly Used Substances on the Newborn

Substance	Effects on Newborn
Alcohol	Difficult to diagnose fetal alcohol spectrum disorder (FASD) in newborn period; newborns with in utero exposure to alcohol may have increased irritability, abnormal muscle tone, tremors, weak grasp. *Fetal alcohol syndrome (FAS):* Facial features include short palpebral fissure (distance between inner and outer corner of eye), flat philtrum (upper lip groove), thin upper lip, flat midface; growth impairment, hyperactivity, cognitive delays, attention deficits, altered receptive and expressive communication. *Partial FAS or alcohol-related neurodevelopmental disorder (ARND):* These are varying forms of FAS, with cognitive, behavioural, and psychosocial issues without all physical features.
Cannabis	Possible preterm birth, low birth weight, growth restriction
Cocaine	Preterm birth, small for gestational age, microcephaly
Opioids	Low birth weight, small for gestational age, hyperirritability, tremors, inconsolability, sleep pattern disturbance, high-pitched cry, feeding difficulties, loose stools, vomiting, respiratory distress, rarely seizures
Methamphetamine	Small for gestational age, preterm birth, poor weight gain, abnormal sleep patterns, agitation, poor feeding, state disorganization
Tobacco	Preterm birth, low birth weight, increased risk for sudden infant death syndrome
Selective serotonin reuptake inhibitors	Preterm birth, sleep disturbances, tremulousness, high-pitched crying, feeding difficulties

than 30 mL/feed, (2) complete 1 hour of sleep uninterrupted, and (3) are soothed within 5 to 10 minutes of caregiver effort without pharmacological aid (Grossman et al., 2018).

Features of Neonatal Abstinence Syndrome. Maternal opioid use during pregnancy is the primary, but not exclusive, cause of NAS. The presentation of clinical symptoms depends on the type and duration of maternal opioid use, the amount of drug taken, and the time of last use prior to birth. Features of NAS may present shortly after birth, usually within the first 72 hours (see Figure 29.7). Because of its longer half-life, infants of mothers using methadone (or buprenorphine) may not present with NAS until later in the first week of life (Lacaze-Masmonteil et al., 2020). A high-pitched cry, difficulties in settling, tremors, and poor feeding are hallmark features of NAS.

Opioid Exposure

The primary cause of NAS is in utero exposure to maternal use of opioids. Opioid use may be prescribed to reduce pain, may be used illicitly to produce a "high," or may be used as part of a therapy program to support persons recovering from opioid use disorder. Drugs classified as opioids include but are not limited to codeine, oxycodone, morphine, hydromorphone, fentanyl, and heroin. Buprenorphine and methadone are also opioids that help to prevent withdrawal symptoms without creating a "high" and are therefore used in treatment programs for opioid use disorder. Offspring of mothers treated with buprenorphine have higher birth weights than those exposed to methadone, have shorter hospital stays, and lower NAS scores. Breastfeeding persons in a methadone treatment program are encouraged to breastfeed, regardless of the methadone treatment dosage.

Data to indicate the prevalence of opioid use in pregnant patients in Canada are reflected in the number of infants who are treated for NAS. The Canadian Institute for Health Information reported that in 2015–16 approximately 0.52% of all infants born in Canada had NAS (Lisonkova et al., 2019).

Opioids cross the placenta; regular in utero exposure to opioids may lead to fetal passive dependence and other sequelae (see Table 29.6). The method of maternal opioid use, such as injection, places mothers at risk for possible bacterial infections or other diseases, including hepatitis or HIV, which can also compound complications for the fetus. Patients using opioids during pregnancy may experience an increased rate of spontaneous abortion. Newborns exposed to in utero opioids may be born prematurely, experience growth restriction, or have LBW (Jackson et al., 2021). Research evaluating neurodevelopmental outcomes, such as compromised school performance, yielded some evidence demonstrating an association with prenatal opioid exposure (Conradt et al., 2019). Social determinants of health affecting children with prenatal opioid exposure include poverty, which also confounds findings and is not uncommon (Conradt et al., 2019).

Maintaining the mother–baby dyad intact by rooming-in, instead of admitting the baby to the NICU, helps in optimizing treatment of NAS for medically stable newborns (Lacaze-Masmonteil et al., 2020). Support and encouragement for establishing breastfeeding are recommended.

! NURSING ALERT

The use of naloxone (Narcan) is contraindicated in infants born to mothers who use opioids because it may exacerbate neonatal abstinence syndrome and contribute to the onset of seizures.

NEONATAL ABSTINENCE SCORING SYSTEM

System	Signs and Symptoms	Score	AM						PM						Comments
Central Nervous System Disturbances	Excessive high-pitched (or other) cry Continuous high-pitched (or other) cry	2 3													Daily weight:
	Sleeps <1 hour after feeding Sleeps <2 hours after feeding Sleeps <3 hours after feeding	3 2 1													
	Hyperactive Moro reflex Markedly hyperactive Moro reflex	2 3													
	Mild tremors disturbed Moderate-severe tremors disturbed	1 2													
	Mild tremors undisturbed Moderate-severe tremors undisturbed	3 4													
	Increased muscle tone	2													
	Excoriation (specific area)	1													
	Myoclonic jerks	3													
	Generalized convulsions	5

Fig. 29.8 Child with fetal alcohol syndrome. (From Markiewicz & Abrahamson, 1999.)

Alcohol Exposure

Alcohol is the most common teratogen that fetuses are exposed to in North America (Jackson et al., 2021). Alcohol (ethanol and ethyl alcohol) interferes with normal fetal development; the effects on the fetal brain are permanent, and even moderate use of alcohol during pregnancy may cause long-term postnatal difficulties, including impaired parental–infant attachment. Maternal alcohol use during pregnancy can lead to a range of effects known as *fetal alcohol spectrum disorder* (FASD), which includes fetal alcohol syndrome (FAS), partial FAS (pFAS) and alcohol-related neurodevelopmental disorder (ARND) (Popova et al., 2019). Health Canada (2017) reports that, in Canada, approximately 3 000 babies with FASD are born each year. Popova and colleagues (2019) identified a 2 to 3% prevalence of FASD in a population-based study of 7- to 9-year-old elementary school students.

FAS, the most severe form of FASD, may not be easily identifiable at birth; a smooth filtrum, thin vermilion border, and short palpebral fissures comprise the sentinel midfacial dysmorphic features associated with FAS, in addition to growth restriction (Figure 29.8). Damage to the CNS may lead to microcephaly, cognitive and/or behavioural issues, speech and language deficits, and visual motor impairments (Box 29.2). Partial FAS represents a diagnostic classification for infants and children with a confirmed prenatal exposure to alcohol and who may not have all of the physical features of FAS; cognitive and behavioural issues are evident. ARND represents a classification of children with a confirmed prenatal alcohol exposure and cognitive and behavioural issues only.

Behavioural symptoms of FAS are nonspecific in newborns. Features include difficulty in establishing respiration, irritability, lethargy, poor suck reflex, and abdominal distension.

Fetal abnormalities are not related to the amount of the mother's alcohol intake per se, but to the amount consumed in excess of the liver's ability to detoxify it. The liver's capacity to detoxify alcohol is limited and inflexible; when the liver receives more alcohol than it is able to handle, the excess is continually recirculated until the organ is able to reduce it to carbon dioxide and water. This circulating alcohol has a special affinity for brain tissue. Poor nutritional state, smoking, polydrug intake, and infrequent or lack of prenatal care may compound

BOX 29.2 Characteristics for Diagnosing Fetal Alcohol Spectrum Disorder (FASD)

Facial Dysmorphia

Despite consideration of ethnic norms (i.e., those appropriate for a person's race), the person exhibits all three of the following characteristic facial features (FAS all three, pFAS any two):

1. Smooth philtrum (University of Washington Lip-Philtrum Guide* rank 4 or 5)
2. Thin upper lip (University of Washington Lip-Philtrum Guide rank 4 or 5)
3. Short palpebral fissures (≤ tenth percentile)

Neurodevelopmental Impairment

Evidence of three or more of the following neurodevelopmental domains (FAS, pFAS, ARND):

- Microcephaly; abnormal neuroanatomy (e.g., reduction in size or change in shape of the frontal or parietal lobe, corpus callosum, cerebellum, hippocampus or basal ganglia)
- Psychological testing to determine impairment of ≥2 SDs or more below the mean in:
  - Motor skills
  - Language (receptive and expressive)
  - Academic achievement
  - Memory
  - Attention
  - Executive function, including impulse control and hyperactivity
  - Affect regulation
  - Adaptive behaviour, social skills, or social communication

Maternal Alcohol Exposure

- Confirmed prenatal exposure to alcohol
- Unknown prenatal exposure to alcohol

Criteria for FASD Diagnosis

Diagnosis may be made based on either of the two sets of criteria:

1. Three sentinel facial features AND evidence of impairment in three or more of the identified neurodevelopmental domains (or microcephaly in infants and young children); prenatal alcohol exposure confirmed or unknown
2. Absence of all three sentinel facial features with evidence of impairment of three or more identified neurodevelopmental domains AND confirmed prenatal alcohol exposure with estimated dose exposure known to be associated with neurodevelopmental effects

ARND, Alcohol-related neurodevelopmental disorder; *FAS,* fetal alcohol syndrome; *pFAS,* partial fetal alcohol syndrome.

the effects of alcohol use during pregnancy (May et al., 2013). Newborns born to mothers who are heavy alcohol drinkers may experience significantly more tremors, hypertonia, restlessness, excessive mouthing movements, crying, and inconsolability when compared to newborns who have had in utero exposure to other substances.

Nursing care of affected infants involves the same assessment and observations employed for any high-risk newborn. Breastfeeding is not contraindicated; however, poor feeding (breast or bottle) is characteristic of newborns with FAS and can be a significant challenge throughout infancy. The provision of individualized developmental care includes the reduction of noxious environmental stimuli and helping the newborn achieve self-regulation. Special emphasis is placed on monitoring weight gain, assessing feeding behaviours, and devising strategies to promote nutritional intake.

There is no cure for FASD; the effects are lifelong. Early diagnosis and access to interventions and resources may assist in providing support for infants and children with FASD, particularly as they enter school years. FASD is recognized as the leading cause of cognitive impairment in children—and it is preventable. There is no safe amount or type of alcohol-based drink to consume at any point during pregnancy (Carson et al., 2017). Pregnant patients who are unable to eliminate alcohol intake may benefit from compassionate and knowledgeable support from professional counsellors trained to assist in harm-reduction strategies.

Tobacco and Nicotine Exposure

Nicotine and tobacco products that might be used during pregnancy include nicotine replacement products, e-cigarettes, rolled cigarettes, and chewing tobacco (Bordelon et al., 2019). Smoking and passive exposure to second-hand smoke during pregnancy increases the risk for LBW and preterm birth (Falck et al., 2020). The effects of tobacco on a fetus are listed in Table 29.6. Carbon monoxide found in tobacco smoke may contribute to intrauterine hypoxia and subsequent neurological injury. In utero exposure to nicotine may interfere with normal neurotransmitter function and disrupt formation of neuronal circuits, leading to issues in cognitive and emotional development (Wickström, 2007). In utero or second-hand exposure, or both, to nicotine from any source, including e-cigarettes and nicotine replacement therapies, may increase the risk of sudden infant death syndrome (SIDS).

Smoking cessation during pregnancy decreases risks of associated fetal complications; thus counselling pregnant patients regarding smoking cessation programs is encouraged (see Chapter 5, Substance Use Cessation). Empowering parents through education to establish smoke-free zones at home and in vehicles may assist in reducing the frequency of asthmatic-related events, bronchitis, and ear infections in their children.

Cannabis Exposure

Canada implemented legislation in 2018 that legalized nonmedicinal use of cannabis. It is the second most commonly used substance, following alcohol, and is recreationally used for its psychoactive properties (PHAC, 2018). Cannabis is usually smoked or inhaled, but it may also be found in edibles, tinctures, and oils. Cannabis is a plant made up of components known as cannabinoids, two of which are better understood: cannabidiol (CBD) and delta-9-tetrahydrocannabinol (THC). CBD does not have psychoactive properties but may be used to help reduce nausea, inflammation, or pain as well as assist in managing seizures. THC is the main psychoactive component and is a cannabinoid receptor agonist, which potentiates the effects of the endogenous cannabinoid system, producing the "high" (Lu & Mackie, 2016).

The potency of THC has increased in cannabis used for inhaling; products analyzed in the 1980s demonstrated 3% THC, and in 2015, upwards of 17% potency has been noted. THC crosses the placenta; there is some evidence to suggest that exposure to the fetus may contribute to an increased risk of growth restriction, preterm birth, spontaneous loss, and stillbirth. However, the data are limited by confounders including polydrug use, self-report, and small sample sizes (Thompson et al., 2019). It is recommended that pregnant patients avoid using cannabis in any form, as it may also exert a negative effect on fetal brain development, as well as on behaviour, cognitive, and academic performance throughout infancy and the pediatric years (Corsi et al., 2020; PHAC, 2018).

There are extremely limited data on the effects of cannabis use while breastfeeding. Low concentrations of THC are transferred in mother's breast milk, approximately 2.5% of the maternal dose, with peak transfer concentrations noted at 1 hour after inhaling (Baker et al., 2018). Cannabis exposure through breast milk is very unlikely to benefit the baby and may be harmful, in view of the limited data available on the effects of THC transfer through the placenta. Breastfeeding provides benefits for both mother and infant, particularly the preterm infant. Abstinence from using cannabis while breastfeeding is encouraged, as with alcohol and tobacco use (Ryan et al., 2018). However, if complete abstinence is not possible, the patient can be encouraged to reduce use of cannabis or consider breastfeeding immediately prior to use.

Cocaine Exposure

Cocaine is a CNS stimulant and peripheral sympathomimetic. The effects on the fetus are secondary to maternal effects of increased blood pressure, decreased uterine blood flow, and increased vascular resistance. Consequently, the fetus suffers decreased blood flow and oxygenation as a result of placental and fetal vasoconstriction. The difficulties encountered by cocaine-exposed infants can be compounded by maternal polydrug use (see Table 29.6). Inadequate prenatal care, poor nutrition, and use of tobacco, alcohol, and other drugs during pregnancy add to the effects of cocaine exposure in the infant.

Sequelae of prenatal cocaine exposure include preterm birth and reduced newborn head circumference, length, and weight. Head growth may be one of the best predictors of long-term development. Early studies of cocaine exposure identified an increased incidence of gastroschisis, genitourinary anomalies, and periventricular and intraventricular hemorrhage; however, meta-analyses have not confirmed these complications (Bandstra et al., 2010). Infants exposed to cocaine in utero do not typically experience features of abstinence syndrome (Jackson et al., 2021). Long-term sequelae for newborns exposed to cocaine may include compromised language, motor, and cognitive skills and an increased risk for learning disabilities. Cocaine has been found in breast milk and may cause the newborn to experience apnea, tremors, and seizures (Jackson et al., 2021). Mothers should be cautioned about these hazards with a strong recommendation to avoid use of breast milk if abstinence from cocaine habits is unlikely. Because mothers and their infants may live in impoverished environments, they are at further risk for lack of child health care, inadequate nutrition, and cognitive delays and may benefit from referral to early intervention programs.

Methamphetamine Exposure

Methamphetamine use creates a significant burden of illness across Canada because of its inherent risk for dependence; it readily crosses the blood–brain barrier of the user, which leads to a rapid onset of euphoria and creates the "hook." Methamphetamine interferes with the neurotransmitters serotonin and norepinephrine, which influence amniotic fluid homeostasis and fetal circulation as well as blood flow through the placenta (Wright et al., 2015). Interruption of the normal neurotransmitter transporter activity contributes to sequelae that negatively affect maternal health and pregnancy. Studies evaluating the fetal and newborn effects of maternal use of methamphetamines in

pregnancy are confounded by variables including polydrug use, poverty, and poor maternal nutrition. An increased likelihood of Caesarean birth due to maternal complications, preterm birth, and low birth weight has been reported in infants exposed to methamphetamines in utero; congenital defects are rare (Wright et al., 2015). In the newborn period, infants may experience abnormal sleep patterns, agitation, poor feeding, and state disorganization (Sherman, 2015).

The long-term effects of methamphetamine exposure on children remain unclear. It is postulated that, like cocaine, methamphetamine exposure may affect areas of the brain responsible for cognitive and behavioural functioning, with effects more likely to manifest when the child reaches school age (Lester & Lagasse, 2010). Breastfeeding is contraindicated for persons unable to abstain from methamphetamine use.

Selective Serotonin Reuptake Inhibitors

Depression is a condition that affects approximately 10% of pregnant patients (Eke et al., 2016). For many patients, selective serotonin reuptake inhibitors (SSRIs) provide an important therapeutic benefit. These medications may result in adverse effects in their newborns, including preterm birth. Congenital malformations, including cardiac anomalies, may occur in infants whose mothers were treated with SSRI therapy in the first trimester, particularly when combined with other adjunctive pharmacotherapy (Olivier et al., 2013). An increased risk of persistent pulmonary hypertension has been reported in newborns exposed to SSRIs early in pregnancy (Cantor Sackett et al., 2009); however, this finding has not been reported consistently (Wilson et al., 2011). Some SSRIs are transferred into breast milk. Breastfeeding newborns whose mothers are taking SSRIs require monitoring for sleep disturbances, irritability, and poor feeding.

Nursing Care

Drug dependence and drug misuse in pregnant patients contribute to the growing population of newborns experiencing NAS at birth. Caring for infants experiencing NAS involves both nonpharmacological and pharmacological interventions. Individualized developmental care can be implemented to facilitate the infant's self-consoling and self-regulating behaviours. Primary nonpharmacological strategies include reducing environmental stimuli, swaddling and rocking the child, and providing feeding on demand (Gomez-Pomar & Finnegan, 2018). Swaddling provides containment; the infant's arms need to remain flexed with hands in close proximity of the mouth for sucking, as sucking on fingers or hands is a form of self-control and comfort. Organizing of nursing activities and clustering of care reduce the amount of handling and help decrease exogenous stimulation. Offering a pacifier can ease the characteristic frantic, excessive sucking commonly demonstrated as part of the withdrawal process. Volunteer cuddler programs may augment and support the role of nurses and parents for newborns in nursery settings. Breastfeeding, when not contraindicated, may mitigate symptoms and reduce the need for pharmacological therapies. In tandem, these interventions can reduce the severity of NAS symptoms an infant may experience.

Hospital settings that facilitate rooming-in for the mother–infant dyad are well positioned to implement the Eat, Sleep, Console (ESC) assessment and supportive approach to treating NAS (Grossman et al., 2018) mentioned earlier. Reports indicate that this approach may result in a reduction in length of hospital stay and in use of pharmacological agents for some infants exposed to methadone (Hudak, 2020).

Supportive and nonpharmacological measures may not meet the needs of some infants experiencing NAS. Infants who score 8 or higher on three consecutive assessments using the Finnegan scoring tool (Figure 29.7) warrant consideration for treatment with pharmacological agents (Weiner & Finnegan, 2021). Common single medication therapies include morphine or clonidine to ease the symptoms of NAS; phenobarbital may also be used as an adjuvant therapy (Gomez-Pomar & Finnegan, 2018). Specific suggestions for providing care to infants experiencing withdrawal are listed in the Guidelines box: Care of the Infant Experiencing Withdrawal.

GUIDELINES

Care of the Infant Experiencing Withdrawal

- Place the infant in a side-lying position with the spine and legs flexed when awake.
- Position the infant's hands in midline.
- Carry the infant in a flexed position.
- When interacting with the infant, introduce one stimulus at a time. Interaction should occur when the infant is in a quiet, alert state. Monitor for time-out or distress signals (e.g., gaze aversion, yawning, sneezing, hiccups, arching, mottled colour).
- When the infant is distressed, swaddle in a flexed position and rock in a slow, rhythmic fashion.
- Put the infant in a sitting position with chin tucked down for feeding.

Loose stools, poor intake, and regurgitation after feeding predispose newborns with NAS to malnutrition, dehydration, and electrolyte imbalance. Infants may rapidly utilize energy sources as a result of continuous activity; thus careful monitoring of intake and output and electrolytes, provision of additional caloric supplementation, and daily weighing may be necessary. Breastfeeding is encouraged for mothers who are not using illicit substances, are negative for HIV infection, and are following a methadone program. Breastfeeding promotes maternal–infant bonding, and the small amount of methadone passed through breast milk has not proved to be harmful to the newborn (Hale, 2021; Lefevere & Allegaert, 2015). Providing prenatal education for the pregnant patient regarding the effects of the recreational drugs discussed earlier remains vital (see Nursing Care Plan The Drug-Exposed Newborn on Evolve).

HEMATOLOGICAL DISORDERS

Hemolytic disease of the newborn (HDN), also called *erythroblastosis fetalis*, is a condition in which red blood cells (RBC) are broken down or destroyed. As the red cell destruction evolves, anemia may ensue. Anemia caused by this destruction stimulates the production of RBCs, which in turn provides increasing numbers of cells for hemolysis. Major causes of increased erythrocyte destruction are isoimmunization (primarily Rh) and ABO incompatibility. Bilirubin is a byproduct of RBC breakdown; excessive bilirubin levels may result with significant hemolysis.

Blood Incompatibility

The membranes of human blood cells contain a variety of antigens, also known as *agglutinogens*, substances capable of producing an immune response if recognized by the body as foreign. The reciprocal relationship between antigens on RBCs and antibodies in the plasma causes *agglutination*, or binding of multiple particles into larger complexes (clumping). In other words, antibodies in the plasma of one blood group produce agglutination when mixed with antigens of a different blood group. In the ABO blood group system, the antibodies occur naturally. In the Rh system, exposure to the Rh antigen is required before significant antibody formation takes place and causes a sensitivity response known as *isoimmunization*.

Rh Incompatibility (Isoimmunization). The Rh blood group consists of several antigens. For simplicity, only the terms *Rh positive* (presence of antigen) and *Rh negative* (absence of antigen) are used in this

discussion. The presence or absence of the naturally occurring Rh factor determines the blood type.

Complications do not typically arise when the Rh blood types are the same in both the childbearing parent and the fetus or when the childbearing parent is Rh positive and the newborn is Rh negative. Complications may arise when the mother is Rh negative and the newborn is Rh positive. Although the maternal and fetal circulations are separate, there is evidence of a bidirectional trafficking of fetal RBCs and cell-free DNA to the maternal circulation (Moise, 2017). However, more commonly, fetal RBCs enter into the maternal circulation at the time of birth. The natural defence mechanism of the childbearing parent responds to these alien cells by producing anti-Rh antibodies.

Under normal circumstances, this process of isoimmunization has no effect during the first pregnancy with an Rh-positive fetus because the initial sensitization to Rh antigens rarely occurs before the onset of labour. However, with the increased risk of fetal blood being transferred to the maternal circulation during placental separation, maternal antibody production is stimulated. During a subsequent pregnancy with an Rh-positive fetus, these previously formed maternal antibodies to Rh-positive blood cells may enter the fetal circulation, leading to destruction of fetal erythrocytes (Figure 29.9). Multiple gestations, placental abruption, placenta previa, manual removal of the placenta, and Caesarean birth increase the incidence of transplacental hemorrhage and subsequent isoimmunization (Diehl-Jones & Fraser, 2015).

The fetus attempts to compensate for progressive hemolysis and anemia by accelerating the rate of erythropoiesis (red blood cell production). As a result, immature RBCs (erythroblasts) appear in the fetal circulation, thus the term **erythroblastosis fetalis**.

There is wide variability in the development of maternal sensitization to Rh-positive antigens. Sensitization may occur during the first pregnancy if the pregnant patient had previously received an Rh-positive blood transfusion. No sensitization may occur in situations in which a strong placental barrier prevents transfer of fetal blood into the maternal circulation. In approximately 10 to 15% of sensitized parents there is no hemolytic reaction in the newborn. In addition, some Rh-negative patients, even though exposed to Rh-positive fetal blood, are immunologically unable to produce antibodies to the foreign antigen.

In the most severe form of erythroblastosis fetalis, **hydrops fetalis**, the progressive hemolysis causes fetal hypoxia, cardiac failure, generalized edema (anasarca), and fluid effusions into the pericardial, pleural, or peritoneal spaces (hydrops). The fetus may be stillborn or the newborn may have severe respiratory distress. Maternal Rh immune globulin (RhIG) administration, early intrauterine detection of fetal anemia by ultrasonography (serial Doppler assessment of the peak velocity in the fetal middle cerebral artery), and subsequent treatment by fetal blood transfusions or high-dose IVIG have dramatically improved the outcome of affected fetuses (Moise, 2017). The detection of cell-free fetal DNA in the maternal plasma of Rh(D)-negative patients to detect an Rh(D)-positive fetus has been shown to be effective and may reduce unnecessary treatment with routine anti-D immunoglobulin (Yang et al., 2019).

ABO Incompatibility. Hemolytic disease can also occur when the major blood group antigens of the fetus are different from those of the pregnant patient.

The major blood groups are A, B, AB, and O. The presence or absence of antibodies and antigens determines whether agglutination will occur. Antibodies in the plasma of one blood group (except the AB group, which contains no antibodies) produce agglutination when mixed with antigens of a different blood group. Naturally occurring antibodies in the recipient's blood cause agglutination of a donor's RBCs. The agglutinated donor cells become trapped in peripheral blood vessels, where they hemolyze, releasing large amounts of bilirubin into the circulation.

The most common blood group incompatibility in the newborn is between a mother with O blood group and an infant with A or B blood group (see Table 29.7 for possible ABO incompatibilities). Naturally occurring anti-A or anti-B antibodies already present in the parental circulation cross the placenta and attack the fetal RBCs, causing hemolysis. Usually the hemolytic reaction is less severe than in Rh incompatibility; however, rare cases of hydrops have been reported (Bagwell &

TABLE 29.7 Potential Maternal–Fetal ABO Incompatibilities

Maternal Blood Group	Incompatible Fetal Blood Group
O (antibodies primarily IgG and may cross placenta leading to hemolysis)	A or B
A or B (antibodies primarily IgM and do not cross placenta)	Fetal blood type not significantly impacted by maternal blood type A, B, or AB

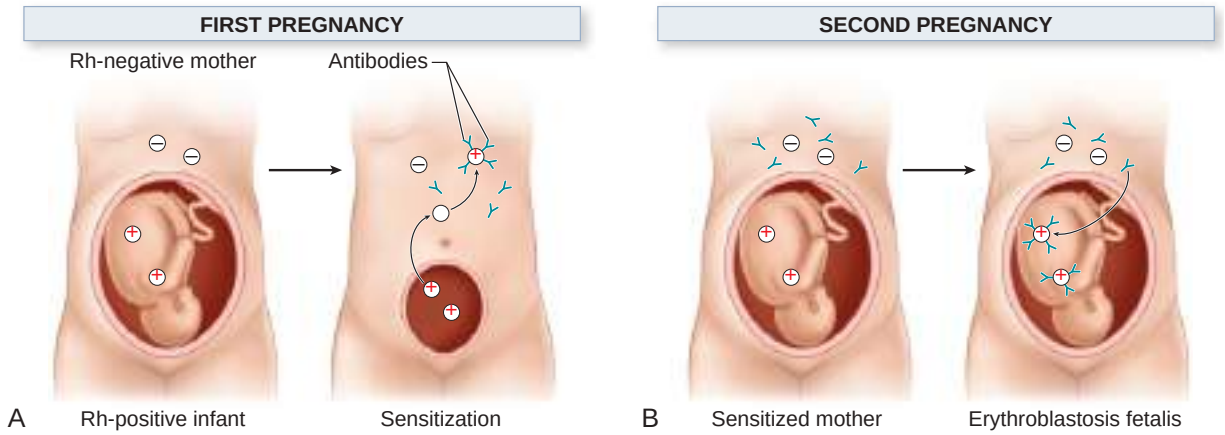

Fig. 29.9 Development of maternal sensitization to Rh antigens. **A:** Fetal Rh-positive erythrocytes enter the maternal system. Maternal anti-Rh antibodies are formed. **B:** Anti-Rh antibodies cross the placenta and attack fetal erythrocytes.

Steward, 2020). Unlike the Rh reaction, ABO incompatibility may occur in the first pregnancy. The risk of significant hemolysis in subsequent pregnancies is higher when the first pregnancy is complicated by ABO incompatibility.

Therapeutic Management and Nursing Care. Early identification and diagnosis of Rh(D) sensitization are important in the management and prevention of fetal complications. A maternal antibody titre (indirect Coombs' test) should be drawn at the first prenatal visit. Genetic testing enables early identification of paternal zygosity at the Rh(D) gene locus, thus allowing earlier detection of the potential for isoimmunization and avoiding further maternal or fetal testing (Egbor et al., 2012). Amniocentesis tests the fetal blood type of a pregnant patient whose antibody screen result is positive; the use of polymerase chain reaction (PCR) may determine the fetal blood type and presence of maternal antibodies. The fetal hemoglobin and hematocrit can also be measured. Risks associated with chorionic villus sampling may preclude its use, including possible spontaneous abortion of the fetus or fetomaternal hemorrhage. With either method, if the fetus is found to be Rh negative, no further treatment is required.

Ultrasonography is considered an important adjunct in the detection of isoimmunization. Alterations in the placenta, umbilical cord, and amniotic fluid volume and the presence of fetal hydrops can be detected with high-resolution ultrasonography and enable early treatment, before the development of erythroblastosis. Doppler ultrasonography of fetal middle cerebral artery peak velocity has been used to detect and measure fetal hemoglobin and, subsequently, fetal anemia (Moise, 2017). Erythroblastosis fetalis caused by Rh incompatibility can also be monitored by evaluating rising anti-Rh antibody titres in the maternal circulation or testing the optical density of amniotic fluid (delta OD450 test) because bilirubin discolours the fluid.

HDN is suspected on the basis of the timing and appearance of jaundice and can be confirmed postnatally by detecting antibodies attached to the circulating erythrocytes of affected infants (direct Coombs' test or direct antiglobulin test). The Coombs' test may be performed on umbilical cord blood samples from infants born to Rh-negative mothers if there is a history of incompatibility or further investigation is warranted.

The primary therapeutic management of isoimmunization is prevention. Postnatal therapy includes phototherapy for mild cases of hemolysis and exchange transfusion for severe unconjugated hyperbilirubinemia. Although phototherapy may control bilirubin levels in mild cases, the hemolytic process may continue, causing severe anemia between 7 and 21 days of life. Families require education at hospital discharge regarding the importance of timely follow-up with a pediatric health care provider for possible repeat laboratory analysis of bilirubin and hemoglobin.

Other Hemolytic Disorders

It is not within the scope of this text to discuss all potential causes of hemolytic jaundice in childhood. However, in some populations there is a high incidence of glucose-6-phosphate dehydrogenase deficiency (G6PD), which may cause an exaggerated jaundice in a newborn within 24 to 48 hours of birth. G6PD red cells hemolyze at a greater rate than healthy red cells, thus overwhelming the immature newborn liver's ability to conjugate the indirect bilirubin. Some of the triggers that potentiate hemolysis include vitamin K, acetaminophen, Aspirin, sepsis, and exposure to certain chemicals. Hereditary spherocytosis may also cause serious neonatal hemolytic anemia as a result of high quantities of fetal hemoglobin; jaundice may develop rapidly and require phototherapy (Merguerian & Gallagher, 2020). Treatment remains the same as for other circumstances in newborns with rapidly rising serum bilirubin levels.

Other metabolic and inherited conditions that increase hemolysis and may cause jaundice in the infant include galactosemia, Crigler-Najjar disease, and hypothyroidism.

Prevention. As stated earlier, the primary way of treating isoimmunization is through prevention. The administration of RhIG, a human gamma globulin concentrate of anti-D, to all unsensitized Rh-negative mothers after birth or abortion of an Rh-positive infant or fetus prevents the development of maternal sensitization to the Rh factor. The injected anti-Rh antibodies are thought to destroy (by subsequent phagocytosis and agglutination) fetal RBCs passing into the maternal circulation before they can be recognized by the mother's immune system. Because the immune response is blocked, anti-D antibodies and memory cells (which produce the primary and secondary immune responses, respectively) are not formed (Blackburn, 2018). The inhibition of memory cell formation is especially important because memory cells provide long-term immunity by initiating a rapid immune response after the antigen is reintroduced (McCance & Huether, 2014).

To be effective, RhIG (e.g., WinRho) must be administered to unsensitized mothers within 72 hours (but possibly as long as 3 to 4 weeks) after the first birth or abortion and repeated in subsequent pregnancies or losses. The administration of RhIG at 26 to 28 weeks of gestation further reduces the risk of Rh isoimmunization. RhIG is not effective against existing Rh-positive antibodies in the maternal circulation.

Intravenous immunoglobulin (IVIG) may be used to decrease the severity of RBC destruction (hemolysis) in HDN and reduce the need for exchange transfusion. However, there is a lack of evidence to support the efficacy of this intervention (Louis et al., 2014).

Therapeutic Management

Intrauterine transfusion. The fetus of a parent already sensitized may be treated by intrauterine transfusion, which consists of infusing blood into the umbilical vein of the fetus. Therapy is indicated on the basis of antenatal diagnosis of fetal anemia by serial Doppler assessments of peak systolic velocity of the middle cerebral artery (Moise, 2017). With the advance of ultrasound technology, fetal transfusion may be accomplished directly via the umbilical vein, infusing type O Rh-negative packed RBCs to raise the fetal hematocrit to 40 to 50%. Fetal movement and transfusion risks are minimized by administering medication to provide temporary fetal muscle relaxation. A fetus that is severely affected may require ongoing transfusions every 1 to 4 weeks until the fetus is more mature or exhibits signs of in utero deterioration (Abbasi et al., 2017). Intraperitoneal blood transfusions are used less commonly for isoimmunization because of higher associated fetal risks; however, they may be used when intravascular access is not achievable.

Exchange transfusion. Exchange transfusions occur infrequently because of the decrease in the incidence of severe hemolytic disease in newborns resulting from isoimmunization. Exchange transfusion is an advanced mode of therapy for treatment of severe hyperbilirubinemia. Exchange transfusion removes the sensitized erythrocytes, lowers the serum bilirubin level to prevent bilirubin encephalopathy, corrects the anemia, and prevents cardiac failure. Indications for exchange transfusion in full-term newborns may include a rapidly increasing serum bilirubin level and hemolysis despite intensive phototherapy. The criteria for exchange transfusions in preterm infants vary according to associated illness factors. Other factors must be considered, particularly the newborn's clinical condition, because it is a procedure with potential complications. Guidelines for the initiation of exchange transfusion for infants 35 weeks of gestation or greater have been developed by the CPS (Barrington et al., 2007/2018).

Severe unconjugated hyperbilirubinemia is considered a newborn emergency and requires prompt intervention to prevent the permanent

sequelae of bilirubin encephalopathy. Exchange transfusion is accomplished by alternately removing a small amount of the newborn's blood and replacing it with an equal amount of donor blood, ideally through umbilical artery and venous catheters. If the newborn has Rh incompatibility, type O Rh-negative blood is used for transfusion, so the maternal antibodies still present in the newborn do not hemolyze the transfused blood. Depending on the newborn's size, gestational age, and condition, 5 to 20 mL of the newborn's blood is removed at one time and replaced with an equal amount of warmed donor blood. Preservatives in donor blood lower the newborn's serum calcium level; therefore, calcium gluconate may be required during the exchange transfusion. The newborn is monitored closely for signs of a blood transfusion reaction as well as hypotension, temperature instability, and cardiorespiratory compromise.

Nursing Care. The initial nursing responsibility is recognizing jaundice in the newborn at risk. The possibility of hemolytic disease can be anticipated from the perinatal history. Prenatal evidence of incompatibility and a positive Coombs' test result are cause for increased vigilance for early signs of jaundice in a newborn.

If an exchange transfusion is required, the nurse prepares the newborn and the family and assists the practitioner with the procedure. The newborn receives nothing by mouth (NPO) during the procedure, which may require several hours to complete; a peripheral infusion of dextrose and electrolytes is established. The nurse documents the blood volume exchanged, including the amount of blood withdrawn and infused, the time of each procedure, and the cumulative record of the total volume exchanged. Vital signs monitored electronically are evaluated frequently and correlated with the removal and infusion of blood. If signs of cardiac or respiratory distress occur, the procedure is stopped temporarily and resumed after the newborn's cardiorespiratory function stabilizes. The nurse also observes for signs of blood transfusion reaction and maintains the newborn's blood glucose levels and fluid balance.

Throughout the procedure, the newborn's thermoregulation must be maintained. The exchange transfusion is performed with the newborn on a radiant warming bed. Hypothermia increases oxygen and glucose consumption, causing metabolic acidosis. These consequences may inhibit the binding capacity of albumin and bilirubin and the hepatic enzymatic reactions, thus increasing the risk of kernicterus. Conversely, hyperthermia damages the donor erythrocytes, elevating the free potassium content and predisposing the newborn to cardiac arrhythmia and potential cardiac arrest. After the procedure is completed, the nurse should continue to provide phototherapy and send specimens for ongoing laboratory analysis of unconjugated bilirubin. Rebound increased bilirubin levels are not unexpected, but only occasionally achieve levels requiring a second exchange transfusion.

CONGENITAL ANOMALIES

Major congenital anomalies are reported to occur in approximately 4% of newborns and are the second leading cause of newborn death, second to prematurity (PHAC, 2021). Common major congenital anomalies include congenital heart disease, abdominal wall defects, imperforate anus, neural tube defects, cleft lip or palate, clubfoot, and developmental dysplasia of the hip. The interaction of multiple genetic and environmental factors contribute to their development.

Prevention and detection of some anomalies continue to improve, as are some surgical techniques for the care of the newborn with certain anomalies. Promoting availability of these services to populations at risk can challenge community health care systems. An interdisciplinary team approach is vital for providing holistic care that encompasses the surgical treatment, rehabilitation, and education of the child, as well as psychosocial and financial assistance for the parents.

A number of congenital anomalies are discussed in the following pediatric systems and conditions chapters (Unit 12):

- Cleft lip and palate, Chapter 46
- Esophageal atresia and tracheoesophageal fistula, Chapter 46
- Omphalocele and gastroschisis, Chapter 46
- Congenital cardiac defects, Chapter 47
- Congenital diaphragmatic hernia and choanal atresia, Chapter 45
- Neural tube defects and myelomeningocele, Chapter 54
- Developmental dysplasia of the hip and clubfoot, Chapter 53
- Hypospadias, disorders of sex development, and bladder exstrophy, Chapter 49

NEWBORN SCREENING FOR DISEASE

A number of genetic diseases can be detected through newborn screening programs. There is no national policy for such detection in Canada; therefore, the extent of newborn screening is determined by provincial and territorial guidelines. Most provinces require screening for phenylketonuria (PKU), galactosemia, congenital hypothyroidism (CH), and hemoglobin defects such as sickle cell disease. Screening for congenital hearing impairment is recommended to be completed at the same time as disease screening in stable term newborns being prepared for discharge home, although this practice is not routine in all provinces and territories (see Chapter 26, Universal Newborn Screening).

Pulse oximetry screening improves detection rates for critical congenital heart disease (CCHD); screening is recommended for all newborns in Canada between 24 and 36 hours after birth (Narvey et al., 2017). For a description of the procedure see Chapter 26, Screening for Critical Congenital Heart Disease (CCHD).

Inborn Errors of Metabolism

Inborn errors of metabolism (IEM) is an umbrella term applied to a large group of inherited diseases caused by the absence or deficiency of a substance essential to cellular metabolism, usually an enzyme. When the normal metabolic process is interrupted as a result of a missing enzyme, an accumulation of substances precedes the interruption, the end product of the process is absent, or the process takes an alternate metabolic pathway. The consequence is manifested as an illness. Most IEMs are characterized by abnormal protein, carbohydrate, or fat metabolism.

Biochemical techniques, including tandem mass spectrometry, provide an opportunity to detect genes responsible for causing errors in metabolism early in the newborn period so that appropriate therapies to prevent morbidity may be implemented.

Phenylketonuria. Classic phenylketonuria (PKU), an autosomal recessive error in metabolism, is caused by a deficiency in or absence of the enzyme needed to metabolize the essential amino acid phenylalanine into tyrosine, resulting in hyperphenylalaninemia. When feeding begins in the newborn period, accumulation of phenylalanine in the bloodstream and urinary excretion of abnormal amounts of its metabolites occur; tyrosine deficiency also ensues. The accumulating phenyl acids give urine the characteristic musty odour associated with the disease.

Tyrosine is needed to form the pigment melanin and the hormones epinephrine and thyroxine (T_4). Decreased melanin production results in similar phenotypes of most individuals with PKU, which is blond hair, blue eyes, and fair skin that is particularly susceptible to eczema and other dermatological conditions. Children with a genetically darker skin colour may be red haired or brunette.

Clinical manifestations in untreated PKU include failure to thrive (growth failure), frequent vomiting, irritability, hyperactivity, and unpredictable, erratic behaviour. Cognitive impairment is thought to be caused by the accumulation of phenylalanine. Tyrosine is necessary for the production of neurotransmitters. Decreased levels of dopamine and tryptophan affect the normal development of the brain and CNS, resulting in defective myelinization, cystic degeneration of the grey and white matter, and disturbances in cortical lamination. Untreated older children become hyperactive with autistic behaviours, including purposeless hand movements, rhythmic rocking, and athetosis (Shchelochkov & Venditti, 2020).

The objective in diagnosing and treating the disorder is to prevent cognitive impairment. Testing for PKU is not reliable until the newborn has ingested the amino acid phenylalanine, a constituent of both human and cow's milk; the blood test should be taken between 24 and 48 hours after birth, regardless of gestation. Early discharge from the hospital has the potential to cause newborns with a disorder such as PKU not to be adequately screened. A number of agencies have developed guidelines to minimize the risk of this happening and recommend the following:

- Obtain a subsequent sample by 2 weeks of age if the initial specimen is collected before the newborn is 24 hours old.
- Designate a primary care provider for all newborns before discharge for adequate newborn screening follow-up.
- Complete a second screen for infants born less than 33 weeks' gestation or less than 1 500 g birthweight (Newborn Screening Ontario, n.d.; Perinatal Services BC, 2018).

! NURSING ALERT

Avoid "layering" the blood specimen on the Guthrie testing paper. Layering is placing one drop of blood on top of the other, or overlapping the specimen, and results in a false-positive reading. Such results require arranging for a diagnostic blood phenylalanine test to determine whether the newborn truly has PKU. Best results are obtained by collecting the specimen with a pipette from the heel stick and spreading the blood uniformly over the blot paper.

Infants with PKU require a diet low in phenylalanine and typically receive a special medical formula; lifelong dietary restrictions are necessary. Breastfeeding or partial breastfeeding may be possible for some infants if the phenylalanine levels are monitored carefully and remain within acceptable limits (Lawrence & Lawrence, 2016). Many affected children have some intellectual impairment. Successful management and outcome are largely dependent on early identification of the condition, modification of the diet, and the ability to follow the treatment regimen throughout the child's entire life.

Galactosemia. Galactosemia is a rare autosomal recessive disorder of carbohydrate metabolism that results from various gene mutations leading to three distinct enzymatic deficiencies. The most common type of galactosemia (classic galactosemia) results from a deficiency of a hepatic enzyme, galactose 1-phosphate uridyltransferase (GALT), and affects approximately 1 in 60 000 births (Kishnani & Chen, 2020). The other two varieties of galactosemia involve deficiencies in the enzymes galactokinase (GALK) and galactose 4′-epimerase (GALE); these are extremely rare disorders. All three enzymes (GALT, GALK, and GALE) are involved in the conversion of galactose into glucose (Kau & Hoe, 2020).

As galactose accumulates in the blood, several organs are affected. Hepatic dysfunction leads to cirrhosis, resulting in jaundice in the infant by the second week of life. The spleen subsequently becomes enlarged as a result of portal hypertension. Cataracts are usually recognizable by 1 or 2 months of age; cerebral damage, manifested by the symptoms of lethargy and hypotonia, is evident soon afterward. Infants with galactosemia appear healthy at birth, but within a few days of ingesting milk (which has a high lactose content) they begin to experience vomiting and diarrhea, leading to weight loss. Sepsis, particularly *E. coli* sepsis, is also a common presenting clinical sign. Death during the first month of life is frequent in untreated infants. Occasionally, classic galactosemia is seen with milder, chronic manifestations, such as growth failure, feeding difficulty, and developmental delay.

Galactosemia is included in some provinces' and territories' newborn screening. Diagnosis can also be made on the basis of the infant's history, physical examination, galactosuria, increased levels of galactose in the blood, and decreased levels of GALT activity in erythrocytes. The infant may display characteristics of malnutrition (i.e., hypoglycemia, jaundice, hepatosplenomegaly, sepsis, cataracts, and decreased muscle tone).

During infancy treatment consists of eliminating all milk and lactose-containing formula, including breast milk. Traditionally, lactose-free formulas are used, with soy-protein formula being the feeding of choice. As the infant progresses to solids, only foods low in galactose can be consumed. Early recognition and treatment improve optimal growth and development.

Nursing interventions are similar to those for PKU. Family support and education provide important foundations for lifelong disease management. Many medications, including some of penicillin preparations, contain lactose as filler and also must be avoided. Lactose is an unlabelled ingredient in many pharmaceuticals. Therefore, parents require supportive education to ask their local pharmacist about galactose content of any over-the-counter or prescription medication.

Congenital Hypothyroidism. Congenital hypothyroidism (CH) is an insufficient production of thyroid hormone in newborns. Early recognition and intervention can prevent severe cognitive disability or other neurological complications. CH can be classified as either permanent or transient depending on the primary etiology. Inadequate thyroid hormone production may result from an anatomical abnormality of the thyroid gland, enzyme failure contributing to thyroid metabolism dysfunction, or iodine deficiency. Despite variations in the cause, the manifestations (Box 29.3) and management are similar.

CH occurs in approximately 1 in 2 000 to 1 in 4 000 newborns, occurring more frequently in female infants (Wassner & Smith, 2020). A higher incidence of other congenital abnormalities has been observed in newborns with CH. Preterm infants may have transient hypothyroidism (hypothyroxinemia) at birth as a result of hypothalamic and pituitary immaturity. Infants born before 28 weeks of gestation may require temporary thyroid hormone replacement.

All provinces in Canada routinely screen for hypothyroidism. Although a heel stick blood sample for the test is best obtained between 2 and 6 days of age, specimens are usually taken within the first 24 to 48 hours or before discharge as part of a concurrent screening for other metabolic defects. At this time, the normally expected increase in T_4 would be lacking in newborns with hypothyroidism. Early screening can result in overdiagnosis (false positives) but is preferable to missing the diagnosis. In the newborn, thyroid function studies are elevated in comparison with values in older children; therefore, it is important to document the timing of the tests. Thyroid function tests are usually lower in preterm and sick full-term newborns than in healthy full-term newborns. A repeat test for T_4 and thyroid-stimulating hormone (TSH) may be evaluated after 30 weeks (corrected age) in newborns born before that time and after resolution of the acute illness in the sick full-term newborn.

Treatment for CH involves lifelong thyroid hormone replacement therapy commencing as soon as possible after diagnosis to abolish all

BOX 29.3 Clinical Manifestations of Congenital Hypothyroidism

Birth*
- Poor feeding
- Irregular stool pattern
- Lethargy, long sleep interval
- Prolonged jaundice (>3 weeks)
- Hypotonia
- Respiratory difficulties
- Cyanosis
- Bradycardia
- Hoarse cry
- Large anterior and posterior fontanelles
- Large for gestational age

Ages 6 to 9 Weeks†
- Depressed nasal bridge
- Pseudohypertelorism
- Short forehead
- Facial edema
- Macroglossia (large tongue)
- Thick, dry, mottled skin
- Coarse, dry, lustreless hair
- Abdominal distension
- Umbilical hernia
- Hyporeflexia
- Bradycardia
- Hypothermia
- Hypotension
- Anemia
- Wide fontanelle with patent cranial sutures

Older Child
- Short stature
- Obesity
- Varying degrees of cognitive deficits
- Abnormal tendon reflexes
- Slow, awkward movements

*Clinical manifestations may not be obvious at birth, possibly because of maternal transfer of thyroid hormone to the fetus. Manifestations may be delayed in infants with certain types of familial hypothyroidism and in breastfed infants (may show after weaning from breast).
†If untreated, classical features.

signs of hypothyroidism and re-establish normal physical and cognitive development. The medication of choice is synthetic levothyroxine sodium (Synthroid, Levothroid). Regular measurement of T_4 levels is important to ensure optimum treatment. Bone age surveys are also performed to ensure optimum growth.

Nurses caring for newborns must be certain that screening is performed, especially in newborns who are preterm, discharged early, or born at home. Approximately 10% of cases are detected only by completion of a second screening at 2 to 6 weeks of age. Nurses in community health need to be aware of the earliest signs of the disorder. Parental remarks about an unusually "quiet and good" baby and demonstrated symptoms such as prolonged jaundice, constipation, and umbilical hernia should lead to a suspicion of hypothyroidism, which requires a referral for specific tests.

After the diagnosis is confirmed, parents need an explanation of the disorder and the necessity of lifelong treatment. The child should be referred to a pediatric endocrinologist for care. The importance of adhering to the medication regimen for the child to achieve healthy growth and development must be stressed (Wassner & Smith, 2020). Parents also need to be aware of signs indicating overdose, such as a rapid pulse, dyspnea, irritability, insomnia, fever, sweating, and weight loss. Ideally, they should know how to count the pulse and be instructed to withhold a dose and consult their health care provider if the pulse rate is above a certain value. Signs of inadequate treatment are fatigue, sleepiness, decreased appetite, and constipation. Unless there are maternal contraindicative factors, breastfeeding is acceptable and encouraged in infants with hypothyroidism (Lawrence & Lawrence, 2016).

Genetic Evaluation and Counselling

Genetic counselling addresses the issues associated with the occurrence or risk of occurrence of a genetic disorder in a family. It involves the relaying of information about the diagnosis, treatment options, recurrence risk, and availability of prenatal diagnosis. It is essential that nurses have a basic understanding of the principles of heredity and how heredity contributes to certain disorders and be aware of the types of genetic testing available (see Chapter 9).

Nurses frequently encounter children with a genetic disorder, including an IEM, as well as families in which there is a risk that a disorder may be transmitted to or occur in an offspring. Neonatal nurses are well positioned to identify situations in which parents may benefit from genetic evaluation and counselling. Nurses also need to be aware of the local genetic resources, aid the family in finding related services, and offer support and care for children and families affected by genetic conditions.

Nursing Care of Parents and Family

While the infant is receiving care, the parents also have needs that must be met as they deal with the crisis of having an infant with an abnormal condition. Their reactions should be carefully assessed and are likely to be those typical of a grief response. Facilitating their understanding of the information given them about their infant's condition is a vital nursing intervention. A newly diagnosed disorder often implies the need for implementation of a therapeutic regimen. For example, the disorder may be an IEM, such as PKU, which requires consistent and rigid adherence to a diet. The family may need help securing the required formula and may require counselling from a clinical dietitian. The importance of maintaining the diet, keeping an adequate supply of special preparations, and avoiding the use of unauthorized substitutions must be impressed upon the family. These conditions often require a drastic change in family lifestyle and functioning; families may depend on others for assistance. Family coping skills and resources may be temporarily diminished with a diagnosis such as PKU or galactosemia.

Referral to appropriate agencies is another essential component of the follow-up management, and the nurse should make the parents aware of all possible sources of aid, including pertinent literature, parent groups, and national organizations. Many organizations and foundations (e.g., Canadian Organization of Rare Disorders) provide services and counselling for families of affected children. Numerous parent support groups are also available, where they can share experiences and derive mutual support in coping with issues similar to those of other group members. Nurses must be familiar with the services available in their community that provide assistance and education to families with these particular needs.

A major nursing role is the provision of emotional support during all phases of care to the family of a newborn with an anomaly or disorder. The feelings that stem from the real or imagined threat posed by a congenital anomaly are varied. Responses may include apathy, denial, anger, hostility, fear, embarrassment, grief, and loss of self-esteem.

KEY POINTS

- The identification of maternal and fetal risk factors in the antepartum and intrapartum periods is vital for planning adequate care of high-risk infants.
- Birth injuries may be decreased by careful assessment for risk factors and anticipatory planning for birth.
- Infection in the newborn may be acquired in utero, at birth, from breast milk, or from within the hospital.
- The most common maternal infections during early pregnancy that are associated with various congenital malformations include toxoplasmosis, herpes, CMV, rubella, parvovirus B19, and varicella.

- HIV transmission from mother to infant occurs transplacentally at various gestational ages, perinatally by maternal blood and secretions, and postnatally through breast milk.
- The nurse often is the first person to observe signs of newborn drug withdrawal.
- Maternal–fetal Rh and ABO incompatibility may cause significant hemolysis and jaundice in the newborn period.
- The injection of Rho(D) immunoglobulin in Rh-negative and Coombs' test–negative perinatal patients minimizes the possibility of isoimmunization.
- The supportive care given to the parents of infants with a congenital anomaly or inborn error of metabolism begins at birth or at the time of diagnosis and continues throughout the pediatric years.

Pediatric Nursing in Canada

Cheryl Sams and Lisa Keenan-Lindsay

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify at least two ways in which knowledge of mortality and morbidity can improve child health.
2. List two major causes of illness during childhood.
3. Outline factors that impact children's health in Canada.
4. Outline the significance of food insecurity.
5. Describe the five core domains of pediatric nursing standards in promoting the health of children.
6. Explain how pediatric nurses incorporate family-centred care.
7. Identify communication strategies for communicating with children of different age groups.
8. Identify communication strategies for interviewing parents.

In the third part of this textbook the focus is on the complex factors that influence health in the Canadian pediatric population, from the infant to the adolescent. Topics addressed include assessment of the child; health promotion; and special needs, illnesses, hospitalization, and health conditions of children. All of these topics are discussed in the context of pediatric nursing. This chapter focuses on significant factors that influence the health of Canadian children as well as how the pediatric nurse works to enhance the health of children and families.

CHILDREN'S HEALTH IN CANADA

In 2016, there were approximately 5 839 570 Canadian children under the age of 14 years (Statistics Canada, 2020), and in 2018 there were 7 million youth in the age range of 15 to 29 years, representing approximately 19% of the country's population (Statistics Canada, 2021a). In 2016, one third of First Nations people (29.2%) were 14 years of age or younger. For Métis, 22.3% of the population was 14 years of age or younger, and among Inuit, one third (33.0%) were 14 years of age or younger (Statistics Canada, 2019a).

The Canadian Public Health Officer reports that Canadians are among the healthiest populations in the world (Public Health Agency of Canada [PHAC], 2020), with significant positive health trends occurring across Canada. These include a decreased incidence of certain chronic and other noninfectious diseases, as well as expanded vaccine coverage, which has helped to improve children's health. Improved social factors that contribute to healthier living include an increase in Canadians completing postsecondary education, and poverty rates, particularly for childhood, are declining (PHAC, 2020). The health of most Canadian children has continued to steadily improve over time with improvements such as the development of new vaccines, decreased tobacco smoking, and improved child health outcomes. For example, hospitalization rates for all causes for males and females has declined among those 0 to 19 years of age. However, Indigenous child health still lags behind that of the non-Indigenous child population (PHAC, 2020).

Advancements in the quality of care and approaches to care, as well as health care reform, have contributed to this decrease in hospitalizations (Canadian Institute of Child Health, 2021). The Canadian Institute of Health (2021) reports that while Canadian children have relatively good health compared to children in other countries in the world, some still confront challenges to their health and well-being. These challenges differ according to gender and age group. In 2019, as in previous years, infants had the highest death rate among children and youth. Male infants had a higher death rate (4.9/1 000), and the rates of female infants is 3.9/1 000 (Statistics Canada, 2021b). Between the ages of 1 and 14 years, death rates were consistently low and did not vary significantly between age groups. For youth 15 to 19 years of age, death rates were slightly higher, which is in part due to the rise in deaths caused by injuries in this age group (Statistics Canada, 2021b).

UNICEF Canada (2017) has determined indicators that have an impact on Canadian children's health and well-being. Positive indicators that have improved (i.e., have decreased rates) over time in Canada include the following:

1. Overall income inequality
2. Child income poverty
3. Neonatal mortality
4. Teen alcohol consumption
5. Teen births
6. Teen suicide
7. Child homicide

Negative indicators that have worsened over time and need to be addressed include:

1. Disparities in income, facilitating those from higher-income families to have greater learning proficiency
2. The number of youth excluded from adequate education and employment
3. Children from families with the lowest incomes being left farther behind
4. Air pollution in cities
5. Unhealthy levels of overweight
6. Teen mental health issues
7. Bullying

The COVID-19 pandemic has also had a negative impact on children's mental health, particularly if the child had a pre-existing mental health diagnosis. The main reason for this is probably the stress from social isolation and lack of socialization due to not attending school (Cost et al., 2021).

Despite these challenges, Canada has excelled at maintaining a high-performing, fair education system and has advanced preschool participation. Young people also show a high level of environmental awareness, another factor that can promote children's health (UNICEF Canada, 2017). Other examples of advances that have helped to improve the health of children and their families include the significantly decreasing mortality rates of childhood cancer and increased survival rates of infant heart transplants. While these advances represent the role technology has played in improving health outcomes, technology has also created many challenges that can have a negative impact on the health of children and their families. For example, global warming from increased industrialization has thinned the ozone layer, leading to a significant increase in the rate of skin cancer, among other health hazards.

These many factors, discussed in this and subsequent chapters, have served to both improve the health and well-being of Canadian children and pose threats to their health and well-being. Thus efforts toward child health promotion need to continue (see Chapter 35).

Childhood Mortality

Over the past 50 years, the mortality rate for children who die before reaching the age of 15 has decreased significantly in Canada; the rate of infant mortality is now lower than it was in previous decades. However, Canada's relative ranking compared to that of other countries has fallen. Other countries have seen much greater reductions in their infant mortality rates (Conference Board of Canada, 2021). Researchers suggest that Canada has had an increase in higher-risk births because of greater success in supporting early preterm newborns and more multiple births occurring from fertility programs. There is also variation in how countries define the parameters of low birth weight (LBW) and in their registration of births and deaths (Conference Board of Canada, 2021). Overall, the rate of infant mortality in Canada has remained stable and very low; in 2019, it was 4.4 deaths per 1 000 live births (Statistics Canada, 2021b).

Risk factors for infant death in Canada include the following (Government of Canada, 2019b):

- Low level of maternal education
- Inadequate housing
- Lack of access to health care
- Food insecurity
- Poverty
- Unemployment

These risk factors are further discussed in Chapter 35.

Areas where more Indigenous peoples live have a seriously higher infant mortality rate and reflect many of the above risk factors. The Indigenous infant mortality rates are as follows: the Inuit rate is 3.9 times higher; First Nations, 2.3 times higher; and Métis, 1.9 times higher than rates for the non-Indigenous population (Government of Canada, 2019b).

Many of the leading causes of death during infancy are issues that occur during the perinatal period. Congenital anomalies and preterm birth are the first two leading causes of infant death. The overall Canadian birth congenital anomaly prevalence rate between 1998 and 2009 decreased from 451 to 385 per 10 000 births, while the number of preterm births increased (PHAC, 2013). This decline in anomalies is likely due to increased prenatal diagnosis and subsequent pregnancy termination, implemented measures such as folic acid fortification in food, and changes in health behaviours and practices to reduce the risk for some congenital anomalies (e.g., tobacco smoking cessation and multivitamin use). Maternal obesity is also an emerging risk factor for some congenital anomalies. Alcohol use and smoking during pregnancy remain key risks that require ongoing public health measures for prevention and prevalence reduction of such anomalies (PHAC, 2013).

Childhood Morbidity

Measurements of the prevalence of specific illnesses in the population at a particular time are known as *morbidity statistics*, generally presented as rates per 1 000 population because of their frequency of occurrence. Unlike mortality, morbidity is difficult to define and may denote acute illness, chronic disease, or disability. Sources of data for morbidity statistics include documented reasons for visits to health care providers, recorded diagnoses qualifying for hospital admission, and household interviews. Unlike death rates, which are updated annually, morbidity statistics are revised less frequently and may not represent actual prevalence of specific illnesses in the general population.

Acute illness is defined as illness with symptoms severe enough to limit activity or require medical attention. Respiratory illness accounts for the majority of all acute conditions; infections, parasitic disease, and injuries are also leading causes of disease. The common cold is the illness that occurs most frequently.

The types of diseases that children contract during childhood vary according to age. For example, incidence of upper respiratory tract infections and diarrhea decreases with age, but other disorders such as acne and headaches increase in occurrence among older children. Children who have had a particular type of health issue are more likely to have that issue again. Morbidity is not distributed randomly among children.

Recent concern has focused on specific groups of children who tend to have increased morbidity: homeless and immigrant children; children living in poverty; Indigenous children; children in care of child services; LBW children; children with **chronic illnesses**; and immigrant adopted children. Examples of challenges to pediatric health that are on the rise include obesity, type 2 diabetes, injuries, violence, vaping, and substance use.

Other changes in contemporary society, including disruptive social and economic influences on the family, and the increase in sedentary activity associated with use of technologies such as playing video games for long periods of time, are contributing to significant medical conditions that affect the health of children.

Social Determinants of Health

In Canada, the Medicare system provides health care for all of its legal residents (see Chapter 1). The government is gradually shifting the emphasis in health care from treatment of illnesses to health promotion and prevention of illness. In order to promote good health, the many,

complex influences on health need to be investigated and understood. To this end, the federal government has outlined the social determinants of health (Government of Canada, 2020) (see Box 1.1). These determinants provide a blueprint for health care policies and help direct population health research with the goal of improving health for its citizens. Understanding of these health determinants is continuing to evolve as researchers discover more evidence to add to the Canadian health database.

An important determinant of health that affects children's health is family income level. The Canadian government has identified income level and socioeconomic status as having the greatest impact on health, with poverty having a significant detrimental effect on children's health. When children live in poverty, they tend to have less access to quality health care, live with food and housing insecurity, and receive inadequate maternal nutrition and prenatal care, resulting in a delay in early childhood development. While Canada's child poverty rate has fallen slightly over the past 30 years, still, 18.6% of children under 18 are experiencing the corrosive effects of poverty (Sarangi et al., 2020). One fifth of these children are preschoolers under the age of 6 who are living in poverty (Sarangi et al., 2020).

Health Inequities Among Children

The Campaign 2000 (Sarangi et al., 2020) report identified systemic discrimination in Canada that is rooted in inequality and poverty and stratified along lines of Indigenous identity, ethnicity, gender, immigration status (or lack of), and ability, among other social, cultural, and economic factors that have led to specific populations being unable to access the opportunities available to all other Canadians. For instance, Indigenous children, whether living on or off reserve, cope more than any other group with high poverty levels. Precarious and low-wage work is widespread and social assistance rates remain exceptionally low. The increase in housing costs, food prices, childcare fees, and costs of prescription medication, including other necessities, means that Indigenous families must make challenging decisions every day about what they can and cannot afford. This is particularly true of Indigenous families living in geographically isolated locations where the basic costs are much higher (Sarangi et al., 2020).

Other Canadian groups that are disproportionately affected by childhood poverty include former or current landed immigrant or permanent resident children and racialized children. *Racialized persons* are defined as individuals who are non-White. In Canada, 1 in 5 racialized families lives in poverty, compared to only 1 in 20 nonracialized families (Canadian Observatory on Homelessness, 2021). Further, 12% of non-Indigenous, nonimmigrant, nonracialized children live in poverty (Sarangi et al., 2020).

Factors such as discrimination, language barriers, historical trauma, and colonization have a cumulative effect—they are also linked to experiencing homelessness and being unable to break the cycle of homelessness in Canadian society. The major strategies toward ending poverty include the following (Sarangi et al., 2020):

- Government transfers, particularly increasing the Canada Child Benefits
- Labour market interventions for low-wage earners so they have decreased unemployment fund requirements and increased opportunities for skills training and career development as well as childcare support
- High-quality accessible public services
- Community-building innovations such as improving inadequate housing in low-income communities

Nurses play an important role in advocating for social policies that reduce poverty and in referring children and families to needed services.

Food Insecurity

One out of six Canadian children are food insecure. Food-insecure households do not have access to an adequate variety or quantity of food because they cannot afford it. Children in families living in poverty are at most risk for experiencing unhealthy nutrient deficiencies, developmental and growth delays, depression, hunger, and behavioural issues. Fresh fruits and vegetables, milk, and other protein-rich foods are important nutritional resources that can be difficult to obtain because of a family's financial constraints or remote geographical location. Two examples of Canadian groups at risk for food insecurity are children in families without a home and families living in isolated Indigenous communities. Table 30.1 further discusses the impact of the determinants of health on child nutrition and physical activity.

In Canada, the most recent statistics from 2011 to 2012 regarding food insecurity indicate that:

- 8.3% of Canadian households experienced food insecurity.
- Nunavut persons had the highest rate of food insecurity (36.7%), over four times the Canadian average.
- The rate of food insecurity was more than three times higher in households where government benefits were the main source of income (21.4%) compared with households with an alternate main source of income (6.1%).
- Among various household types, lone-parent families with children under 18 reported the highest rate of household food insecurity, at 22.6% (Roshanafshar & Hawkins, 2018).

Health Promotion

The World Health Organization (WHO), Health and Welfare Canada, and the Public Health Agency of Canada (1986) developed the Ottawa Charter of Health Promotion which assists in providing a health prevention focus for health care in Canada. The Charter defines *health promotion* as the process of enabling people to increase control over and improve their health. To reach a state of complete physical, mental, and social well-being, an individual or group must be able to identify and realize goals, satisfy needs, and change or cope with the environment. Health promotion and disease prevention are important for optimizing the health of children and their families. Nurses who work with children and their families in a variety of health care settings promote health through teaching, modelling, and programming.

Many of the leading causes of death, disease, and disability—including cardiovascular disease, cancer, chronic lung diseases, depression, **violence**, **substance use**, injuries, nutritional deficiencies, and human **immunodeficiency** virus/acquired immunodeficiency syndrome (HIV/AIDS)—can be significantly reduced in children and adolescents through the prevention of six categories of behaviour (Jepson et al., 2010):

1. Tobacco use
2. Drug misuse
3. Alcohol and substance use
4. Unhealthy dietary and hygienic practices that cause disease
5. Sedentary lifestyle
6. Sexual risk taking in young people that causes unintended pregnancy and disease

Child health promotion opens up opportunities to reduce differences in health status among members of various groups and helps ensure that all children have equal opportunities and resources to achieve their fullest health potential.

Immunizations

The Government of Canada (2021b) has identified vaccination as one of the most important public health interventions provided to Canadians. Effective vaccine protection at the population level requires

TABLE 30.1 Determinants of Health That Influence Food Intake and Physical Activity in Childhood and Adolescence

Income	Family income determines access to quality food. In isolated and northern communities, food costs are higher and fresh fruits and vegetables are very difficult to obtain. Family income shapes access to physical activity facilities and organized sports.
Education	Increased education increases resources (i.e., literacy and numeracy) available for decision making related to food and activity choices.
Social environment	Strong communities can strengthen localized food systems. Lack of control over personal lives and communities limits opportunities to promote health (e.g., in many Indigenous communities).
Physical environment/ geographic location	Children and youth living in advantaged neighbourhoods have a far lower risk of becoming obese than those in disadvantaged neighbourhoods. Parental perceptions of public safety influence child and youth physical activity. The cost of food varies widely according to community location, with prices far higher in isolated and northern communities. Access to low-fat, nutritious foods varies by location.
Values and norms	Values and norms vary widely and affect food and physical activity patterns among children and youth.
Biological/genetic factors	Indigenous and South Asian populations have a genetic susceptibility to type 2 diabetes. Availability and accessibility of quality health promotion and health intervention services vary.
Culture	Availability of television, computers, tablets, cell phones, and video games varies. Family eating patterns vary by culture. Peer group activities and eating patterns vary by culture.
Gender	Adolescent boys, on average, are more active than adolescent girls.

Adapted from Government of Canada, Report of the Standing Senate Committee on Social Affairs, Science and Technology. (2016). *Obesity. A whole-of-society approach for a healthier Canada*. https://sencanada.ca/content/sen/committee/421/SOCI/Reports/2016-02-25_Revised_report_Obesity_in_Canada_e.pdf.

maintaining high vaccination rates of 95% for all recommended childhood vaccines across the country. See Chapter 35 for an in-depth discussion of immunizations. Measles were eliminated in Canada in 1988, but in 2017 measles vaccine coverage rate among 2-year-olds in Canada was only 90%, which is below the minimum 95% vaccination coverage needed at the population level to maintain measles elimination status (Government of Canada, 2019a). For the past 20 years, there have not been any endemic measles outbreaks, and Canada still has the status of having eliminated measles. Periodic outbreaks of measles have occurred in Canadian children who are not vaccinated, often in local communities that are vaccine hesitant, or in children who have incomplete vaccination schedules who are travelling outside of Canada.

Globally, there are many measles outbreaks; the Canadian government advises parents when travelling internationally to check for countries that have current outbreaks (Sondagar et al., 2020). The WHO reported that, worldwide, more than 140 000 people died from measles in 2018, with most deaths occurring among children under 5 years of age. Babies and very young children are at greatest risk from measles, with potential complications including pneumonia and encephalitis as well as lifelong disability including permanent brain damage, blindness, or hearing impairment (WHO, 2019).

Canada still needs to improve children's vaccination rates. Without doing so, the Canadian elimination of measles status may not stand over the long term. Mumps and pertussis are also present in Canada and periodic outbreaks have occurred. Vaccinations become even more important as antimicrobial resistance becomes more prevalent (see discussion below) and in managing the COVID-19 pandemic. The Government of Canada (2021b) has sought to address the public's concerns regarding vaccination by explaining immunization myths and tracking outbreaks of vaccinated conditions (see Additional Resources). Nonetheless, vaccine hesitancy among the public has continued, and some parents do not want their children vaccinated. It is important for the nurse to build trust, present the benefits and risks of vaccinations, and discuss parental concerns to ensure that they have the correct information on how the vaccines work and protect their child (see Chapter 35, Vaccine Hesitancy).

At each clinic visit a child's immunization record should be reviewed and parents should be encouraged to keep immunizations current. Most children's vaccines are paid for by the Canadian provincial and territorial governments (Government of Canada, 2021a). The immunization schedule and types of vaccines vary between provinces and territories (see Figure 35.16).

Antimicrobial Resistance

Antimicrobial resistance (AMR) to antibiotics and fungal infections is reducing treatment choices for children in Canada and worldwide. AMR is categorized by the World Health Organization (WHO Advisory Board, 2020) as one of the 13 most significant dangers to the global health. For example, from 2013 to 2017 alone, over 10 000 MRSA infections were identified in Canada (Mitevska et al., 2021). The Canadian Paediatric Society (CPS) (Le Saux et al., 2014/2020) recommends the practice of antimicrobial stewardship, which represents the common-sense, cautious use of antimicrobials to decrease adverse outcomes from antimicrobials while maximizing the treatment of bacterial infections to decrease the emergence of resistant pathogens in children and adults. This stewardship includes testing to diagnose whether infections are viral or bacterial and using clinical follow-up rather than antibiotics in cases where a child is not very ill and the microbial strain is uncertain. Other stewardship-specific actions include questioning if positive urine cultures are contaminated when there is no evidence of pyuria or inflammation and confirming pneumonia with a lung X-ray (Le Saux et al., 2014/2020).

While infection rates of some of the most resistant organisms, for example, carbapenem-resistant *Enterobacteriaceae* (CRE), have been steady, a five-fold increase in carriers of CRE between 2014 and 2017 is very troublesome. Canada has experienced some decrease in AMR levels, mostly in hospitals. For example, health care–associated *Clostridioides difficile* decreased by 36% and health care–associated MRSA infections decreased 6% from 2012 to 2017 in recent long-term studies of the effect of antimicrobial therapy (Xia et al., 2019).

Childhood Injuries

Injuries are the most common cause of death and disability among children in Canada (Pike et al., 2015). For Canadian children ages 1 to 14, unintentional injuries are the leading cause of death. Injury accounts for more childhood deaths than all other causes combined, and the majority of these injuries are preventable. Indigenous children in particular have higher rates of injuries due to living in unsafe homes and unsafe communities. These rates are also linked to poverty experienced by Indigenous families and poor access to health care. See Chapter 35, Safety Promotion and Injury Prevention, for further discussion of childhood pediatric injury prevention.

Violence

Children are one of the most vulnerable populations in the context of violence. Between 2017 and 2018, Canadian family violence against children and youth increased by 7% while non-family violence decreased slightly (Conroy & Statistics Canada, 2019). In 2018, there were 60 651 child and youth victims (aged 17 and younger) of police-reported violence in Canada. Of these victims, 57% were female and 43% were male. Altogether, child and youth victims of violence were most often maltreated by a casual acquaintance (32%) or a family member (31%) and less commonly by a stranger (17%) (Conroy & Statistics Canada, 2019).

Often child and youth maltreatment are difficult to identify, especially in cases of family violence, because younger children may not be aware that they are being maltreated or know how to get help and report the abuse. Children and youth may be dependent on the abuser. These factors can lead to an underestimation of the level of abuse (Conroy & Statistics Canada, 2019).

The rate of physical assault is higher than for sexual assault, and rates of family violence are nearly twice as high in rural communities than in urban centres (Conroy & Statistics Canada, 2019). Children who witness family violence are also at significant risk for short- and long-term harmful consequences. Children who see and hear violent acts or see violent outcomes can have emotional, behavioural, and developmental challenges over the long term (Conroy & Statistics Canada, 2019). See discussion below on toxic stress and Chapter 35 for discussion of child maltreatment.

Toxic Stress

Defined from both a physiological and an emotional point of view, *stress* is an imbalance between demands on a person and the ability of a person to cope with those demands, which can disrupt the equilibrium of the person.

There are three levels of stress that affect a child's development. The first is *positive stress,* which is healthy for children's development of their brains and bodies and helps them learn how to adapt to meet future challenges, such as joining a group. *Tolerable stress* occurs with more significant events, such as a flood or a pandemic; this stress can be mitigated by supportive caregivers so that it does not have long-term effects on children's development. The third type of stress, *toxic stress*, weakens brain architecture and can disturb healthy development (Alberta Family Wellness Initiative, 2021).

Toxic stress originates from major, frequent, or protracted occurrences of adverse childhood events (ACE) that can have an early and profound impact across multiple systems—neurological, immunological, psychiatric, and behavioural—that can continue into adulthood (Bucci et al., 2016). Adverse childhood experiences that are stressful or traumatic events in childhood include abuse, neglect, parental separation or divorce, witnessing violence, parental addiction, or mental illness. Childhood adversity is common across all socioeconomic groups and its effects are cumulative. There are mitigating factors that help build resilience in children to help withstand, adapt to, and recover from adversity (Traub & Boynton-Jarrett, 2017). Supportive relationships with caregivers and positive parenting techniques appear to be important in helping children to develop resilience (Williams et al., 2019).

Although all children experience stress, some youngsters appear to be more vulnerable than others and are affected by age, temperament, life situation, and state of health in their reactions and ability to handle stress. While it is impossible and undesirable to protect children from stress, reducing stress, building responsive relationships, and strengthening life skills can prevent the long-term negative effects of stress (Center on the Developing Child, Harvard University, 2020).

It is important that parents and persons working with children understand the nature of childhood stress and ways in which it can be recognized or anticipated. Caregivers must listen to children so that they are aware of children's fears and concerns. They need to let children know that they are important and that what they say matters. Physical contact is usually comforting and reassuring to children. Simply holding, touching, or hugging the child can be both relaxing and comforting and facilitate communication. Spending unhurried time with the child, taking family outings or vacations, and exposing the child to positive influences can help build their resilience by building strength and a sense of security. By recognizing signs of stress parents and caregivers can help children cope with stressors before they become overwhelming. When a succession of stressors produces an excessive stress load (toxic stress), children may experience a serious change in health or behaviour.

Mental Health

Many children and youth in Canada have mental health issues; as many as 15%, or 1.2 million, Canadian children are affected by anxiety, attention deficit, depression, addiction, autism spectrum disorders, behavioural disorders, eating disorders, or schizophrenia, as well as other mental health issues (Butler & Pang, 2014). Mental illness in this age group is often the beginning of an adult mental disorder (Mental Health Commission of Canada, 2021). LGBTQ2 children are more likely than heterosexual Canadians to have low self-rated mental health, and these higher rates may be linked to internalized stress related to gender expectations and experienced discrimination in the LGBTQ2 population (PHAC, 2020).

Mental health issues, such as developmental, emotional, and behavioural disorders, have a direct and significant impact on families and caregivers. Nurses play an important role in helping children and their families identify early signs of mental illness and psychological stressors (see Chapter 55). Teaching the child and the family resiliency strategies can help them cope with some of the stress. Unfortunately, there are many gaps in service and long waits for services for this population;

75% of children with emotional disorders do not have access to specialized treatment services (Centre for Addiction and Mental Health, 2020). Canada needs a national program to coordinate the various mental health services.

Suicide among children and youth remains a serious issue in Canada. Adolescents who have attempted suicide are a high-risk group who require assessment of their mental state, including current suicidal thoughts and behaviours, and assessment of the key risk factors known to be associated with eventual suicide. Most adolescents who die by suicide are struggling with mental illness (Korczak et al., 2015/2021) (see further discussion in Chapter 55).

Indigenous adolescents are at particular risk for suicide, with four to five times greater rates of suicide in these populations compared with non-Indigenous youth. Research shows that strong cultural continuity of the band, including women leaders; pursuit of land claims; culture-designated buildings; and community control of child services, lowering of fostering rates, band school, band health, and fire and police services help protect Indigenous youth from suicide (Chandler & Lalonde, 2009). LGBTQ2 youth also have higher rates of suicidality (Canadian Mental Health Association Ontario, 2021).

Suicide is preventable; early identification and treatment of mental illness are important ways in which to assist in suicide prevention (Korczak et al., 2015/2021). Nurses are well positioned to identify the at-risk child or adolescent who may display mental health and emotional challenges. In addition, more completely integrated medical and mental health services for children and adolescents are needed. Mental health issues affecting children and youth are discussed in more detail in Chapter 55.

Substance Use

Substance use is a major health problem in Canada. Early substance use and hazardous drug ingestion during adolescence can lead to the development of serious long-term challenges in adulthood, such as **addiction**. Evolving research in this age group suggests that some adolescents use substances to help cope with difficult environments, untreated trauma, and underlying psychological conditions (see Chapter 55).

Risk-taking behaviours, particularly among males, tend to begin in the first decade of life and continue into adolescence with drinking of alcohol while driving, speeding, or using illicit drugs. In children and young adults, alcohol and illicit drug use occurs most commonly between ages 12 and 24 and is associated with violence and injury. Alcohol is the most commonly used substance. While tobacco smoking rates among adolescents have decreased, cannabis rates remain high. Daily or almost daily cannabis consumption is more common among 15- to 24-year-old Canadians (Statistics Canada, 2019b). An additional threat to health is vaping (electronic cigarettes or e-cigarettes), in which a flavoured nicotine liquid is heated into an aerosol that is inhaled into the lungs; vaping is highly addictive. Vaping can cause irreversible lung damage and, in some cases, death (Canadian Lung Association, 2021).

THE ART OF PEDIATRIC NURSING

Pediatric nurses are involved in every aspect of a child's and family's growth and development. Nursing functions vary according to regional job structures, individual education and experience, and personal career goals. Just as patients (children and their families) have unique backgrounds, each nurse brings an individual set of variables that affect the nurse–patient relationship. No matter where pediatric nurses practise, their primary concern is the welfare of the child and family.

The pediatric nurse has a very important role in helping children and their families achieve optimum health. The major goal of pediatric nursing is to improve the quality of health care for children. When providing nursing care to children, it is essential that the pediatric nurse do so in the context of the family. To provide effective care, the pediatric nurse must develop a trusting and collaborative relationship with the child and family. Respect for social and cultural differences and beliefs is the cornerstone of high-quality pediatric care. The practice of a pediatric nurse is based on both the science and art of nursing. Evidence-informed nursing care provides the scientific base; the art of pediatric nursing care requires a strong sense of compassion and caring for children of all ages and stages and for their families. The qualities of an excellent pediatric nurse include creativity, effective communication skills, playfulness, patience, and resilience.

Philosophy of Care

The foundation of pediatric nursing is a strengths-based approach to the protection, promotion, and optimization of health and abilities for children. Using a child and family-centred care approach, pediatric nurses require knowledge of psychomotor, psychosocial, and cognitive growth and development, as well as of the health issues and needs specific to people in this age group (Canadian Association of Pediatric Nurses [CAPN], 2017). Pediatric nursing in Canada follows the practice standards set by CAPN as well as the individual provincial and territorial regulatory bodies.

The Canadian pediatric nursing standards are divided into five domains ("Standards") that identify unique characteristics of pediatric nursing practice (Box 30.1) (CAPN, 2017). Under each domain is a description of a specific outcome that will positively impact the care experience of the child and their family. Each domain is also supported by behaviours that are so important to patients and families that health care providers must aim to perform them consistently and reliably for every patient, every time (CAPN, 2017).

Family-Centred Care

The philosophy of family-centred care recognizes the family as the one constant in a child's life. The Canadian pediatric nursing standards are built on the child- and family-centred care principles presented in Standard I (see Box 30.1). These include supporting, respecting, encouraging, and enhancing the family's strength and competence by developing a collaborative and information-sharing partnership with parents. Nurses support families in their natural caregiving and decision-making roles by building on families' unique strengths and acknowledging their expertise in caring for their child both within and outside the hospital setting. The needs of all family members, not just the child's, are considered. Family-centred care addresses the diversity among family structures and backgrounds; family goals, dreams, strategies, and actions; and family support, service, and information needs. It is essential that the pediatric nurse work within the framework of family-centred care. See Additional Resources on family-centred care.

The important outcomes of family-centred care are enabling and empowerment. Health care providers enable families by creating opportunities for all family members to carry out their current abilities and competencies and to acquire new ones that are necessary for meeting the needs of the child and family. Empowerment involves interaction of health care providers with families in a way that assists families

BOX 30.1 Core Domains of Pediatric Nursing Standards

Standard I: Supporting and Partnering With the Child and the Family

Pediatric nurses partner with the child and their family to achieve their optimal level of health and well-being, leading to resilient families and healthy communities.

The pediatric nurse always:

- Establishes an intentional therapeutic relationship with the child and family
- Respects the child and family in goal setting and decision making
- Collects and uses information from the child and family context to inform care
- Communicates with both the child and family as partners in care
- Advocates for optimal use of resources to support the child and family
- Recognizes and fosters the parenting role to support child well-being

Standard II: Advocating for Equitable Access and the Rights of Children and Their Family

Pediatric nurses demonstrate and mobilize their understanding of the social determinants and other systemic factors that impact child health.

The pediatric nurse always:

- Completes a comprehensive assessment (beyond physical assessment) through an advocacy lens considering social determinants of health and child well-being
- Facilitates an appropriate environment to perform assessment and intervention considering privacy and confidentiality
- Builds capacity in the child and their family to self-advocate
- Engages in a community of practice or network that focuses on pediatric nursing practice and knowledge and resources for children and families
- Supports the child and family to navigate the health care system

Standard III: Delivering Developmentally Appropriate Pediatric Care

Nurses perform assessment based on growth and development and deliver pediatric-specific care.

The pediatric nurse always:

- Demonstrates knowledge of typical development and variation from what is considered typical
- Demonstrates knowledge of safety risks appropriate for developmental stage
- Provides anticipatory guidance and coaching for the family on typical development and safety related to the developmental stage of the child
- Performs safety assessments at point of care to minimize risk and harm with developmental stage
- Incorporates developmentally appropriate play and/or recreational activities into care
- Performs age- and developmentally appropriate biopsychosocial assessment
- Uses developmentally appropriate strategies when preparing for and performing interventions
- Considers development that is influenced by ethnicity, spirituality, and culture

Standard IV: Creating a Child- and Family-Friendly Environment

Pediatric nurses play an essential role in creating a child- and family-friendly environment that welcomes families and promotes hope and healing. It is understood that the environment changes as the child grows and is influenced by multiple factors, including, but not exclusive to, psychological, spiritual, and social factors.

The pediatric nurse always:

- Completes a child and family assessment
- Demonstrates cultural competency and humility in all child and family interactions
- Engages with the child and family in all care decisions and the plan of care in a respectful nonjudgemental, culturally safe manner
- Shares information relevant to the plan of care and collaborates with and among the circle of health care providers
- Recognizes and fosters family strengths and supports
- Uses strategies to support and foster resiliency
- Demonstrates caring and compassion to both the child and family

Standard V: Enabling Successful Transitions

Pediatric nurses support the child and family through health care transitions to maximize their well-being. This may include, but is not limited to, hand-off between health care providers, admission and discharge, and facility transfer (such as from pediatric to adult care institutions).

The pediatric nurse always:

- Uses effective communication strategies at all transitions in care
- Engages in planning of health education and coaching at all transitions
- Provides health education and information to optimize transition of the child and family
- Assesses readiness and supports safe transition
- Anticipates resources to support transitions in care
- Plays an active role in facilitating effective transition

Adapted from The Canadian Association of Pediatric Nurses. (2017). *Canadian paediatric nursing standards*. https://paednurse.ca/resources/Documents/FINAL-Paediatric%20Nursing%20Standards%20September%202017.pdf.

to maintain or acquire a sense of control over their lives and make positive changes through the fostering of their own strengths, abilities, and actions (Institute for Patient- and Family-Centered Care, 2017).

The Hospital for Sick Children (SickKids), in Toronto, has developed a model of family-centred care (Figure 30.1). The model centres the child at the core, as the first priority. The family is adjacent to the child to represent the centrality of the family to the child's life. The model demonstrates that children and families experience health care at SickKids through clinical practice, administration, research, and education. SickKids interacts locally, nationally, and internationally to support health care service delivery through the community and health system. Respect, communication, and partnership are the three essential integrated elements to include in the process of delivering care. The model can influence and foster positive outcomes for children and families by promoting optimal health, ensuring patient safety, achieving health equity, and maximizing the patient experience.

Atraumatic Care

Atraumatic care is the provision of therapeutic care in settings, by personnel, and through the use of interventions that eliminate or minimize the psychological and physical distress experienced by children and their families in the health care system. *Therapeutic care* encompasses the prevention, diagnosis, treatment, and palliation of chronic or acute conditions. *Setting* refers to whatever place in which care is given—the home, the hospital, or any other health care setting. *Personnel* include anyone directly involved in providing therapeutic care. *Interventions* range from psychological approaches, such as preparing children for procedures, to physical interventions, such as providing space for a parent to room-in with a child. *Psychological distress* may include anxiety, fear, anger, disappointment, sadness, shame, or guilt. *Physical distress* may range from sleeplessness and immobilization to disturbing sensory stimuli such as pain, temperature extremes, loud noises, bright lights, or darkness. Thus atraumatic care is concerned with the who, what, when,

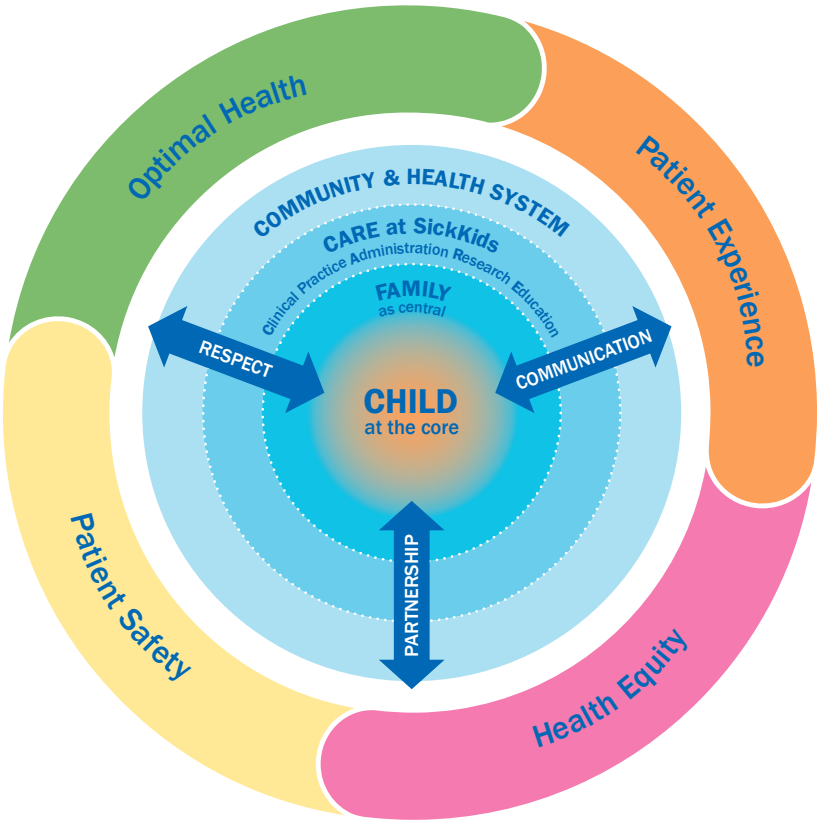

Fig. 30.1 SickKids model of child- and family-centred care.

where, why, and how of any procedure performed on a child, for the purpose of preventing or minimizing psychological and physical stress.

The overriding goal in providing atraumatic care is first, *do no harm*. Three principles constitute the framework for achieving this goal: (1) prevent or minimize the child's separation from the family; (2) promote a sense of control; and (3) prevent or minimize bodily injury and pain. Examples of atraumatic care include fostering the parent–child relationship during hospitalization, preparing the child before any unfamiliar treatment or procedure, controlling pain, allowing the child privacy, providing play activities for expression of fear and aggression, offering choices to children, and respecting cultural differences.

Therapeutic Relationships

The establishment of a **therapeutic relationship** is the essential foundation for providing high-quality nursing care. Pediatric nurses need to have meaningful relationships with the children and families they encounter and yet remain separate enough to distinguish their own feelings and needs. In a therapeutic relationship, caring, well-defined boundaries separate the nurse from the child and family. These boundaries are positive and professional and promote the family's control over the child's health care. For effective family advocacy to occur, these boundaries need to be established and therapeutic relationships promoted. Both the nurse and the family are empowered, and open communication is maintained. In a nontherapeutic relationship, these boundaries are blurred, and many of the nurse's actions may serve personal needs, such as a need to feel wanted and involved, rather than the family's needs.

Exploring whether relationships with patients are therapeutic or nontherapeutic can help nurses identify problem areas early in their interactions with children and families. Although questions for exploring types of involvement can be labelled negative or positive, no one action makes a relationship therapeutic or nontherapeutic. For example, nurses may spend additional time with the family but still recognize their own needs and maintain professional separateness. An important clue to nontherapeutic relationships is the staff's concerns about their peer's actions with the family. See Guidelines box: Building Relationships With Children and Families.

GUIDELINES

Building Relationships With Children and Families

To foster therapeutic relationships with children and families, you must first become aware of your caregiving style, including how effectively you take care of yourself. The following questions should help you understand the therapeutic quality of your professional relationships.

Negative Actions

- Are you overinvolved with children and their families?
- Do you work overtime to care for the family?
- Do you spend off-duty time with children's families, either in or out of the hospital?
- Do you call frequently (either the hospital or home) to see how the family is doing?
- Do you show favouritism toward certain patients?
- Do you buy clothes, toys, food, or other items for the child and family?
- Do you compete with other staff members for the affection of certain patients and families?
- Do other staff members comment to you about your closeness to the family?
- Do you attempt to influence families' decisions rather than facilitate their informed decision making?
- Are you underinvolved with children and families?
- Do you restrict parent or visitor access to children, using excuses such as the unit is too busy?

Continued

GUIDELINES—CONT'D

- Do you focus on the technical aspects of care and lose sight of the person who is the patient?
- Are you overinvolved with children and underinvolved with their parents?
- Do you become critical when parents do not visit their children?
- Do you compete with parents for their children's affection?

Positive Actions

- Do you strive to empower families?
- Do you explore families' strengths and needs in an effort to increase family involvement?
- Have you developed teaching skills to instruct families rather than doing everything for them?
- Do you work with families to find ways to decrease their dependence on health care providers?
- Can you separate families' needs from your own needs?
- Do you strive to empower yourself?
- Are you aware of your emotional responses to different people and situations?
- Do you seek to understand how your own family experiences influence reactions to patients and families, especially as they affect tendencies toward overinvolvement or underinvolvement?
- Do you have a calming influence, not one that will amplify emotionality?
- Have you developed interpersonal skills in addition to technical skills?
- Have you learned about ethnic and religious family patterns?
- Do you communicate directly with persons with whom you are upset or take issue?
- Are you able to "step back" and withdraw emotionally, if not physically, when emotional overload occurs, yet remain committed?
- Do you take care of yourself and your needs?
- Do you periodically interview family members to determine their current issues (e.g., feelings, attitudes, responses, wishes), communicate these findings to peers, and update records?
- Do you avoid relying on initial interview data, assumptions, or gossip regarding families?
- Do you ask questions if families are not participating in care?
- Do you assess families for feelings of anxiety, fear, intimidation, worry about making a mistake, a perceived lack of competence to care for their child, or fear of health care providers overstepping their boundaries into family territory, or vice versa?
- Do you explore these issues with family members and provide encouragement and support to enable families to help themselves?
- Do you keep communication channels open among self, family, physicians, and other care providers?
- Do you resolve conflicts and misunderstandings directly with those who are involved?
- Do you clarify information for families or seek the appropriate person to do so?
- Do you recognize that from time to time a therapeutic relationship can change to a social relationship or an intimate friendship?
- Are you able to acknowledge the fact when it occurs and understand why it happened?
- Can you ensure that there is someone else who is more objective who can take your place in the therapeutic relationship?

Communication With Families and Children. Communication is the cornerstone of providing nursing care to children and their families. When a nurse meets a child and the family, they are starting the process of building a relationship with all of the individuals involved. It essential that the nurse be able to develop a rapport and a sense of trust with the family in order to encourage the child and the family to share information relevant to the child's care. Sharing information will help in obtaining an accurate history and health assessment of the child. The most widely used method by nurses to communicate with parents and children on a professional basis is the interview process. Unlike social conversation, interviewing is a specific form of goal-directed communication. As nurses converse with children and adults, they focus on the individuals to determine their usual mode of handling problems, whether help is needed, and the way they react to counselling. Developing interviewing skills requires time and practice, but following some guiding principles can facilitate this process. An organized approach is most effective when using interviewing skills in patient teaching.

Appropriate introduction. When first meeting a patient and their family, the nurse needs to introduce themselves to the family members and ask each person's name. Parents and other adults should be addressed by their appropriate titles, such as "Mr.," "Mrs.," or "Ms.," unless they specify a preferred name. The nurse should record the preferred name on the medical record. Using formal address or their preferred names, rather than using first names or "mother" or "father" conveys respect for the parents or other caregivers (Solomon et al., 2019).

At the beginning of the visit, to establish rapport, children should be included in the interaction, by asking them their name, age, grade, and favourite activities. Nurses often direct all questions to adults, even when children are old enough to speak for themselves, which can exclude a valuable source of information: the patient. When the child is a participant in the interview, the nurse should use the general rules for communicating with children that are given in the Guidelines box: Communicating With Children.

GUIDELINES

Communicating With Children

- Allow children time to feel comfortable.
- Avoid sudden or rapid advances, broad smiles, extended eye contact, or other gestures that may be seen as threatening.
- Talk to the parent if the child is initially shy.
- Communicate through transition objects such as dolls, puppets, and stuffed animals before questioning a young child directly.
- Give older children the opportunity to talk without the parents present.
- Assume a position that is at eye level with the child (see Figure 30.3).
- Speak in a quiet, unhurried, and confident voice.
- Speak clearly, be specific, and use simple words and short sentences.
- State directions and suggestions positively.
- Offer a choice only when one exists.
- Be honest with children.
- Allow them to express their concerns and fears.
- Use a variety of communication techniques.

Assurance of privacy and confidentiality. The place where the interview is conducted is almost as important as the interview itself. The physical environment should allow for as much privacy as possible, with distractions such as interruptions, noise, or other visible activity kept to a minimum. If young children are present, the environment should have some toys to keep them occupied during the parent–nurse interview (Figure 30.2). Parents who are constantly interrupted by their children are unable to concentrate fully and may give brief answers in order to finish the interview as quickly as possible.

Confidentiality is another essential component of the interview. One of the primary nursing values of the Canadian Nurses Association (CNA, 2017) is the importance of privacy and confidentiality; the nurse needs to protect personal, family, and community information obtained within the framework of a professional relationship. Since the interview is usually shared with other members of the health team care or possibly with a teacher (in the case of students), it is imperative

Fig. 30.2 A child plays while the nurse interviews the parents.

to inform the family of the limits regarding confidentiality. If confidentiality is a concern in a particular situation, such as when talking to a parent suspected of child abuse or a teenager contemplating suicide, this should be dealt with directly and the person informed that, in such instances, confidentiality cannot be ensured.

Communicating With Parents. When providing nursing care for children, the nurse's relationship with the child is frequently mediated by the parent, particularly for younger children. For the most part, information about the child is acquired by direct observation or is communicated to the nurse by the parents. Usually it can be assumed that, because of the parent's close contact with the child, the parent is giving reliable information. To make an assessment of the child the nurse needs input from the child (verbal and nonverbal), information from the parent(s), and the nurse's own observations of the child and interpretation of the relationship between the child and parent(s). Counselling and guidance must be directed to the caregiver of infants and small children; when children are old enough to be active participants in their own health maintenance, the parent becomes a collaborator in health care.

Encouraging parents to talk. Interviewing parents provides the opportunity to not only determine the child's health and developmental status but also to obtain information about factors that influence the child's well-being. Whatever the parent sees as an issue should be a concern for the nurse. Such issues are not always easy to identify; nurses need to be alert for clues and signals by which a parent communicates worries and anxieties. Careful phrasing with broad, open-ended questions, such as "What is Jack eating now?" provides more information than several single-answer questions, such as "Is Jack eating what the rest of the family eats?" Sometimes the parent will take the lead without prompting. At other times it may be necessary to direct another question on the basis of an observation, such as "Angelica seems unhappy today" or "How do you feel when Jamil cries?" If the parent appears to be tired or distraught, consider asking, "What do you do to relax?" or "What help do you have with the children?" A comment such as "You handle the baby very well. What kinds of experience have you had with babies?" to new parents who appear comfortable with their first child gives positive reinforcement and provides an opening for any questions they might have regarding the infant's care. Often all that is required to maintain communication is a nod or saying "yes" or "uh-huh."

When attempting to elicit feelings or information regarding issues more difficult for parents to address, closed-ended questions that begin with "Does … ," "Did … ," or "Is … ," should be avoided as these usually require only a single response. Asking questions such as "Does your son have any problems at school?" subtly implies a lack of parental skills and can evoke defensiveness. Instead, use questions that begin with "What … ," "How … ," or "Tell me about … ," and encourage elaboration with phrases like "You were saying …" or "You say that … " or by reflecting back a key word. Open-ended questions are nonthreatening and encourage description.

Directing the focus. The ability to direct the focus of the interview while allowing for maximum freedom of expression is one of the most difficult goals in effective communication. One approach is the use of open-ended or broad questions, followed by guiding statements. For example, if the parent proceeds to list the other children by name, say, "Tell me their ages, too." If the parent continues to describe each child in depth, which is not the purpose of the interview, redirect the focus by stating, "Let's talk about the other children later. You were beginning to tell me about Olivia's activities at school." This approach conveys interest in the other children but focuses the assessment on the patient.

Listening and cultural awareness. Listening is the most important component of effective communication. When listening is truly aimed at understanding the patient, it is an active process that requires concentration and attention to all aspects of the conversation—verbal, and nonverbal. Major blocks to listening are environmental distraction and premature judgement.

The nurse's attitudes and feelings are easily injected into an interview. Often nurses' perceptions of a parent's behaviour are influenced by their own perceptions, prejudices, and assumptions, which may include racial, religious, and cultural stereotypes. What may be interpreted as a parent's passive hostility or lack of interest may be shyness or an expression of anxiety. For example, in Western cultures, eye contact and directness are signs of paying attention. However, in many non-Western cultures, including some Indigenous cultures, directness, such as looking someone in the eye, is considered rude. Children are taught to avert their gaze and to look down when being addressed by an adult, especially one with authority (Solomon et al., 2019). Therefore, judgements about listening and verbal interactions need to be made with an appreciation of cultural differences (see Chapters 2 and 31).

The nurse's minimal speaking, along with active listening, can facilitate parents' involvement. While it is tempting to spend time explaining, describing, and interpreting health information when the opportunity presents itself, it is possible to provide effective health education by timing the information properly and presenting only as much as is necessary at the moment.

Careful listening relies on the use of clues, verbal leads, or signals from the interviewee to move the interview along. Frequent references to an area of concern, repetition of certain key words, or special emphasis on something or someone can serve as cues to the interviewer for directing the inquiry. Concerns and anxieties are often mentioned in a casual, offhand manner; however, they are nonetheless important and deserve careful scrutiny to identify problem areas. For example, a parent who is concerned about a child's habit of bed-wetting may casually mention that the child's bed was "wet this morning."

Providing anticipatory guidance. The ideal way to handle a situation is to deal with it before it becomes a concern. In nursing the best preventive measure is anticipatory guidance. Traditionally, anticipatory guidance has focused on providing families with information on children's growth and development. Parents who are unprepared for their child's development can be disturbed by many normal developmental changes, such as a toddler's diminished appetite, negativism, altered sleeping patterns, and anxiety toward strangers. (See Chapter 35 for informing parents about pediatric health promotion according to developmental age.) Anticipatory guidance also includes nurturing

child-rearing practices that promote the health of the child, for example, injury prevention. Beginning prenatally, parents need specific instructions on home safety. As the child's developmental skills mature and change, so too should home safety measures be implemented to minimize risks to the child. However, anticipatory guidance should extend beyond giving general information during health care visits; families should also be encouraged to use the information as a means of building competence in their parenting abilities. To achieve this level of anticipatory guidance, the nurse should do the following:

- Base interventions on needs identified by the family, not by the health care provider.
- View the family as competent or as having the ability to be competent.
- Provide opportunities for the family to achieve competence.

Avoiding blocks to communication. A number of blocks or hindrances to communication can adversely affect the quality of the helping relationship. Often the interviewer unwittingly introduces some of these blocks, such as giving unrestricted advice or forming prejudged conclusions. Sometimes interviewees experience information overload when presented with too much information or information that is overwhelming and will demonstrate signs of increasing anxiety or decreasing attention. Such signals should alert the interviewer to give less information or to clarify what has been said. Box 30.2 lists some of the more common blocks to communication, including signs of information overload.

Communicating with families through an interpreter. Sometimes communication is impossible because the health care provider and the patient speak different languages. In this case, it is necessary to obtain information through a third party, the interpreter. When an interpreter is used, the same interviewing guidelines as those used without an interpreter apply. Specific guidelines for using an adult interpreter are presented in Box 2.6.

Communicating With Children. Although the greatest amount of verbal communication is usually carried out with the parent, the child should not be excluded during the interview. Infants and younger children can be observed through play; occasionally, younger children can answer questions or respond to remarks. Older children should be included as active participants in the interview. See Nursing Skills on Evolve: Communicating With Children—Age-Related Techniques.

Fig. 30.3 The nurse assumes position at the child's level.

In communication with children of all ages, the nonverbal components of the communication process convey the most significant messages. It is difficult to disguise feelings, attitudes, and anxiety when relating to children. They are alert to surroundings and attach meaning to every gesture and move that is made; this is particularly true of very young children.

Active attempts to make friends with children before they have had an opportunity to evaluate an unfamiliar person tend to increase their anxiety. It is helpful to continue to talk to the child and parent but go about activities that do not involve the child directly, thus allowing the child to observe from a safe position (Figure 30.3). If the child has a special toy or doll, the nurse can "talk" to the doll first. Simple questions such as "Does your teddy bear have a name?" can be asked to ease the child into conversation. Other guidelines for communicating with children are presented in the Guidelines box: Communicating With Children.

Communication and development of thought processes. The normal development of language and thought in children offers a frame of reference for communicating with children. Thought processes progress from sensorimotor to perceptual to concrete and, finally, to abstract, formal operations. An understanding of the typical characteristics of these stages provides the nurse with a framework to facilitate social communication.

Infancy. Because infants are unable to use words, they primarily use and understand nonverbal communication. Infants communicate their needs and feelings through nonverbal behaviours and vocalizations that can be interpreted by someone who is around them for a sufficient time. Infants smile and coo when content and cry when distressed. Crying is provoked by unpleasant stimuli from inside or outside, such as hunger, pain, body restraint, or loneliness. Adults interpret this to mean that an infant needs something and consequently try to alleviate the discomfort and reduce tension. Crying (or the desire to cry) persists as a part of everyone's communication repertoire.

Infants respond to adults' nonverbal behaviours. They become quiet when they are cuddled, are patted, or receive other forms of gentle physical contact. They derive comfort from the sound of a voice, even though they do not understand the words spoken. Until infants reach the age at which they experience stranger anxiety, they readily respond

BOX 30.2 Blocks to Communication

Communication Barriers (Nurse)

- Socializing
- Giving unrestricted and sometimes unasked-for advice
- Offering premature or inappropriate reassurance
- Giving over-ready encouragement
- Defending a situation or opinion
- Using stereotyped comments or clichés
- Limiting expression of emotion by asking directed, closed-ended questions
- Interrupting and finishing the person's sentence
- Talking more than the interviewee
- Forming prejudged conclusions
- Deliberately changing the focus

Signs of Information Overload (Patient)

- Long periods of silence
- Wide eyes and fixed facial expression
- Constant fidgeting or attempting to move away
- Nervous habits, such as tapping, playing with hair
- Sudden disruptions, such as asking to go to the bathroom
- Looking around
- Yawning, eyes drooping
- Frequently looking at a watch or clock
- Attempting to change the topic of discussion

to any firm, gentle handling and quiet, calm speech. Loud, harsh sounds and sudden movements are frightening to infants.

Early childhood. Children younger than 5 years of age are egocentric. They see things only in relation to themselves and from their point of view. Therefore, communication needs to be focused on them. They should be told what they can do or how they will feel. Experiences of others are usually of no interest to them; it is futile to use another child's experience in an attempt to gain the collaboration of small children. During the health assessment they should be allowed to touch and examine articles that will come in contact with them. A stethoscope bell will feel cold; palpating a neck might tickle. Although they have not yet acquired sufficient language skills to express their feelings and wants, toddlers are able to communicate effectively with their hands to transmit ideas without words. For example, they will push an unwanted object away, pull another person to show them something, point, and cover the mouth or ears when they wish to not say or hear something.

Everything is direct and concrete to small children. They are unable to work with abstractions and they interpret words literally. Analogies escape them because they are unable to separate fact from fantasy. For example, they attach literal meaning to such common phrases as "two-faced," "sticky fingers," or "coughing your head off." Children who are told they will get "a little stick in the arm" may not be able to envision an injection (Figure 30.4). Therefore, nurses should avoid using a phrase that might be misinterpreted by a small child.

Young children assign human attributes to inanimate objects. Consequently, they fear that objects may jump, bite, cut, or pinch all by themselves. Children do not know that these devices are unable to perform without human direction. To minimize their fear, unfamiliar equipment should be kept out of view until it is needed.

School-age years. Younger school-age children rely less on what they see and more on what they know, when faced with new problems. They want explanations and reasons for everything but require no verification beyond that. They are interested in the functional aspect of all procedures, objects, and activities. They want to know why an object exists, why it is used, how it works, and the intent and purpose of its user. They need to know what is going to take place and why it is being done to them specifically. For example, to explain a procedure such as taking blood pressure, the child should be shown how squeezing the bulb pushes air into the cuff and makes the arrow move. The child should be allowed to operate the bulb. An explanation for the procedure might be as simple as "I want to see how far the arrow moves when the cuff squeezes your arm." The child then usually becomes an enthusiastic participant.

Fig. 30.4 A young child may take the expression "a little stick in the arm" literally.

School-age children have a heightened concern about body integrity. Because of the special importance they place on their body, they are sensitive to anything that constitutes a threat or suggestion of injury to it. This concern extends to their possessions, so they may appear to overreact to loss or threatened loss of treasured objects. Helping children voice their concerns enables the nurse to provide reassurance and to implement activities that can reduce their anxiety. For example, if a shy child dislikes being the centre of attention, the child should be ignored, by talking and relating to other children in the family or group. When children feel more comfortable, they will usually interject personal ideas, feelings, and interpretations of events.

Older children have an adequate and satisfactory use of language. They still require relatively simple explanations, but their ability to think concretely can facilitate communication and explanation. Commonly, they have sufficient experience with health care workers to understand what is transpiring and what is generally expected of them.

Adolescence. As children move into adolescence, they fluctuate between child and adult thinking and behaviour. They are riding a current that is moving them rapidly toward a maturity that may be beyond their coping ability. Thus, when tensions arise, they may seek the security of the more familiar and comfortable expectations of childhood. Anticipating these shifts in identity allows the nurse to adjust the course of interaction to meet the needs of the moment. No single approach can be relied on consistently; one can expect to encounter cooperation, hostility, anger, bravado, and a variety of other behaviours and attitudes. It is as much a mistake to regard the adolescent as an adult with an adult's wisdom and control as it is to assume that the teenager has the concerns and expectations of a child.

Frequently, adolescents are more willing to discuss their concerns with an adult outside the family, and they often welcome the opportunity to interact with a nurse away from the presence of their parents. They are usually accepting of anyone who displays a genuine interest in them. However, adolescents are quick to reject persons who attempt to impose their values on them, whose interest is feigned, or who appear to have little respect for who they are and what they think or say.

Interviewing the adolescent presents some special issues. The first may be whether to talk with the adolescent alone or with the adolescent and parents together. Of course, if the parent is not there, the only question is whether to suggest to the teenager that the parents be interviewed at another time. If the parents and teenager are together, talking with the adolescent first has the advantage of immediately identifying with the young person, thus fostering the relationship. However, talking with the parents initially may provide insight into the family dynamics. In either case, both parties should be given an opportunity to be included in the interview. If there are time constraints, such as during history taking, this should be clarified at the outset, to avoid the appearance of "taking sides" by talking more with one person than with the other.

Confidentiality is of great importance when interviewing adolescents. Parents and teenagers need to have the limits of confidentiality explained to them, specifically that young persons' disclosures will not be shared unless they indicate a need for intervention, as in the case of suicidal behaviour.

Another dilemma in interviewing adolescents is that two views of an issue frequently exist—the teenager's and the parents'. However, providing both parties an opportunity to discuss their perceptions in an open and unbiased atmosphere can, by itself, be therapeutic.

The demonstration of positive communication skills can help families communicate more effectively (see Guidelines box: Communicating With Adolescents).

GUIDELINES

Communicating With Adolescents

Build a Foundation

- Spend time together.
- Encourage expression of ideas and feelings.
- Respect their views.
- Tolerate differences.
- Praise good points.
- Respect their privacy.
- Set a good example.

Communicate Effectively

- Give undivided attention.
- Listen, listen, listen.
- Be courteous, calm, and open-minded.
- Try not to overreact. If you do, take a break.
- Avoid judging or criticizing.
- Avoid the "third degree" of continuous questioning.
- Choose important issues when taking a stand.
- After taking a stand:
  - Think through all options.
  - Make expectations clear.

Communication Techniques. Nurses use a variety of verbal techniques to encourage communication. In addition to such conventional interviewing methods as reflection and open-ended questions, a number of techniques encourage family members to express their thoughts and feelings in a less directive and confrontational manner. However, for many children and adults, talking about feelings is difficult, and verbal communication may be more stressful than supportive. In such instances, several nonverbal techniques can be used to encourage communication.

Box 30.3 describes both verbal and nonverbal communication techniques used with children. Because of the importance of play in communicating with children, play is discussed more extensively in Chapter 32. Any of the verbal or nonverbal techniques can give rise to strong feelings that surface unexpectedly. The nurse should be prepared to handle them or to recognize when issues go beyond their ability to deal with them. At that point, an appropriate referral can be considered.

Family Advocacy and Caring

Although nurses are responsible to themselves, the profession, and the institution of employment, their primary responsibility is to the consumer of nursing services—the child and the family. The nurse must work with family members, identify their goals and needs, and plan interventions that meet the defined concerns. As an advocate, the nurse can assist children and their families in making informed choices and acting in the child's best interest. **Advocacy** involves ensuring that families are aware of all available health services, informed of treatments and procedures, involved in the child's care, and encouraged to change or support existing health care practices. The United Nations Declaration of the Rights of the Child (Box 30.4) provides guidelines for nursing practice that can be used to ensure that every child receives optimal care. The nurse can use this knowledge to adapt care for the child's physical and emotional well-being.

As nurses care for children and families, they must demonstrate caring, compassion, and **empathy** for others. Aspects of caring embody the concepts of atraumatic care and the development of a therapeutic relationship with patients. Parents perceive caring as a sign of high-quality nursing care, which is often focused on the nontechnical needs of the child and family. Parents describe "personable" care as actions by the nurse that include acknowledging the parents' presence, listening, making the parents feel comfortable, involving both the parents and the child in care, showing interest in and concern for their welfare, showing sensitivity toward the parent and child, communicating with them, and individualizing the nursing care. Parents perceive personable nursing care as an integral part of a positive relationship.

Disease Prevention and Health Promotion

Every nurse involved with child care must understand the importance of disease prevention and health promotion. A nursing care plan must include a thorough assessment of all aspects of child growth and development, including nutrition, immunizations, safety, dental care, socialization, **discipline**, and education. If issues are identified, the nurse can intervene directly or refer the family to other health care providers or agencies.

The best approach to prevention is education and **anticipatory guidance**. An appreciation of the hazards or conflicts of each developmental period enables the nurse to guide parents regarding child-rearing practices aimed at preventing potential problems. One of the most significant examples is safety. Because each age group is at risk for special types of injuries, preventive teaching can significantly reduce the rate of injuries, in turn lowering permanent disability and mortality rates (see Chapter 35).

Prevention also involves less obvious aspects of care. In addition to preventing physical disease or injury, the nurse should also promote mental health. For example, it is not sufficient to administer immunizations without regard to the psychological trauma associated with the procedure. The nurse and all other health care providers must ensure that humane care is provided.

Health Teaching

Health teaching is inseparable from family advocacy and prevention. Health teaching may be the nurse's direct goal, such as during parenting classes, or may be indirect, such as by:

- Helping parents and children understand a diagnosis or treatment
- Encouraging children to ask questions about their bodies
- Referring families to health-related professional or lay groups
- Supplying appropriate literature
- Providing anticipatory guidance

Health teaching is one area in which nurses often need preparation and practice with competent role models, as it involves the transmission of information at the child's and family's levels of understanding and desire for information. As an effective educator, the nurse focuses on providing the appropriate health teaching along with generous feedback and evaluation to promote learning.

Support and Counselling. Attention to emotional needs requires support and sometimes counselling. The role of child advocate or health teacher requires an individualized approach. The nurse can offer support by listening, touching, and being physically present. Touching and physical presence are helpful to use with children because these interventions facilitate nonverbal communication.

Counselling involves a mutual exchange of ideas and opinions that provides the basis for mutual problem solving. It involves supporting, teaching, fostering expression of feelings or thoughts, and helping families cope with stress. Optimally, counselling not only helps resolve a

BOX 30.3 Creative Communication Techniques With Children

First- and Second-Person Techniques

"I" messages

Relate a feeling about a behaviour in terms of "I."

Describe the effect that the behaviour had on the person.

Avoid use of "you;" "you" messages are judgemental and provoke defensiveness.

Example—"You" message: "You are being uncooperative about doing your treatments."

Example—"I" message: "I am concerned about how the treatments are going because I want to see you get better."

Third-Person Technique

Express a feeling in terms of a third person ("he," "she," "they"). This is less threatening than directly asking children how they feel, because it gives them an opportunity to agree or disagree without being defensive.

Example—"Sometimes when a person is sick a lot, he feels angry and sad because he cannot do what others can." Either wait silently for a response or encourage a reply with a statement such as "Did you ever feel that way?"

This approach allows children three choices: (1) to agree and possibly express how they feel; (2) to disagree; or (3) to remain silent, which means they probably have such feelings but are unable to express them at this time.

Facilitative Response

Listen carefully and reflect back to patients the feelings and content of their statements.

Responses are empathic and nonjudgemental and legitimize the person's feelings.

Formula for facilitative responses: "You feel _____ because _____."

Example—If the child states, "I hate coming to the hospital and getting needles," a facilitative response is, "You feel unhappy because of all the things that are done to you."

Storytelling

Use the language of children to probe into areas of their thinking while bypassing conscious inhibitions or fears.

The simplest technique is asking the child to relate a story about an event, such as "being in the hospital."

Other approaches:

Show the child a picture of a particular event, such as a child in a hospital with other people in the room, and ask the child to describe the scene.

Cut out comic strips, remove words, and have the child add statements for scenes.

Mutual Storytelling

Reveal the child's thinking and attempt to change the child's perceptions or fears by retelling a somewhat different story (more therapeutic approach than storytelling).

Begin by asking the child to tell a story about something, then tell another story that is similar to the child's tale but with differences that help the child in difficult areas.

Example—The child's story is about going to the hospital and never seeing their parents again. The nurse's story is also about a child (using different names but similar circumstances) in a hospital, but whose parents visit every day, in the evening after work, until the child is better and goes home with them.

Bibliotherapy

Use books in a therapeutic and supportive process.

Provide children with an opportunity to explore an event that is similar to their own but sufficiently different to allow them to distance themselves from it and remain in control.

General guidelines for using bibliotherapy are as follows:

1. Assess the child's emotional and cognitive development in terms of readiness to understand the book's message.
2. Be familiar with the book's content (intended message or purpose) and the age for which it is written.
3. Read the book to the child if they are unable to read.
4. Explore the meaning of the book with the child by having child do the following:
   - Retell the story.
   - Read a special section with the nurse or parent.
   - Draw a picture related to the story and discuss the drawing.
   - Talk about the characters.
   - Summarize the moral or meaning of the story.

Dreams

Dreams often reveal unconscious and repressed thoughts and feelings.

Ask the child to talk about a dream or nightmare.

Explore with the child what meaning the dream could have.

"What If" Questions

Encourage the child to explore potential situations and to consider different problem-solving options.

Example—"What if you got sick and had to go the hospital?" Children's responses reveal what they know already and what they are curious about, providing an opportunity for them to learn coping skills, especially in potentially dangerous situations.

Three Wishes

Ask, "If you could have any three things in the world, what would they be?"

If the child answers, "That all my wishes come true," ask the child for specific wishes.

Rating Game

Use some type of rating scale (numbers, sad to happy faces) to have the child rate an event or feeling.

Example—Instead of asking youngsters how they feel, ask how their day has been "on a scale of 1 to 10, with 10 being the best."

Word Association Game

State key words and ask children to say the first word they think of when they hear the word.

Start with neutral words and then introduce more anxiety-producing words, such as "illness," "needles," "hospitals," and "operation."

Select key words that relate to some relevant event in the child's life.

Sentence Completion

Present a partial statement and have the child complete it. Some sample statements are as follows:

The thing I like best (least) about school is _____.

The best (worst) age to be is _____.

The most (least) fun thing I ever did was _____.

The thing I like most (least) about my parents is _____.

The one thing I would change about my family is _____.

If I could be anything I wanted, I would be _____.

The thing I like most (least) about myself is _____.

BOX 30.3 Creative Communication Techniques With Children—cont'd

Pros and Cons

Select a topic, such as "being in the hospital," and have the child list "five good things and five bad things" about it.

This is an exceptionally valuable technique when applied to relationships, such as things family members like and dislike about each other.

Nonverbal Techniques

Writing

Writing is an alternative communication approach for older children and adults. Specific suggestions include the following:

Keep a journal or diary.

Write down feelings or thoughts that are difficult to express.

Write "letters" that are never mailed (a variation is making up a pen pal to write to).

Keep an account of the child's progress from both a physical and an emotional viewpoint.

Drawing

Drawing is one of the most valuable forms of communication—both nonverbal (from looking at the drawing) and verbal (from the child's story of the picture).

Children's drawings tell a great deal about them because they are projections of their inner selves.

Spontaneous drawing involves giving the child a variety of art supplies and providing the opportunity to draw.

Directed drawing involves a more specific direction, such as "draw a person" or the "three themes" approach (state three things about the child and ask the child to choose one and draw a picture).

Guidelines for Evaluating Drawings

Use spontaneous drawings and evaluate more than one drawing whenever possible.

Interpret drawings in light of other available information about the child and family, including the child's age and stage of development.

Interpret drawings as a whole rather than focusing on specific details of the drawing.

Consider individual elements of the drawing that may be significant:

Gender of figure drawn first—Usually relates to child's perception of their own gender role

Size of individual figures—Expresses importance, power, or authority

Order in which figures are drawn—Expresses priority in terms of importance

Child's position in relation to other family members—Expresses feelings of status or alliance

Exclusion of a member—May denote feeling of not belonging or desire to eliminate a family member

Accentuated parts—Usually express concern for areas of special importance (e.g., large hands may be a sign of aggression)

Absence of or rudimentary arms and hands—Suggest timidity, passivity, or intellectual immaturity; tiny, unstable feet may express insecurity, and hidden hands may mean guilt feelings

Placement of drawing on the page and type of stroke—Free use of paper and firm, continuous strokes express security, whereas drawings restricted to a small area and lightly drawn in broken or wavering lines may be a sign of insecurity

Erasures, shading, or cross-hatching—Expresses ambivalence, concern, or anxiety with a particular area

Magic

Use simple magic tricks to help establish rapport with the child, encourage collaboration with health interventions, and provide effective distraction during painful procedures.

Although the magician talks, no verbal response from the child is required.

Play

Play is the universal language and "work" of children.

It tells a great deal about children because they project their inner selves through the activity.

Spontaneous play involves giving the child a variety of play materials and providing the opportunity to play.

Directed play involves a more specific direction, such as providing medical equipment or a dollhouse for focused reasons, such as exploring the child's fear of injections or exploring family relationships.

crisis or problem but also enables the family to attain a higher level of functioning, greater **self-esteem**, and closer relationships. Although counselling is often the role of nurses in specialized areas, some counselling techniques are discussed in various sections of this text to help students and nurses cope with immediate crises and refer families for additional professional assistance.

BOX 30.4 United Nations Declaration of the Rights of the Child

All children need:

- To be free from discrimination
- To develop physically and mentally in freedom and dignity
- To have a name and nationality
- To have adequate nutrition, housing, recreation, and medical services
- To receive special treatment, if handicapped
- To receive love, understanding, and material security
- To receive an education and to develop their abilities
- To be the first to receive protection in disaster
- To be protected from neglect, cruelty, and exploitation
- To be brought up in a spirit of friendship among people

Coordination and Collaboration

As a member of the health care team, the nurse coordinates nursing services with the activities of other health care providers. Working in isolation does not serve the child's best interest. The concept of holistic care can only be realized through a unified, interdisciplinary approach. Being aware of individual contributions and limitations to the child's care, the nurse collaborates with other specialists to provide high-quality health services.

Health Care Planning

As the largest health care profession, nursing has a valuable voice, especially as a family and consumer advocate. Nurses must become aware of community needs, be interested in the formulation of legislative bills, and be supportive of politicians to ensure passage (or rejection) of significant legislation. Nurses also need to become actively involved with groups dedicated to the welfare of children (e.g., professional nursing societies, parent–teacher organizations, parent support groups, and volunteer organizations).

Health care planning involves not only providing new services to children and their families but also promoting the highest quality in existing services. In the past, pediatric nursing had no national or international standards of care or education. Most pediatric nurses merged pediatrics with other specialties within nursing and followed the standards of maternal-child health nursing or the standards of several of the pediatric specialties, such as pediatric oncology nursing or school nursing. However, as a profession, pediatric nursing is increasing in momentum in Canada. For example, the CNA offers the Critical Care Pediatric Certificate, and the British Columbia Institute of Technology offers the Pediatric Nursing Specialty Option.

The highest standards of nursing practice are reflected in the emphasis on thorough assessment, the focus on scientific rationale as the basis for care, the summary of nursing care goals and responsibilities, and the comprehensive discussion of growth and development.

Future Trends

The current shift from treatment of disease to promotion of health has expanded nurses' roles in ambulatory care and highlighted the prevention and health-teaching aspects of nursing practice. The need for home care and community health services requires nurses to be more independent and to acquire skills useful in settings beyond the hospital. As changing social policy shapes the expanding health care arena, the focus of nursing care has shifted from what nurses do *for* families to what nurses do *in partnership with* them. The philosophy of family-centred care is no longer an option but a mandate.

Changing demographics will also influence pediatric nursing. The adult population is growing faster than the pediatric population (Statistics Canada, 2020). Consequently, the decrease in the number of children in Canada means fewer hospitalized children and less need for pediatric beds. As well, medical innovations shorten hospital stays for children, and there is an increase in children being treated medically at home rather than in the hospital (see Chapter 41, General Concepts of Home Care). Pediatric units may amalgamate with obstetrical units, creating maternal-child nursing units. Because older persons make up a larger percentage of the population, health care dollars will be split between the youngest and oldest groups, with shrinking resources available to meet the needs of both. Cost containment will present an ever-present challenge to providing high-quality care.

As the Canadian population becomes more diverse, nurses will need to continually adapt their care to the cultural milieu in which they practise. Finally, with the general trend of increasing complexity in pediatric medicine, nurses will need to be aware of developments in this field.

KEY POINTS

- The Government of Canada has broadened the health care objectives of the past and shifted the focus to health promotion as the method to accomplish health goals.
- While the infant mortality rate in Canada is at an all-time low, it continues to be seriously higher among Indigenous people.
- Childhood morbidity encompasses acute illness, chronic disease, and disability.
- Morbidity refers to behavioural, social, and educational problems that can significantly alter a child's health.
- Many children and families in Canada experience poverty, food insecurity, and health inequities.
- Immunizations is one of the most important health promotion strategies for Canadian children.
- The philosophy of family-centred care recognizes the family as the constant in a child's life and that service systems and personnel must support, respect, encourage, and enhance the family's strength and competence.
- Children's vulnerability and reaction to stress depend to a large extent on their age, coping behaviours, and support systems.
- Atraumatic care is the provision of therapeutic care in settings, by personnel, and through the use of interventions that eliminate or minimize the psychological and physical distress experienced by children and their families in the health care system.
- In order to effectively establish a setting for communication, nurses must make an appropriate introduction and ensure privacy and confidentiality.
- When communicating with parents, nurses need to encourage parental involvement, listen carefully, use silence, and be empathic.
- Communication with children needs to reflect their developmental stage.
- Roles of the pediatric nurse include establishing a therapeutic relationship, advocating for families, preventing disease and promoting health, providing health teaching, providing support and counselling, coordinating and collaborating on care, making ethical decisions, and doing research.
- With the shift in focus from treatment of disease to promotion of health, nurses' roles have expanded beyond working in traditional health care facilities to providing care in ambulatory care centres, schools, the family's home, and the community.

Family, Social, and Cultural Influences on Children's Health

Valerie Bertoni

Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Discuss the relationship that the nurse builds with the child and family.
2. Discuss role transitions experienced by new parents.
3. Explain various parenting behaviours, such as parenting styles, disciplinary patterns, and communication skills.
4. Demonstrate an understanding of particular parenting situations, such as adoption, divorce, lone parenting, parenting in reconstituted families, and LGBTQ2 parenting, and how these situations affect the child.
5. Discuss key influences that parents have on their children's socialization.
6. Identify key social determinants of health and be able to describe the influences of socioeconomic status, culture, religion, peer groups, and schools on child development.
7. Identify the importance of culture in the health care of a child.
8. Demonstrate an understanding of health beliefs and practices that can have an impact on a family's view of their child's illness and their treatment-seeking behaviours.

PEDIATRIC NURSING AND THE FAMILY

Nurses need to be aware of the various family structures, functions, and processes within a family. Once a child is brought into a new family, the nurse needs to understand how this changes the family dynamics. The nurse can provide guidance for directing family-oriented interventions as needed and how to care for children in the context of individual families (Kaakinen, 2018).

Family Nursing Interventions

In working with children, nurses must include family members in their care plan. To discover family dynamics, strengths, and weaknesses, a thorough family assessment is necessary (see Chapters 2 and 33). For example, family systems theory is a common approach that nurses use to understand and assess families as a whole, as well as in understanding and assessing the individuals that make up that whole, by using concepts that help one think about the family as a system. The various theories and assessment models that are relevant to family nursing practice are summarized in Table 2.2. When working with families, the nurse's choice of interventions depends on the theoretical family model that is used (Box 31.1).

Nurses need to be cautious not to rely too heavily on one specific theoretical model or framework when working in diverse settings, as a broad knowledge base is required in order to adequately assess and act on challenging health issues faced by families (Kaakinen, 2018).

Families' Roles, Relationships, and Strengths

Each family has its own traditions and values and sets its own standards for interaction within and outside the group. Each family decides on and influences the experiences their children should have, those they are to be shielded from, and how each of these experiences meets the needs of family members. When family ties are strong, social control is highly effective, and most members conform to their roles willingly and with commitment. Conflicts arise when people do not fulfill their roles in ways that meet other family members' expectations, either because they are unaware of the expectations, they choose not to meet them, or they are incapable of meeting them. Knowledge of characteristics that help families function effectively can help the nurse predict ways that families may cope and respond to a stressful event, such as a child's illness. It is important for the nurse to provide individualized support that builds on family strengths and unique functioning style and to assist family members in obtaining requisite resources. Family strengths and their unique ways of functioning are significant resources that nurses can use to meet family needs (Box 31.2). By building on qualities that make a family work well and including supportive family resources, the family

BOX 31.1 Family Nursing Interventions

- Behaviour modification
- Case management and coordination
- Collaborative strategies
- Contracting
- Counselling, including support, cognitive reappraisal, and reframing
- Empowering families through active participation
- Environmental modification
- Family advocacy
- Family crisis intervention
- Networking, including use of self-help groups and social support
- Providing information and technical expertise
- Role modelling
- Role supplementation
- Teaching strategies, including stress management, lifestyle modifications, and anticipatory guidance

From Friedman, M. M., Bowden, V. R., & Jones, E. G. (2003). *Family nursing: Research theory and practice* (5th ed.). Pearson Education.

BOX 31.2 Qualities of Strong Families

- A belief and sense of commitment toward promoting the well-being and growth of individual family members, as well as the family unit
- Appreciation for the small and large things that individual family members do well and encouragement to do better
- Concentrated effort to spend time and do things together, no matter how formal or informal the activity or event
- A sense of purpose that permeates the reasons and basis for "going on" in both bad and good times
- A sense of congruence among family members regarding the value and importance of assigning time and energy to meet needs
- The ability to communicate with one another in a way that emphasizes positive interactions
- A clear set of family rules, values, and beliefs that establishes expectations about acceptable and desired behaviour
- A varied repertoire of coping strategies that promote positive functioning in dealing with both normative and non-normative life events
- The ability to engage in problem-solving activities designed to evaluate options for meeting needs and procuring resources
- The ability to be positive and see the positive in almost all aspects of their lives, including the ability to see crisis and difficulties as an opportunity to learn and grow
- Flexibility and adaptability in the roles necessary to procure resources to meet needs
- A balance between the use of internal and external family resources for coping and adapting to life events and planning for the future

From Dunst, C., Trivette, C., & Deal, A. (1988). *Enabling and empowering families: Principles and guidelines for practice.* Brookline Books.

unit can become even stronger, or increasingly resilient, taking into account that all families have strengths as well as vulnerabilities (Kaakinen, 2018).

It is important for the nurse to remember that the family has a crucial impact on the well-being of a child. For example, a child with a chronic illness such as cystic fibrosis requires a significant amount of time and commitment from family members to optimize the child's well-being; a specific diet, chest physiotherapy, medication administration, and physical activity are only some of the tasks to be carried out by family members to meet the child's needs.

Parental Roles

Historically, the family was headed by socially recognized and sanctioned roles of father (male) and mother (female). These traditional roles modelled what were considered appropriate sexual behaviour and family responsibilities, including child-rearing. The behaviours these gender roles served were intended to provide stability and prolonged care for children.

Parental roles have changed and continue to change significantly as a result of shifts in the economy, increased opportunities for women, evolving gender roles within family structures, and greater variety in family configurations. Women have achieved and continue to achieve equality with men in education, more women have entered the workforce, and the number of women who choose to have fewer children or none at all is increasing. As the roles of women have changed, the complementary roles of men have also changed. Many fathers are taking a more active part in child-rearing and household tasks. In Canada, new family structures such as lone-parent families and families with same-sex or transgender parents have also redefined traditional gender roles (see Chapter 2, Family Organization and Structure). Role conflicts in families may still occur because of a cultural lag of persisting traditional role definitions assumed by some of the family members.

Role Learning

Roles are learned through the socialization process. During all stages of **development**, children learn and practise, through interaction with others and in their play, a set of social roles and characteristics of other roles. They behave in patterned and more or less predictable ways because they learn roles that define mutual expectations in typical social relationships. Although role definitions are changing, the basic determinants of parenting remain the same. Several determinants of parenting infants and young children are parental personality and mental well-being, systems of support, and child characteristics. These determinants have been used as consistent measurements to determine a person's success in fulfilling the parental role.

Parents, peers, and authority figures (such as care providers and teachers), who use positive and negative sanctions to ensure conformity, transmit role conceptions to children. Role behaviours positively reinforced by rewards, such as love, affection, friendship, and honours, are strengthened. Negative reinforcement can take the form of ridicule, withdrawal of love, expressions of disapproval, or banishment.

In some cultures, the role behaviour expected of children conflicts with desirable adult behaviour. One of the family's responsibilities is to develop what they feel is culturally appropriate role behaviour in children. Children learn to perform in expected ways consistent with their position in the family and culture. The observed behaviour of each child is a single manifestation—a combination of social influences and individual psychological processes. In this way, the uniting of the child's intrapersonal system (the self) with the interpersonal system (the family) is simultaneously understood as the child's conduct (Figure 31.1).

Role structuring initially takes place within family units, in which children fulfill a set of roles and respond to the roles of their parents and other family members. Children's roles are shaped primarily by their parents or primary caregivers, who apply direct or indirect pressure to induce or force children into desired patterns of behaviour or direct their efforts toward modification of the child's role responses on a mutually acceptable basis. Children respond to life situations according to behaviours learned in reciprocal transactions. As they acquire important role-taking skills, their relationships with others change. For instance, when a teenager is also a mother but lives in a household with their grandmother, the teenager may be viewed more as an adolescent than as a mother. Children become proficient at understanding others as they acquire the ability to discriminate their

Fig. 31.1 Older school-age children often enjoy taking responsibility for the care of a younger sibling.

Fig. 31.2 An older sister lovingly embraces her adopted sister.

own perspectives from those of others. Children who get along well with others and attain status in the peer group have well-developed role-taking skills.

The ability of parents to provide optimal care and support is dependent on having an adequate structure for healthy growth and development, sufficient income, a safe family environment, appropriate housing, adequate nutrition, opportunities to participate in recreational activities, healthy coping strategies, and timely health care, as well as on using noncoercive discipline (Deatrick, 2017; Kaakinen, 2018).

Special Parenting Situations

Parenting is a demanding task under ideal circumstances, but when parents and children face challenges the potential for family disruption is increased. Situations that can present challenges are divorce, lone parenthood, blended families, adoption, and dual-career families. In addition, as cultural diversity increases in our communities, many immigrants are making the transition to parenthood and to a new country, culture, and language simultaneously. Other situations that create unique parenting challenges are parental alcoholism, homelessness, and incarceration.

Parenting the Adopted Child. While adoption laws in Canada vary among provinces and territories, in general they follow similar requirements and guidelines from child protection legislation, defining *parent* as anyone who has decision-making authority over a child and assumes all the rights, duties, obligations, and responsibilities of the child. Certain provincial and territorial government offices and adoption agencies may have specific requirements for adoptive parents, but in general anyone who is over 18 years of age and is a Canadian citizen without a criminal record is eligible to adopt a child (Canada Adopts, 2021).

Adoption establishes a legal relationship between a child and parents who are not related by birth but who have the same rights and obligations that exist between children and their biological parents. In the past, the biological parent alone made the decision to relinquish the rights to their child. In recent years, the courts have acknowledged the legal rights of the biological father regarding this decision. Concerned child advocates have questioned whether decisions that honour the father's rights are in the child's best interests. As the rights of the child have become recognized, older children have successfully dissolved their legal bond with their biological parents to pursue adoption by adults of their choice. Furthermore, there is a growing demand among lesbian, gay, bisexual, transgender, queer, and two-spirit (LGBTQ2) adults to adopt.

Unlike biological parents, who prepare for their child's birth with prenatal classes and the support of friends and relatives, adoptive parents may have fewer opportunities to prepare, although they often have support of family and friends. Nurses can provide added information, support, and reassurance needed to reduce parental anxiety regarding the adoptive process and can refer adoptive parents to parental support groups. See Additional Resources at the end of the chapter for further information.

The sooner infants enter their adoptive home, the better the chances of **parent–infant attachment**. The more caregivers the infant had before adoption, the greater the risk for attachment issues. The infant must break the bond with the previous caregiver and form a new bond with the adoptive parents. Difficulties in forming an attachment depend on the amount of time infants have spent with earlier caregivers (e.g., birth mother, nurse, adoption agency personnel).

Siblings, adopted or biological, who are old enough to understand should be included in decisions regarding the commitment to adopt, with reassurance that they are not being replaced. Ways in which the siblings can interact with the adopted child should be stressed (Figure 31.2).

Issues of origin. The task of telling children that they are adopted can be a cause of deep concern and anxiety. There are no clear-cut guidelines for parents to follow in determining when and at what age children are ready for the information. Parents are naturally reluctant to present children with such potentially unsettling news. It is important that parents not withhold knowledge of the adoption from the child, since it is an essential component of the child's identity.

The timing arises naturally, as parents become aware of the child's readiness. Most authorities believe that children should be informed at an age young enough so that, as they grow older, they do not remember a time when they did not know they were adopted. The time is highly individual but must be right for parents and the child. It may be when children ask where babies come from, at which time children can also be told the facts of their adoption. If they are told in a way that conveys the idea that they were active participants in the selection process, they will be less likely to feel that they were abandoned, helpless victims. For example, parents can tell children that their personal qualities drew the parents to them. It is wise for parents to tell children that they are adopted before the children enter school, to avoid having them hear it from third parties. Complete honesty between parents and children strengthens the relationship.

Parents should anticipate behaviour changes after disclosure, especially in older children. Children who are struggling with the revelation that they are adopted may benefit from individual and family counselling. Children may use the fact of their adoption as a weapon to

manipulate and threaten parents. Statements such as "My real mother would not treat me like this" or "You don't love me as much because I'm adopted" can hurt parents and increase their feelings of insecurity. Such statements may also cause parents to become overpermissive. Adopted children need the same undemanding love, combined with firm discipline and limit setting, as any other child.

Cross-racial and international adoption. Since 1993, Canadian parents considering international adoption must follow the laws of the adopting countries, which are governed by the Hague Convention. The Hague Convention on Protection of Children and Co-operation in Respect of Intercountry Adoption's main goals are to (1) protect the best interests of adopted children, (2) standardize the process between countries, and (3) prevent child abuse and child trafficking.

Since 2000, 1 500 to 2 000 international adoptions have been reported in Canada every year, with the majority of children being welcomed from China, followed by the United States, Russia, Ethiopia, Vietnam, South Korea, and Haiti (Baxter, 2018). Canadian law offers parents seeking international adoptions two avenues: (1) the citizenship process, which makes the child a Canadian citizen, or (2) the immigration process, which makes the child a permanent resident (Government of Canada, 2017a).

Adoption of children of a racial or ethnic background different from that of the family is commonplace. In addition to the issues faced by adopted children in general, children of a cross-racial adoption must deal with physical and sometimes cultural differences. It is advised that parents who adopt such children do everything possible to preserve the adopted children's cultural heritage.

! NURSING ALERT

As a health care provider, it is important not to ask insensitive questions, such as the following: "Is she yours?" "Is she adopted?" "What do you know about the 'real' mother?" "Do they have the same father?" "How much did it cost to adopt him?" "Your children look so different, which one is yours?"

Although cross-racial adopted children are full-fledged members of an adopting family and citizens of the adopted country, if they have a strikingly different appearance from other family members or exhibit distinct racial or ethnic characteristics, challenges may be encountered outside the family. Strangers may make thoughtless comments and talk about the children as though they were not members of the family. It is vital that family members declare to others that this is their child and a cherished member of the family. It may help to have a response already prepared in anticipation of insensitive remarks.

In international adoptions the medical information that parents receive may be incomplete or inaccurate; weight and height, and sometimes head circumference are often the only objective information present in the child's medical record. There are potential health risks for children who are being adopted internationally and the prevalence of these risks depends on the child's country of origin as well as the child's individual health patterns. Adoptive children come from many different parts of the world, and countries often open and then close the option of allowing international adoptions. International children may be healthy and well cared for while others may have received very little medical care. Children who come from institutions overseas may be more prone to developmental or language delays, while some have complex emotional or neurobehavioural needs (Baxter, 2018). Some children have serious or multiple health conditions, which can be stressful for the parents.

Adolescence. Adolescence may be an especially trying time for parents of adopted children. Whether adopted children have more adjustment issues than nonadopted children is debatable; more evidence-informed research on this area needs to be done in Canada. The normal confrontations of adolescents and parents can assume more painful aspects in adoptive families. Adolescents may use their adoption to defy parental authority or as a justification for aberrant behaviour. As they attempt to master the task of **identity formation**, the feeling of abandonment by their biological parents can come into awareness and may be intensified. Gender differences in reacting to adoption may surface.

Adopted children can fantasize about their biological parents and may feel the need to discover their parents' identity to define themselves and their own identity. It is important for parents to keep the lines of communication open and to reassure their child that they understand the need to search for their identity. Access to biological birth certificates differs between provinces and territories. Some provinces and territories make them legally available to adopted children when they come of age, while others require court orders to have the original birth record released. Adoptive parents should be honest with questioning adolescents and tell them of this possibility (the parents themselves are unable to obtain the birth certificate; it is the children's responsibility if they desire it).

Parenting and Divorce. Since the introduction of the divorce laws in 1968, there has been a steady increase in the Canadian divorce rate. However, since the 1990s, the divorce rate has remained relatively stable, with a less than 2% increase per year. Out of the 19.9 million people aged 25 to 64 in Canada in 2017, the majority were married (56%) or living in a common-law union (15%); 6% were separated or divorced from a marriage and 8% were separated from a common-law union (Statistics Canada, 2019b). The process of divorce begins with a period of marital conflict of varying length and intensity, followed by a separation, the actual legal divorce, and re-establishment of different living arrangements. Because a function of parenthood is to provide for the security and emotional welfare of children, disruption of the family structure often engenders strong feelings of guilt in the divorcing parents.

During a divorce, parents' coping abilities may be compromised. The parents may be preoccupied with their own feelings, needs, and life changes and unable to be available and supportive to their children. Newly employed parents, usually mothers, are likely to leave children with new caregivers, in strange settings, or alone after school. The parent may also spend more time away from home, searching for or establishing new relationships. Sometimes, the adults feel frightened and alone and begin to depend on children as a substitute for the absent parent, which places an enormous burden on the child.

Impact of divorce on children. Numerous studies indicate that divorce has a profound effect on children. Many youngsters suffer for years from psychological and social difficulties associated with continuing or new stresses in the post-divorce family. Even when a divorce is amicable and open, children recall parental separation with the same emotions felt by victims of a natural disaster: loss, grief, and vulnerability to forces beyond their control. Children may also exhibit physiological symptoms as a result of the stress related to the changes caused by the divorce. It is important for the nurse in any setting (hospital, community health care facility, home) to include observations and assessments in order to accurately determine if the divorce is affecting the child.

The impact of divorce on children depends on several factors, including children's age and gender, the outcome of the divorce, and the quality of the parent–child relationship and parental care during the years following the divorce. Family characteristics are more crucial to the child's well-being than specific child characteristics, such as age or gender. High levels of ongoing family conflict are related to issues of social development, emotional stability, and cognitive skills for the child.

Complications associated with divorce include efforts on the part of one parent to subvert the child's loyalties to the other, abandonment to other caregivers, and adjustment to a stepparent. A major difficulty is when children are "caught in the middle" between divorced parents. They become message bearers between parents, are often quizzed about activities of the other parent, and have to listen to one parent criticize the other. A nurse may be able to intercede by helping the child get out of the middle by using "I messages" based on the formula of "I feel . . . (state the feeling) when you . . . (state the source). I would like it if you. . . ." An example of an "I message" is as follows: "I do not feel comfortable when you ask me questions about Mom; maybe you could ask her yourself." This approach enables children to feel in control.

Feelings of children toward divorce vary with age (Box 31.3). Some children feel a sense of shame and embarrassment about the family situation. Some feelings cause children to see themselves as different, inferior, or unworthy of love, especially if they feel responsible for the family dissolution. Although the social stigma attached to divorce no longer produces the emotions it did in the past, such feelings may still exist in small towns or in some cultural groups and can reinforce children's negative self-image. The lasting effects of divorce depend on the children's and parents' adjustment to the transition from an intact family to a lone-parent family and, often, to a reconstituted family.

Although most studies have concentrated on the negative effects of divorce on youngsters, some positive outcomes of divorce have been reported. A successful post-divorce family, either a lone-parent or a reconstituted family, can improve the quality of life for adults and children. If conflict is resolved, a better relationship with one or both parents may result, and some children may have less contact with a disturbed parent. Greater stability in home settings and the removal of arguments between parents at home can be a positive outcome for children's long-term well-being.

Telling the children. Parents are understandably hesitant to tell children about their decision to divorce. Most parents neglect to discuss either the divorce or its inevitable changes with their preschool child. Without preparation, even children who remain in the family home are confused by parental separations. Frequently, children are already experiencing vague, uneasy feelings that are more difficult to cope with than being told the truth about the situation. If possible, the initial disclosure should include both parents and siblings, followed by individual discussions with each child. Sufficient time should be set aside for these discussions in a period of calm, not after an argument, and include reasons for the divorce (if age appropriate) and reassurance that the divorce is not the children's fault.

Parents should not fear crying in front of the children because their crying gives the children permission to cry also. Children may feel guilt, a sense of failure, or that they are being punished for misbehaviour. They normally feel anger and resentment and should be allowed to communicate these feelings without punishment. They need

BOX 31.3 Children's Feelings and Behaviours Related to Divorce

Infants
- Effects of reduced mothering or lack of mothering
- Increased irritability
- Disturbance in eating, sleeping, and elimination
- Interference with attachment process

Toddlers (Ages 2 to 3 Years)
- Frightened and confused
- Blame themselves for the divorce
- Fear of abandonment
- Increased irritability, whining, tantrums
- Regressive behaviours (e.g., thumb sucking, loss of elimination control)
- Separation anxiety

Preschool Children (Ages 3 to 4 Years)
- Fear of abandonment
- Blame themselves for the divorce; decreased self-esteem
- Bewilderment regarding all human relationships
- Become more aggressive in relationships with others (e.g., siblings, peers)
- Engage in fantasy to seek understanding of the divorce

Early School-Age Children (Ages 5 to 6 Years)
- Depression and immature behaviour
- Loss of appetite and sleep disorders
- May be able to verbalize some feelings and understand some divorce-related changes
- Increased anxiety and aggression
- Feelings of abandonment by departing parent

Middle School-Age Children (Ages 6 to 8 Years)
- Panic reactions
- Feelings of deprivation—loss of parent, attention, money, and secure future
- Profound sadness, depression, fear, and insecurity
- Feelings of abandonment and rejection
- Fear about the future
- Difficulty expressing anger at parents
- Intense desire for reconciliation of parents
- Impaired capacity to play and to enjoy outside activities
- Decline in school performance
- Altered peer relationships—become bossy, irritable, demanding, and manipulative
- Frequent crying, loss of appetite, sleep disorders
- Disturbed routine, forgetfulness

Later School-Age Children (Ages 9 to 11 Years)
- More realistic understanding of divorce
- Intense anger directed at one or both parents
- Divided loyalties
- Ability to express feelings of anger
- Ashamed of parental behaviour
- Desire for revenge; may wish to punish the parent they hold responsible
- Feelings of loneliness, rejection, and abandonment
- Altered peer relationships
- Decline in school performance
- May develop somatic discomforts or illnesses
- May engage in aberrant behaviour such as lying, stealing
- Temper tantrums
- Dictatorial attitude

Adolescents (Ages 12 to 18 Years)
- Able to disengage themselves from parental conflict
- Feelings of a profound sense of loss—of family, childhood
- Feelings of anxiety
- Worry about themselves, parents, siblings
- Expression of anger, sadness, shame, embarrassment
- May withdraw from family and friends
- Disturbed concept of sexuality
- May engage in acting-out behaviours

consistency and order in their lives. They want to know where they will live, who will take care of them, if they will be with their siblings, and if there will be enough money to live on. Children fear that if their parents stopped loving each other, they could stop loving them. Their need for love and reassurance is tremendous at this time. Children may also wonder what will happen on special days such as birthdays and holidays, whether both parents will come to school events, and whether they will still have the same friends.

Custody and parenting partnerships. In the past, when parents separated, mothers were given custody of the children, with visitation agreements for fathers. Now both parents and the courts are seeking alternatives. Current belief is that neither fathers, partners, nor mothers should be awarded custody automatically. Custody should be awarded to parents who are best able to provide for the children's welfare. In some cases, children experience severe stress when living or spending time with a parent.

Two other types of custody arrangements are divided custody and joint custody. *Divided*, or *split, custody* means that each parent is awarded custody of one or more of the children, thereby separating siblings. For example, sons might live with the father and daughters with the mother.

Joint custody takes one of two forms. In *joint physical custody*, the parents alternate the physical care and control of the children on an equitable basis while maintaining shared parenting responsibilities legally. This custody arrangement works well for families who live close to each other and whose occupations permit an active role in the care and rearing of the children. In *joint legal custody*, children reside with one parent but both parents are the children's legal guardians and participate in child-rearing.

Co-parenting offers substantial benefits for the family: children can be close to both parents, and life with each parent can be more normal (as opposed to having, for instance, a disciplinarian mother and a recreational father). To be successful, parents in these arrangements must place high value on the commitment to provide normal parenting and to separate their marital conflicts from their parenting roles. No matter what type of custody arrangement is awarded, the primary consideration is the welfare of the children.

The nurse providing care to a child of divorced parents must be aware of the family situation and of the details regarding custody. Depending on the details of the custody, one of the parents or both if they have joint custody have the legal right to make decisions about the child's health treatment. It is important to ask the parent for the details about custody and to document them in the child's health record to ensure that all health care providers caring for the child are aware of the situation. Although one parent might have legal custody, it is not uncommon for both parents to participate in decision making regarding their children, especially in the matter of health. Nurses have a unique role in supporting the child and family through an illness, but if custody issues are complex or if challenges arise, the nurse should involve others who can assist with moving the family forward toward resolution—this could include social workers and hospital legal counsel.

Lone Parenting. An individual may become a lone parent as a result of divorce, separation, death of a spouse, or birth or adoption of a child. Although divorce rates have stabilized, the number of lone-parent households continues to rise. In 2016, these families accounted for 19.2% of all Canadian families, compared to 16.3% in 2011, and 81.3% of children aged 0 to 14 in lone-parent families were living with their mother, and 18.7% were living with their father (Statistics Canada, 2019d). Although some women are lone parents by choice, some never planned on being parents on their own, and may feel pressures to be in a long-term relationship.

Managing shortages of money, time, and energy is often a concern for lone parents. These families are often forced by their financial status to live in communities with inadequate housing and personal safety concerns. Lone parents are singly responsible for ensuring the financial viability of the family. This can lead to long hours away from the home, relying on other caregivers or their adolescents to provide care to the younger children. This can result in lone parents feeling guilty about the time spent away from their children and the burden they may feel they are placing on others. Many lone parents have trouble arranging for adequate child care, particularly for a sick child.

Teen mothers are often lone parents, with all the additional challenges faced when trying to further their education, establish long-term relationships, and provide for their child over the short and long term. Teenage pregnancy rates have been steadily declining in Canada; in 2018, the rate of adolescent pregnancies was 1.7% of all births (Statistics Canada, 2021). Teen mothers should be encouraged to seek out programs that enable them to finish high school while still caring for their child. These programs typically exist within high schools and include services such as case management services, collaboration with community agencies designed to support teenage mothers, on-site child care, on-site counselling, and academic support services that also assist with career preparation.

Fathers and partners who have custody of their children face many of the same challenges that single mothers do. They feel overburdened by the responsibility, depressed, and concerned about their ability to cope with the emotional needs of their children. Some partners find it difficult at first to coordinate household tasks, school visits, and other activities associated with managing a household alone.

Social supports and community resources needed by lone-parent families include health care services that are open on evenings and weekends; high-quality child care; respite child care to relieve parental exhaustion and prevent burnout; and parent enhancement centres for advancing education and job skills, providing recreational activities, and offering parenting education. Lone parents need social contacts separate from their children for their own emotional growth and that of their children.

Parenting in Reconstituted Families. In North America, many of the children living in homes where parents have divorced will experience another major change in their lives, such as the addition of a stepparent or new siblings. The Canadian 2016 census revealed 9.8% of total families are stepfamilies (Statistics Canada, 2019d). The entry of a stepparent into an existing family requires adjustments for all family members. Some obstacles to the role adjustments and family problem solving include disruption of previous lifestyles and interaction patterns, complexity in the formation of new ones, and lack of social supports. Despite these issues, most children from divorced families want to live in a two-parent home.

Cooperative parenting relationships can allow more time for each set of parents to be alone to establish their own relationship with the children. Under ideal circumstances, power conflicts between the two households can be reduced, and tension and anxiety can be lessened for all family members. In addition, the children's self-esteem can be increased, and there is a greater likelihood of continued contact with grandparents. Flexibility, mutual support, and open communication are critical to forming successful relationships in stepfamilies and step-parenting situations.

LGBTQ2 Marriages and Parenting. In Canada, same-sex marriage became legal in 2005. The 2016 census reported 0.9% same-sex couple families, an increase of more than 42% from the 2006 census. Among married same-sex couples, 12% had children in their home in 2016

compared to 8.6% in 2001; in 2016, female couples accounted for four-fifths of the couples who were living with children (Statistics Canada, 2019e). The cultural and legal conflicts that drive many of the concerns for children of LGBTQ2 married parents have become less pronounced as LGBTQ2 family living arrangements have become more commonplace. See Additional Resources for information on working with LGBTQ2 families.

Foster Parenting. **Foster care** can be defined as the placement of a child in a stable and approved environment with a nonrelated family. The living situation may be an approved foster home, possibly with other children, or a preadoptive home. The 2016 census indicated that there are more than 28 000 children aged 14 years and under living in foster households across Canada (Statistics Canada, 2019d). The Child Welfare Services from each province and territory offer training and ongoing education for foster parents. Each province and territory has guidelines regarding the relative health of the prospective foster parents and their families, background checks regarding legal issues for the adults, personal interviews, and a safety inspection of the residence and surroundings.

The 2016 census in Canada indicated that 52.2% of children in foster care are Indigenous but they account for only 7.7% of the child population. This means that 14 970 out of 28 665 foster children in private homes under the age of 15 are Indigenous (Indigenous Services Canada, 2021). The Canadian government has co-developed, with Indigenous peoples, provinces, and territories, new legislation that is designed to decrease the number of Indigenous children and youth in care and improve child and family services. This new legislation, enacted in January 2020, permits Indigenous governing bodies to exercise their jurisdiction over child and family services, and their laws on child and family services prevail over federal, provincial, and territorial laws (Indigenous Services Canada, 2021).

Children in foster care tend to have a higher-than-normal incidence of acute and chronic health conditions and may experience feelings of isolation or confusion (Ponti & Canadian Paediatric Society, 2008/2018). Foster children are often at risk because of their previous caregiving environment. Nurses should strive to implement strategies to improve the health care for this group of children. In particular, assessment and case management skills are required to involve other disciplines in meeting their needs.

SOCIAL AND CULTURAL FACTORS THAT IMPACT HEALTH

The health of Canadians is not dependent primarily on the health care provided but rather by access to the social determinants of health, or broadly speaking, the living conditions to which people are subjected. Since the mid-1800s the impact of living conditions on health has been recognized, and since the 1970s this view has been embedded in Canadian government policy (Raphael, 2016). Social determinants of health exist at an individual as well as a population level, and they affect the degree to which each person has the necessary resources to meet their daily needs and achieve their goals. The key determinants that are generally accepted as affecting the health of Canadians are listed in Box 1.1.

Social Determinant Influences

There is strong evidence that social factors are interconnected and complex and that they have a significant influence on health. Health is a developmental process, a product of interactions among personal, physical, and environmental factors. Children are particularly sensitive to social determinants, especially in their younger years; the first 3 years of life present a crucial period during which they are susceptible to both negative and positive influences. If the exposure to negative influences outweighs that to positive ones, their adaptation can be compromised, setting the stage for greater difficulties later in life. While very young children are dependent on supportive caregiving for healthy development, older children are more dependent on relationships with peers and on school, neighbourhood, and community environments (Institute of Medicine and National Research Council, 2015).

Culture. Children interact within a cultural context every day and are affected by its influences. Social values and beliefs differ among cultures, and children learn directly through the teachings of their families and indirectly through the behaviours around them. Children learn and apply the values and beliefs common to their culture; for example, in some cultures, competition and individual achievement are highly valued, whereas in other cultures collaboration and working with others are highly valued.

Culture also influences health and illness, as there are differences in the ways people of diverse cultures conceptualize sickness, seek health care, relate to health care providers, and accept treatments (Mayhew, 2018). If the adults have their own cultural biases or interpretations about illness and appropriate treatments, their description and management of the illness may be shaped and altered by these beliefs and understandings. Demonstrating awareness of a patient's culture can promote trust, better health care, lead to higher rates of acceptance of diagnoses, and improve treatment adherence (Mayhew, 2018).

Except in rare situations, children grow and develop in a blend of cultures and subcultures (Figure 31.3). In a large, complex society such as that of Canada, different groups have their own sets of standards, values, and expectations within the collective ways of the larger culture. Although many cultural differences are related to geographic boundaries, subcultures are not always restricted by location, especially in the context of Internet support groups and social media. Considering children, in particular, some subcultures are related to the stages of development. For example, the behaviour of school-age children and of adolescents demonstrate age-related subcultures. Although there are countless subcultures or co-cultures within Canada, those that seem to exert great influence on children and their families are ethnicity,

Fig. 31.3 Children grow up within a shared cultural, social, and linguistic heritage.

social class, minority group membership, religion or spirituality, schools, communities, and peer groups.

Social roles. Family roles, like cultural beliefs and values, are learned and transmitted through generations. A role prohibits some behaviours and allows others. Much of children's self-concept comes from their ideas about their social roles. Parents use praise, punishment, and role modelling to teach children culturally acceptable roles. Because roles are shaped and clarified according to the prevailing culture, it has a significant influence on the development of children's self-concept (i.e., attitudes and beliefs they have about themselves). To establish their place in the group, children learn to follow a mode of behaviour that is in agreement with the standards specific to the group and learn how they can expect others to behave toward them. They take their cues by observing and imitating those to whom they are exposed consistently.

When discussing social roles it is helpful to define what constitutes a social group. A social group consists of a system of roles carried out in primary and secondary groups. A *primary group* is characterized by intimate, continued, face-to-face contact; mutual support of members; and the ability to order or constrain a considerable proportion of individual members' behaviour. Two such groups are the family and the peer group, both of which exert a great deal of influence on the child.

Secondary groups are groups that have limited, intermittent contact and in which there is generally less concern about members' behaviour. These groups offer little in terms of support or pressure toward conformity except in rigidly limited areas. Examples of secondary groups are church organizations, Girl Guides and Boy Scouts, sports organizations, and formal recreational children's play groups. None of these groups is highly dominant in its influence; children are exposed to an eclectic set of values, some in agreement and some in conflict with the others. From these they must ultimately select those values that they determine to be best for them and adopt them to form a consistent set of roles and behaviours to be incorporated into their self-concept.

Self-esteem. Culture influences a child's sense of self-esteem, often referred to as self-view or self-evaluation. People from different cultures share a common motivation to be a good person—to live up to the standards of what is perceived to be appropriate and significant in the context of their own culture. These perceptions vary greatly across cultures. In North America, a highly individualistic environment, the most valued attributes are those associated with self-evaluation of competence, talent, independence, and risk-taking to achieve success. In East Asia, by contrast, it is how others perceive an individual's competence and success and their ability to apply the criticisms to self-improvement that dictate self-esteem. In other cultures, it is the achievements and successes of group efforts that lead to more positive self-esteem.

For children, school experiences that focus on personal achievement may promote positive self-esteem in some children but not in others who are more dependent on the success of a whole family or peer group. A child's sense of control may not come from individual self-reliance but rather from a feeling of worthiness in their family or community.

Socioeconomic Status. Socioeconomic status relates to a family's economic and education levels. As a determinant of health, the influence of socioeconomic class cannot be overlooked; the most overwhelming adverse influence on health is low socioeconomic status. At any one time, a higher percentage of low-income individuals suffers from some health condition than any other group.

The number of children living in poverty has continued to increase into the twenty-first century. The child poverty rate in Canada is among the highest in the developed world. In 2017, an average of 19% of children were living in poverty, despite the continued economic growth in Canada and the introduction of a Canadian Child Tax Benefit and National Child Benefit Supplement for lower-income families (Sarangi et al., 2020). In 7 of Canada's 35 large urban centres, one in five children are living in a low-income household (Statistics Canada, 2019a). Persistent poverty puts children at risk for suffering health challenges, including infant mortality, asthma, obesity, low literacy, developmental delays, and behavioural and mental health difficulties. These children also tend to attain lower levels of education and are more likely to live in poverty as adults (Fleury, 2008).

Families living in poverty struggle to provide health care for themselves and for their children. Travel to health care facilities often requires finding money for public transit or a taxi, borrowing a car, or seeking other means of transportation. They must find care for dependents, such as other infants and small children, or have them accompany them when taking the child for care. Families tend to delay preventive care indefinitely unless health services are relatively accessible. They are more likely to consult traditional practitioners or other persons within their community. Day-to-day needs of food, clothing, and lodging take precedence over health care as long as the ailing person feels able to perform activities of daily living.

One of the more pressing concerns in Canada is the growing number of homeless families. Homeless children experience all of the health conditions associated with poverty, as well as other types of disorders. Most of these children experience poor health. They may not have a regular source of health care, and the focus of their care may not be preventive. Their care is likely fragmented, crisis oriented, and often sought in urgent care centres or emergency departments of hospitals. Another group of homeless children are "runaway" adolescents, who are at risk for violence, victimization, sexually transmitted infections, and substance use (Kidd et al., 2017).

Social Supports

Communities. The child's or adolescent's community is made up of the family, school, neighbourhood, youth organizations, and other members. Communities can be sites of opportunity and growth for children and families. Communities can also be a site where poverty and disenfranchisement are minimized through connections with high-quality early childhood education, job training for adolescents and parents, and safe, effective schools. Communities can also contribute to toxic stress if violence and poverty are pervasive and resources are absent. Assets within a community can bolster healthy decision making, minimize high-risk behaviours, and support positive child and adolescent development and decrease the impact of toxic stress (Center on the Developing Child, Harvard University, 2020).

Four categories of external assets that youth receive from the community are as follows (Search Institute, 2021):

1. **Support**—Young people need to feel support, care, and love from their families, neighbours, and others. They also need organizations and institutions that offer positive, supportive environments.
2. **Empowerment**—Young people need to feel valued by their community and be able to contribute to others. They need to feel safe and secure.
3. **Boundaries and expectations**—Young people need to know what is expected of them and what actions and behaviours are within the community boundaries and what are outside of them.
4. **Constructive use of time**—Young people need opportunities for growth through constructive, enriching opportunities and quality time at home.

Internal assets must also be nurtured in the community's younger members. These internal qualities guide choices and create a sense of centredness, purpose, and focus. The four categories of internal assets are as follows (Search Institute, 2021):

1. **Commitment to learning**—Young people need to develop a commitment to education and life-long learning.
2. **Positive values**—Youth need to have a strong sense of values that direct their choices.
3. **Social competencies**—Young people need competencies that help them make positive choices and build relationships.
4. **Positive identity**—Young people need a sense of their own power, purpose, worth, and promise.

School. When children enter school, their radius of relationships extends to include a wider variety of peers and a new source of authority. Although parents continue to exert the major influence on children, in the school environment, teachers have the most significant psychological impact on children's development and socialization. In addition to academic and cognitive progress, teachers are concerned with the emotional and social development of the children in their care. Both parents and teachers act to model, shape, and promote positive behaviour, constrain negative behaviour, and enforce standards of conduct. Ideally, parents and teachers work together for the benefit of the children in their care.

Next to family, schools are a major force in providing continuity between generations by conveying a vast amount of culture from older members of society to the young. In this way, children are prepared to carry out the traditional social roles expected of them as adults in society. School rules and regulations regarding attendance, authority relationships, and the system of sanctions and rewards based on achievement transmit to the child the behavioural expectations of the adult world of employment and relationships. School is often the only institution in which children systematically learn about the negative consequences of behaviours that deviate from societal expectations. Teachers are expected to stimulate and guide the intellectual development of children and their sense of aesthetics and to foster their capacity for creative problem solving. Access to education is an important determinant of health. Through education, individuals of lower socioeconomic status are offered the opportunity and capacity to move up in the social strata.

Traditionally, the socialization process of school began when the child entered kindergarten or first grade. Today, with almost 70% of mothers whose youngest child is aged 3 to 5 years old working outside the home, this socialization process begins much earlier for a significant number of children in a variety of child care settings. This statistic increases to more than 78% for mothers whose youngest child is 6 to 15 years old (Moyser, 2017). For adolescents, close school connectedness and socialization has been linked with fewer health risk behaviours and better long-term health outcomes (Centers for Disease Control and Prevention, 2020).

Peer groups. The aspects of everyday life that are most important to people are typically family life, time with friends, school, work, and play—all involving relationships with other humans. From birth, humans are social beings who spend their lifetime actively engaging with others in small and large groups. Through social interactions children gain a sense of belonging, companionship, and social stimulation; they learn about themselves and how the world works. Personal and interpersonal skills are developed and children learn what is expected of them and about the values inherent in the society in which they live.

Children are active learners, not waiting for others to provide information or opportunities for learning. They make sense of social experiences through observing, experimenting in situations, interacting with other people, and reflecting on what happens. Through these activities they form ideas about how their social world works, gradually adjusting their thinking and constructing new ideas about codes of behaviour and strategies to use.

Peer groups provide natural opportunities for social learning as children are able to practise and receive feedback about skills (e.g., sharing) rather than just hearing or talking about skills and behaviours. The social negotiation that occurs helps children learn to understand others' thoughts, emotions, and intentions and results in better understanding about consequences of their behaviours both for themselves and for others.

The value systems that children are exposed to can vary greatly as they grow. Their family, social class, and ethnic group provide some value constancy from a young age, while peer groups typically provide a diverse set of values. These peer group values can compel children to change their own values, since acceptance to the group is largely based on conformity. If there is a fair degree of similarity between the values of the peer group and those of family and teachers, the small difference creates the separation between children and the adults in their lives, strengthening the bond with their peers. Although the peer group has neither the traditional authority of the parents nor the legal authority of the schools for teaching information, it manages to convey a substantial amount of information to its members, especially on taboo subjects such as sex and drugs. Children's need for the friendship of their peers brings them into an increasingly complex social system (Figure 31.4). The peer-group culture has secrets, mores, and codes of ethics that promote group solidarity and detachment from adults. Through peer relationships, children learn to deal with dominance and hostility and to relate with people in positions of leadership and authority. Other functions of the peer subculture are to relieve boredom and to provide the recognition that individual members do not receive from teachers and other authority figures.

The Child and Family in North America

In North America there tends to be a basic optimistic view of the world, a belief that things can be better and that the children can and will be better off than their parents. This hopeful outlook and a general future orientation, together with the possibility of upward social mobility, have created a pervasive attitude of optimism. Increasing development of self-confidence and autonomy in children is fostered and encouraged. Children in North America are generally permitted a greater degree of freedom than in some more tradition-oriented cultures, where individuals remain in one class for life.

Family life in North America is characterized by increasing geographic and economic mobility. There is less reliance on tradition, families are fragmented, and there may be fewer opportunities to transmit and acquire traditional and accepted customs of a culture. Consequently, young adults rely to a greater extent on professed experts,

Fig. 31.4 Youngsters from different cultural backgrounds interact within the larger culture. (iStock.com/FatCamera)

peers, and mass media for acquisition of acceptable patterns of behaviour, including child-rearing practices. Conflicting information can be a source of confusion and frustration as parents attempt to determine the comparatively stable, essential components of the culture and transmit these to their children.

In Canada, diversity is embraced and valued. People of all races and ethnicities need to be respected and children encouraged to feel secure and confident in their racial or ethnic identity. As with all children, the most important influences on development of a positive self-image are warm, understanding parents who take an active interest in fostering their children's growth. Parents who have established a healthy and loving relationship with their children and react positively will help their children develop feelings of self-worth, self-esteem, and self-acceptance. The more adequate children feel, generally, the more positive their attitudes will be toward children of all backgrounds. Parents who have not established a close relationship with their children and who treat them in nonsupportive ways put their children at risk of acting aggressively and bullying others, particularly those who appear or act differently (Davison, 2016).

Indigenous People. Unlike the rest of Canada's population, Indigenous youth make up over 50% of the Indigenous populations (Figure 31.5). This population comprises the youngest population in Canada, with 44% under the age of 25 years in 2016 (Government of Canada, 2017b).

Indigenous peoples tend to experience health conditions that are common to people living in poverty, related largely to the position they have historically held in Canadian society. The health of Indigenous children under 16 years of age lags behind that of other Canadian children. Infant mortality rates are three times higher, immunization rates are lower, and infectious diseases continue to be a key factor of morbidity for Indigenous children. The rates of diabetes for Indigenous adolescents are higher, and the number of deaths related to injuries (motor vehicle accidents, fires, self-harm, and harm to others) is four times higher than that for the overall Canadian population. In addition, the suicide rate is almost four times higher than the national average, and suicide frequently occurs in clusters. The most common reasons for poorer health status among Indigenous peoples are lower incomes, a higher jobless rate, poor shelter, lower education level, inadequate water and sewage systems, living in remote communities, discrimination, historical trauma, and colonization (see discussion in Chapter 1, Indigenous People) (National Collaborating Centre for Aboriginal Health, 2013).

Fig. 31.5 This Inuit family represents a subculture that interrelates with the larger Canadian culture. (iStock.com/Ryerson Clark)

Immigrant Families. Immigration to Canada has been on the rise over the past two decades. In the 2016 census, immigrants made up 21.9% of the population, up from 17.4% in 1996 (Statistics Canada, 2019c). In 2019, more 341 000 people immigrated to Canada, many of whom are children (Immigration, Refuges and Citizenship Canada, 2020). Since 2015, Canada has welcomed over 44 000 new immigrants from Syria (Government of Canada, 2021).

For decades it was generally accepted that immigrants to Canada arrived with a variety of health issues and needed health care that was absent in their countries of origin. More recent research and observations have indicated that new immigrants arrive with relatively better overall health (lower chronic disease and age-standardized mortality rates) than that of their Canadian-born counterparts (with the exception of HIV/AIDS and tuberculosis)—this is termed the *healthy migrant effect* (Lu & Ng, 2019).

Social determinants of health are thought to affect immigrants to Canada more significantly than native-born Canadians, leading to a phenomenon known as *immigrant overshoot*, where immigrants' health not only deteriorates to the Canadian average but also may get worse as a result of the impact of the social determinants of health that affect immigrants more powerfully (Vang et al., 2015). Immigrant families face unique challenges, including language barriers, lack of recognition of their skills and credentials, lack of access to affordable housing and to appropriate community and settlement supports, limited health care coverage until provincial or territorial health insurance is arranged, limited access to and navigation of the health care system, and health care providers who lack any significant knowledge of and sensitivity to their diverse health care needs.

UNDERSTANDING CULTURES IN THE HEALTH CARE ENCOUNTER

Cultures and co-cultures contribute to the uniqueness of children in such a subtle way and at such an early age that children grow up believing their beliefs, attitudes, values, and practices are the "correct" or "normal" ones. A set of values learned in childhood may characterize children's attitudes and behaviours for life, influencing long-range goals and short-range impulses. Thus every society socializes each succeeding generation to its cultural heritage (see Chapter 2 for further discussion). By observing the various influences on the child's and the family's lives, nurses can better understand how these factors affect their health and how they make decisions about their health.

Bridging the Gap

Some health care institutions may depend on teachings about cultural competence to ensure that holistic care is provided to their patients. Teachings based on cultural competence, while informative, do not provide nurses with the skills to effectively engage with families and are a short-sighted way to approach this contextualized part of children's lives. Cultural competence does spur reflection on elements of society that perpetuate social inequity or injustices, such as racism, ageism, or homophobia. **Cultural safety** is the goal and outcome of practising in a culturally competent environment (Canadian Nurses Association [CNA], 2018).

Cultural humility, by contrast, recognizes that children and families are affected by the intersection of social elements of society and that this can contribute to health inequity or poor health outcomes. Cultural humility is a "commitment and active engagement in a lifelong process that individuals enter into for an ongoing basis with patients, communities, colleagues, and themselves" (First Nations Health Authority,

2016). Cultural humility includes the following tenets (Chavez, 2012; CNA, 2018):

- Lifelong commitment to self-reflection and critique
- Addressing the power imbalances in the nurse–patient relationship
- Developing mutually beneficial and nonpaternalistic partnerships with the community in which one is working

Similarly, Furlong and Wright (2011) encourage health care providers to be "critically aware." This means that nurses should engage with children and families from a stance of curiosity and "informed not-knowing" by changing the dynamic of the encounter to learn from the family, rather than only being the expert clinician (Furlong & Wright, 2011). This liberates the nurse from a reliance on static knowledge that may not be relevant for the patient and allows the nurse to be a "knowledge-seeker" who tries to understand what life is like for the child and family. This critical awareness also calls nurses to assess their own history and the contextual factors that have shaped their own lives. Critical awareness draws nurses to reflect on aspects of North American culture that may be invisible or taken for granted, such as emphasis on independence and individualism, and the ways in which this may not match the needs of children and families.

The manner and sequence of growth and development are universal and fundamental features of all children; however, children's varied behavioural responses to similar events are often determined by their culture. Culture plays a critical role in the parenting behaviors that facilitate children's development. Children acquire the skills, knowledge, beliefs, and values that are important to their own family and culture.

Standards and norms vary from culture to culture and from location to location; a practice that is accepted in one area may meet with disapproval or create tension in another. The extent to which cultures tolerate divergence from the established norm also varies among cultures and subcultural groups. Although conforming to cultural norms provides a degree of security, it is a decided deterrent to change.

! NURSING ALERT

North American cultures and co-cultures can be so diverse that it is essential that nurses be aware of and knowledgeable about the predominant groups in their work community and apply this knowledge in their practice. It is also essential that nurses practise with an openness to learning about cultures and co-cultures different from their own and have some questions that they can use to ask families about what shapes their lives, what they find meaningful, and how they carry that out in their lives. These questions should be simple and open-ended, such as "What is important to you in caring for your child?" "Please tell me a little bit about your family," and "What is important to you as a family?"

HEALTH BELIEFS AND PRACTICES

For many families, traditional practices and beliefs are an integral part of their daily lives. Health care workers should be aware that other people might live by different rules and priorities that decisively influence their health-related behaviours.

A model for learning about health traditions that differ from the Western health care system is based on the following three dimensions:

1. What are the physical aspects of caring for the body (e.g., are there special clothes, foods, medicines)?
2. What are the mental components of caring for health (e.g., feelings, attitudes, rituals, actions)?
3. What are the spiritual aspects of health (e.g., self-discovery, spiritual customs, prayers, healers)?

For each of these dimensions, one must consider the cultural traditions used to maintain health, protect health, and restore health (Spector, 2017).

Health Beliefs

Generally speaking, health care providers in North America and many other parts of the world believe that illness is a result of a biological cause and use scientific methods and processes to diagnose and address health issues. A family's cultural heritage fundamentally shapes their beliefs related to the cause of illness and the maintenance of health. These beliefs can be closely linked with religious or spiritual beliefs and influence the way families cope with illness and respond to health care providers. Families can assign meaning to illnesses and believe that the illness is a result of some wrongdoing on their part or the part of the child. Predominant among many cultures are beliefs related to natural forces, supernatural forces, and imbalance between forces. Because families are such an important part of the care process, it is important to understand their health beliefs in developing and carrying out a child's plan of care.

Natural and Supernatural Forces. The most common natural forces blamed for ill health if the body is not adequately protected are cold air entering the body and impurities in the air. For example, a Chinese parent may overdress an infant in an effort to keep cold wind from entering the child's body. The innate energy, *chi*, is an example of this. A lack of chi is believed to cause fatigue and a variety of ailments. Alternatively, some cultures view supernatural forces as a cause of illness, especially illnesses that cannot be explained by other means. Examples of such forces include voodoo, witchcraft, or evil spirits. Belief in the "evil eye" is another example. It stems from a belief in health as a state of balance and illness as a state of imbalance. As long as an individual's strength and weakness remain in balance, they are unlikely to become a victim of the evil eye. Weaknesses are not necessarily physical. For example, an excess of some emotion, such as envy, can create weakness. Infants and small children, because of immature development of their internal strength-weakness states, are especially vulnerable to the gaze of the evil eye.

Imbalance of Forces. The concept of balance or equilibrium is widespread throughout the world. One of the most common imbalances is the one between "hot" and "cold." This belief derived from the ancient Greek concept of body humors, which states that illness is caused by imbalance of the four humors. Such imbalance is thought to cause internal damage or altered function. Treatment of the illness is directed at restoring balance. The hot and cold understanding of disease is based in this concept. Diseases, areas of the body, foods, and illnesses are classified as either "hot" or "cold." Foods and beverages are designated hot or cold based on the effect they exert, not their actual temperature. In traditional Chinese medicine, the forces are termed *yin* (cold) and *yang* (hot) (Spector, 2017).

Health care workers who are aware of such beliefs are better able to understand why some people refuse to eat certain foods. It is often useful to discuss the diet with the family to determine their beliefs regarding food choices. Nurses can help families devise a diet that contains the necessary balance of basic food groups prescribed by the medical subculture while conforming to the beliefs of the ethnic subculture (Figure 31.6). By determining a family's preferences during well-child visits or prior to discharge, the nurse can help prevent adverse effects.

Health Practices

There are numerous similarities among cultures regarding prevention and treatment of illness. All cultures have some types of home remedies that are applied before seeking help from other persons. Within some ethnic communities, traditional healers who are endowed with the ability to treat maladies are sought for special situations or when home remedies are unsuccessful. Chinese traditional medicine has a very long

Fig. 31.6 Food customs outside the home can differ significantly from traditional cultural practice. (iStock/SolStock)

history and is commonly used. Asian families frequently consult herbalists, who are knowledgeable in herbal remedies and tonics, or ethnic practitioners experienced in Asian therapies, including acupuncture (insertion of needles), acupressure (application of pressure), and moxibustion (application of heat). These traditional remedies are frequently applied in addition to Western medical treatments. Indigenous peoples may consult a variety of traditional healers with specific skills and knowledge. The Truth and Reconciliation Commission (2015) has recommended that health care providers work with traditional healers when caring for Indigenous people. Specialized healers diagnose illness, provide nonsacred treatments (usually by way of massage and herbs), and care for souls. Other specialists perform services or effect cures through spiritual means.

Traditional healers are powerful and respected persons in their community. They "speak the language" of the family who seeks help and often combine their rituals and potions with prayer and entreaties to God or other spiritual powers. They also are able to create an atmosphere conducive to healing and often can acquire important information about the illness without asking too many probing questions. Furthermore, they exhibit a sincere interest in the family and their situation.

Nurses must respect traditional practices that do not harm patients. Overcoming the effect of the evil eye usually requires specialized rituals conducted by the appropriate practitioner. Sometimes the faith in the traditional practitioner results in a delay in obtaining needed medical treatment, although the practitioner will usually suggest medical care if their ministrations are unsuccessful.

Health practices of different cultures may also present issues of assessment and interpretation. For example, certain cultural practices or remedies can be mistakenly judged as evidence of child abuse by uninformed professionals (Box 31.4). It is important to keep the lines of communication open with families and approach the situation with a sense of cultural humility.

Faith healing and religious rituals are closely allied with many traditional healing practices. The wearing of amulets, medals, and other religious relics believed by the culture to protect the individual and facilitate healing is a common practice. It is important for health workers to recognize the value of this practice and keep the items where the family has placed them or nearby. Such objects can offer comfort and support and rarely impede medical and nursing care. If an item must be removed during a procedure, it should be replaced, if possible, when the procedure is completed. The reason for its temporary removal should be explained to the family, and they should be reassured that their wishes will be respected (see Cultural Awareness box: Being Culturally Mindful).

CULTURAL AWARENESS

Being Culturally Mindful

Three-year-old Han is in the respiratory clinic with her parents, who emigrated to Canada from Vietnam less than a year ago. Han has been treated for asthma since her arrival in Canada and was hospitalized once for a short period when her asthma flared as a result of a respiratory illness. Han and her family live with her maternal grandparents. When entering Han's examination room the nurse notes that the parents appear quite tentative. They speak little English and have some difficulty answering the health care provider's initial questions. The nurse knows that it is important that the health care provider have a thorough understanding of how Han has been doing and if they are having any challenges with her medication regime (inhalers and steroids), so the nurse asks their permission to contact an interpreter through a telephone interpretation service. The nurse gives the family sufficient time to answer the questions through the interpreter, keeping a calm and steady voice. The nurse understands that in the Vietnamese culture, being loud or appearing in a rush is considered impolite. The nurse ensures that the interpreter stays on the line while the nurse performs a physical assessment and also when the health care provider is in the examination room so that any additional information can be relayed immediately. Toward the end of the visit, the family appears significantly more relaxed, and through the interpreter they ask if the nurse and health care provider could assist them by providing information that would help the grandfather understand how his smoking might be negatively affecting Han's asthma, as they are concerned that if she gets another respiratory infection she might need hospitalization again, a very distressing event for them.

BOX 31.4 Cultural Practices the Dominant Culture May Consider Abusive

Coin rubbing or spooning—An Asian practice of repeated pressured strokes with the smooth edge of a coin, cup, or other object with a smooth edge over skin lubricated with water or oil to rid the body of a disease.

Cupping—An Old World practice (also practised by the Vietnamese) of placing a container (e.g., tumbler, bottle, jar) containing steam against the skin to "draw out the poison" or other evil element. When the heated air in the container cools, a vacuum is created that produces a bruise-like blemish on the skin directly beneath the mouth of the container.

Burning—A practice of some Southeast Asian groups whereby small areas of skin are burned with specific herbs to treat enuresis and temper tantrums.

Female genital cutting (FGC)—Removal of or injury to any part of the female genitalia; practised in Africa, the Middle East, Latin America, India, Asia, North America, Australia, and Western Europe.

Forced kneeling—A discipline measure of some Caribbean groups in which a child is forced to kneel for long periods of time.

Topical garlic application—A practice of Yemenite Jews in which crushed garlic cloves or garlic–petroleum jelly plaster is applied to the wrists to treat infectious disease. The practice can result in blisters or garlic burns.

Traditional remedies that contain lead—*Greta* and *azarcon* (Mexico; used for digestive issues), *payloooah* (Southeast Asia; used for rash or fever), and *surma* (India; used as a cosmetic to improve eyesight).

Concepts that come from medical anthropology can provide a framework for addressing health care issues and their use can have a direct impact on patient care. In this framework the nurse moves away from an ethnocentric or medicocentric view of the health care encounter into the health care reality as constructed by the patient and family. It is also important for nurses to recognize that disease and illness are distinct entities. Clinicians diagnose and treat diseases—that is, abnormalities in the structure and function of body organs and systems. Illness and disease are not interchangeable; illness may occur even when disease is not present, and the course of a disease may vary substantially from the experience of illness. Illness is culturally constructed; an individual's culture influences how a sickness is perceived, labelled, and explained. Culture also influences the meaning assigned to the illness, the role the individual with the sickness adopts, and the response of the family and community to the sickness.

Tension may arise when the perception of the illness and disease varies widely among the patient, family, and health care team. Failure of health care providers to recognize these disparities may be partially to blame in cases of difficulty carrying out proposed treatment, delivery of inadequate care, and patient or family dissatisfaction. To begin addressing these issues, it is important for nurses to understand the various domains of health care in which individuals operate in Canadian society, including professional (health care providers and institutions), popular (family, community, and lay literature), and folk (nonprofessional healers). Each domain possesses a method for defining and explaining the sickness and what should be done to address it. The challenge for nurses and other health care providers is to address the tensions that may exist in understanding these domains with families and develop mutually agreed-upon goals. Nurses are in a prime position to facilitate this process because understanding the human response to disease is central to their role. In addition, collaboration with the child and family is central to the role of the pediatric nurse.

One method of addressing families and beginning the process of collaboration is by understanding the family's explanatory model of illness. The questions in Box 31.5 aid in eliciting an individual's beliefs about illness, the meaning that is attached to it, goals and expected outcomes, and the roles of health care providers. Nurses can use these questions to discern areas of discrepancy for further dialogue, negotiation, and collaboration. This discussion, when conducted with a genuine interest in the family's and child's perspective, is a significant step toward building trusting relationships, promoting treatment adherence, decreasing disparities, and increasing health care satisfaction.

Nurses are frequently asked by family members to provide advice about or assistance with using traditional health practices, including practices that seem extraordinary or abusive. The nurse needs to ensure that personal feelings are not used to guide the interaction; the focus should be instead on attempting to understand the meaning of the practice. For example, if asked about how to arrange for the excision of female genitalia (a practice most common in Africa, Asia, and the Middle East), the nurse should explore fully with the family what their motivation is and provide information on the potential health risks and the illegal nature of the practice in Canada. Through an open and sincere approach, the nurse has the ability to help the family find alternative options toward achieving their goal.

BOX 31.5 Exploring a Family's Culture, Illness, and Care

Significant understanding can be gained by asking the family straightforward questions, such as:

- What do you think is causing your child's illness?
- Why do you think it started when it did?
- How severe do you think your child's illness is, and do you think it will be a short or long illness?
- How do you think this illness affects the rest of the family?
- What are the major issues that this illness has caused?
- What have you done for the illness until now?
- What kind of treatment do you think your child should receive?
- What are the most important results you hope to receive from your child's treatment?
- What do you fear most about your child's illness?

Adapted from Kleinman, A., Eisenberg, L., & Good, B. (1978). Culture, illness, and care: Clinical lessons from anthropologic and cross-cultural research. *Annals of Internal Medicine,* 88, 251–258.

KEY POINTS

- Because there is no consensus on the definition of family, a family is what an individual considers it to be.
- Three areas of special concern to adoptive families include the initial attachment process, the task of telling children that they are adopted, and identity formation during adolescence.
- Marital factors within the home significantly influence a child's development. The impact of divorce on a child depends on the child's age, the outcome, and the quality of the parent–child relationship and parental care following the divorce.
- Lone parenting and stepparenting can create adjustment difficulties and add stress to the already demanding parental role. Significant numbers of children will live in a lone-parent or reconstituted family at some point.
- A child's self-concept evolves from ideas about their social roles.
- Socioeconomic influences play a major role in opportunities for health promotion and wellness.
- Groups of children who have more physical and mental health issues are those living in poverty; those who are homeless; Indigenous children; and those who are recent immigrants to Canada.
- Culture is the pattern of assumptions, beliefs, and practices encompassing other products of human work and thoughts specific to members of an intergenerational group, community, or population.
- No cultural group is homogeneous; every racial and ethnic group contains great diversity.
- The practice of cultural humility is continual and an important concept in the nursing process. Nurses can facilitate this process by recognizing cultural differences, integrating cultural knowledge, being aware of their own beliefs and practices, and acting in a culturally appropriate manner.
- Cultural and religious beliefs related to the cause of illness and maintenance of health may focus on natural forces, supernatural forces, or imbalance of forces.

Developmental Influences on Child Health Promotion

Constance O'Connor
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe major trends in growth and development.
2. Explain the alterations in the major body systems that take place during the process of growth and development.
3. Discuss the development and relationships of personality, cognition, language, morality, spirituality, and self-concept.
4. Describe the role of play in the growth and development of children.
5. Demonstrate an understanding of the role of innate and environmental factors in the physical and emotional development of children.
6. Describe the influence of mass media on children and how parents can help children to grow and develop within this context.

FOUNDATIONS OF GROWTH AND DEVELOPMENT

Growth and development, usually referred to as a unit, express the sum of the numerous changes that take place during the lifetime of an individual. The entire course is a dynamic process that encompasses several interrelated dimensions:

Growth—An increase in the number and size of cells as they divide and synthesize new proteins; results in increased size and weight of the whole or any of its parts

Development—A gradual change and expansion; advancement from lower to more advanced stages of complexity; the emerging and expanding of the individual's capacities through growth, maturation, and learning

Maturation—An increase in competence and adaptability; aging; usually used to describe a qualitative change; a change in the complexity of a structure that makes it possible for that structure to begin functioning; to function at a higher level

Differentiation—Processes by which early cells and structures are systematically modified and altered to achieve specific and characteristic physical and chemical properties; development from simple to more complex activities and functions

All of these processes are interrelated, simultaneous, and ongoing; none occurs apart from the others. The processes depend on a sequence of endocrine, genetic, constitutional, environmental, and nutritional influences (Ball et al., 2019). The child's body becomes larger and more complex; the personality simultaneously expands in scope and complexity. Very simply, *growth* can be viewed as a quantitative change, and *development* as a qualitative change.

Stages of Development

Most authorities in the field of child development conveniently categorize child growth and behaviour into approximate age stages or in terms that describe the features of an age group. The age ranges of these stages are admittedly arbitrary and, because they do not take into account individual differences, cannot be applied to all children with any degree of precision. However, categorization affords a convenient means to describe the characteristics associated with the majority of children at periods when distinctive developmental changes appear and specific developmental tasks must be accomplished. (A **developmental task** is a set of skills and competencies peculiar to each developmental stage that children must accomplish or master in order to deal effectively with their environment.) It is also significant for nurses to know that there are characteristic health issues peculiar to each major phase of development. The sequence of descriptive age periods and subperiods that are used here and elaborated on in subsequent chapters is listed in Box 32.1.

Patterns of Growth and Development

There are definite and predictable patterns in growth and development that are continuous, orderly, and progressive. While these patterns, or trends, are universal and basic to all human beings, each person accomplishes these in a manner and time unique to that individual.

Directional Trends. Growth and development proceed in regular, related directions, or gradients, and reflect the physical development and maturation of neuromuscular functions (Figure 32.1). The first pattern is the *cephalocaudal*, or head-to-tail, direction. The head end of the organism develops first and is large and complex, whereas the

BOX 32.1 Developmental Age Periods

Prenatal Period—Conception to Birth

Germinal—Conception to approximately 2 weeks
Embryonic—2 to 8 weeks
Fetal—8 to 40 weeks (birth)

A rapid growth rate and total dependency make this one of the most crucial periods in the developmental process. The relationship between maternal health and certain manifestations in the newborn emphasizes the importance of adequate prenatal care to the health and well-being of the infant.

Infancy Period—Birth to 12 Months

Newborn—Birth to 27 or 28 days
Infancy—Birth to approximately 12 months

The infancy period is one of rapid motor, cognitive, and social development. Through mutuality with the caregiver (parent), the infant establishes a basic trust in the world and the foundation for future interpersonal relationships. The critical first month of life, although part of the infancy period, is often differentiated from the remainder because of the newborn major physical adjustments to extrauterine existence and the psychological adjustment of the parent.

Early Childhood—1 to 6 Years

Toddler—1 to 3 years
Preschool—3 to 4 years

This period, which extends from the time children attain upright locomotion until they enter school, is characterized by intense activity and discovery. It is a time of marked physical and personality development. Motor development advances steadily. Children at this age acquire language and wider social relationships, learn role standards, gain self-control and mastery, develop increasing awareness of dependence and independence, and begin to develop a self-concept.

Middle Childhood—5 to 12 Years

Frequently referred to as the school age, this period of development is one in which the child is directed away from the family group and centred on the wider world of peer relationships. There is steady advancement in physical development and sexual maturity, which is measured by the Tanner stages of development tool (see Chapter 40 for more information). Mental and social development is occurring with emphasis on developing skill competencies. Social cooperation and early moral development take on more importance with relevance for later life stages. This is a critical period in the development of a self-concept.

Later Childhood—12 to 18 Years

Prepubertal—10 to 13 years
Adolescence—13 to approximately 18 years

The tumultuous period of rapid maturation and change known as adolescence is considered to be a transitional period that begins at the onset of puberty and extends to the point of entry into the adult world—usually high school graduation. Biological and personality maturation are accompanied by physical and emotional turmoil, and there is redefining of the self-concept. In the late adolescent period, the young person begins to internalize all previously learned values and to focus on an individual, rather than a group identity.

lower end is small and simple and takes shape at a later period. While the physical evidence of this trend is most apparent during the period before birth, it also applies to postnatal behaviour development. Infants achieve structural control of the head before they have control of the trunk and extremities, hold their back erect before they stand, use their eyes before their hands, and gain control of their hands before they have control of their feet.

Fig. 32.1 Directional trends in growth.

The second pattern, the **proximodistal**, or near-to-far, trend, applies to midline-to-peripheral development. A conspicuous illustration is the early embryonic development of limb buds, which is followed by rudimentary fingers and toes. In the infant, shoulder control precedes mastery of the hands, the whole hand is used as a unit before the fingers can be manipulated, and the central nervous system develops more rapidly than the peripheral nervous system.

These trends or patterns are bilateral and appear symmetrical (i.e., each side develops in the same direction and at the same rate as the other). For some of the neurological functions, this symmetry is only external because of unilateral differentiation of function at an early stage of postnatal development. For example, by the age of approximately 5 years, the child has demonstrated a decided preference for the use of one hand over the other, even though previously either one had been used.

The third trend, *differentiation*, describes development from simple operations to more complex activities and functions. From broad, global patterns of behaviour, more specific, refined patterns emerge. All areas of development (physical, mental, social, and emotional) proceed in this direction. Through the process of development and differentiation, early embryonal cells with vague, undifferentiated functions progress to an immensely complex organism composed of highly specialized and diversified cells, tissues, and organs. Generalized development precedes specific or specialized development; gross, random muscle movements take place before fine muscle control.

Sequential Trends. In all dimensions of growth and development there is a definite, predictable sequence, with each child normally passing through every stage. Children crawl before they creep, creep before they stand, and stand before they walk. Later facets of the personality are built on the early foundation of **trust**. The child babbles, then forms words and, finally, sentences; writing emerges from scribbling.

Developmental Pace. Although development has a fixed, precise order, it does not progress at the same rate or pace in each child. There are periods of accelerated growth and periods of decelerated growth in both total body growth and the growth of subsystems. Not all areas develop at the same pace. When a spurt occurs in one area such as gross motor, minimal advances may take place in language, fine motor, or social skills. Once the gross motor skill has been achieved, then development will shift to another area. The rapid growth before and after birth gradually levels off throughout early childhood. Growth is relatively slow during middle childhood, markedly increases at the beginning of adolescence, and levels off in early adulthood. Each child grows at their own pace. Distinct differences are observed between children as they reach developmental milestones.

Sensitive Periods. There are limited times during the process of growth when the organism will interact with a particular environment in a specific manner. Periods termed *critical*, *sensitive*, *vulnerable*, and *optimal* are those times in the life of an organism when it is more susceptible to positive or negative influences.

The quality of interactions during these sensitive periods determines whether the effects on the organism will be beneficial or harmful. For example, physiological maturation of the central nervous system is influenced by adequacy and timing of contributions from the environment, such as stimulation and nutrition. The first 3 months of prenatal life are sensitive periods for physical growth of the fetus. Children are increasingly exposed to environmental exposures during critical periods of growth. For example, infants, toddlers, and preschoolers are engaged in a lot of hand-to-mouth activities and those closer to the ground, which can expose them to increased levels of toxins such as garden pesticides and new carpet toxins. It is also a time of rapidly dividing cells and active development, and exposure to toxins can have a detrimental effect. For example, lead exposure from lead paint on toys and furniture can have a negative impact on a child's intelligence quotient.

Psychological development also appears to have sensitive periods when an environmental event has maximal influence on the developing personality. For example, primary socialization occurs during the first year, when the infant makes the initial social attachments and establishes a basic trust in the world. A close relationship with a parent figure is fundamental to a healthy personality. The same concept might be applied to readiness for learning skills such as toilet independence or reading. In these instances, there appears to be an opportune time when the skill is best learned.

Individual Differences. Each child grows in their own unique and personal way. Great individual variation exists in the age at which developmental milestones are reached. The sequence is predictable; the exact timing is not. Rates of growth vary, and measurements are defined in terms of ranges to allow for individual differences. Some children are fast growers, others are moderate, and some are slower to reach maturity. Periods of fast growth, such as the pubescent growth spurt, may begin earlier or later in some children than in others. Children may grow fast or slowly during the spurt and may finish sooner or later than other children. Gender is an influential factor; girls seem to be more advanced in physiological growth at all ages.

Biological Growth and Physical Development

As children grow, their external dimensions change. These changes are accompanied by corresponding alterations in structure and function of internal organs and tissues that reflect the gradual acquisition of physiological competence. Each part has its own rate of growth, which may be directly related to alterations in the child's size (e.g., the heart rate). Skeletal muscle growth approximates whole-body growth; brain, lymphoid, adrenal, and reproductive tissues follow distinct and individual patterns (Figure 32.2). When growth deficiency has a secondary cause, such as severe illness or acute malnutrition, recovery from the illness or establishment of an adequate diet will produce a dramatic acceleration of the growth rate that usually continues until the child's individual growth pattern is resumed.

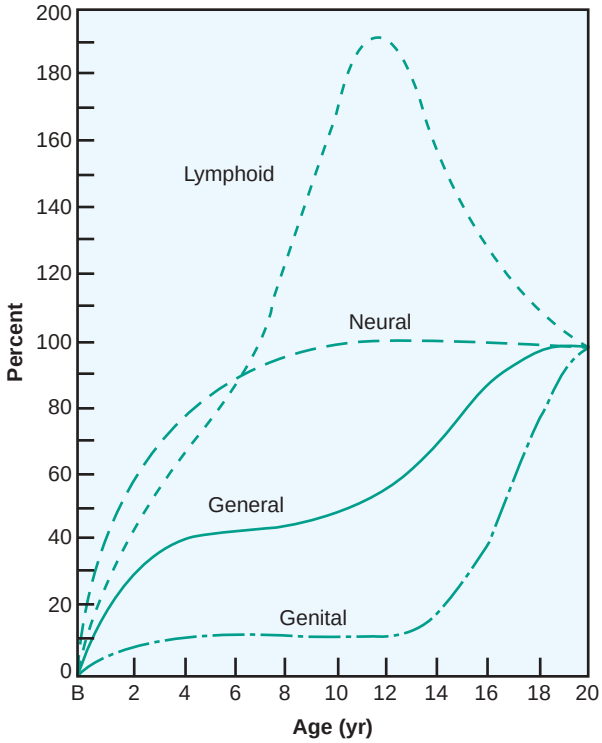

Fig. 32.2 Growth rates for the body as a whole and examples of some specific tissue growth patterns. Lymphoid: thymus, lymph nodes, and intestinal lymph masses. Neural: brain, dura, spinal cord, optic apparatus, and head dimensions. Genital: reproductive tissues. General: body as a whole; external dimension; and respiratory, digestive, renal, circulatory, and musculoskeletal systems. *B,* Birth. (From Jackson, J. A., Patterson, D. G., & Harris, R. E. [1930]. *The measurement of man.* University of Minnesota Press.)

External Proportions. Variations in the growth rate of different tissues and organ systems produce significant changes in body proportions during childhood. The cephalocaudal trend of development is most evident in total body growth as indicated by these changes. During fetal development, the head is the fastest-growing body part, and at 2 months of gestation the head constitutes 50% of total body length. During infancy, growth of the trunk predominates; the legs are the most rapidly growing part during childhood; in adolescence, the trunk once again elongates. In the newborn, the lower limbs are one third the total body length but only 15% of the total body weight; in the adult, the lower limbs constitute one half of the total body height and 30% or more of the total body weight. As growth proceeds, the midpoint in head-to-toe measurements gradually descends from a level even with the umbilicus at birth to the level of the symphysis pubis at maturity.

Biological Determinants of Growth and Development. The most prominent feature of childhood and adolescence is physical growth (Figure 32.3). Throughout development various tissues in the body undergo changes in size, composition, and structure. In some tissues the changes are continuous (e.g., bone growth and dentition); in others,

Fig. 32.3 Changes in body proportions occur dramatically during childhood.

significant alterations occur at specific stages (e.g., appearance of secondary sex characteristics). When these measurements are compared with standardized norms, a child's developmental progress can be determined with a high degree of confidence. The Canadian pediatric growth charts have been developed jointly by the Canadian Paediatric Society (CPS), Dietitians of Canada, the College of Family Physicians of Canada, Community Health Nurses of Canada, and the Canadian Pediatric Endocrine Group (Marchand et al., 2010/2018) and are based on the 2007 World Health Organization (WHO) reference growth charts. These charts are based on the child's gender, height, weight, body mass index (BMI), and head circumference. The charts define growth norms and obesity levels for Canadian children. Some pediatric illnesses will lead to slower growth patterns. Pediatric disorders of genetic, developmental, intellectual, or other types have growth patterns that are different from the standard growth charts. Growth in children with Down syndrome differs from that in other children. They have slower growth velocity between 6 months and 3 years of age and then again in adolescence. Puberty occurs earlier, and they achieve shorter stature. In this population, patients are frequent users of the health care system, often with multiple providers, and benefit from the use of the Down syndrome growth chart to monitor their growth (Zemel et al., 2015).

Linear growth, or height, occurs almost entirely as a result of skeletal growth and is considered a stable measurement of general growth. Growth in height is not uniform throughout life but ceases when maturation of the skeleton is complete. The maximum rate of growth in length occurs before birth, but the newborn continues to grow at a rapid, though slower, rate.

At birth, weight is more variable than height and is, to a greater extent, a reflection of the intrauterine environment. The average newborn weighs from 3 175 to 3 400 g. In general, the birth weight doubles by 4 to 7 months of age and triples by the end of the first year. By the age of 2 to 2½ years the birth weight usually quadruples. After this point the "normal" rate of weight gain, just as the growth in height, assumes a steady annual increase of approximately 2 to 2.75 kg per year until the adolescent growth spurt.

Both bone age determinants and state of dentition are used as indicators of development. These indicators are discussed elsewhere in the text (see next section for bone age; see also Chapter 35 for dentition).

! NURSING ALERT

Double the child's height at 2 years of age to estimate how tall they may be as an adult.

Skeletal Growth and Maturation. The most accurate measure of general development is skeletal or bone age, the radiological determination of osseous maturation. Skeletal age appears to correlate more closely with other measures of physiological maturity (such as onset of menarche) than with chronological age or height. Bone age is determined by comparing the mineralization of ossification centres and advancing bony form to age-related standards.

Bone formation begins during the second month of fetal life when calcium salts are deposited in the intercellular substance (matrix) to form calcified cartilage first and then true bone. In small bones, the bone continues to form in the centre and cartilage continues to be laid down on the surfaces. In long bones, the ossification begins in the *diaphysis* (the long central portion of the bone) and continues in the *epiphysis* (the end portions of the bone). Between the diaphysis and the epiphysis an epiphyseal cartilage plate (or growth plate) unites with the diaphysis by columns of spongy tissue, the *metaphysis*. Active growth in length takes place in the epiphyseal growth plate. Interference with this growth site by trauma or infection can result in deformity.

The first centres of ossification appear in the 2-month-old embryo, and at birth the number is approximately 400, about half the number at maturity. New centres appear at regular intervals during the growth period and represent bone age. Postnatally the earliest centres to appear (at 5 to 6 months of age) are those of the capitate and hamate bones in the wrist. Therefore, radiographs of the hand and wrist provide the most useful areas for screening to determine skeletal age, especially before age 6 years. These centres appear earlier in girls than in boys.

Nurses must understand that the growing bones of children possess many unique characteristics. Bone fractures occurring at the growth plate may be difficult to discover and may significantly affect subsequent growth and development. Factors that may influence skeletal muscle injury rates and types in children and adolescents include the following factors related to overuse injuries (Karlin et al., 2020):

- Extrinsic factors: training errors, poor equipment, workout surface, or less emphasis placed on conditioning, especially flexibility
- Intrinsic factors: athlete's anatomy or medical conditions

In adolescents, fractures are more common than ligamentous ruptures because of the rapid growth rate of the physeal (segment of tubular bone that is concerned mainly with growth) zone of hypertrophy. Twenty five percent of those fractures involve an epiphyseal growth plate or physis (Karlin et al., 2020) (see Soft-Tissue Injury, Chapter 53 for further information).

Neurological Maturation. In contrast to other body tissues, which grow rapidly after birth, the nervous system grows proportionately more rapidly before birth. Two periods of rapid brain cell growth occur during fetal life: a dramatic increase in the number of neurons between 15 and 20 weeks of gestation and another increase at 30 weeks, which extends to 1 year of age. The rapid growth of infancy continues during early childhood and then slows to a more gradual rate during later childhood and adolescence.

Postnatal growth consists of increasing the amount of cytoplasm around the nuclei of existing cells, increasing the number and intricacy of communications with other cells, and advancing their peripheral axons to keep pace with expanding body dimensions. This allows for increasingly complex movement and behaviour. Neurophysiological changes also provide the foundation for language, learning, and behaviour development. Neurological or electroencephalographic development is sometimes used as an indicator of maturational age in the early weeks of life.

Lymphoid Tissues. Lymphoid tissues contained in the lymph nodes, thymus, spleen, tonsils, adenoids, and blood lymphocytes follow a growth pattern unlike that of other body tissues. These tissues are small in relation to total body size, but they are well developed at birth. They increase rapidly to reach adult dimensions by 6 years of age and continue to grow. At about age 10 to 12 years, they reach a maximum development that is approximately twice their adult size. This is followed by a rapid decline to stable adult dimensions by the end of adolescence. For example, children are constantly fighting off new organisms and infections and their lymphatic system quickly responds to fight these antigens. Because of this response, it is quite common for children to have slightly enlarged lymph nodes in certain areas of the body some of the time. However, changes in the lymph nodes can also indicate certain conditions or diseases that need special treatment.

Development of Organ Systems. All tissues and organ systems undergo changes during development. Some are striking; others are subtle. Many have implications for assessment and care. Because the major importance of these changes relates to their dysfunction, the developmental characteristics of various systems and organs are discussed throughout the book as they relate to these areas. Physical characteristics and physiological changes that vary with age are included in age group descriptions; see Unit 10.

Physiological Changes

Physiological changes that take place in all organs and systems are discussed in this book as they relate to abnormalities or health conditions. Other changes such as pulse and respiratory rates and blood pressure are an integral part of physical assessment (see Chapter 33). In addition, changes occur in basic functions, including metabolism, temperature, and patterns of sleep and rest.

Metabolism. The rate of metabolism when the body is at rest (**basal metabolic rate** [BMR]) demonstrates a distinctive change throughout childhood. Highest in the newborn, the BMR closely relates to the proportion of surface area to body mass, which changes as the body increases in size. In both sexes the proportion decreases progressively to maturity. The BMR is slightly higher in boys at all ages and further increases during pubescence over that in girls.

The rate of metabolism determines the child's caloric requirements. The basal energy requirement is about 108 kcal/kg of body weight in newborns and decreases to 40 to 45 kcal/kg at maturity. Water requirements throughout life remain at approximately 1.5 mL/calorie of energy expended. Children's energy needs vary considerably at different ages and with changing circumstances. The energy requirement to build tissue steadily decreases with age, following the general growth curve; however, energy needs vary with the individual child and may be considerably higher. For short periods (e.g., during strenuous exercise) and more prolonged periods (e.g., illness) the needs can be very high.

! NURSING ALERT

Each degree of fever increases the basal metabolism 10%, with a correspondingly increased fluid requirement.

Temperature. Body temperature, reflecting metabolism, decreases over the course of development. Thermoregulation is one of the most important adaptation responses of the newborn during the transition from intrauterine to extrauterine life (see Chapter 25, Thermogenesis). In the healthy newborn, hypothermia can result in several negative metabolic consequences, such as hypoglycemia, elevated bilirubin levels, and metabolic acidosis (see Figure 25.5). Skin-to-skin contact is an effective way to prevent hypothermia in newborns (see Chapter 27, Evidence-Informed Practice box: Skin-to-Skin Contact for Full-Term Newborns). The unclothed, diapered newborn is placed on the parent's bare chest after birth, promoting thermoregulation and attachment. After the unstable regulatory ability in the newborn period, heat production steadily declines as the infant grows into childhood. Individual differences of 0.7 of a Celsius degree are normal, and occasionally a child will normally display an unusually high or low temperature. Beginning at approximately 12 years of age, girls' temperature remains relatively stable, whereas the temperature in boys continues to fall for a few more years. Females maintain a temperature slightly above that of males throughout life.

Even with improved temperature regulation, infants and young children are highly susceptible to temperature fluctuations. Body temperature responds to changes in environmental temperature and is increased with active exercise, crying, and emotional stress. Infections can cause a higher and more rapid temperature increase in infants and young children than in older children. In relation to body weight, an infant produces more heat per unit than adolescents. Consequently, during active play or when heavily clothed, an infant or small child is likely to become overheated.

Sleep and Rest. Sleep, a protective function in all organisms, allows for repair and recovery of tissues after activity. As in most aspects of development, there is wide variation among individual children in the amount and distribution of sleep at various ages. As children mature, the total time they spend in sleep and the amount of time they spend in deep sleep change.

Newborns sleep much of the time. As infants grow older, the total sleep time gradually decreases, they remain awake for longer periods, and they sleep longer at night. The average sleep patterns for different age groups are listed in Box 35.1.

The quality of sleep changes as children mature. As children develop through adolescence, their need for sleep does not decline, but their opportunity for sleep may be affected by social activity and academic schedules. The time spent in deep, restful sleep increases from 50% in infancy to 80% in the older child.

Nutrition

Nutrition is probably the single most important influence on growth. Dietary factors regulate growth at all stages of development, and their effects are exerted in numerous and complex ways. During the rapid prenatal growth period, poor nutrition may influence development from the time of implantation of the ovum until birth. During infancy and childhood, the demand for calories is relatively great, as evidenced by the rapid increase in both height and weight. At this time, protein and caloric requirements are higher than at almost any period of postnatal development. As the growth rate slows, with its concomitant decrease in metabolism, there is a corresponding reduction in caloric and protein requirements.

Growth is uneven during the periods of childhood between infancy and adolescence, when there are plateaus and small growth spurts. The child's appetite fluctuates in response to these variations until the turbulent growth spurt of adolescence, when adequate nutrition is extremely important but may be subject to numerous emotional influences. Adequate nutrition is closely related to good health throughout life, and an overall improvement in nourishment is evidenced by the gradual increase in size and early maturation of children in this century (see Community Focus box: Healthy Food Choices).

Canada's Food Guide was revised in 2019 to meet nutrient standards (Dietary Reference Intakes [DRI] for vitamins, elements [minerals], and macronutrients) and to be consistent with evidence linking diet to a reduced risk of chronic diseases. See Appendix A to review *Canada's Food Guide*. The new guide recommends plenty of vegetables and fruits (half a dinner plate) with one-quarter protein and one-quarter whole-grain foods. Water is the drink of choice (Health Canada, 2020) (see Chapter 35 for specific age group recommendations).

COMMUNITY FOCUS

Healthy Food Choices

Canada remains the only G7 country without a national school food program. Canada's current patchwork of school food programming reaches only a small percentage of over five million students (Critch & CPS Nutrition and Gastroenterology Committee, 2020; Hernandez et al., 2018). Because students consume about 30% of their daily food at school, this situation can contribute to a higher rate of obesity. Indeed, obesity is on the increase in the pediatric population in Canada, which can have a long-term negative impact on health. Provision of healthy food at school can improve children's health and academic outcomes while creating economic opportunities for local, sustainable agriculture. The federal government has recently committed to developing a national program with the provinces and territories but needs to establish food procurement criteria and regulations to protect against corporate food and beverage companies, which may offer less healthy foods, from gaining entry into schools (Hernandez et al., 2018).

The Canadian Paediatric Society (CPS) has supported the development and implementation of nutrition policies and guidelines in Canadian schools (Critch & CPS Nutrition and Gastroenterology Committee, 2020). These polices align with the Canada's Food Guide recommendations and have increased the availability and consumption of nutrient-rich foods while decreasing access to and consumption of foods and beverages that are high in sugars, sodium, and saturated fats. These changes can result in improved health outcomes for children and youth, such as improved body mass indices (Critch & CPS Nutrition and Gastroenterology Committee, 2020). More research is needed and strategic planning required to encourage lower-fat and low-salt food options. For example, a study was done to evaluate out-of-school snack programs. The research showed that children chose sliced fruit over whole fruit. Fruit was chosen over unflavoured grain product. However, fruit was rarely chosen over sugar-sweetened and salty snacks (6% vs. 58%). Snack policies that want to serve fruit need to limit less-healthful snack options simultaneously (Beet et al., 2014). The provision of healthier choices in food delivery in schools remains a challenge.

Temperament

Temperament is defined as the manner of thinking, behaving, or reacting characteristic of an individual and comprises traits that stay relatively constant over time and refers to the way in which a person deals with life (Baum, 2020). From the time of birth, children exhibit marked individual differences in the way they respond to their environment and the way that others, particularly the parents, respond to them and their needs. A genetic basis has been suggested for some differences in temperament. Nine characteristics of temperament have been identified through interviews with parents (Box 32.2). *Temperament* refers to behavioural tendencies, not to discrete behavioural acts; there are no implications of good or bad. Most children can be placed into one of three common categories, based on their overall pattern of temperamental attributes:

The easy child—Easy-going children are even-tempered, are regular and predictable in their habits, and have a positive approach to new stimuli. They are open and adaptable to change and display a mild to moderately intense mood that is typically positive. Approximately 40% of children fall into this category.

The difficult child—Difficult children are highly active, irritable, and irregular in their habits. Negative withdrawal responses are typical, and they require a more structured environment. These children adapt slowly to new routines, people, or situations. Mood expressions are usually intense and primarily negative. They exhibit frequent periods of crying, and frustration often produces violent tantrums. This group represents about 10% of children.

The slow-to-warm-up child—Slow-to-warm-up children typically react negatively and with mild intensity to new stimuli and, unless pressured, adapt slowly with repeated contact. They respond with only mild but passive resistance to novelty or changes in routine. They are inactive and moody but show only moderate irregularity in functions. Approximately 15% of children demonstrate this temperament pattern.

Roughly 35% of children either have some, but not all, of the characteristics of one of the categories or are inconsistent in their behavioural responses. Many children demonstrate this wide range of behavioural patterns.

BOX 32.2 Attributes of Temperament

Activity—Level of physical motion during activity such as sleep, eating, play, dressing, and bathing

Rhythmicity—Regularity in the timing of physiological functions such as hunger, sleep, and elimination

Approach–withdrawal—Nature of initial responses to new stimuli such as people, situations, places, foods, toys, and procedures (*Approach* responses are positive and are displayed by activity or expression; *withdrawal* responses are negative expressions or behaviours.)

Adaptability—Ease or difficulty with which the child adapts or adjusts to new or altered situations

Threshold of responsiveness (sensory threshold)—Amount of stimulation, such as sounds or light, required to evoke a response in the child

Intensity of reaction—Energy level of the child's reactions, regardless of quality or direction

Mood—Amount of pleasant, happy, friendly behaviour compared with unpleasant, unhappy, crying, unfriendly behaviour exhibited by the child in various situations

Distractibility—Ease with which a child's attention or direction of behaviour can be diverted by external stimuli

Attention span and persistence—Length of time a child pursues a given activity (attention) and the continuation of an activity in spite of obstacles (persistence)

Significance of Temperament. Observations indicate that children who display the difficult or slow-to-warm-up patterns of behaviour are more vulnerable to the development of behavioural problems in early and middle childhood. Any child can develop behavioural issues if there is dissonance between the child's temperament and the environment. Demands for change and adaptation that are in conflict with the child's capacities can become excessively stressful. However, authorities emphasize that it is not the children's temperament patterns that place them at risk; it is the degree of fit between children and their environment, specifically their parents, that determines the degree of vulnerability. The potential for optimal development exists when environmental expectations and demands fit with the individual's style of behaviour and the parents' ability to navigate this period (Baum, 2020).

BOX 32.3 Activities to Promote Mastery Motivation in Infants

- Provide inconspicuous assistance during play.
- Share pleasure with infant in accomplishments.
- Do not give immediate assistance during tasks.
- Do not interrupt infant during tasks.
- Let infant initiate activities.
- Limit controlling feedback during play.
- Provide audio and visually responsive toys.
- Provide early kinesthetic stimulation (picking up, rocking).

From Morrow, J. D., & Camp, B. W. (1996). Mastery motivation and temperament of 7-month-old infants. *Pediatric Nursing, 22*(3), 211–217.

Early identification of temperament provides a useful tool for caregivers in anticipating probable areas of difficulty or risk associated with development. For example, "difficult" children may be prone to colic in infancy, active children require more vigilance to prevent injury, and school entry requires different approaches for children with different temperaments.

Research indicates that irritable and uncooperative infants can raise doubts in mothers about the mother's competence. Additional research indicates that a child's temperament can affect parent–child interactions and influence the parents' self-esteem, marital harmony, mood, and overall satisfaction as parents. Studies on the relationship between temperament and the ability to perform a task successfully (mastery motivation) have found that infants with high mastery are more easy-going. Activities that parents can use to promote their infants' mastery of performing tasks are listed in Box 32.3.

Pediatric nurses play an important role in helping parents understand the normal growth and development of their children. The nurse can use anticipatory guidelines that are age specific to help parents develop tools and techniques for managing their child's behaviour in a preventative, positive way.

DEVELOPMENT OF PERSONALITY AND COGNITIVE FUNCTION

Personality and cognitive skills develop in much the same manner as biological growth—new accomplishments build on previously mastered skills. Many aspects depend on physical growth and maturation. The following discussion acts as an introduction to the multiple facets of personality and behaviour development; many aspects of this development are also integrated into the book's later discussion of children's emotional and social development at various ages. Table 32.1 summarizes some of the relevant developmental theories.

TABLE 32.1 Summary of Personality, Cognitive, and Moral Development Theories

Psychosexual (Freud)	Psychosocial (Erikson)	Cognitive (Piaget)	Moral Judgement (Kohlberg)	Spiritual (Fowler)
I. Infancy—Birth to 1 Year				
Oral-sensory	Trust vs. mistrust If an infant is hungry and not given food consistently then fear and a sense that the world is unpredictable can result	Sensorimotor (birth–2 years)		Undifferentiated
II. Toddlerhood—1 to 3 Years				
Anal-urethral	Autonomy vs. shame and doubt If a child is not consistently allowed to choose clothing to wear or food to eat then a sense of inadequacy and self-doubt can result	Preoperational thought, preconceptual phase (transductive reasoning [e.g., specific to specific]) (2–4 years)	Preconventional (premoral) level Punishment and obedience orientation	Intuitive-projective
III. Early Childhood—3 to 5 Years				
Phallic-locomotion	Initiative vs. guilt If a child is not encouraged to play and be creative then if over-directed by adults, may struggle to develop a sense of initiative and confidence in their own abilities	Preoperational thought, intuitive phase (transductive reasoning) (4–7 years)	Preconventional (premoral) level Naive instrumental orientation	Mythical-literal
IV. Middle Childhood—5 to 12 Years				
Latency	Industry vs. inferiority	Concrete operations (inductive reasoning and beginning logic) (7–11 years)	Conventional level Good-boy, nice-girl orientation Law-and-order orientation	Synthetic-convention
V. Adolescence—12 to 18 Years				
Genitality	Identity vs. role confusion Those who do not receive encouragement and reinforcement through personal experiences may struggle to develop a strong sense of self and feeling of independence and control and feel insecure and uncertain of the future	Formal operations (deductive and abstract reasoning) (11–15 years)	Postconventional or principled level Social-contract orientation Universal ethical principle orientation	Individuating-reflexive

Theoretical Foundations of Personality Development

Psychosexual Development (Freud). According to Freud (1923/1961), all human behaviour is energized by psychodynamic forces, and this psychic energy is divided among three components of personality: the id, the ego, and the superego. The *id*, the *unconscious mind*, is the inborn component that is driven by instincts (Freud, 1923/1961). The id obeys the pleasure principle of immediate gratification of needs, regardless of whether the object or action can actually do so. The *ego*, the *conscious mind*, serves the reality principle. It functions as the conscious or controlling self that is able to find realistic means for gratifying the instincts while blocking the irrational thinking of the id. The *superego*, the *conscience*, functions as the moral arbitrator and represents the ideal. It is the mechanism that prevents individuals from expressing undesirable instincts that might threaten the social order.

Freud considered the sexual instincts to be significant in the development of the personality. However, he used the term *psychosexual* to describe any sensual pleasure. During childhood, certain regions of the body assume a prominent psychological significance as the source of new pleasures and new conflicts gradually shifts from one part of the body to another at particular stages of development:

Oral stage (birth to 1 year)—During infancy, the major source of pleasure seeking is centred on oral activities such as sucking, biting, chewing, and vocalizing. Children may prefer one of these over the others, and the preferred method of oral gratification can provide some indication of the personality they develop.

Anal stage (1 to 3 years)—Interest during the second year of life centres on the anal region as sphincter muscles develop and children are able to withhold or expel fecal material at will. At this stage, the climate surrounding toilet training can have lasting effects on children's personalities.

Phallic stage (3 to 6 years)—During the phallic stage, the genitalia become an interesting and sensitive area of the body. Children recognize differences between the sexes and become curious about the dissimilarities. This is the period around which the controversial issues of the Oedipus and Electra complexes, penis envy, and castration anxiety are centred.

Latency period (6 to 12 years)—During the latency period, children elaborate on previously acquired traits and skills. Physical and psychic energy are channelled into acquisition of knowledge and into vigorous play.

Genital stage (age 12 and older)—The last significant stage begins at puberty with maturation of the reproductive system and production of sex hormones. The genital organs become the major source of sexual tensions and pleasures, but energies are also invested in forming friendships and preparing for permanent relationships.

Psychosocial Development (Erikson). The most widely accepted theory of personality development is that advanced by Erikson (1963). Although built on Freudian theory, it is known as *psychosocial* development and emphasizes a healthy personality as opposed to a pathological approach. Erikson also uses the biological concepts of critical periods and epigenesis, describing key conflicts or core problems that the individual strives to master during critical periods in personality development. Successful completion or mastery of each of these core conflicts is built on the satisfactory completion or mastery of the previous stage.

Each psychosocial stage has two components—the favourable and the unfavourable aspects of the core conflict—and progress to the next stage depends on resolution of this conflict. No core conflict is ever mastered completely but remains a recurrent problem throughout life. No life situation is ever secure. Each new situation presents the conflict in a new form. For example, when children who have satisfactorily achieved a sense of trust encounter a new experience (e.g., hospitalization), they must again develop a sense of trust in those responsible for their care in order to master the situation. Erikson's lifespan approach to personality development consists of eight stages; however, only the first five relating to childhood are included here:

1. **Trust versus mistrust (birth to 1 year)**—The first and most important attribute to develop for a healthy personality is basic *trust*. Establishment of basic trust dominates the first year of life and describes all of the child's satisfying experiences at this age. Corresponding to Freud's oral stage, it is a time of "getting" and "taking in" through all the senses. It exists only in relation to something or someone; therefore, consistent, loving care by a mothering person is essential for development of trust. *Mistrust* develops when trust-promoting experiences are deficient or lacking or when basic needs are inconsistently or inadequately met. Although shreds of mistrust are sprinkled throughout the personality, from a basic trust in parents stems trust in the world, other people, and oneself. The result is faith and optimism.
2. **Autonomy versus shame and doubt (1 to 3 years)**—Corresponding to Freud's anal stage, the problem of *autonomy* can be symbolized by the holding on and letting go of the sphincter muscles. The development of autonomy during the toddler period is centred on children's increasing ability to control their bodies, themselves, and their environment. They want to do things for themselves, using their newly acquired motor skills of walking, climbing, and manipulating and their mental powers of selecting and decision making. Much of their learning is acquired by imitating the activities and behaviour of others. Negative feelings of *doubt* and *shame* arise when children are made to feel small and self-conscious, when their choices are disastrous, when others shame them, or when they are forced to be dependent in areas in which they are capable of assuming control. The favourable outcomes are *self-control* and *willpower*.
3. **Initiative versus guilt (3 to 6 years)**—The stage of *initiative* corresponds to Freud's phallic stage and is characterized by vigorous, intrusive behaviour; enterprise; and a strong imagination. Children explore the physical world with all their senses and powers (Figure 32.4). They develop a conscience. No longer guided only by outsiders, they have an inner voice that warns and threatens. Children sometimes undertake goals or activities that are in conflict with those of parents or others, and being made to feel that their activities or imaginings are bad produces a sense of guilt. Children must learn to retain a sense of initiative without impinging on the rights and privileges of others. The lasting outcomes are *direction* and *purpose*.
4. **Industry versus inferiority (6 to 12 years)**—The stage of *industry* is the latency period of Freud. Having achieved the more crucial stages in personality development, children are ready to be workers and producers. They want to engage in tasks and activities that they can carry through to completion; they need and want real achievement. Children learn to compete and cooperate with others, and they learn the rules. It is a decisive period in their social relationships with others. Feelings of *inadequacy* and *inferiority* may develop if too much is expected of them or if they believe that they cannot measure up to the standards set for them by others. The ego quality developed from a sense of industry is *competence*.
5. **Identity versus role confusion (12 to 18 years)**—Corresponding to Freud's genital period, the development of *identity* is characterized by rapid and marked physical changes. Previous trust in their bodies is shaken, and children become overly preoccupied with the way they appear in the eyes of others as compared with their own self-concept. Adolescents struggle to fit the roles they have played and those they hope to play with the current roles and fashions

Fig. 32.4 The stage of initiative is characterized by physical activity and imagination while children explore the physical world around them.

adopted by their peers, to integrate their concepts and values with those of society, and to come to a decision regarding an occupation. Inability to solve the core conflict results in *role confusion*. The outcome of successful mastery is *devotion* and *fidelity* to others and to values and ideologies.

Cognitive Development (Piaget). The term *cognition* refers to the process by which developing individuals become acquainted with the world and the objects it contains. Children are born with inherited potential for intellectual growth, but they must develop that potential through interaction with the environment. By assimilating information through the senses, processing it, and acting on it, they come to understand relationships between objects and between themselves and their world. With cognitive development, children acquire the ability to reason abstractly, to think in a logical manner, and to organize intellectual functions or performances into higher-order structures. Language, morals, and spiritual development emerge as cognitive abilities advance. Cognitive development consists of age-related changes that occur in mental activities.

The best-known theory regarding children's thinking, and a more comprehensive developmental theory than those already described, was developed by the Swiss psychologist Jean Piaget (1969). According to Piaget, intelligence enables individuals to make adaptations to the environment that increase the probability of survival, and through their behaviour individuals establish and maintain equilibrium with the environment.

Piaget (1969) proposed three stages of reasoning: (1) intuitive, (2) concrete operational, and (3) formal operational. When children enter the stage of concrete logical thought at about age 7 years, they are able to make logical **inferences**, classify, and deal with quantitative relationships about concrete things. Not until adolescence are they able to reason abstractly with any degree of competence. Each stage is derived from and builds on the accomplishments of the previous stage in a continuous, orderly process. The course of intellectual development is both maturational and invariant and is divided into the following stages (ages are approximate):

Sensorimotor (birth to 2 years)—The sensorimotor stage of intellectual development consists of six substages (see Chapter 36 for more in-depth discussion) that are governed by sensations in which simple learning takes place. Children progress from reflex activity through simple repetitive behaviours to imitative behaviour. They develop a sense of cause and effect as they direct behaviour toward objects. Problem solving is primarily by trial and error. They display a high level of curiosity, experimentation, and enjoyment of novelty and begin to develop a sense of self as they are able to differentiate themselves from their environment. They become aware that objects have *permanence*—that an object exists even though it is no longer visible. Toward the end of the sensorimotor period, children begin to use language and representational thought.

Preoperational (2 to 7 years)—The predominant characteristic of the preoperational stage of intellectual development is **egocentrism**, which in this sense does not mean selfishness or self-centredness but the inability to put oneself in the place of another. Children interpret objects and events not in terms of general properties but in terms of their relationships or their use to them. They are unable to see things from any perspective other than their own; they cannot see another's point of view, nor can they see any reason to do so. Preoperational thinking is concrete and tangible. Children cannot reason beyond the observable, and they lack the ability to make deductions or generalizations. Thought is dominated by what they see, hear, or otherwise experience. However, they are increasingly able to use language and symbols to represent objects in their environment. Through imaginative play, questioning, and other interactions, they begin to elaborate concepts and to make simple associations between ideas. In the latter stage of this period, their reasoning is intuitive (e.g., the stars have to go to bed just as children do), and they are only beginning to deal with problems of weight, length, size, and time. Reasoning is also transductive—because two events occur together, they cause each other, or knowledge of one characteristic is transferred to another (e.g., all women with big bellies have babies).

Concrete operations (7 to 11 years)—At this age, thought becomes increasingly logical and coherent. Children are able to classify, sort, order, and otherwise organize facts about the world to use in problem solving. They develop a new concept of permanence—**conservation** (see Chapter 38, Cognitive Development [Piaget]); that is, they realize that physical factors such as volume, weight, and number remain the same even though outward appearances are changed. They are able to deal with a number of different aspects of a situation simultaneously. They do not have the capacity to deal in abstraction; they solve problems in a concrete, systematic fashion based on what they can perceive. Reasoning is inductive. Through progressive changes in thought processes and relationships with others, thought becomes less self-centred. They can consider points of view other than their own. Thinking has become socialized. For example, a child can classify objects according to several features, such as choose dolls with blond hair and blue eyes and put the dolls in order along a single dimension such as size.

Formal operations (11 to 15 years)—Formal operational thought is characterized by adaptability and flexibility. Adolescents can think in abstract terms, use abstract symbols, and draw logical conclusions from a set of observations. For example, they can solve the following question: If A is larger than B, and B is larger than C, which symbol is the largest? (The answer is A.) They can make hypotheses and test them; they can consider abstract, theoretical, and philosophical matters. Although they may confuse the ideal with the practical, most contradictions in the world can be dealt with and resolved.

Moral Development (Kohlberg). Children also acquire moral reasoning in a developmental sequence. Moral development, as described

by Kohlberg (1968), is based on cognitive developmental theory and consists of the following three major levels, each of which has two stages:

Preconventional level—The preconventional level of moral development parallels the preoperational level of cognitive development and intuitive thought. Culturally oriented to the labels of good/bad and right/wrong, children integrate these in terms of the physical or pleasurable consequences of their actions. At first, children determine the goodness or badness of an action in terms of its consequences. They avoid punishment and obey without question those who have the power to determine and enforce the rules and labels. They have no concept of the basic moral order that supports these consequences. Later, children determine that the right behaviour consists of that which satisfies their own needs (and sometimes the needs of others). Although elements of fairness, give and take, and equal sharing are evident, they are interpreted in a practical, concrete manner without loyalty, gratitude, or justice.

Conventional level—At the conventional stage, children are concerned with conformity and loyalty. They value the maintenance of family, group, or community expectations regardless of consequences. Behaviour that meets with approval and pleases or helps others is considered good. One earns approval by being "nice." Obeying the rules, doing one's duty, showing respect for authority, and maintaining the social order are the correct behaviours. This level is correlated with the stage of concrete operations in cognitive development.

Postconventional, autonomous, or principled level—At the postconventional level, the individual has reached the cognitive stage of formal operations. Correct behaviour tends to be defined in terms of general individual rights and standards that have been examined and agreed on by the entire society. Although procedural rules for reaching consensus become important, with emphasis on the legal point of view, there is also emphasis on the possibility for changing law in terms of societal needs and rational considerations.

The most advanced level of moral development is one in which self-chosen ethical principles guide decisions of conscience. These are abstract and ethical but universal principles of justice and human rights with respect for the dignity of persons as individuals. Kohlberg believed that few persons reach this stage of moral reasoning.

Spiritual Development (Fowler). Spiritual beliefs are closely related to the moral and ethical portion of the child's self-concept and, as such, must be considered as part of the child's basic needs assessment. Children need to have meaning, purpose, and hope in their lives. Also, the need for confession and forgiveness is present, even in very young children. Extending beyond religion (an organized set of beliefs and practices), spirituality affects the whole person: mind, body, and spirit. Fowler (1981) identified six stages in the development of faith, four of which are closely associated with and parallel cognitive and psychosocial development in childhood:

Stage 0: Undifferentiated—This stage of development encompasses the period of infancy, during which children have no concept of right or wrong, no beliefs, and no convictions to guide their behaviour. However, the beginnings of a faith are established with the development of basic trust through their relationships with the primary caregiver.

Stage 1: Intuitive-projective—Toddlerhood is primarily a time of imitating the behaviour of others. Children imitate the religious gestures and behaviours of others without comprehending any meaning of or significance to the activities. During the preschool years, children assimilate some of their parents' values and beliefs. Parental attitudes toward moral codes and religious beliefs convey to children what they consider to be good and bad. Children still imitate behaviour at this age and follow parental beliefs as part of their daily lives rather than through an understanding of their basic concepts.

Stage 2: Mythic-literal—Through the school-age years, spiritual development parallels cognitive development and is closely related to children's experiences and social interaction. Many have a strong interest in religion during the school-age years. They accept the existence of a deity, and petitions to an omnipotent being are important and expected to be answered; good behaviour is rewarded, and bad behaviour is punished. Their developing conscience bothers them when they disobey. They have a reverence for thoughts about spiritual matters and are able to articulate their faith. They may even question its validity.

Stage 3: Synthetic-conventional—As children approach adolescence, however, they become increasingly aware of spiritual disappointments. They recognize that prayers are not always answered (at least on their own terms), and they may begin to abandon or modify some religious practices. They begin to reason, to question some of the established parental religious standards, and to drop or modify some religious practices.

Stage 4: Individuative-reflective—Adolescents become more skeptical and begin to compare their parents' religious standards with those of others. They attempt to determine which to adopt and incorporate into their own set of values. They also begin to compare religious standards with a scientific viewpoint. It is a time of searching rather than reaching conclusions. Adolescents are uncertain about many religious ideas but will not achieve profound insights until late adolescence or early adulthood.

Language Development. Children are born with the mechanism and capacity to develop speech and language skills. However, they do not speak spontaneously. The environment must provide a means for them to acquire these skills. Speech requires intact physiological structure and function (including respiratory, auditory, and cerebral) plus intelligence, a need to communicate, and stimulation.

The rate of speech development varies from child to child and is directly related to neurological competence and cognitive development. Gesture precedes speech, and in this way a small child communicates satisfactorily. As speech develops, gesture recedes but never disappears entirely. Research suggests that infants can learn sign language before vocal language and that it may enhance the development of vocal language. Therapists frequently teach alternative-communication systems, such as picture exchanges or manual signs, to individuals with developmental disabilities who present with expressive language deficits. The picture exchange proved to be an alternative technique to help these children enhance their learning (Barlow et al., 2013). At all stages of language development, children's comprehension vocabulary (what they understand) is greater than their expressed vocabulary (what they can say), and this development reflects a continuing process of modification that involves both the acquisition of new words and the expansion and refinement of word meanings previously learned. By the time they begin to walk, children are able to attach a name to objects and persons.

The first parts of speech used are nouns, sometimes verbs (e.g., "go"), and combination words (such as "bye-bye"). Responses are usually structurally incomplete during the toddler period, although the meaning is clear. Next they begin to use adjectives and adverbs to qualify nouns, followed by adverbs to qualify nouns and verbs. Later, pronouns and gender words are added (such as "he" and "she"). By the

time children enter school, they are able to use simple, structurally complete sentences that average five to seven words.

Development of Self-Concept

Self-concept is how an individual describes themselves. The term *self-concept* includes all the beliefs and convictions that constitute an individual's self-knowledge and that influence relationships with others. It develops gradually as a result of unique experiences within the self, with significant others, and with the realities of the world. However, an individual's self-concept may or may not reflect reality.

In infancy the self-concept is primarily an awareness of one's independent existence learned in part as a result of social contacts and experiences with others. The process becomes more active during toddlerhood as children explore the limits of their capacities and the nature of their impact on others. School-age children are more aware of differences among people, are more sensitive to social pressures, and become more preoccupied with issues of self-criticism and self-evaluation. During early adolescence, children focus more on physical and emotional changes taking place and on peer acceptance. Self-concept is crystallized during later adolescence as young people organize their self-concept around a set of values, goals, and competencies acquired throughout childhood.

Body Image. A vital component of self-concept, *body image* refers to the subjective concepts and attitudes that individuals have toward their own bodies. It consists of the physiological (the perception of one's physical characteristics), psychological (values and attitudes toward the body, abilities, and ideals), and social nature of one's image of self (the self in relation to others). All three components interrelate with one another. Body image is a complex phenomenon that evolves and changes during the process of growth and development. Any actual or perceived deviation from the "norm" (no matter how this is interpreted) is cause for concern and is influenced by the attitudes and behaviour of those around them.

The significant others in children's lives exert the most important and meaningful impact on children's body image. Labels that are attached to them (such as "skinny," "pretty," or "fat") or body parts (such as "ugly mole," "bug eyes," or "yucky skin") are incorporated into the body image. Because they lack the understanding of deviations from the physical standard or norm, children notice prominent differences in others and unwittingly make rude or cruel remarks about such minor deviations as large or widely spaced front teeth, large or small eyes, moles, or extreme variations in height.

Infants receive input about their bodies through self-exploration and sensory stimulation from others. As they begin to manipulate their environment, they become aware of their bodies as separate from others. Toddlers learn to identify the various body parts and are able to use symbols to represent objects. Preschoolers become aware of the wholeness of their bodies and discover the genitalia. Exploration of the genitalia and the discovery of differences between the sexes become important. At this age, children have only a vague concept of internal organs and function.

School-age children begin to learn about internal body structure and function and become aware of differences in body size and configuration. They are highly influenced by the cultural norms of society and current fads. Children whose bodies deviate from the norm are often criticized or ridiculed. Adolescence is the age when children become most concerned about the physical self. The unfamiliar body changes, and the new physical self must be integrated into the self-concept. Adolescents face conflicts over what they see and what they visualize as the ideal body structure. Body image formation during adolescence is a crucial element in the shaping of identity, the psychosocial crisis of adolescence.

Self-Esteem. Self-esteem is the value that an individual places on themselves and refers to an overall evaluation of oneself. *Self-esteem* is described as the affective component of the self, whereas *self-concept* is the cognitive component; however, the two terms are almost indistinguishable and are often used interchangeably.

The term *self-esteem* refers to a personal, subjective judgement of one's worthiness derived from and influenced by the social groups in the immediate environment and individuals' perceptions of how they are valued by others. Self-esteem changes with development. Highly egocentric toddlers are unaware of any difference between competence and social approval. By contrast, preschool and early school-age children are increasingly aware of the discrepancy between their competencies and the abilities of more advanced children. Being accepted by adults and peers outside the family group becomes more important to them. Positive feedback enhances their self-esteem; they are vulnerable to feelings of worthlessness and are anxious about failure.

As children's competencies increase and they develop meaningful relationships, their self-esteem rises. Their self-esteem is again at risk during early adolescence when they are defining an identity and sense of self in the context of their peer group. Unless children are continually made to feel incompetent and of little worth, a decrease in self-esteem during vulnerable times is only temporary. Children assess the following aspects of themselves in forming an overall evaluation of their self-esteem:

Competence—How adequate are my cognitive, physical, and social skills?

Sense of control—How well can I complete tasks needed to produce desired actions? Are my successes or failures due to someone or something specific or are they due to luck?

Moral worth—How well do my actions and behaviours meet moral standards that have been set?

Worthiness of love and acceptance—How worthy am I of love and acceptance from parents, other significant adults, siblings, and peers?

Factors that influence the formation of a child's self-esteem include (1) the child's temperament and personality, (2) abilities and opportunities available to accomplish age-appropriate developmental tasks, (3) how significant others interact with the child, and (4) social roles assumed and the expectations surrounding these roles.

ROLE OF PLAY IN DEVELOPMENT

Through the universal medium of play, children learn what no one can teach them. They learn about their world and how to deal with this environment of objects, time, space, structure, and people. They learn about themselves operating within that environment—what they can do, how to relate to things and situations, and how to adapt themselves to the demands that society makes on them. Play is the work of the child. In play, children continually practise the complicated, stressful processes of living, communicating, and achieving satisfactory relationships with other people.

From a developmental point of view, patterns of children's play can be categorized according to content and social character. In both there is an additive effect; each pattern builds on past accomplishments, and some element of each is maintained throughout life. At each stage in development, the new predominates.

Content of Play

The content of play involves primarily the physical aspects of play, although social relationships cannot be ignored. Play follows the simple to the complex:

Social-affective play—Play begins with social-affective play, in which infants take pleasure in relationships with people. As adults talk to, touch, and nuzzle an infant and in various ways elicit a response from an infant, the infant soon learns to provoke parental emotions and responses with such behaviours as smiling, cooing, or initiating games and activities. The type and intensity of the adult behaviour with children vary among cultures.

Sense-pleasure play—Sense-pleasure play is a nonsocial stimulating experience that originates from without. Objects in the environment—light and colour, tastes and odours, textures and consistencies—attract children's attention, stimulate their senses, and give them pleasure. Pleasurable experiences are derived from handling raw materials (water, sand, food), from body motion (swinging, bouncing, rocking) and from other uses of senses and abilities (smelling, humming) (Figure 32.5).

Skill play—After infants have developed the ability to grasp and manipulate, they persistently demonstrate and exercise their newly acquired abilities through skill play, repeating an action over and over (Figure 32.6). The element of sense-pleasure play is often evident in practising a new ability, but frequently the determination to conquer the elusive skill produces pain and frustration (e.g., putting blocks into a box and taking them out).

Unoccupied behaviour—In unoccupied behaviour, children are not playful but focusing their attention momentarily on anything that strikes their interest. Children daydream, fiddle with clothes or other objects, or walk aimlessly. This role differs from that of onlookers, who actively observe the activity of others.

Dramatic, or pretend, play—One of the vital elements in children's process of identification is dramatic play, also known as **symbolic** or **pretend** play. It begins in late infancy (11 to 13 months) and is the predominant form of play in the preschool child. After children begin to invest situations and people with meanings and to attribute affective significance to the world, they can pretend and fantasize almost anything. By acting out events of daily life, children learn and practise the roles and identities modelled by the members of their family and society. Children's toys, replicas of the tools and pastimes of society, provide a medium for learning about adult roles and activities that may be puzzling and frustrating to them. Interacting with the world is one way children get to know it. The simple, imitative, dramatic play of the toddler, such as using the telephone or computer, driving a car, or rocking a doll, evolves into more complex, sustained dramas of the preschooler, which extend beyond common domestic matters to the wider aspects of the world and the society, such as playing police officer, storekeeper, teacher, or nurse. Older children work out elaborate themes, act out stories, and compose plays.

Fig. 32.5 Children derive pleasure from handling raw materials. (Paints in this picture are nontoxic.)

Fig. 32.6 After infants develop new skills to grasp and manipulate, they begin to conquer new abilities, such as getting on a play motorcycle.

Games—Children in all cultures engage in games alone and with others. Solitary activity involving games begins as very small children participate in repetitive activities and progress to more complicated games that challenge their independent skills, such as puzzles, solitaire, and computer or video games. Very young children participate in simple, imitative games, such as pat-a-cake and peek-a-boo. Preschool children learn and enjoy formal games, beginning with ritualistic, self-sustaining games, such as ring-around-a-rosy and London Bridge. With the exception of some simple board games, preschool children do not engage in competitive games. Preschoolers hate to lose and will try to cheat, want to change rules, or demand exceptions and opportunities to change their moves. School-age children and adolescents tend to enjoy competitive games, including computer or smartphone video games, cards, chess, and physically active games such as baseball.

Social Character of Play

The play interactions of infancy are between the child and an adult. Children continue to enjoy the company of adults but are increasingly able to play alone. As children grow, interaction with age-mates increases in importance and becomes an essential part of the socialization process. Through interaction, highly egocentric infants, unable to tolerate delay or interference, ultimately acquire concern for others and the ability to delay gratification or even to reject gratification at the expense of another. A pair of toddlers will engage in considerable combat because their personal needs cannot tolerate delay or compromise. By the time they reach age 5 or 6 years, children are able to arrive at a compromise or make use of arbitration, usually after they have attempted but failed to gain their own way. Through continued interaction with peers and the growth of conceptual abilities and social skills,

children are able to increase participation with others in the following types of play:

Onlooker play—During onlooker play, children watch what other children are doing but make no attempt to enter into the play activity. There is an active interest in observing the interaction of others but no movement toward participating. Watching an older sibling bounce a ball is a common example of the onlooker role.

Solitary play—During solitary play, children play alone with toys different from those used by other children in the same area. They enjoy the presence of other children but make no effort to get close to or speak to them. Their interest is centred on their own activity, which they pursue with no reference to the activities of the others.

Parallel play—During parallel activities, children play independently but among other children. They play with toys similar to those that the children around them are using but as each child sees fit, neither influencing nor being influenced by the other children (Figure 32.7). There is no group association. Parallel play is the characteristic of toddlers, but it may occur at other ages. Individuals who are involved in a creative craft with each person separately working on an individual project are engaged in parallel play.

Associative play—In associative play, children play together and are engaged in a similar or even identical activity, but there is no organization, division of labour, leadership assignment, or mutual group goal. Children borrow and lend play materials, follow each other with wagons and tricycles, and sometimes attempt to control who may or may not play in the group. Each child acts according to their own wishes; there is no group goal (Figure 32.8). For example, two children play with dolls, borrowing articles of clothing from each other and engaging in similar conversation, but neither directs the other's actions or establishes rules regarding the limits of the play session. There is a great deal of behavioural contagion: when one child initiates an activity, often, the entire group follows the example.

Cooperative play—Cooperative play is organized, and children play in a group with other children (Figure 32.9). They discuss and plan activities for the purposes of accomplishing an end—to make something, to attain a competitive goal, to dramatize situations of adult or group life, or to play formal games. The group is loosely formed, but there is a marked sense of belonging or not belonging. The goal and its attainment require organization of activities, division of labour, and role playing. The leader–follower relationship is definitely established, and the activity is controlled by one or two members who assign roles and direct the activity of the others. The activity is organized to allow one child to supplement another's function to complete the goal.

Functions of Play

Sensorimotor Development. Sensorimotor activity is a major component of play at all ages and is the predominant form of play in infancy. Active play is essential for muscle development and serves a useful purpose as a release for surplus energy. Through sensorimotor play, children explore the nature of the physical world. Infants gain impressions of themselves and their world through tactile, auditory, visual, and kinesthetic stimulation. Toddlers and preschoolers revel in body movement and exploration of objects in space. With increasing maturity, sensorimotor play becomes more differentiated and involved. Whereas very young children run for the sheer joy of body movement, older children incorporate or modify the motions into increasingly complex and coordinated activities, such as racing, playing games, skateboarding, and bicycle riding.

Intellectual Development. Through activities involving exploration and manipulation of objects, children learn colours, shapes, sizes, textures, and the significance of objects. They learn the significance of numbers and how to use them; they learn to associate words with objects; and they develop an understanding of abstract concepts and spatial relationships, such as *up*, *down*, *under*, and *over*. Activities such as puzzles and games help them develop problem-solving skills. Books,

stories, films, and collections expand knowledge and provide enjoyment as well. Play provides a means to practise and expand language skills. Through play, children continually rehearse past experiences to assimilate them into new perceptions and relationships. Play helps children comprehend the world in which they live and distinguish between fantasy and reality.

Socialization. From very early infancy children show interest and pleasure in the company of others. Their initial social contact is with the mothering person, but through play with other children they learn to establish social relationships and solve the problems associated with these relationships. They learn to give and take, which is more readily learned from critical peers than from more tolerant adults. They learn the sex role that society expects them to fulfill and approved patterns of behaviour and deportment. Closely associated with socialization is development of moral values and ethics. Children learn right from wrong, the standards of the society, and to assume responsibility for their actions.

Creativity. In no other situation is there more opportunity to be creative than in play. Children can experiment and try out their creative ideas in play through every medium at their disposal, including raw materials, fantasy, and exploration. Creativity is stifled by pressure toward conformity; therefore, striving for peer approval may inhibit creative endeavours in the school-age or adolescent child. Creativity is primarily a product of solitary activity, yet creative thinking is often enhanced in group settings where listening to others' ideas stimulates further exploration of one's own ideas. After children feel the satisfaction of creating something new and different, they transfer this creative interest to situations outside the world of play.

Self-Awareness. Beginning with active explorations of their bodies and awareness of themselves as separate from the mother, the process of developing a self-identity is facilitated through play activities. Children learn who they are and their place in the world. They become increasingly able to regulate their own behaviour, to learn what their abilities are, and to compare their abilities with those of others. Through play, children are able to test their abilities, to assume and try out various roles, and to learn the effect their behaviour has on others. They learn the gender role that society expects them to fulfill, as well as approved patterns of behaviour and deportment.

Therapeutic Value. Play is therapeutic at any age (Figure 32.10). In play, children can express emotions and release unacceptable impulses in a socially acceptable fashion. Children are able to experiment and test fearful situations and can assume and vicariously master the roles and positions that they are unable to perform in the world of reality. Children reveal much about themselves in play. Through play, children are able to communicate to the alert observer the needs, fears, and desires that they are unable to express with their limited language skills. Throughout their play, children need the acceptance of adults and their presence to help them control aggression and channel their destructive tendencies.

Moral Value. Although children learn at home and at school those behaviours considered right and wrong in the culture, the interaction with peers during play contributes significantly to their moral training. Nowhere is the enforcement of moral standards as rigid as in the play situation. If they are to be members of the group, children must adhere to the accepted codes of behaviour of the culture (e.g., fairness, honesty, self-control, consideration for others). Children soon learn that their peers are less tolerant of violations than are adults and that to maintain a place in the play group, they must conform to the group's standards.

Fig. 32.10 Play is therapeutic at any age and provides a means for release of tension and stress.

Toys

The type of toys chosen by or provided for children can support and enhance the child's development in the areas just described. Although no scientific evidence shows that any toy is necessary for optimal learning, toys offer an opportunity to bring the child and parent together. Toys that are small replicas of the culture and its tools help children assimilate into their culture. Toys that require pushing, pulling, rolling, and manipulating teach them about physical properties of the items and help develop muscles and coordination. Rules and the basic elements of cooperation and organization are learned through board and some video games.

Because they can be used in a variety of ways, raw materials allow children to exercise their own creativity and imagination and are sometimes superior to ready-made items. For example, building blocks can be used to construct a variety of structures, to count, and to learn shapes and sizes.

SELECTED FACTORS THAT INFLUENCE DEVELOPMENT

Heredity

Inherited characteristics have a profound influence on development. The child's sex, determined by random selection at the time of conception, directs both the pattern of growth and the behaviour of others toward the child. In all cultures, attitudes and expectations are shaped by the child's sex. Sex and other hereditary determinants strongly affect

the progress and end result of growth. There is a high correlation between parent and child with regard to traits such as height, weight, and rate of growth. Most physical characteristics, including shape and form of features, body build, and physical peculiarities, are inherited and can influence the way in which children grow and interact with their environment. Many dimensions of personality, such as temperament, activity level, responsiveness, and a tendency toward shyness, are believed to be inherited.

Differences in children's health and vigour may be attributed to hereditary traits. An inherited physical or emotional disorder will alter or modify a child's physical or emotional growth and interactions.

Altered growth and development are one of the clinical manifestations in a number of hereditary disorders. Growth impairment is particularly marked in skeletal disorders, such as the various forms of dwarfism and at least one of the chromosomal anomalies (Turner syndrome). Many of the disorders of metabolism, such as vitamin D–resistant rickets, the mucopolysaccharidoses, and the numerous endocrine disorders, interfere with the normal growth pattern. In other disorders (e.g., Klinefelter and Marfan syndromes) the tendency is toward the upper percentile of height.

Many chronic illnesses associated with varying degrees of growth failure are congenital cardiac anomalies, chronic renal disease, and respiratory disorders, such as cystic fibrosis. Any disorder characterized by the inability to digest and absorb body nutrients will have an adverse effect on growth and development.

Genes, Genetics, and Genomics. All nurses need to be prepared to use genetic and genomic information and technology when providing care. Often the nurse is the first one to recognize the need for genetic evaluation by identifying an inherited disorder in a family history or noting physical, cognitive, or behavioural abnormalities when performing a nursing assessment. Evidence is also growing that genes play an important role in human susceptibility and resistance to infection, even in cases with a clear environmental cause of the infectious disease. Evidence for this genetic element in resistance gained heightened recognition during the first decade of the acquired immunodeficiency syndrome (AIDS) epidemic. Researchers discovered that adults with a specific deletion in both copies of the *CCR5* genes did not become infected with human immunodeficiency virus (HIV) despite repeated exposures. Later it was discovered that children exposed in utero to HIV typically had a significantly delayed onset of disease if at least one of their *CCR5* genes had the specific mutation (McLaren & Carrington, 2015).

Neuroendocrine Factors

The hypothalamic–pituitary axis produces a number of releasing and inhibitory hormones that influence growth. Probably all hormones affect growth in some fashion. Three hormones—growth hormone, thyroid hormone, and androgens—when given to persons deficient in these hormones, stimulate protein anabolism and thereby produce retention of elements essential for building protoplasm and bony tissue. It appears that each of the hormones that has a significant influence on growth manifests its major effect at a different period of growth (see Chapter 51).

Interpersonal Relationships

Relationships with significant others play a critical role in development, particularly in emotional, intellectual, and personality development. Not only do the quality and quantity of contacts with other persons exert an influence on the growing child, but the widening range of contacts is essential to learning and developing a healthy personality.

The mothering person is unquestionably the single most influential person during early infancy who meets the infant's basic needs of food, warmth, comfort, and love. They stimulate the child's senses and facilitate the child's expanding capacities. Through this person the child learns to trust the world and feel secure to venture in increasingly wider relationships.

Generally, the parents or caregivers are most influential in helping the child to assume sex-role identification. Parents define and reinforce sex-role behaviour and provide sex-appropriate role models for the child. In the absence of a same-sex role model in the family setting, the child may adopt some characteristics of the opposite-sex parent or sibling. Frequently, the child identifies with a teacher or other significant person of the same sex.

Siblings are children's first peers, and the way in which they learn to relate to each other affects later interactions with peers outside the family group. The sphere of persons from whom children seek approval widens to include other members of their family, their peers, and, to a lesser extent, other authority figures (e.g., teachers) (Figure 32.11). The increasing importance of the peer group in determining the behaviour of school-age children and adolescents is well documented.

When children fail to have high-quality interpersonal relationships with mothering persons they experience *emotional deprivation*. The most prominent feature of emotional deprivation, particularly during the first year, is developmental delays. The term *masked deprivation* has been used to describe children reared in homes in which there is a distorted parent–child relationship or otherwise disordered home environment. Infants do not thrive if the caregiving person is hostile, fearful of handling them, or indifferent to them and their needs. Such children exhibit poor growth even though they are apparently free of physical disease. Growth delays in these children are believed to be caused by a psychologically induced endocrine imbalance that interferes with growth. These same infants and children display "catch-up" growth in a changed environment, however (see Chapter 36, Failure to Thrive [Growth Failure]). Children who have been adopted from orphanages in foreign countries where they may have received minimal

Fig. 32.11 Peers become increasingly important as children develop friendships outside the family group.

mothering often have growth delays when they are adopted but they usually thrive and achieve normal growth. Although catch-up growth is viewed as a positive improvement among post-institutionalized children, rapid or continuous increases in body size can pose a health concern. It is important to pay attention to monitoring weight gain, diet, and physical activity (Tang et al., 2018).

Socioeconomic Level

The family's socioeconomic level can have a significant impact on children's growth and development as significant determinants of health. At all ages, children from upper- and middle-class families are taller than comparative children of families in lower socioeconomic strata. The cause of these differences is less definite, although the poorer health and nutrition of children in lower socioeconomic levels are probably significant factors. Families from lower socioeconomic groups may lack the knowledge or resources needed to provide the safe, stimulating, and enriched environment that fosters optimum development for children (see Chapter 30, Social Determinants of Health).

Environmental Hazards

Hazards in the environment, another determinant of health, are a source of concern to health care providers and others interested in health and safety. Physical injuries are the most prevalent consequences of environmental dangers.

Children are at a high risk for harm resulting from the chemical residues present in the environment. The hazards of these chemical residues relate to their potential carcinogenicity, enzymatic effects, and accumulation. The harmful agents most often associated with health risks are chemicals and radiation, including sun exposure. Water, air, and food contamination from a variety of sources are well documented. Significant means of exposure are substances such as asbestos and lead in the immediate environment; secretion of chemicals in breast milk (especially prescribed medications and nicotine); and contamination within well-insulated homes (especially from disinfectants or burning of substances that produce toxic fumes). Passive inhalation of tobacco or cannabis through smoking or vaping is a hazard at all stages of development (see Chapter 45). The harmful effects of large doses of radiation are unquestioned, although the effects of low-dose or short-term radiation are debatable, as are the dosage levels that are considered safe or harmful.

Stress and Coping

Coping refers to a special class of individual reactions to stressors—specifically, a reaction to a stressor that resolves, reduces, or replaces the affective state classified as stressful. *Coping strategies* are the specific ways in which children cope with stressors, as distinguished from *coping styles*, which are relatively unchanging personality characteristics or outcomes of coping. As children age, they tend toward a more internal locus of control and use more vigilant modes of coping. Children, like adults, respond to everyday stress by trying to change the circumstances or trying to adjust to circumstances the way they are. Any strategy that provides relaxation is effective in reducing stress, and most children have their own natural methods of dealing with stress, such as withdrawing, engaging in physical activity, reading, listening to music, working on a project, or taking a nap. Some turn to parents to solve their problems, or they may develop socially unacceptable strategies, such as cheating, stealing, or lying.

Children can be taught stress-reduction techniques to use in coping. First, they must be helped to recognize signs of tension in themselves. Then they can be taught any of a variety of appropriate strategies—special exercises, relaxation and breathing, mental imagery, and numerous other simple activities. Also, parents and other caregivers can anticipate possible stress-provoking events and prepare children for coping by role playing a scenario or "talking it through" so that they can learn how to solve problems. When children can view any new situation as a problem to be solved and an opportunity to learn, they are not vulnerable to the control of others. It provides them with a sense of mastery over their own lives and reinforces the fact that they have within themselves the ability and information to handle whatever comes their way. Problem-solving skill gives them the confidence to know where and how to seek help when they need it.

When a succession of stressors produces an excessive stress load (toxic stress), children may experience a serious change in health or behaviour. Parents and other caregivers can try to recognize signs of stress to help children deal with stressors before they become overwhelming (see Chapter 30, Toxic Stress for further discussion).

Mass Media

The media can have an enormous influence on the developing child. There is no doubt that the media provide children with a means of extending their knowledge about the world in which they live and have helped narrow the differences between classes. However, there is growing concern about the enormous influence that the media can have on the developing child because of the large number of hours that children spend watching media, such as movies, video games, and television shows. The portable technology of hand-held electronic devices has given children even more access to the multitude sources of media. For instance, the images of risky behaviour presented in the media may establish or reinforce teenagers' perceptions of their social environment. Children may identify closely with and be influenced by people or characters portrayed in reading materials, movies, video games, and television programs and commercials.

Most researchers have concluded that protracted electronic device viewing can have detrimental effects on children. For example, in one study, technology use was implicated as contributing to irregular sleep schedules in children; evidence indicated a substantial association between longer electronic screen viewing and shorter sleep duration among very young children (under 2 years of age) (Chen et al., 2019). Use of any electronic device at bedtime was associated with significantly increased use of multiple forms of technology at bedtime and use in the middle of the night, both of which reduced sleep quantity and quality. A significant association was also found between bedtime technology use and elevated body mass index (Fuller et al., 2017). Recognizing the negative effects of electronic device use, the CPS (2017) recommends that children under age 2 not participate in screen-based activities and that children ages 2 to 5 years old limit routine or regular screen time to less than 1 hour per day and that older children watch no more than 1 to 2 hours of high-quality television a day.

For all children, house rules that specify the type and amount of television can help children understand limits, and recorded selections of appropriate programs can be substituted for less desirable offerings. Parents need to carefully monitor cable and other pay-television programming. Lockboxes, V-chips, and blocking devices are available for cable receivers to prevent children from viewing uncensored programs when unsupervised.

Like movies, some television programs and commercials contain many implicit and explicit messages that promote consumerism, alcohol consumption, smoking, violence, and promiscuous or unsafe sexual activity. There is evidence, although limited, documenting a relationship between viewing these activities on television and the actual use of alcohol or tobacco, exposure to violence, and aggressive behaviour (Mitrofan et al., 2014). Children are vulnerable to advertising, which can encourage unhealthy habits, such as asking parents for sugary, low-fibre cereals.

Parents can help children evaluate violence on television by pointing out the subtleties that children miss, such as the aggressor's motives

and intentions and the unpleasant consequences that the perpetrators suffer as a result of their aggressive acts. Often the consequence is separated from the act by a commercial, thus children cannot make the correlation. Parents need to point out that conflicts can be resolved without resorting to violent behaviour. They can also stress the program's purpose—primarily entertainment—and explain why they like or dislike something on television (e.g., "This show is trying to tell you that crime does not pay and that if people do wrong, they will go to jail"). Explanations and discussions can take place between shows (with the volume turned down), and young children can learn from both older children and adults. These discussions can be effective when begun early and carried out consistently.

Television is the medium by which most children learn of a natural disaster or act of terrorism. Research on the effects of these terrorist attacks suggests that post-traumatic stress reactions increase with greater exposure to media coverage. Reading about the event rather than watching it on television may produce less traumatic associations of the experience (Hamblen & Dart Center for Journalism and Trauma, 2016). In addition, parents should limit the exposure to media coverage of traumatic events, talk to their child about the event, and maintain daily routines as much as possible.

Digital media has been shown, however, to also have a positive influence on children's abilities to deal with a variety of social issues, such as divorce, the arrival of a new baby, discrimination, honesty, and helpfulness. Children who view educational programming for an extended period tend to become more affectionate, considerate, cooperative, and helpful toward their playmates. Preschoolers who watched digital programming found that educational viewing can increase their knowledge, positively affect their attitudes toward racial difference, and increase their imaginative behaviour (CPS, 2017).

In short, parents need to supervise the amount and type of media programs their children watch and to teach their children how to watch media (Family-Centred Care box: Media Viewing). As the CPS (2017) recommends, parental role modelling may have a more positive influence on the child's behaviour than media programming. Parents watching media with their child can help the child understand the difference between their own life and habits and those of persons represented on television.

FAMILY-CENTRED CARE

Media Viewing

Provide a positive role model by developing media substitutes such as reading, athletics, physical conditioning, and hobbies.

Together with your child, construct a time chart of activities (homework, media viewing, scheduled and other outside activities, playing with a friend).

Require that the child choose doing something from this list before watching media.

For children over 5 years of age, limit the child's viewing to 2 hours or less per day.

Rule out media viewing at specific times (e.g., mealtimes, before breakfast, or on school nights).

Discuss the purpose of a program and of commercial content with the child:

- Distinguish between the real and the unreal.
- Correlate consequences with actions.
- Point out subtle messages.
- Explore alternatives to aggressive conflict resolution.

Remove televisions and hand-held electronic devices from children's bedrooms.

Limit use of media viewing as a distraction to potentially stressful times (e.g., keeping the children occupied while the parent gets organized after a difficult day).

Nurses and parents can be powerful forces in influencing the media. They can watch closely for an increase in violence and other undesirable programming and express their concerns to sponsors and television stations if they believe it is not appropriate. Good programming can be both educational and entertaining.

Internet. The use of computers and personal tablets in both the classroom and home has affected childhood learning and development. Many schools offer computer programs and use digital devices that enable children of all ages to research a range of topics and broaden their world view. These technologies can be used for interactive learning, and their use can improve hand–eye coordination. Parents have a wide variety of computer software to choose from for their children's learning and gaming.

The Internet and email have made correspondence and information available to children from around the world in seconds. Social networking sites (e.g., Twitter, Facebook, Tumblr, Instagram, Kik Messenger, Snapchat, Tik-Tok) provide opportunities for children and adolescents to express themselves through blogs, music, pictures, and videos, and the overwhelming majority of adolescents use these sites responsibly (Holloway et al., 2014; Steeves et al., 2020).

Although computer and digital technology has enhanced many forms of learning and recreation, there are potential dangers to children. The negative aspects of television and video games also apply to the Internet. It is important for parents to be aware of the websites that their children access, as they are vulnerable to exposure to pornographic sites. Children can also be lured into interactions with pedophiles. Locks that block certain websites should be considered. Children can also spend too much time sitting in front of a computer screen. With excessive use of digital devices such as smartphones they can also develop repetitive-use injuries. Another potential serious risk is the rise of bullying, including cyberbullying. Cyberbullying involves the use of social media and other Internet sites to bully children, which can have a powerful impact on vulnerable children. Victims of bullying often report a negative effect on their body image and experience worry, sadness, anxiety, depression, and nightmares. Their response can also include self-harm behaviours such as cutting, suicidal ideation, and violence (see Chapters 39, 40, and 55).

Nurses should encourage parents to be knowledgeable of their children's Internet activities and to provide appropriate learning activities unique to computers and digital devices. One helpful strategy is to locate the computer in a public area of the home, such as the kitchen or family room, to enable parents to easily monitor its use. Nurses can engage parents in conversations about the negative and positive consequences of watching too much television and of their child viewing shows that are inappropriate for their age. In hospitals, many bedsides have a television or computer and video games with Wi-Fi available for children to use. Nurses can help to set limits on viewing and encourage other activities for these children. See Additional Resources for Canada's Centre for Digital and Media Literacy, which helps children and parents navigate the Web with safety tips.

KEY POINTS

- Growth describes a change in quantity and occurs when cells divide and synthesize new proteins.
- Maturation, a qualitative change, describes the aging process or an increase in competence and adaptability.
- Differentiation refers to biological processes by which early cells and structures are modified and altered to achieve specific and characteristic physical and chemical properties.

- Development involves change from a lower to a more advanced stage of complexity.
- The five major developmental periods are prenatal, infancy, early childhood, middle childhood, and later childhood (pubescence and adolescence).
- Growth and development proceed in predictable patterns of direction, sequence, and pace.
- The directional trends in growth and development are cephalocaudal, proximodistal, and mass to specific.
- Physical development includes increase in height and weight and changes in body proportion, dentition, and some body tissues.
- The three broad classifications of child temperament are the easy child, the difficult child, and the slow-to-warm-up child.
- The developmental theories most widely used in explaining child growth and development are Freud's psychosexual stages, Erikson's stages of psychosocial development, Piaget's stages of cognitive development, Kohlberg's stages of moral development, and Fowler's stages of spiritual development.
- To develop a positive self-concept, children need recognition for their achievements and the approval of others.
- Through play, children learn about their world and how to relate to objects, people, and situations.
- Play provides a means of development in the areas of sensorimotor and intellectual progress, socialization, creativity, self-awareness, and moral behaviour; it serves as a means for the release of tension and expression of emotions.
- Growth and development are affected by a variety of conditions and circumstances, including heredity, physiological function, gender, disease, physical environment, nutrition, and interpersonal relationships.
- All nurses should be familiar with genetic or genomics information as it relates to their patient's care.
- Mass media can be influential in children's learning and behaviour.

Pediatric Health Assessment

Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. State the components of a complete health history.
2. List three areas that are evaluated as part of a nutritional assessment.
3. Identify developmental assessment tools that can be used to perform a developmental assessment.
4. Prepare a child for a physical examination on the basis of their developmental needs.
5. Perform a comprehensive physical examination in a sequence appropriate to the child's age.
6. Recognize expected findings for children at various ages.
7. Record the physical examination according to the head-to-toe format.

Pediatric health assessment is a critical skill that every nurse must perform in order to accurately assess the level of health of a child. Building a rapport and trust with the child and the family is key to gathering precise information that will allow the nurse to analyze the data (see Chapter 30 for communication techniques to develop trust). Health assessment of a child and family consists of many different components. To formulate the assessment the nurse collects information from many sources, including direct dialogue with the child and family, medical records, other practitioners, and other health-related sources.

HISTORY TAKING

Performing a Health History

The format used for history taking may be (1) *direct*, where the nurse asks for information via direct interview with the child, parent(s), or both, or (2) *indirect*, where the patient or authorized family member supplies the information by completing some type of questionnaire. The direct method is superior to the indirect approach or a combination of both. However, in view of time constraints of health assessments the direct approach is not always practical. If the direct approach cannot be used, the parents' written responses should be reviewed and the parents questioned regarding any unusual answers. The categories listed in Box 33.1 encompass children's current and past health status and information about their psychosocial environment.

Identifying Information

Much of the identifying information may already be available from other recorded sources. However, if the parent and child seem anxious, history taking provides an opportunity to ask about such information and to help them feel more comfortable.

One of the important elements of identifying information is the informant, the person(s) who furnish the information. The nurse should record (1) who the person is (child, parent, or other), (2) an impression of reliability and willingness to communicate, and (3) any special circumstances, such as the use of an interpreter or conflicting answers by more than one person.

Presenting Health Issue or Concern

The presenting health concern is the specific reason for the child's visit to the clinic, office, or hospital. It may be viewed as the theme, with the present illness providing the description of the health concern. The health issue is elicited by asking open-ended, neutral questions, such as "What seems to be the matter?" "How may I help you?" or "Why did you come here today?" Labelling-type questions, such as "How did you get sick?" and wording such as "What is the problem?" should be avoided; it is possible that the reason for the visit is not an illness or problem.

Occasionally, it is difficult to isolate one symptom or condition as the health issue because the parent may identify many. In this situation, the nurse should be as specific as possible when asking questions. For example, asking informants to state which one issue or symptom prompted them to seek help now may help them focus on the most immediate concern.

Present Illness. The history of the present illness is a narrative of the health issue from its earliest onset through its progression to the present. The term *illness* is used in its broadest sense to denote any concern

BOX 33.1 Outline of a Pediatric Health History

Identifying information
- Name
- Address
- Telephone and email address
- Birth date and place
- Gender
- Religion
- Date of interview
- Informant

Presenting health issue—To establish the major specific reason for the child's and parents' seeking professional health attention

History of present illness (PI)—To obtain all details related to the chief health concern

Past history (PH)—To elicit a profile of the child's previous illnesses, injuries, or operations
- Birth history (pregnancy, labour and birth, perinatal history)
- Previous illnesses, injuries, or operations
- Allergies
- Current medications
- Immunizations
- Growth and development
- Habits

Family medical history—To identify genetic traits or diseases that have familial tendencies and to assess exposure to a communicable disease in a family member and family habits that may affect the child's health, such as smoking and chemical use

Family history—To develop an understanding of the child as an individual and as a member of a family and a community
- Family composition
- Home and community environment
- Occupation and education of family members
- Cultural and religious traditions
- Family function and relationships

Review of systems (ROS)—To elicit information concerning any potential health issue
- General
- Integument
- Head
- Eyes
- Ears/nose/mouth/throat
- Neck
- Chest
- Respiratory
- Cardiovascular
- Gastrointestinal
- Genitourinary
- Gynecological
- Musculoskeletal
- Neurological
- Endocrine

Psychosocial history—To elicit information about the child's self-concept

Sexual history—To elicit information about the child's sexual concerns or activities and any pertinent data regarding adults' sexual activity that influences the child

Nutritional assessment—To elicit information on the adequacy of the child's nutritional intake and needs
- Dietary intake
- Clinical examination

of a physical, emotional, or psychosocial nature. It is actually a history of the health issue. The four major components are (1) the details of onset, (2) a complete interval history, (3) the present status, and (4) the reason for seeking help now. The focus of the present illness is on all factors relevant to the main issue, even if they have disappeared or changed during the onset, interval, and present.

Analyzing a symptom. Because pain is often the most characteristic symptom denoting the onset of a physical condition, it is used as an example for analysis of a symptom. Assessment includes type, location, severity, duration, and influencing factors (see Guidelines box: Analyzing the Symptom: Pain and also Chapter 34, Pain Assessment).

GUIDELINES

Analyzing the Symptom: Pain

Type
Be as specific as possible. With young children, asking the parents how they know the child is in pain may help describe its type, location, and severity. For example, a parent may state, "My child must have a severe earache because she pulls at her ears, rolls her head on the floor, and screams. Nothing seems to help." Help older children describe the "hurt" by asking them if it is sharp, throbbing, dull, or stabbing. Record whatever words they use in quotes.

Location
Be specific. "Stomach pains" is too general a description. Children can better localize the pain if they are asked to "point with one finger to where it hurts" or to "point to where Mommy or Daddy would put a Band-Aid." Determine if the pain radiates, by asking, "Does the pain stay there or move? Show me with your finger where the pain goes."

Severity
Severity is best determined by finding out how it affects the child's usual behaviour. Pain that prevents a child from playing, interacting with others, sleeping, and eating is most often severe. Assess pain intensity using a rating scale, such as a numeric or Wong-Baker FACES® Pain Rating Scale (see Table 34.2).

Duration
Include the duration, onset, and frequency of the pain. Describe this in terms of activity and behaviour, such as "pain reported to last all night, child refused to sleep and cried intermittently."

Influencing Factors
Include anything that causes a change in the type, location, severity, or duration of the pain: (1) precipitating events (those that cause or increase the pain), (2) relieving events (those that lessen the pain, such as medications), (3) temporal events (times when the pain is relieved or increased), (4) positional events (standing, sitting, lying down), and (5) associated events (meals, stress, coughing).

History

The history contains information relating to all previous aspects of the child's health status and concentrates on several areas that are ordinarily passed over in the history of an adult. Since a great deal of information is included in this section, a combination of open-ended and fact-finding questions should be used. For example, interviewing for each section can start with an open-ended statement, such as "Tell me about your child's birth," to provide the informants with the opportunity to relate what they think is most important. Fact-finding questions related to specific details can be asked whenever necessary to focus the interview on certain topics.

Birth History. The birth history includes all data concerning (1) the mother's health during pregnancy, (2) the labour and birth, and (3) the newborn's condition immediately after birth. Since prenatal influences have significant effects on a child's physical and emotional development, a thorough investigation of the birth history is essential. Because parents may question what relevance pregnancy and birth have on the child's present condition, particularly if the child is past infancy, the nurse needs to explain why such questions are included. An appropriate statement may be "I will be asking you some questions about your pregnancy and ____'s [refer to child by name] birth. Your answers will give me a more complete picture of your child's overall health."

Because emotional factors also affect the outcome of pregnancy and the subsequent parent–child relationship, it is important to investigate (1) concurrent crises during pregnancy and (2) presence of perinatal mood disorders (see Chapter 24). It is best to approach the topic of feelings about pregnancy and crisis through indirect questioning. Parents should be encouraged to disclose this information by asking open-ended questions such as "Tell me about your stresses or emotions during pregnancy and after the birth." Parents can choose to explore such statements with further explanations or, for the moment, may not be able to reveal related feelings. If the parents or parent remains silent, this topic can be revisited later in the interview.

Previous Illnesses, Injuries, and Operations. When inquiring about past illnesses, the nurse should begin with a general statement, such as "What other illnesses has your child had?" Since parents are most likely to recall serious health conditions, they should be asked specifically about colds; earaches; and childhood diseases such as measles, rubella (German measles), chicken pox, mumps, pertussis (whooping cough), diphtheria, tuberculosis, scarlet fever, strep throat, tonsillitis, or allergic manifestations.

In addition to illnesses, the nurse needs to ask about injuries that required medical intervention, operations, and any other reason for hospitalization, including the dates of each incident. It is important to focus on injuries such as accidental falls, poisoning, choking, or burns, since these may be potential areas for parental guidance.

Allergies. It is important to ask about commonly known allergic disorders, such as hay fever and asthma; unusual reactions to medications, food, or latex products; and reactions to other contact agents, such as poisonous plants, animals, household products, or fabrics. If asked appropriate questions, most people can give reliable information about medication reactions (see Guidelines box: Taking an Allergy History).

GUIDELINES

Taking an Allergy History

- Has your child ever taken any medications or tablets that have disagreed with them or caused an allergic response? If yes, can you remember the name(s) of these medications?
- Can you describe the reaction?
- Was the medication taken by mouth (as a tablet or syrup), or was it an injection?
- How soon after starting the medication did the reaction happen?
- How long ago did this happen?
- Did anyone tell you it was an allergic reaction, or did you decide for yourself?
- Has your child ever taken this medication, or a similar one, again? If yes, did your child experience the same symptoms?
- Have you told the doctors or nurses about your child's reaction or allergy?
- Has your child had allergy testing?

! NURSING ALERT

Information about allergic reactions to medications or other products is essential. Failure to document a serious reaction places the child at risk if the medication is given.

Current Medications. The nurse should inquire about current medication regimens, including prescription medications and over-the-counter medications, such as antipyretics, vitamins, minerals, herbal remedies, or supplements, and the use of illegal or illicit drugs (appropriate to age). All medications should be listed, including name, dose, schedule, duration, and reason for administration. Often parents are unaware of the medication's actual name. Whenever possible, parents should bring the containers with them to the next visit, or the nurse can ask for the name of the pharmacy and call for a list of all the child's recent prescription medications. However, this list will not include over-the-counter medications or herbal remedies, which are important to know.

Immunizations. A record of all immunizations is essential. Since many parents are unaware of the exact name and date of each immunization, the most reliable source of information is a private practitioner's record or an "Immunization Record" (either on paper or on an online version) provided to the family to keep and updated after each vaccine. All immunizations and "boosters" will be listed, stating (1) the name of the specific disease, (2) the number of injections, (3) the dosage (sometimes lesser amounts are given if a reaction is anticipated), (4) the ages when administered, and (5) the occurrence of any reaction following the immunization. See Chapter 35 for more information on specific age-group immunizations.

Growth and Development. The most important previous growth patterns to record are the following:

- Approximate weight at 1 week, 2 months, 4 months, 6 months, 12 to 13 months, and 18 months, then yearly (Greig et al., 2016; Rourke et al., 2020)
- Approximate length at 1 week, 2 months, 4 months, 6 months, 12 to 13 months, and 18 months, then yearly (Greig et al., 2016; Rourke et al., 2020)
- Dentition, including age of onset, number of teeth, and symptoms during teething
- Developmental milestones include the following:
  - Age of holding up head steadily
  - Age of sitting alone without support
  - Age of walking without assistance
  - Age of saying first words with meaning
- Present grade in school
- Scholastic grades
- If the child has a best friend
- Interactions with other children, peers, and adults
- Family income insecurity
- Presence of bullying
- Mental health concerns
- Substance use

The nurse should use specific and detailed questions when inquiring about each developmental milestone. For example, "sitting up" can mean many different activities, such as sitting propped up, sitting in someone's lap, sitting with support, sitting up alone but in a hyperflexed position for assisted balance, or sitting up unsupported with the back slightly rounded. A clue to misunderstanding of the requested

BOX 33.2 Habits to Explore During a Health Interview

- Behaviour patterns such as nail biting, thumb sucking, pica (habitual ingestion of nonfood substances), rituals ("security" blanket or toy), and unusual movements (head banging, rocking, overt masturbation, walking on toes)
- Activities of daily living, such as the hour of going to sleep and arising, duration of nighttime sleep and naps, type and duration of exercise, regularity of stools and urination, age of toilet training, and daytime or nighttime bedwetting
- Unusual disposition; response to frustration
- Use of alcohol, drugs, coffee, or tobacco

activity may be an unusually early age of achievement. See Developmental Assessment tools later in this chapter.

Habits. Habits are an important area to explore during the interview (Box 33.2). Parents frequently express concerns during this part of the history. The nurse needs to encourage their input, by saying, "Please tell me any concerns you have about your child's habits, activities, or development." Any concerns expressed should be investigated further.

One of the most common concerns relates to sleep. Many children develop a normal sleep pattern, and all that is required during the assessment is a general overview of nighttime sleep and nap schedules. However, a number of children also develop sleep challenges (see Sleep in Chapter 35). When issues with sleep do occur, a more detailed sleep history is required to guide appropriate interventions.

Habits related to misuse of substances apply primarily to older children and adolescents. If a youngster admits to smoking, drinking, or using drugs, they should be asked about the quantity and frequency. Questions such as "Many kids your age are experimenting with drugs and alcohol; have you ever had any drugs or alcohol?" may give more reliable data than questions such as "How much do you drink?" or "How often do you drink or take drugs?" Clarify that "drinking" includes all types of alcohol, including beer and wine. When quantities such as a "glass" of wine or a "can" of beer are given, the size of the container needs to be determined.

If older children deny use of substances, they should be asked about past experimentation. Asking, "You mean you never tried to smoke or drink?" implies that the nurse expects some such activity, and the youngster may be more inclined to answer truthfully. It is important to be aware of the confidential nature of such questioning, the adverse effect that the parents' presence may have on the adolescent's willingness to answer, and the fact that self-reporting may not be an accurate account of substance use.

Family Health History

The family health history is used primarily for discovering the potential existence of hereditary or familial diseases in the parents and child. In general, it is confined to first-degree relatives (parents, siblings, grandparents, and immediate aunts and uncles). Information for each family member includes age, state of health if living, cause of death if deceased, and any evidence of the following conditions: early heart disease, stroke, sudden death from unknown cause, hypercholesterolemia, hypertension, cancer, diabetes mellitus, obesity, congenital anomalies, allergies, asthma, seizures, tuberculosis, abnormal bleeding, sickle cell disease, cognitive impairment, hearing or visual deficits, and mental health disorders such as depression or psychosis, or emotional disorders. The nurse needs to confirm the accuracy of the reported disorders by inquiring about the symptoms, course, treatment, and sequelae of each diagnosis.

Geographic Location. One of the important areas to explore when assessing the family health history is geographic location, including the patient's birthplace and travel to different areas in or outside of the country, for identification of possible exposure to endemic diseases. Relevant information includes current and past housing, whether they rent or own, whether they reside in an urban or rural location, the age of the home, and whether there are significant threats such as moulds or pests within the housing structure. Although the primary interest focuses on the child's temporary residence in various localities, the nurse should also inquire about close family members' travel, especially travel during tours of military service or business trips. Children are particularly susceptible to parasitic infestation in areas of poor sanitary conditions and to vector-borne diseases, such as those from mosquitoes or ticks in warm and humid or heavily wooded regions.

Family Structure. Assessment of the family, both its structure and function, is an important component of the history-taking process. Because the quality of the relationship between the child and family members is a major factor in emotional and physical health, family assessment is discussed here separately and in greater detail apart from the more traditional health history.

Family assessment is the collection of data about the family's composition and the relationships among its members. In its broadest sense, *family* refers to all those individuals who are considered by the patient to be significant to the nuclear unit, including relatives, friends, and social groups (e.g., school and church). Although family assessment is not family therapy, it can be therapeutic. Involving family members in the discussion of family characteristics and activities can provide insight into family dynamics and relationships. See Chapter 2 for more discussion on family assessment models.

Because of the time involved in performing an in-depth family assessment as presented here, the nurse needs to be selective in deciding when knowledge of family function may facilitate nursing care (see Guidelines box: Initiating a Comprehensive Family Assessment). During brief contacts with families, a full assessment is not appropriate; screening with one or two questions from each category may reflect the health of the family system or the need for additional assessment.

GUIDELINES

Initiating a Comprehensive Family Assessment

Perform a comprehensive assessment in the following situations:

- Children receiving comprehensive well-child care
- Children experiencing major stressful life events (e.g., chronic illness, disability, parental divorce, death of a family member)
- Children requiring extensive home care
- Children with developmental delays
- Children with repeated accidental injuries and those with suspected child abuse
- Children with behavioural or physical issues that could be caused by family dysfunction

The most common method of eliciting information on the family structure is to interview family members. The principal areas of concern (Box 33.3) are family composition, home and community environment, occupation and education of family members, and cultural and religious traditions.

! NURSING ALERT

In assessing family composition, it is sometimes difficult to ascertain the status of the adult relationships. If the parent fails to mention the other parent, ask, "Is there another parent in the child's life?" Avoid saying "husband" or "wife" because this assumes that only marital relationships exist and also assumes heterosexuality.

BOX 33.3 Family Assessment Interview

General Guidelines

Schedule the interview with the family at a time that is most convenient for all parties; include as many family members as possible; clearly state the purpose of the interview.

Begin the interview by asking each person's name and their relationship to one another.

Restate the purpose of the interview and the objective.

Keep the initial conversation general to put members at ease and to learn the "big picture" of the family.

Identify major concerns and reflect these back to the family to be certain that all parties receive the same message.

Terminate the interview with a summary of what was discussed and a plan for additional sessions, if needed.

Structural Assessment Areas

Family Composition

Immediate members of the household (names, ages, and relationships)

Significant extended family members

Previous marriages, separations, death of spouses, or divorces

Home and Community Environment

Type of dwelling, number of rooms, occupants

Sleeping arrangements

Number of floors, accessibility of stairs and elevators

Adequacy of utilities

Safety features (fire escape, smoke and carbon monoxide detectors, guardrails on windows, use of car restraint)

Environmental hazards (e.g., chipped paint, poor sanitation, pollution, heavy street traffic)

Availability and location of health care facilities, schools, play areas

Relationship with neighbours

Recent crises or changes in home

Child's reaction and adjustment to recent stresses

Occupation and Education of Family Members

Types of employment

Work schedules

Work satisfaction

Exposure to environmental or industrial hazards

Sources of income and adequacy

Effect of illness on financial status

Highest degree or grade level attained

Cultural and Religious Traditions

Religious beliefs and practices

Cultural and ethnic beliefs and practices

Language spoken in home

Assessment questions include the following:

- Does the family identify with a particular religious or ethnic group? Are both parents from that group?
- How is religious or ethnic background part of family life?
- What special religious or cultural traditions are practised in the home (e.g., food choices and preparation)?
- Where were family members born, and how long have they lived in this country?
- What language does the family speak most often?
- Do they speak and understand English?
- What do they believe causes health or illness?
- What religious or ethnic beliefs influence the family's perception of illness and its treatment?
- What methods are used to prevent or treat illness?
- How does the family know when a health issue needs medical attention?
- Whom does the family contact when a member is ill?
- Does the family rely on cultural or religious healers or remedies? If so, ask them to describe the type of healer or remedy.
- Whom does the family go to for support (clergy, medical healer, relatives)?
- Does the family experience discrimination because of their race, beliefs, or practices? Ask them to describe.

Functional Assessment Areas

Family Interactions and Roles

Interactions refer to ways in which family members relate to each other. The chief concern is the amount of intimacy and closeness among the members, especially spouses. *Roles* refer to behaviours of people as they assume a different status or position. Observations include the following:

- Family members' responses to each other (cordial, hostile, cool, loving, patient, short tempered)
- Obvious roles of leadership versus submission
- Support and attention shown to various members

Assessment questions include the following:

- What activities does the family perform together?
- Whom do family members talk to when something is bothering them?
- What are members' household chores?
- Who usually oversees what is happening with the children, such as at school or for health care?
- How easy or difficult is it for the family to change or accept new responsibilities for household tasks?

Power, Decision Making, and Problem Solving

Power refers to individual member's control over others in the family; it is manifested through family decision making and problem solving. The chief concern is clarity of boundaries of power between parents and children. One method of assessment involves offering a hypothetical conflict or problem, such as a child failing school, and asking the family how they would handle this situation. Assessment questions include the following:

- Who usually makes the decisions in the family?
- If one parent makes a decision, can the child appeal to the other parent to change it?
- What input do children have in making decisions or discussing rules?
- Who makes and enforces the rules?
- What happens when a rule is broken?

Communication

Communication is concerned with clarity and directness of communication patterns. Further assessment includes periodically asking family members if they understood what was just said and to repeat the message.

Observations include the following:

- Who speaks to whom?
- If one person speaks for another or interrupts
- If members appear uninterested when certain individuals speak
- If there is agreement between verbal and nonverbal messages

Assessment questions include the following:

- How often do family members wait until others are through talking before "having their say"?
- Do parents or older siblings tend to lecture and preach?
- Do parents tend to "talk down" to the children?

Expression of Feelings and Individuality

Expressions are concerned with personal space and freedom to grow with limits and structure needed for guidance. Observing patterns of communication offers clues to how freely feelings are expressed.

Assessment questions include the following:

- Is it OK for family members to get angry or sad?
- Who gets angry most of the time? What do they do?
- If someone is upset, how do other family members try to comfort this person?
- Who comforts specific family members?
- When someone wants to do something, such as try out for a new sport or get a job, what is the family's response (offer assistance, discouragement, or no advice)?

Psychosocial History

The traditional medical history includes a personal and social section that concentrates on children's personal status, such as school adjustment and any unusual habits, and the family and home environment. Since several personal aspects are covered under development and habits, only those issues related to children's ability to cope and their self-concept are presented here.

Through observation, the nurse can obtain a general idea of how confident children are in dealing with others, answering questions, and coping with new situations. It is important to observe the parent–child relationship for the types of messages sent to children about their coping skills and self-worth. Do the parents treat the child with respect, focusing on strengths, or is the interaction one of constant reprimands, with emphasis on weaknesses and faults? Do the parents help the child learn new coping strategies or support the ones the child uses?

Parent–child interactions also convey messages about body image. Do the parents label the child and body parts, such as "bad boy," "skinny legs," or "ugly scar"? Do the parents handle the child gently, using soothing touch to calm an anxious child, or do they treat the child roughly, using slaps or restraint to force compliance? If the child touches certain parts of the body, such as the genitalia, do the parents make comments that suggest a negative connotation?

With older children many of the communication strategies discussed earlier in the chapter are useful in eliciting more definitive information about their coping and self-concept. Children can write down five things they like and dislike about themselves. The nurse can use sentence-completion statements, such as "The thing I like best (or least) about myself is _____," "If I could change one thing about myself, it would be _____," or "When I am scared, I _____."

Mental Health Screening. During the interview and history taking, the nurse may become concerned about potential psychosocial or mental health issues in the child or family being assessed. The Canadian Paediatric Society (CPS) has recommended preliminary mental health screening tools that are available that can help the nurse assess potential concerns in areas such as sleep habits, social skills, family relationships, and learning difficulties. More detailed information on mental health concerns in children is provided in Chapter 55.

Review of Systems

The *review of systems* is a specific review of each body system, following an order similar to that of the physical examination (see Guidelines box: Review of Systems). Often the history of the present illness provides a complete review of the system involved in the chief health concern. Since asking questions about other body systems may appear unrelated and irrelevant to the parents or child, the questioning should be preceded by an explanation of why the data are needed (similar to the explanation concerning the relevance of the birth history) and the parents reassured that the child's main health concern has not been forgotten.

GUIDELINES

Review of Systems

General—Overall state of health, fatigue, recent or unexplained weight gain or loss (period of time for either), contributing factors (change of diet, illness, altered appetite), exercise tolerance, fevers (time of day), chills, night sweats (unrelated to climatic conditions), frequent infections, general ability to carry out activities of daily living

Integument—Pruritus, pigment or other colour changes, acne, eruptions, rashes (location), tendency for bruising, petechiae, excessive dryness, general texture, disorders or deformities of nails, hair growth or loss, hair colour change (for adolescents, use of hair dyes or other potentially toxic substances, such as hair straighteners)

Head—Headaches, dizziness, injury (specific details)

Eyes—Visual issues (behaviours indicative of blurred vision, such as bumping into objects, clumsiness, sitting close to television, holding a book close to the face, writing with head near the desk, squinting, rubbing the eyes, bending head in an awkward position), cross-eyes (strabismus), eye infections, edema of lids, excessive tearing, use of glasses or contact lenses, date of last vision exam

Ears/nose/mouth/throat: Earaches, ear discharge, evidence of hearing impairment (ask about behaviours such as the need to repeat requests, loud speech, inattentive behaviour), results of any previous auditory testing, nosebleeds (epistaxis), constant or frequent runny or stuffy nose, nasal obstruction (difficulty breathing), alteration or loss of sense of smell, mouth breathing, gum bleeding, number of teeth and pattern of eruption/loss, toothaches, tooth brushing, use of fluoride, difficulty with teething (symptoms), last visit to the dentist (especially if temporary dentition is complete), sore throats, difficulty swallowing, choking, hoarseness or other voice irregularities

Neck—Pain, limitation of movement, stiffness, difficulty holding head straight (torticollis), thyroid enlargement, enlarged nodes or other masses

Chest—Breast enlargement, discharge, masses, enlarged axillary nodes

Respiratory—Chronic cough, frequent colds (number per year), wheezing, shortness of breath at rest or on exertion, difficulty breathing, sputum production, infections (pneumonia, tuberculosis), date of last chest X-ray examination, skin reaction from tuberculin testing

Cardiovascular—Cyanosis or fatigue on exertion, history of heart murmur or rheumatic fever, tachycardia, syncope, edema

Gastrointestinal (questions in regard to appetite, food tolerance, and elimination habits are asked elsewhere)—Nausea, vomiting (not associated with eating, may be indicative of brain tumour or increased intracranial pressure), jaundice or yellowing skin or sclera, belching, flatulence, recent change in bowel habits (blood in stools, change of colour, diarrhea, or constipation)

Genitourinary—Pain on urination, frequency, hesitancy, urgency, hematuria, nocturia, polyuria, unpleasant odour to urine, force of stream, discharge, change in size of scrotum, date of last urinalysis

Gynecological—Menarche, date of last menstrual period, regularity or difficulties with menstruation, vaginal discharge, pruritus, if sexually active, type of contraception, sexually transmitted infection and type of treatment

Musculoskeletal—Weakness, clumsiness, lack of coordination, unusual movements, back or joint stiffness, muscle pains or cramps, abnormal gait, deformity, fractures, serious sprains, activity level

Neurological—Seizures, tremors, dizziness, memory impairment, general affect, fears, nightmares, speech issues, any unusual habits

Endocrine—Intolerance to weather changes, excessive thirst or urination, excessive sweating, salty taste to skin, signs of early or late puberty

Hematological/lymphatic: Easy bruising or bleeding, anemia, date and result of last blood count, blood transfusions, swollen or painful lymph nodes (cervical, axillary, inguinal)

Allergic/immunological: Allergic responses, anaphylaxis, eczema, rhinitis, unusual sneezing, autoimmunity, recurrent infections, infections associated with unusual complications

Mental health: General affect, anxiety, depression, mood changes, hallucinations, attention span, tantrums, behaviour issues, suicidal ideation, substance use

The review of a specific system begins with a broad statement such as "How has your child's general health been?" or "Has your child had any problems with his eyes?" If the parent states that the child has had difficulties with some body function, this should be pursued with an encouraging statement, such as "Tell me more about that." If the parent denies any concerns, the nurse can query for specific symptoms: "No headaches, bumping into objects, or squinting?" If the parent reconfirms the absence of such symptoms, the nurse should record positive statements in the history, such as "Parent denies headaches, bumping into objects, or squinting." In this way, anyone who reviews the health history is aware of exactly what symptoms were investigated.

Reproductive Health History. The sexual history is an essential component of adolescents' health assessment. The history uncovers areas of concern related to sexual activity, alerts the nurse to circumstances that may indicate screening for sexually transmitted infections (STIs) or testing for pregnancy, and provides information related to the need for sexual counselling, such as safer sex practices. Guidelines for anticipatory guidance topics for parents and adolescents are found in Box 33.4.

One approach to initiating a conversation about sexual concerns is to begin with a history of peer interactions. Open-ended statements such as "Tell me about your social life" or "Who are your closest friends?" generally lead into a discussion of dating and sexual issues. To probe further, the nurse can include questions about the adolescent's attitudes on such topics as sex education, having an intimate friend or partner, living together, and premarital sex. Such questions should be phrased to reflect concern rather than judgement or criticism of sexual practices.

In any conversation regarding sexual history, it is important to be aware of the language used in either eliciting or conveying sexual information. For example, the nurse should avoid asking whether the adolescent is "sexually active," because this term is broadly defined. "Are you having sex with anyone?" is probably the most direct and best understood question. Since same-sex experimentation may occur, all sexual contacts should be referred to in nongender terms, such as "anyone" or "partners," rather than "girlfriends" or "boyfriends."

A detailed account of sexual partners is needed if the patient has a history of, displays any symptoms of, or asks for treatment of an STI. A difficult but necessary part of the interview is to determine the sites of possible infection. Since sexual diseases can be contracted in any of the body orifices, the adolescent should be informed that an STI can be acquired without visible signs of disease at nongenital sites.

Performing a Nutritional Assessment

Dietary Intake. Knowledge of the child's dietary intake is an essential component of a nutritional assessment. However, it is also one of the most difficult factors to assess. Individuals' recall of food consumption, especially amounts eaten, is frequently unreliable. The food intake history of children and adolescents is prone to reporting error, mostly in the form of underreporting. Also, people from different cultures may have difficulty adequately describing the types of food they eat. Despite these obstacles, it is important to include a dietary evaluation in the child's assessment.

Specific questions used to conduct a nutritional assessment are listed in Box 33.5. Every nutritional assessment should begin with a dietary history. The exact questions used to elicit a dietary history vary with the child's age. In general, the younger the child, the more specific and detailed the history should be. The overview elicited from the dietary history can be helpful in evaluating food frequency records. The history should also be concerned with food security and cultural factors that influence food selection and preparation (see Cultural Awareness box: Food Practices).

CULTURAL AWARENESS

Food Practices

Because cultural practices are prevalent in food preparation, the kinds of questions asked and the judgements made during the assessment need to be considered carefully. For example, many cultures eat food that is different from food listed in *Canada's Food Guide* (see Appendix A).

The most common and probably easiest method of assessing daily intake is the 24-hour recall. The child or parent recalls every item eaten in the past 24 hours and the approximate amounts. The 24-hour recall is most beneficial when it represents a typical day's intake. Some of the difficulties with a daily recall are the family's inability to remember

BOX 33.4 Anticipatory Guidance—Sexuality

Ages 12 to 14 Years

Have the adolescent identify a supportive adult to discuss sexuality issues and concerns with.
Discuss advantages of delaying sexual activity and provide an opportunity to practice saying no.
Discuss making responsible decisions regarding normal sexual feelings and activity.
Discuss roles of gender, peer pressure, and the media in sexual decision making.
Discuss contraceptive options (advantages and disadvantages).
Provide education regarding sexually transmitted infections (STIs) and human immunodeficiency virus (HIV) infection; clarify risks, and discuss the use of condoms.
Discuss abuse prevention: avoiding dangerous situations, the role of drugs and alcohol, and the use of self-defence.
Have the adolescent clarify values, needs, and the ability to be assertive.
If the adolescent is sexually active, discuss the use of condoms and contraceptive options.
Have a confidential interview with the adolescent (including a sexual history).
Discuss the evolution of sexual identity and expression.

Ages 15 to 18 Years

Clarify values; encourage responsible decision making.
Discuss alternatives to intercourse.
Discuss "When are you ready for sex?"
Discuss consequences of unprotected sex: early pregnancy; STIs, including HIV infection.
Discuss negotiating with the partner and barriers to safer sex.
If the adolescent is sexually active, discuss the use of condoms and contraceptive options.
Emphasize that sex should be safe and pleasurable for both partners.
Have a confidential interview with the adolescent.
Discuss concerns about sexual identity and expression.

Data from Fonseca, H., Greydanus, D. (2007). Sexuality in the child, teen and young adult: Concepts for the clinician. *Primary Care Clinical Office Practice, 34,* 275–292; Wright, K. (1997). Anticipatory guidance: Developing a healthy sexuality. *Pediatric Annals, 26*(2 Suppl.), S142–S144, C3.

BOX 33.5 Dietary Assessment for a Child

Dietary History

What are the family's usual mealtimes?
Do family members eat together or at separate times?
Who does the family grocery shopping and meal preparation?
Does the child help with food preparation?
How much money is spent to buy food each week?
How are most foods prepared—baked, broiled, fried, other?
How often does the family or child eat out?
- What kinds of restaurants do they go to?
- What kinds of food does the child typically eat at restaurants?

Does the child eat breakfast regularly?
Where does the child eat lunch?
What are the child's favourite foods, beverages, and snacks?
- What are the average amounts eaten per day?
- What foods are artificially sweetened?
- What are the child's snacking habits?
- When are sweet foods usually eaten?

What special cultural practices are followed? What ethnic foods are eaten?
What foods and beverages does the child dislike?
How would parents describe the child's usual appetite (hearty eater, picky eater)?
What are the child's feeding habits (breast, bottle, cup, spoon, eats by self, needs assistance, any special devices)?
Does the child take vitamins or other supplements? Do they contain iron or fluoride?
Does the child have any known or suspected food allergies? Is the child on a special diet?
Has the child lost or gained weight recently?
Are there any feeding difficulties (excessive fussiness, spitting up, colic, difficulty sucking or swallowing)? Are there any dental issues or appliances, such as braces, that affect eating?
Is there a family history of cancer, diabetes, heart disease, high blood pressure, or obesity?

Additional Questions Regarding Infants

What was the infant's birth weight? When did it double? Triple?
Was the infant preterm?
Is the mother breastfeeding or have they breastfed their infant? For how long?
If formula is used, what is the brand?
- When was formula feeding started?
- How many millilitres does the infant drink a day?
- Is the infant receiving cow's milk (whole, low fat, skim)?
- When was it started?

Does the infant receive extra fluids (water, juice)?
If the infant takes a bottle to bed at nap time or nighttime, what is in the bottle?
At what age did the child start on cereal, meat or other protein sources, vegetables, fruit or juice, finger food, table food?
Do the parents make their own baby food or use commercial foods, such as infant cereal?
Does the infant take a vitamin or mineral supplement? If so, what type?
Has the infant had an allergic reaction to any food(s)? If so, list the foods and describe the reaction.
Does the infant spit up frequently; have unusually loose stools; or have hard, dry stools? If so, how often?
How often is the infant fed?
How would the parents describe their infant's appetite?

exactly what was eaten and inaccurate estimation of portion size. To increase accuracy of reporting portion sizes, the use of food models and additional questioning are recommended. In general, this method is most useful in providing qualitative information about the child's diet.

To improve the reliability of the daily recall, the family can complete a food diary by recording every food and liquid consumed for a certain number of days. A 3-day record consisting of 2 weekdays and 1 weekend day is representative for most people. Providing specific charts to record intake can enhance completion of the form. The family should record items immediately after eating.

Clinical Examination of Nutrition. A significant amount of information regarding nutritional deficiencies can be elicited from a clinical examination, especially from assessing the skin, hair, teeth, gums, lips, tongue, and eyes. The hair, skin, and mouth are vulnerable because of the rapid turnover of epithelial and mucosal tissue. Table 33.1 summarizes clinical signs of possible nutritional deficiency or excess. Few are diagnostic for a specific nutrient, and if suspicious signs are found, they must be confirmed with dietary and biochemical data. Generally, the clinical examination does not reveal children's risk for a deficiency or excess.

Anthropometry, an essential parameter of nutritional status, is the measurement of height, weight, head circumference, proportions, skin fold thickness, and arm circumference in young children. Height and head circumference reflect past nutrition, whereas weight, skin fold thickness, and arm circumference reflect present nutritional status, especially of protein and fat reserves. Skin fold thickness is a measurement of the body's fat content; approximately half the body's total fat stores are directly beneath the skin. The upper arm muscle circumference is correlated with measurements of total muscle mass. Since muscle serves as the body's major protein reserve, this measurement is considered an index of the body's protein stores. Ideally, growth measurements are recorded over time, and comparisons are made regarding the velocity of growth based on previous and present values.

Numerous biochemical tests available for assessing nutritional status include analysis of plasma, blood cells, urine, and tissues from liver, bone, hair, and fingernails. Many of these tests are complicated and are not performed routinely. Common laboratory procedures for nutritional status include measurement of hemoglobin, hematocrit, transferrin, albumin, creatinine, and nitrogen. Laboratory values for these tests and more specific nutrient measurements are given in Appendix B.

Evaluation of Nutritional Assessment. After collecting the data needed for a thorough nutritional assessment, the nurse needs to evaluate the findings to plan appropriate counselling. From the data, assessment can be made as to whether the child is malnourished, at risk for becoming malnourished, or well-nourished with adequate reserves or overweight or obese.

The **Dietary Reference Intakes** (DRIs) are a set of four nutrient-based reference values that provide quantitative estimates of nutrient intake for use in assessing and planning dietary intake (Government of Canada, 2006). The specific DRIs include the following:

TABLE 33.1 Clinical Assessment of Nutritional Status

Evidence of Adequate Nutrition	Evidence of Deficient or Excess Nutrition	Deficiency or Excess*
General Growth		
Normal weight gain, growth velocity, and head growth for age and gender	Weight loss or poor weight gain, growth failure	Protein, calories, fats, and other essential nutrients, especially vitamin A, pyridoxine, niacin, calcium, iodine, manganese, zinc
	Excess weight gain	Excess calories
Sexual development appropriate for age	Delayed sexual development	Excess vitamins A, D
Skin		
Smooth, slightly dry to touch Elastic and firm Absence of lesions Colour appropriate to genetic background	Hardening and scaling	Vitamin A
	Seborrheic dermatitis	Excess niacin
	Dry, rough, petechiae	Riboflavin
	Delayed wound healing	Vitamin C
	Scaly dermatitis on exposed surfaces	Riboflavin, vitamin C, zinc
	Wrinkled, flabby	Niacin
	Crusted lesions around orifices, especially nares	Protein, calories, zinc
	Pruritus	Excess vitamin A, riboflavin, niacin
	Poor turgor	Water, sodium
	Edema	Protein, thiamine
		Excess sodium
	Yellow tinge (jaundice)	Vitamin B_{12}
		Excess vitamin A, niacin
	Depigmentation	Protein, calories
	Pallor (anemia)	Pyridoxine; folic acid; vitamins B_{12}, C, E (in preterm infants); iron
		Excess vitamin C, zinc
	Paresthesia	Excess riboflavin
Hair		
Lustrous, silky, strong, elastic	Stringy, friable, dull, dry, thin	Protein, calories
	Alopecia	Protein, calories, zinc
	Depigmentation	Protein, calories, copper
	Raised areas around hair follicles	Vitamin C
Head		
Even moulding, occipital prominence, symmetrical facial features	Softening of cranial bones, prominence of frontal bones, skull flat and depressed toward middle	Vitamin D
Fused sutures after 18 months	Delayed fusion of sutures	Vitamin D
	Hard, tender lumps in occiput	Excess vitamin A
	Headache	Excess thiamine
Neck		
Thyroid not visible, palpable in midline	Thyroid enlarged, may be grossly visible	Iodine
Eyes		
Clear, bright	Hardening and scaling of cornea and conjunctiva	Vitamin A
Good night vision	Night blindness	Vitamin A
Conjunctiva—Pink, glossy	Burning, itching, photophobia, cataracts, corneal vascularization	Riboflavin
Ears		
Tympanic membrane—Pliable	Calcified (hearing impairment)	Excess vitamin D
Nose		
Smooth, intact nasal angle	Irritation and cracks at nasal angle	Riboflavin
		Excess vitamin A
Mouth		
Lips—Smooth, moist, darker colour than skin	Fissures and inflammation at corners	Riboflavin
		Excess vitamin A
Gums—Firm, coral pink, stippled	Spongy, friable, swollen, bluish red or black, bleed easily	Vitamin C
Mucous membranes—Bright pink, smooth, moist	Stomatitis	Niacin
	Glossitis	Niacin, riboflavin, folic acid

Continued

TABLE 33.1 Clinical Assessment of Nutritional Status—cont'd

Evidence of Adequate Nutrition	Evidence of Deficient or Excess Nutrition	Deficiency or Excess
Tongue—Rough texture, no lesions, taste sensation	Diminished taste sensation	Zinc
Teeth—Uniform white colour, smooth, intact	Brown mottling, pits, fissures	Excess fluoride
	Defective enamel	Vitamins A, C, D; calcium; phosphorus
	Caries	Excess carbohydrates
Chest		
In infants, shape almost circular	Depressed lower portion of rib cage	Vitamin D
In children, lateral diameter increased in proportion to anteroposterior diameter	Sharp protrusion of sternum	Vitamin D
Smooth costochondral junctions	Enlarged costochondral junctions	Vitamins C, D
Breast development—Normal for age	Delayed development	See under General Growth; especially zinc
Cardiovascular System		
Pulse and blood pressure (BP) within normal limits	Palpitations	Thiamine
	Rapid pulse	Potassium
		Excess thiamine
	Arrhythmias	Magnesium, potassium
		Excess niacin, potassium
	Increased BP	Excess sodium
	Decreased BP	Thiamine
		Excess niacin
Abdomen		
In young children, cylindrical and prominent	Distended, flabby, poor musculature	Protein, calories
	Prominent, large	Excess calories
In older children, flat	Potbelly, constipation	Vitamin D
Normal bowel habits	Diarrhea	Niacin
		Excess vitamin C
	Constipation	Excess calcium, potassium
Musculoskeletal System		
Muscles—Firm, well developed, equal strength bilaterally	Flabby, weak, generalized wasting	Protein, calories
	Weakness, pain, cramps	Thiamine, sodium, chloride, potassium, phosphorus, magnesium
		Excess thiamine
	Muscle twitching, tremors	Magnesium
	Muscular paralysis	Excess potassium
Spine—Cervical and lumbar curves (double S curve)	Kyphosis, lordosis, scoliosis	Vitamin D
Extremities—Symmetrical; legs straight with minimum bowing	Bowing of extremities, knock-knees	Vitamin D, calcium, phosphorus
	Epiphyseal enlargement	Vitamins A, D
	Bleeding into joints and muscles, joint swelling, pain	Vitamin C
Joints—Flexible, full range of motion, no pain or stiffness	Thickening of cortex of long bones with pain and fragility, hard tender lumps in extremities	Excess vitamin A
	Osteoporosis of long bones	Calcium
		Excess vitamin D
Neurological System		
Behaviour—Alert, responsive, emotionally stable	Listless, irritable, lethargic, apathetic (sometimes apprehensive, anxious, drowsy, cognitively delayed, confused)	Thiamine, niacin, pyridoxine, vitamin C, potassium, magnesium, iron, protein, calories
		Excess vitamins A, D; thiamine; folic acid; calcium
Absence of tetany, convulsions	Masklike facial expression, blurred speech, involuntary laughing	Excess manganese
	Convulsions	Thiamine, pyridoxine, vitamin D, calcium, magnesium
		Excess phosphorus (in relation to calcium)
Intact peripheral nervous system	Peripheral nervous system toxicity (unsteady gait, numb feet and hands, fine motor clumsiness)	Excess pyridoxine
Intact reflexes	Diminished or absent tendon reflexes	Thiamine, vitamin E

*Nutrients listed are deficient unless specified as excess.

Estimated Average Requirement (EAR)—Nutrient intake estimated to meet the requirement of half the healthy individuals (50%) for a specific age and gender group. The EAR is used to examine the possibility of inadequacy.

Recommended Dietary Allowance (RDA)—Sufficient to meet the nutrient requirement of nearly all healthy individuals for a specific age and gender group. Dietary intake at or above this level usually has a low probability of inadequacy.

Adequate Intake (AI)—Recommended intake level based on estimates of nutrient intake by healthy groups of individuals. Dietary intake at or above this level usually has a low probability of inadequacy.

Tolerable Upper Intake Level (UL)—Highest average daily nutrient intake level likely to pose no risk of adverse health effects. As intake increases above the UL, risk of adverse effects increases. Dietary intake above this level usually places an individual at risk for adverse effects from excessive nutrient intake.

Another resource for assessing nutrition is *Canada's Food Guide* (see Appendix A). The *Food Guide* is based on current nutritional science and is intended to help individuals make good food choices that promote health and prevent nutrition-related illnesses. When assessing a child's food intake, it is important to analyze the daily food diary for the variety and amounts of foods suggested in *Canada's Food Guide*. For example, if the list includes no vegetables, the nurse can inquire about this rather than assuming that the child dislikes vegetables, since it could be that none were served that day. Also, information should be evaluated in terms of the family's ethnic practices and financial resources. Further nutritional information is available on the Dietitians of Canada website (see Additional Resources).

DEVELOPMENTAL ASSESSMENT

One of the essential components of a complete health appraisal of children includes a developmental surveillance to assess if children are achieving their developmental milestones. The surveillance includes assessment of age-appropriate developmental milestones that have been sequentially acquired for gross- and fine-motor, social, emotional, language, and cognitive domains. Milestone ages should be based on the oldest age by which the skill should have been achieved. The Canadian Task Force on Preventive Health Care (2016) recommends against screening for developmental delay using standardized tools in children aged 1 to 4 years with no apparent signs of developmental delay and whose parents and clinicians have no concerns about development. If the parents do have concerns, a variety of standardized developmental screening tools can be used to further assess development in children ages 1 to 4 years. Tools that are commonly used to provide consistent and accurate data across Canada are presented in Table 33.2. Screening tools are designed to quickly and reliably identify whether a child's developmental level is what is expected for their age and whether the child requires further investigation because of not meeting common developmental levels. They also provide a means of recording objective measurements of present developmental function for future reference. Nurses play a vital role in providing a developmental assessment of children, particularly children with disabilities. The procedures discussed in this section can be administered in a variety of settings, such as home, school, day care centres, hospitals, health care providers' offices, or clinics. Parents and teachers sometimes complete them as well and the information is analyzed by the practitioner.

Most physicians and nurse practitioners perform a developmental screening of some kind during the well-child visits, but it is unknown how many use a consistent, standardized assessment. Often, nurses perform the developmental assessment. The Canadian Task Force on Preventive Care (2016) notes that it is important to achieve a balance between identifying children as developmentally delayed and identifying too many as such (i.e., too many false-positive findings) as the latter scenario can lead to unnecessary stigma, caregiver anxiety, and excess cost. False-negative results, by contrast, can lead to delays in treatment.

TABLE 33.2 Developmental Assessment Screening Tools

Type	Description	Age Group	Who Performs the Test
Physical, Cognitive, and Social Development Assessment			
Nipissing District Developmental Screen	Tests 13 critical developmental stages. The Screen examines a child's skills in the following areas: • Vision • Hearing • Speech and language • Communication • Gross motor and fine motor • Cognitive • Social/emotional • Self-help	1, 2, 4, 6, 9, 12, 15, 18, 24, and 30 months, 3 to 6 years	Parent, caregiver, nurse, or physician
Ages and Stages Questionnaires (ASQ)	Assesses a child's global development: gross motor, fine motor, language functions and social-emotional development, adaptive skills. Screening tool for developmental delay and to identify specific strengths and weaknesses a child may have	4 months to 5 years	Parent, caregiver, nurse, physician, or teacher
Child Developmental Inventory (CDI)	Assesses development in eight areas of functioning, including cognitive and language	15 months to 6 years	Parent, nurse, physician, or teacher
Children's Sleep Habits Questionnaire	Evaluates sleep on the basis of child's behaviour within eight different subscales: bedtime resistance, sleep-onset delay, sleep duration, sleep anxiety, night wakenings, parasomnias, sleep-disordered breathing, daytime sleepiness	4 to 10 years	Parent

Continued

TABLE 33.2 Developmental Assessment Screening Tools—cont'd

Type	Description	Age Group	Who Performs the Test
Conners Early Childhood	Assesses a child's social, emotional, and behavioural development	2 to 6 years	Parent, teacher, or caregiver
HEADSS for Adolescents	Identifies risky behaviours and used for health promotion, such as seat belt, helmet, protective gear use	12 to 18 years	Nurse or physician with the patient
PEDS: Parents' Evaluation of Developmental Status	Screens for developmental delays in children	Birth to 11 years	Parent or caregiver
Youth Resiliency: Assessing Development Strengths (YR:ADS)	Assesses factors associated with adolescent resilience: parental support/expectations, peer relationships, community cohesiveness, commitment to learning, school culture, cultural sensitivity, self-control, empowerment, self-concept, social sensitivity	13 to 18 years	Self-report
WHO Growth Charts for Canada	Charts to measure BMI for age and gender and used to assess weight relative to height	Growth chart for males and females, birth to 24 months, 2 to 19 years	Nurse or physician
Preliminary Mental Health Assessment			
Achenbach Child Behaviour Checklists (CBCL)	Provides information on general functioning (e.g., social skills, family relationships, learning)	1 ½ to 5 and 6 to 18 years	Parent, teacher, or patient, depending on the version
Pediatric Symptom Checklist	A brief screening questionnaire used by pediatricians and other health care providers to improve recognition and treatment of psychosocial challenges in children	4 years of age and older	Parent and self-report
Child/Adolescent Psychiatry Screen (CAPS)	Initial screening for 18 mental health issues	3 to 21 years	Parent
Weiss Symptom Record	A nonvalidated, comprehensive screening tool for various mental health conditions	5 to 19 years	Parent/teenager or teacher
Weiss Function Impairment Scales (Self-Report and Parent-Report)	A nonvalidated tool, recommended to collect systematic information from patient and parent about various disorders, including learning, developmental, and personality difficulties	14 to 19 years	Parent/teenager

BMI, Body mass index.

More research is needed to investigate the effectiveness of developmental screening tools and that of early intervention treatment of developmental delay. Early diagnosis and intervention may be critical to improving long-term outcomes. Developmental delay affects between 4 and 16% of children and is the leading cause of disability among children younger than 4 years of age in Canada (Limbos et al., 2010). However, only 30% of children with disabilities are identified before starting school (Limbos et al., 2010). Furthermore, it is estimated that up to one quarter of first-grade children have learning, health, and behavioural issues that will interfere with their academic and social performance (Limbos et al., 2010).

HEALTH SUPERVISION GUIDES

Children need to have periodic health checkups, conducted by health care providers, in order to optimize their health. These checkups are means of following health patterns, providing preventive care, and making early diagnoses of health issues. Such visits customarily occur at 1 and 2 weeks of age; at 1, 2, 4, 6, 9, 12, and 18 months of age; and subsequently at 1- or 2-year intervals.

Rourke Baby Record

The Rourke Baby Record is a guide for health care providers in their health supervision of children in the first 5 years of life (Rourke et al., 2020). The Rourke Baby Record consists of guides for charting well-baby/child visits, an immunization chart, and resources pages. It also includes information regarding growth monitoring, assessing nutrition, physical examination, education, and health care advice. The Rourke Baby Record can be used to chart development, child behaviour, parenting resources, immunization, and infectious diseases (see Additional Resources at the end of this chapter for checklists and record forms).

Greig Health Record

The Greig Health Record is an evidence-informed health promotion guide for clinicians caring for children and adolescents aged 6 to 17 years (Greig et al., 2016). It provides a template for periodic health visits that is easy to use and is easily adaptable for electronic medical records. Checklist templates are divided into three age ranges: 6 to 9, 10 to 13, and 14 to 17 years (inclusive) (Greig et al., 2016). The checklist templates include sections for weight, height, and body mass index; psychosocial history and development; nutrition; education and advice; specific concerns; examination; an assessment, immunization; and medications. There are resource sheets for each age group with more details to help assess for items such as injury prevention, poverty, child abuse, and bullying (see Additional Resources at the end of this chapter for checklists, resource sheets, and record forms).

GENERAL APPROACHES TOWARD EXAMINING THE CHILD

Although the approach to and sequence of the physical examination differs according to the child's age, the traditional model for physical

assessment, outlined here, can be used for all pediatric age groups and as a baseline for conducting assessments that are more age specific (see Chapter 26 for a detailed discussion of a newborn assessment).

Sequence of the Examination

Ordinarily, the sequence for examining patients follows a head-to-toe direction. The main function of such a systematic approach is to provide a general guideline for assessment of each body area to avoid omitting segments of the examination. The standard recording of data also facilitates exchange of information among different health care providers. This orderly sequence is frequently altered to accommodate the child's developmental needs, although the examination is recorded following the head-to-toe model. Using developmental and chronological age as the main criteria for assessing each body system accomplishes several goals:

- Minimizes stress and anxiety associated with assessment of various body parts
- Fosters a trusting nurse–child–parent relationship
- Allows for maximum **preparation** of the child
- Preserves the essential security of the parent–child relationship, especially with young children
- Maximizes the accuracy and reliability of assessment findings

Preparation of the Child

Although the physical examination consists of painless procedures, to a child the use of a tight arm cuff, probes in the ears and mouth, pressure on the abdomen, and a cold piece of metal to listen to the chest can be stressful. Therefore, the same considerations discussed in Chapter 44 for preparing children for procedures are followed here. In addition to that discussion, general guidelines related to the examining process are presented in the Guidelines box: Performing a Pediatric Physical Examination.

GUIDELINES

Performing a Pediatric Physical Examination

Perform the examination in an appropriate, nonthreatening area.
- Have the room well lit.
- Have room temperature comfortably warm.
- Place all strange and potentially frightening equipment out of sight.
- Have some toys, dolls, stuffed animals, and games available for the child.
- If possible, have rooms decorated and equipped for different-age children.
- Provide privacy, especially for school-age children and adolescents.

Provide time for play and becoming acquainted.

Observe behaviours that signal the child's readiness to collaborate:
- Talking to the nurse
- Making eye contact
- Accepting the offered equipment
- Allowing physical touching
- Choosing to sit on the examining table rather than the parent's lap

If signs of readiness are not observed, use the following techniques:
- Talk to the parent while essentially "ignoring" the child; gradually focus on the child or a favourite object, such as a doll.
- Make complimentary remarks about the child, such as appearance, dress, or a favourite object.
- Tell a funny story or play a simple magic trick.
- Have a nonthreatening "friend" available, such as a hand puppet to "talk" to the child for the nurse (see Figure 33.21, *A*).

If the child refuses to assist, use the following techniques:
- Assess reason for behaviour; consider that a child who is unduly afraid may have had a traumatic experience.
- Try to involve the child and parent in the process.
- Avoid prolonged explanations about the examining procedure.
- Use a firm, direct approach regarding expected behaviour.
- Perform the examination as quickly as possible.
- Have an attendant gently restrain the child.
- Minimize any disruptions or stimulation.
- Limit the number of people in the room.
- Use an isolated room.
- Use a quiet, calm, confident voice.

Begin the examination in a nonthreatening manner for young children or children who are fearful:
- Use activities that can be presented as games, such as the test for cranial nerves (see Table 33.3) or parts of developmental screening tests.
- Use approaches such as "Simon Says" to encourage the child to make a face, squeeze a hand, stand on one foot, and so on.
- Use the paper-doll technique:

1. Lay the child supine on an examining table or floor that is covered with a large sheet of paper.
2. Trace around the child's body outline.
3. Use body outline to demonstrate what will be examined, such as drawing a heart and listening with a stethoscope, before performing the activity on the child.

If several children in the family will be examined, begin with the child who is most willing to be examined to model desired behaviour.

Involve the child in the examination process:
- Provide choices, such as sitting on the table or in the parent's lap.
- Encourage the child to handle or hold equipment.
- Encourage the child to use equipment on a doll, family member, or examiner.
- Explain each step of the procedure in simple language.

Examine the child in a comfortable and secure position:
- Sitting in a parent's lap
- Sitting upright if in respiratory distress

Proceed to examine the body in an organized sequence (usually head to toe) with the following exceptions:
- Alter sequence to accommodate needs of different-age children (see Table 33.3).
- Examine painful areas last.
- In an emergency situation, examine vital functions (airway, breathing, and circulation) and injured area first.

Reassure the child throughout examination, especially about bodily concerns that arise during puberty.

Discuss findings with the family (if appropriate) at the end of the examination.

Praise the child for their assistance during the examination; give a reward such as a small toy or sticker.

The physical examination should be as pleasant as possible as well as educational. The paper-doll technique is a useful approach to teaching children about the body part that is being examined (Figure 33.1). At the conclusion of the visit, the child can bring home the paper doll as a memento.

Table 33.3 summarizes guidelines for positioning, preparing, and examining children at various ages. Because no child fits precisely into one age category, it may be necessary to vary the approach after a preliminary assessment of the child's developmental achievements and needs. Even with the best approach, many toddlers find the procedure difficult and are inconsolable for much of the physical examination. However, some seem intrigued by the new surroundings and unusual equipment and respond more like preschoolers than toddlers. Likewise,

TABLE 33.3 Age-Specific Approaches to Physical Examination of Children

Position	Sequence	Preparation
Infant		
Before able to sit alone—Supine or prone, preferably in parent's lap; before 4–6 months, can place on examining table **After able to sit alone**—Sitting in parent's lap whenever possible; if on table, place with parent in full view.	If quiet, auscultate heart, lungs, abdomen. Record heart and respiratory rates. Palpate and percuss same areas. Proceed in usual head-to-toe direction. Perform traumatic procedures last (eyes, ears, mouth [while crying]). Elicit reflexes as body part is examined. Elicit Moro reflex last.	Completely undress infant if room temperature permits. Leave diaper on male infant. Gain cooperation with distraction, bright objects, rattles, talking. Smile at infant; use soft, gentle voice. Use pacifier (with parent's permission) or feeding if necessary. Enlist parent's aid for restraining to examine ears, mouth. Avoid abrupt, jerky movements.
Toddler		
Sitting or standing on or by parent Prone or supine in parent's lap	Inspect body area through play: "count fingers," "tickle toes." Use minimum physical contact initially. Introduce equipment slowly. Auscultate, percuss, palpate whenever quiet. Perform traumatic procedures last (same as for infant).	Have parent remove outer clothing. Remove child's underwear as body part is examined. Encourage child to inspect equipment; demonstrating use of equipment is usually ineffective. Perform procedures quickly if child has difficulty cooperating. Use restraint when appropriate; request parent's assistance. Talk about examination; use short phrases. Praise for assisting.
Preschool Child		
Prefer standing or sitting Usually most helpful prone or supine Prefer parent's closeness	Proceed in head-to-toe direction unless child is having difficulty with examination. If having difficulty, proceed as with toddler.	Request self-undressing. Encourage child to wear underpants if shy. Offer equipment for inspection; briefly demonstrate use. Make up story about procedure (e.g., "I'm seeing how strong your muscles are" [blood pressure]). Use paper-doll technique. Give choices when possible. Use positive statements (e.g., "Open your mouth").
School-Age Child		
Prefer sitting Helpful in most positions Younger child prefers parent's presence. Older child may prefer privacy.	Proceed in head-to-toe direction. May examine genitalia last in older child	Respect need for privacy. Request self-undressing. Encourage to wear underpants. Give gown to wear. Explain purpose of equipment and significance of procedure, such as otoscope to see eardrum, which is necessary for hearing. Teach about body function and care.
Adolescent		
Same as for school-age child Offer option of parent's presence.	Same as older school-age child May examine genitalia last	Encourage to undress in private. Give gown. Expose only area to be examined. Respect need for privacy. Explain findings during examination: "Your muscles are firm and strong." Matter-of-factly comment about sexual development: "Your breasts are developing as they should be." Emphasize normalcy of development. Examine genitalia as any other body part; may leave to end.

some early preschoolers may require more of the "security measures" employed with younger children, such as continued parent–child contact, and less of the preparatory measures used with preschoolers, such as playing with the equipment before and during the actual examination (Figure 33.2).

Physical Examination

Although the variations in the general approaches are numerous, some common ones are elaborated on here. For example, the suggested sequence may change considerably when the child is in pain or when obvious physical defects are present. In either situation, the affected area needs to be examined last, to minimize distress early in the examination and to focus on healthy, functioning body parts.

Growth Measurements. Measurement of physical growth in children is a key element in evaluating their health status. Physical growth parameters include weight, height (length), skin fold thickness, arm circumference, and head circumference. Values for these growth

Fig. 33.1 Using paper-doll technique to prepare child for physical examination.

Fig. 33.2 Preparing children for physical examination.

parameters are plotted on percentile charts, and the child's measurements in percentiles are compared with those of the general population. See Nursing Skills on Evolve: Measuring Physical Growth.

Growth charts. The growth charts used in Canada were adapted in 2014 from the 2006 and 2007 World Health Organization (WHO) Growth Standards and Growth References (Dietitians of Canada et al., 2014b). The charts were adapted to provide health care providers with consistent practices in monitoring growth and assessing patterns of linear growth and weight gain to support healthy children. These new charts reflect the 0- to 19-years-of-age population with optimal health conditions. It also reflects an increase in the multiethnic international population and an improvement in the tool to identify children at risk for obesity. (See Additional Resources at the end of this chapter for a parent handout on using growth charts.)

Children whose growth may be questionable include the following:

- Children whose height and weight percentiles are widely disparate (e.g., height in the tenth percentile and weight in the ninetieth percentile, especially with above-average skin fold thickness)
- Children who fail to show the expected growth rates in height and weight, especially during the rapid growth periods of infancy and adolescence

Fig. 33.3 These children of identical age (8 years) are markedly different in size. The child on the left, is at the fifth percentile for height and weight. The child on the right is above the ninety-fifth percentile for height and weight. However, both children demonstrate normal growth patterns.

- Children who show a sudden increase (except during puberty) or decrease in a previously steady growth pattern
- Children who are short in the absence of short parents

Because growth is a continuous but uneven process, the most reliable evaluation lies in comparing growth measurements over time. It is important to remember that normal growth patterns vary among children of the same age (Figure 33.3).

Special groups. The WHO growth charts do not include premature infants or very low-birth-weight infants who weigh less than 1 500 g. These infants do not grow in the same manner as full-term infants. Once these preterm infants are discharged from the neonatal intensive care unit, the WHO charts can then be used for them. Measurements should be plotted with the corrected postnatal age for prematurity (40 weeks—gestational age in weeks) until the child is 24 to 36 months of age. As an alternative, Fenton's growth chart (Fenton & Kim, 2013) can be used for plotting growth from 22 gestational weeks to 10 weeks post-term (Dietitians of Canada, 2014b). Children with specific intellectual, developmental, genetic, or other conditions often have growth patterns that are different from those of healthy children (e.g., children with Down syndrome). Their growth can also be plotted on the WHO growth charts alone or in conjunction with specific growth curves that exist for some of these disorders (Dietitians of Canada, 2014a).

Length. The term *length* refers to measurements taken when children are supine (also referred to as *recumbent length*). Until children are 24 months old (or 36 months if using the chart for birth to 36 months), recumbent length is measured. Because of the normally flexed position during infancy, the body should be fully extended by (1) holding the head in midline, (2) grasping the knees together gently, and (3) gently pushing down on the knees until the legs are fully extended and flat against the table. If using a measuring board, the nurse should place the head firmly at the top of the board and the heels of the feet firmly against the footboard.

If such a measuring device is not available, length can be measured by placing the child on a paper-covered surface, marking the end points of the top of the head and the heels of the feet, and measuring between these two points (Figure 33.4). For accurate measurement, the nurse should hold the writing utensil at a right angle to the table when marking the cephalic point; the feet are positioned with the toes pointing directly to the ceiling when marking the heel point. Regardless of the method used, someone needs to assist the nurse in holding the child's head in midline while extending the legs and taking the measurements.

Height. The term *height* (or *stature*) refers to the measurement taken when children are standing upright. Wall charts and flip-up horizontal bars (floppy-arm devices) mounted to weighing scales should not be used to measure the height of children (Foote et al., 2011). These devices are not steady and do not maintain a right angle to the vertical ruler, preventing an accurate and reliable height. Height is measured by having the child, with shoes removed, stand as tall and straight as possible, with the head in midline and the line of vision parallel to the ceiling and floor (Frankfort plane). The child's back needs to be against the wall or other vertical flat surface, with the heels, buttocks, and back of the shoulders touching the wall and the medial malleoli touching, if possible (Figure 33.5). The nurse should check for and correct bending of the knees, slumping of the shoulders, or raising of the heels.

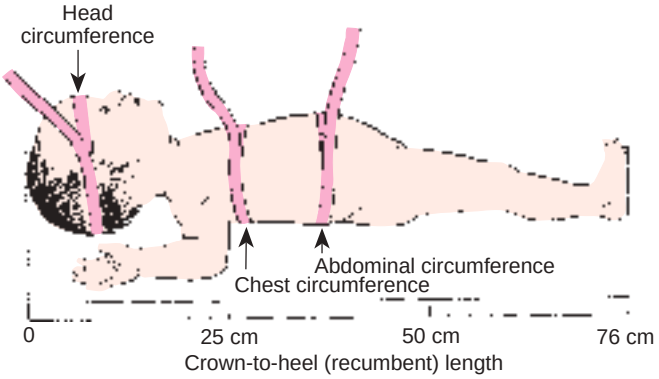

Fig. 33.4 Measurement of head, chest, and abdominal circumference and crown-to-heel (recumbent) length.

For the most accurate measurement, a wall-mounted unit (stadiometer; see Figure 33.5) can be used. The movable measuring rod of platform scales is accurate only if it maintains a parallel position to the floor and rests securely on the topmost part of the head. To improvise a flat surface for measuring length, the nurse should attach a paper or metal tape or yardstick to the wall, position the child adjacent to the tape, and place a three-dimensional object, such as a thick book or box, on top of the head. The side of the object should rest firmly against the wall to form a right angle. Length or stature should be measured to the nearest 1 mm.

Weight. Weight is measured with an electronic or appropriately sized beam balance scale, which measures weight to the nearest 10 g for infants and 100 g for children. With a balance scale, before the child is weighed, the nurse needs to zero the scale prior to use. When precise measurements are needed, two nurses should take the weight independently; if there is a discrepancy, a third reading should be taken.

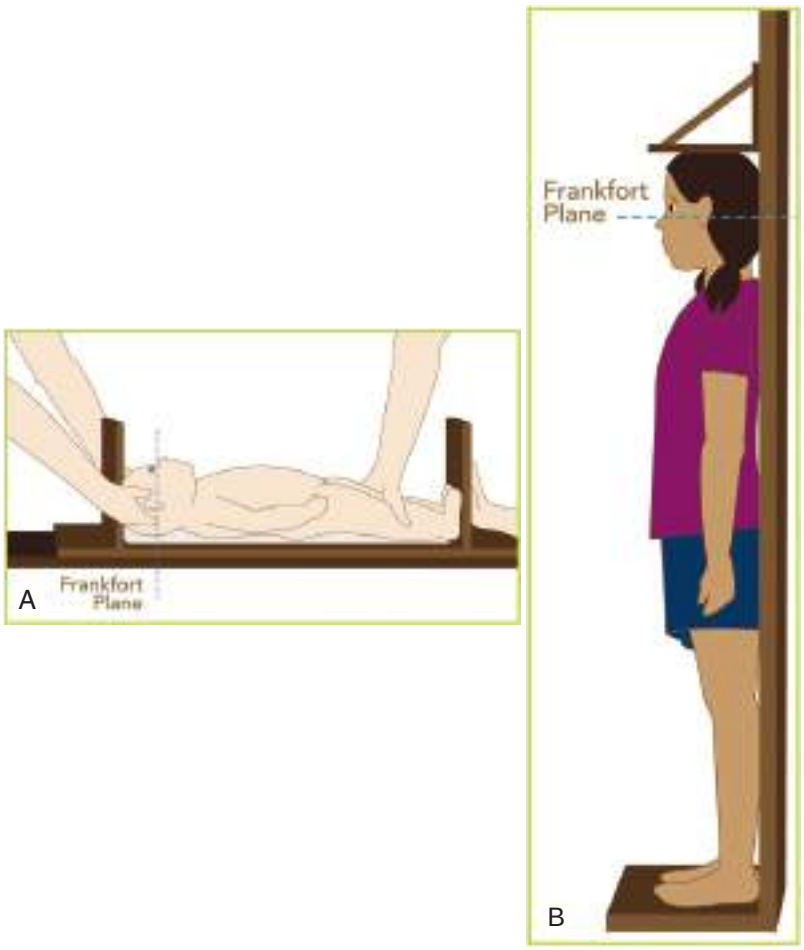

Fig. 33.5 Measurement of height. **A,** Infant. **B,** Child. (Courtesy of Jan M. Foote.)

Fig. 33.6 **A:** Infant on scale. **B:** Toddler on scale. Note presence of nurse to prevent falls. (**B,** Courtesy Paul Vincent Kuntz.)

Measurements should be taken in a comfortably warm room. When the birth–to–2-year or birth–to–36-month growth charts are used, children should be weighed nude. Older children are usually weighed while wearing their underpants or a light gown. However, the privacy of all children should always be respected. If the child must be weighed wearing some article of clothing or some type of special device, such as a prosthesis or an armboard for an intravenous device, the nurse needs to note this when recording the weight. Children who are measured for recumbent length are usually weighed on an infant platform scale and placed in a lying or sitting position. When weighing an infant, the nurse should place a hand lightly above the infant's body to prevent the child from accidentally falling off the scale (Figure 33.6, *A*). When weighing a toddler, the nurse should stand close to the child, ready to prevent a fall (see Figure 33.6, *B*). For maximum infection control, the scale should be covered with a clean sheet of paper and cleaned between each child's measurement.

Skin fold thickness and arm circumference. Measures of relative weight and stature cannot distinguish between adipose (fat) tissue and muscle. One convenient measure of body fat is skin fold thickness, which is increasingly recommended as a routine measurement. Skin fold thickness is measured with special calipers, such as the Lange calipers. The most common sites for measuring skin fold thickness are the triceps (most practical for routine clinical use), subscapula, suprailiac, abdomen, and upper thigh. For greatest reliability, the nurse needs to follow the exact procedure for measurement and record the average of at least two measurements of one site.

Arm circumference is an indirect measure of muscle mass. Measurement of arm circumference follows the same procedure as that for skin fold thickness, except the midpoint is measured with a paper or steel tape. The tape is placed vertically, along the posterior aspect of the upper arm from the acromial process to the olecranon process; half the measured length is the midpoint.

Head circumference. Head circumference in children is measured up to 36 months of age and in any child whose head size is questionable. The head is measured at its greatest circumference, usually slightly above the eyebrows and pinna of the ears and around the occipital prominence at the back of the skull (see Figure 33.4). Because head shape can affect the location of the maximum circumference, more than one measurement at points above the eyebrows may be needed to obtain the most accurate measure. A paper or metal tape should be used, since a cloth tape can stretch and give a falsely small measurement. For greatest accuracy, devices with tenths of a centimetre are best, since the percentile charts have only 0.5-cm increments.

The nurse can plot the head size on the appropriate growth chart under head circumference. Generally, head and chest circumferences are equal at about 1 to 2 years of age. During childhood, chest circumference exceeds head size by about 5 to 7 cm (for newborns, see Table 26.2).

Vital Signs

Physiological measurements, key elements in evaluating physical status of vital functions, include temperature, pulse, respiration, and blood pressure (BP). Each physiological recording should be compared with normal values for that age group. In addition, the values taken on preceding health visits need to be compared with present recordings. For example, a falsely elevated BP reading may not indicate hypertension if previous recent readings have been within normal limits. The isolated recording may indicate some stressful event in the child's life.

As in most procedures carried out with children, older children and adolescents are treated much the same as adults. However, special consideration must be given to preschool children (see Atraumatic Care box: Reducing Young Children's Fears). For best results in taking vital signs of infants, the nurse should count respirations first (before the infant is disturbed), take the pulse next, and measure temperature last. If vital signs cannot be taken without disturbing the child, the nurse should record the child's behaviour, such as crying, along with the measurement.

ATRAUMATIC CARE

Reducing Young Children's Fears

Young children, especially preschoolers, fear intrusive procedures because of their poorly defined body boundaries. Therefore, avoid invasive procedures, such as measuring rectal temperature, whenever possible. Also, avoid using the word "take" when measuring vital signs, since young children interpret words literally and may think that their temperature or other function will be taken away. Instead, say, "I want to know how warm you are."

Temperature. *Temperature* is the measure of heat content within an individual's body. The core temperature most closely reflects the temperature of the blood flow through the carotid arteries to the hypothalamus. Core temperature is relatively constant despite wide fluctuations in the external environment. When a child's temperature is altered, receptors in the skin, spinal cord, and brain respond in an attempt to achieve *normothermia*, a normal temperature state. In pediatrics, there is a lack of consensus on what temperature constitutes normothermia for every child. For rectal temperatures in children, 36.6° to 38°C is an acceptable range, where heat loss and heat production are balanced (CPS, 2020). For newborns, a core body temperature between 36.5° and 37.5°C is a desirable range (see Chapter 26). In the newborn,

temperature measurements are obtained for monitoring adequacy of thermoregulation, not fever; therefore, temperature measurements in each infant should be carefully considered in the context of the purpose and the environment. See Appendix C for normal temperature values.

The nurse can measure temperature in healthy children at several body sites via oral, rectal, axillary, tympanic membrane, temporal artery, or skin route (Box 33.6). See Nursing Skills on Evolve: Measuring Body Temperature. For the ill child, other sites for temperature measurement have been investigated. The pulmonary artery is the closest to the hypothalamus and best reflects the core temperature (Batra et al., 2012). Other sites used are the distal esophagus, urinary bladder, and nasopharynx (Box 33.7). All of these methods are invasive and difficult to use in clinical practice. One of the most important influences on the accuracy of temperature is improper temperature-taking technique. Detailed discussion of temperature-taking methods and visual examples of proper techniques are given in Table 33.4.

BOX 33.6 Recommended Temperature Screening Routes in Infants and Children

Birth to 2 Years

Axillary
Rectal—if definitive temperature reading is needed

2 to 5 Years

Oral—when a child is able to hold a thermometer under the tongue
Axillary
Tympanic or temporal artery—if in hospital for screening
Rectal—if definitive temperature reading is needed

Over 5 Years

Oral—definitive
Axillary, tympanic or temporal artery—if in hospital for screening

Adapted from Canadian Paediatric Society. (2020). *Fever and temperature taking.* https://www.caringforkids.cps.ca/handouts/health-conditions-and-treatments/fever_and_temperature_taking.

The following sites are used for temperature measurement in children. The site that is used depends on the age of the child as well as the condition of the child.

- Rectal temperature is the clinical gold standard for the precise diagnosis of fever in infants and children, compared with other methods (Fortuna et al., 2010; Holzhauer et al., 2009). However, this procedure is more invasive and is not recommended in young children because of the risk for rectal perforation. Children with recent rectal surgery, diarrhea, or anorectal lesions or who are receiving chemotherapy (cancer treatment usually affects the mucosa and causes neutropenia) should not undergo rectal thermometry.
- Oral temperature (OT): OT indicates rapid changes in core body temperature, but accuracy may be an issue compared with the rectal site (Batra et al., 2012). OTs are considered the standard for temperature measurement, but they are contraindicated in children who have an altered level of consciousness, are receiving oxygen, are mouth breathing, are experiencing mucositis, had recent oral surgery or trauma, or are younger than 5 years of age. Limitations of OT include the effects of ambient room temperature and recent oral intake.
- Axillary temperature: This method is recommended for initial assessment of newborns, although it is not as accurate as a rectal or oral temperature. In newborns with fever, the axillary temperature should not be used interchangeably with rectal measurement (Hissink Muller et al., 2008). It can be used as a screening tool for fever in young infants (Batra et al., 2012).
- Ear (aural) temperature: This is not a precise measurement of core body temperature and should not be used for a diagnosis of fever.
- Temporal artery temperature (TAT): TAT is as not predictable for fever in young children but can be used as a screening tool for detecting fever less than 38°C (100.4°F) in children 3 months to 4 years of age (Fortuna et al., 2010). A study by Batra and Goyal (2013) found that TAT correlated better with rectal temperature than axillary and tympanic measures in a group of 50 afebrile children between 2 and 12 years of age.

Based on this information, there is no single site used for temperature assessment that provides unequivocal estimates of core body temperature. When an accurate method of obtaining a correct reflection of core temperature is needed, the rectal temperature is recommended in

BOX 33.7 Alternative Temperature Measurement Sites for the Ill Child

Skin

Probe is placed on the skin to determine heat output in response to changes in the patient's skin temperature.
Skin temperature sensors are most often used for newborns placed in radiant heat warmers or isolettes (using servocontrol feature of the apparatus). In turn, the heater unit warms to a set point to maintain the newborn's temperature within a specified range.

Urinary Bladder

A thermistor or thermocouple is placed within the in-dwelling bladder catheter. The catheter tip immersed in the bladder provides a continuous temperature readout on the bedside monitor.
This is not a true measure of core temperature but responds better than rectal and skin temperatures to core body changes.
Because of thermistor sizes, this method is unusable in newborns and small infants.

Pulmonary Artery

A catheter is placed into the heart to obtain a reading in the pulmonary artery.
It is used in critical care settings or operating rooms only in patients requiring aggressive monitoring.
The catheter is not available in sizes for newborns or small infants.

Esophageal Site

Probe is inserted into the lower third of the esophagus at the level of the heart.
This is used in critical care settings or operating rooms.
Several companies have esophageal stethoscopes with temperature probe monitors that show a continuous temperature reading for patients in the operating room.

Nasopharyngeal Site

Probe is inserted into the nasopharynx, posterior to the soft palate, and provides an estimate of hypothalamic temperature.
This is used in critical care settings or operating rooms.

Data from Kumar, P. R., Nisarga, R., & Gowda, B. (2004). Temperature monitoring in newborns using ThermoSpot. *Indian Journal of Pediatrics, 71*(9), 795–796; Martin, S. A., & Kline, A. M. (2004). Can there be a standard for temperature measurement in the pediatric intensive care unit? *AACN Clinical Issues, 15*(2), 254–266; Maxton, F. J., Justin, L., & Gilles, D. (2004). Estimating core temperature in infants and children after cardiac surgery: A comparison of six methods. *Journal of Advanced Nursing, 45*(2), 214–222.

TABLE 33.4 Temperature Measurement Locations for Infants and Children

Temperature Site

Oral

Place tip under tongue in right or left posterior sublingual pocket, not in front of tongue. Have child keep the mouth closed without biting on thermometer. Oral method is used only when a child is capable of holding onto a thermometer.

Pacifier thermometers measure intraoral or supralingual temperature and are available but lack support in the literature.

Several factors affect mouth temperature: eating and mastication, hot or cold beverages, open-mouth breathing, and ambient temperature.

Axillary

Place tip under the arm in centre of axilla and keep close to the skin, not clothing. Hold child's arm firmly against side. Temperature may be affected by poor peripheral perfusion (results in lower value), clothing or swaddling, use of radiant warmer, or amount of brown fat in cold-stressed newborns (results in higher value).

The advantage is that use of this site avoids an intrusive procedure and eliminates the risk of rectal perforation.

Ear Based (Aural)

Insert small infrared probe deeply into canal to allow sensor to obtain measurement. The size of probe (most are 8 mm) may influence accuracy of the result. In young children this may be a concern because of the small diameter of the canal. For proper placement of the ear, it is debated as to whether the pinna should be pulled in a manner similar to that used during otoscopy (see Figure 33.19). Aural thermometers are not recommended for children under age 2 years because of small diameter of ear canal, which makes the temperature more inaccurate.

Continued

TABLE 33.4 Temperature Measurement Locations for Infants and Children—cont'd

Rectal

Place well-lubricated tip at maximum 2.5 cm into rectum for children and 1.5 cm for infants; securely hold thermometer close to anus.
Child may be placed in side-lying, supine, or prone position (i.e., supine with knees flexed toward abdomen); cover the penis, since the procedure may stimulate urination. A small child may be placed prone across the parent's lap.

Temporal Artery

An infrared sensor probe scans across the forehead, capturing heat from arterial blood flow. The temporal artery is the only artery close enough to the skin's surface to provide access for accurate temperature measurement.
These probes have been shown to be more accurate than tympanic thermometry and are better tolerated than rectal thermometry.

Oral, axillary, rectal, and temporal artery images courtesy Paul Vincent Kuntz.
Data from Leduc, D., Woods, S., & Canadian Paediatric Society, Community Paediatrics Committee. (2000). *Temperature measurement in paediatrics*. https://academic.oup.com/pch/article/5/5/273/2655772.

younger children and the oral route in children older than 5 years, although the axillary route is recommended as the next preferred site (CPS, 2020). Temperature depends on the time of day, age, and physical activity. In general, *fever* is defined as a temperature of 38°C or greater (100.4°F) rectally (see Appendix C).

The most frequently used temperature measurement devices in infant and children include the following:

Electronic intermittent thermometers—Measure the patient's temperature at oral, rectal, and axillary sites and are used as primary diagnostic indicators

Infrared thermometers—Measure the patient's temperature by collecting emitted thermal radiation from a particular site (e.g., tympanic membrane)

Electronic continuous thermometers—Measure the patient's temperature during the administration of general anaesthesia, treatment of hypothermia or hyperthermia, and other situations that require continuous monitoring

! NURSING ALERT

The belief that core temperature can be estimated by adding 1°C to the temperature taken in the axilla is incorrect. Do not add a degree to the finding obtained by taking a temperature by the axillary route.

Pulse. A satisfactory pulse can be taken radially in children older than 2 years of age. However, in infants and young children, the apical impulse (heard through a stethoscope held to the chest at the apex of the heart) is more reliable (see Figure 33.28 for location of apical pulse). The pulse is counted for 1 full minute in infants and young children because of possible irregularities in rhythm. However, when frequent apical rates are needed, shorter counting times (e.g., 15- or 30-second intervals) can be used. For greater accuracy, the apical rate should be measured while the child is asleep if possible and the child's behaviour recorded along with the rate. Pulses may be graded according to the criteria in Table 33.5. Radial and femoral pulses need to be compared at least once during infancy to detect the presence of circulatory

TABLE 33.5 Grading of Pulses

Grade	Description
0	Not palpable
+1	Difficult to palpate, thready, weak, easily obliterated with pressure
+2	Difficult to palpate, may be obliterated with pressure
+3	Easy to palpate, not easily obliterated with pressure (normal)
+4	Strong, bounding, not obliterated with pressure

impairment, such as coarctation of the aorta. (See Appendix C for normal rates for pediatric age groups.)

Respiration. The respiratory rate in children is measured in the same manner as for the adult patient. However, in newborns and infants, respirations are **auscultated** at the same time as observing the abdomen for movement, since respirations are primarily diaphragmatic. Because the movements are irregular, they should be counted for 1 full minute for accuracy (see also Appendix C).

Blood Pressure. BP measurement by noninvasive methods is part of a routine vital sign determination. Routine regular BP screening in children over 3 years of age is recommended (Nerenberg et al., 2018). BP may be measured with a mercury sphygmomanometer, aneroid sphygmomanometer, or oscillometric device.

Oscillometric devices measure mean arterial BP and then calculate systolic and diastolic values. The algorithms used by companies are proprietary and differ from company to company and device to device. These devices can yield results that vary widely when one is compared with another, and they do not always closely match BP values obtained by auscultation. An elevated BP reading obtained with an automated or oscillometric device should be repeated using auscultation. Abnormal oscillometric values should be confirmed with auscultation (Nerenberg et al., 2018). Oscillometric devices may serve as a suitable alternative to auscultation for initial BP screening in the pediatric population (Duncombe et al., 2017). See Appendix C for pediatric parameters of blood pressure values.

Selection of cuff. No matter what type of noninvasive technique is used, the most important factor in accurately measuring BP is the use of an appropriately sized cuff (cuff size refers only to the inner inflatable bladder, not the cloth covering). A technique to establish an appropriate cuff size is to choose a cuff having a bladder width that is approximately 40% of the arm circumference midway between the olecranon and the acromion. This will usually be a cuff bladder that covers 80 to 100% of the circumference of the arm (Nerenberg et al., 2018) (Figure 33.7). Cuffs that are either too narrow or too wide affect the accuracy of BP measurements. If the cuff size is too small, the reading on the device is falsely high. If the cuff size is too large, the reading is falsely low (Table 33.6).

When using a site other than the arm, BP measurements using noninvasive techniques may differ. Generally, systolic BP in the lower extremities (thigh or calf) is greater than pressure in the upper extremities, and systolic BP in the calf is higher than that in the thigh (Schell et al., 2011) (Figure 33.8).

! NURSING ALERT

When taking BP, use an appropriately sized cuff. When the correct size is not available, use an oversized cuff rather than an undersized one, or use another site that more appropriately fits the cuff size. Do not choose a cuff based on the name of the cuff (e.g., an "infant" cuff may be too small for some infants). When taking an extremity BP, ensure that the cuff is specific for taking extremity BP measurements.

! NURSING ALERT

Comparing BP in the upper and lower extremities will help detect abnormalities, such as coarctation of the aorta, in which the lower extremity pressure is less than the upper extremity pressure.

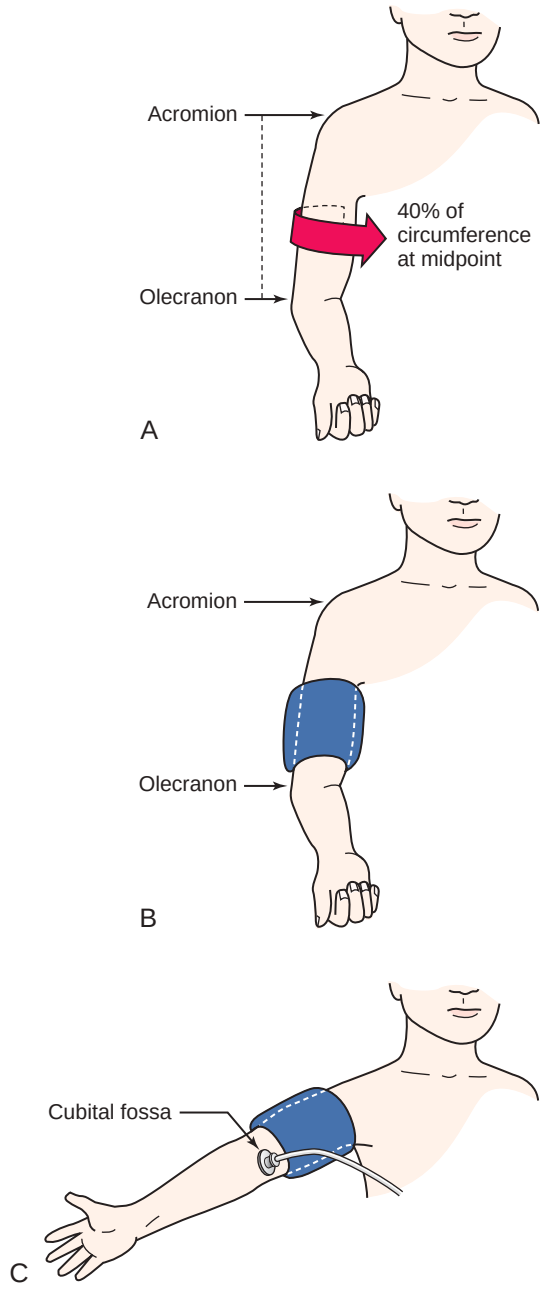

Fig. 33.7 Determination of proper cuff size. **A:** Cuff bladder width should be approximately 40% of circumference of arm measured at a point midway between olecranon and acromion. **B:** Cuff bladder length should cover 80 to 100% of circumference of arm. **C:** Blood pressure should be measured with cubital fossa at heart level. The arm should be supported. The stethoscope bell is placed over brachial artery pulse, proximal and medial to cubital fossa and below the bottom edge of the cuff. (From National Institutes of Health, National Heart, Lung, and Blood Institute. [1996, September]. *Update on the Task Force Report [1987] on high blood pressure in children and adolescents: A working group report from the National High Blood Pressure Education Program* [NIH Pub No 96-3790]. Author.)

Measurement and interpretation. Measuring and interpreting BP in infants and children requires additional attention to correct procedure because (1) limb sizes vary and cuff selection must accommodate the circumference; (2) excessive pressure on the antecubital fossa affects the Korotkoff sounds; (3) children easily become anxious,

TABLE 33.6 Recommended Dimensions for Blood Pressure Cuff Bladders

Age Range	Width (cm)	Length (cm)	Maximum Arm Circumference (cm)*
Newborn	4	8	10
Infant	6	12	15
Child	9	18	22
Small adult	10	24	26
Adult	13	30	34
Large adult	16	38	44
Thigh	20	42	52

*Calculated so that largest arm would still allow bladder to encircle arm by at least 80%.

which can elevate BP; and (4) BP values change with age and growth. The right arm is the preferred location to assess BP in children (Nerenberg et al., 2018). In children and adolescents, the normal range of BP is determined by body size and age. BP standards that are based on gender, age, and height provide a more precise classification of BP according to body size. This approach avoids misclassifying children who are very tall or very short. The revised BP tables include the 50th, 90th, 95th, and 99th percentiles (with standard deviations) by gender, age, and height (see Additional Resources and Appendix C). See Guidelines box: Diagnosing Hypertension in Children.

GUIDELINES

Diagnosing Hypertension in Children

- Using office BP measurements, children can be diagnosed as hypertensive if the systolic blood pressure (SBP) or diastolic blood pressure (DBP) is greater than or equal to the 95th percentile for age, sex, and height, measured on at least three separate occasions.
- If the BP is greater than or equal to the 95th percentile, BP should be staged:
  - Stage 1 is defined by BP between the 95th percentile and 99th percentile plus 5 mm Hg.
  - Stage 2 is defined by BP greater than the 99th percentile plus 5 mm Hg.
- If BP is stage 1, BP measurements should be repeated on two more occasions within 1 month; if hypertension is confirmed, evaluation should be initiated within 1 month.
- If BP is stage 2, prompt referral should be made for evaluation and therapy.
- All children with suspected or confirmed hypertension should undergo a hypertension-focused history and physical evaluation.

BP, Blood pressure.

From Nerenberg, K. A., Zarnke, K., Leung, A., et al. (2018). Hypertension Canada's 2018 guidelines for diagnosis, risk assessment, prevention, and treatment of hypertension in adults and children. *Canadian Journal of Cardiology, 34*(5), 506–525. https://doi.org/10.1016/j.cjca.2018.02.022.

Orthostatic hypotension. Orthostatic hypotension (OH), also called *postural hypotension* or *orthostatic intolerance*, is often manifested as syncope (fainting), vertigo (dizziness), or lightheadedness and is caused by decreased blood flow to the brain (cerebral hypoperfusion). Normally, blood flow to the brain is maintained at a constant level by a number of compensating mechanisms that regulate systemic BP. When one assumes a sitting or standing position from a supine or recumbent position, peripheral capillary vasoconstriction occurs, and blood that was pooling in the lower vasculature is returned to the heart for redistribution to the head and remainder of the body. When this mechanism fails or is slow to respond, the person may experience vertigo or syncope. One of the most common causes of OH is hypovolemia, which may be induced by medications such as diuretics, vasodilators, and prolonged immobility or bed rest. Other causes of OH include dehydration, diarrhea, emesis, fluid loss from sweating and exertion, alcohol intake, dysrhythmias, diabetes mellitus, sepsis, and hemorrhage.

BP measurements taken with the child first supine then standing (at least 2 minutes in each position) may demonstrate variability and assist in the diagnosis of OH. The child with a sustained drop in systolic pressure of more than 20 mm Hg or in diastolic pressure of more than 10 mm Hg after standing for 2 minutes without an increase in heart rate of more than 15 beats/min most likely has an autonomic deficit. Non-neurogenic causes of OH have a compensatory increase in pulse of more than 15 beats/min as well as a drop in BP, as noted previously. For the child or adolescent who is seen with vertigo, lightheadedness, nausea, syncope, diaphoresis, and pallor, it is important to monitor BP and heart rate to determine the original cause. BP is an important diagnostic measurement in children and adolescents and must be a part of the routine monitoring of vital signs.

! NURSING ALERT

Published norms for BP are valid only if the same method of measurement (auscultation and cuff size determination) is used in clinical practice.

General Appearance

The child's general appearance is a cumulative, subjective impression of the child's physical appearance, state of nutrition, behaviour, personality, interactions with parents and nurse (also siblings, if present), posture, development, and speech. Although general appearance is recorded at the beginning of the physical examination, it encompasses all the observations of the child during the interview and physical assessment.

The nurse should note the facies (the child's facial expression and appearance). For example, the facies may give clues to children who are in pain; have difficulty breathing; feel frightened, discontented, or unhappy; are emotionally delayed; or are acutely ill.

The posture, position, and types of body movement should also be observed. The child with hearing or vision impairment may characteristically tilt the head in an awkward position to hear or see better. The child in pain may favour a body part. The child with low self-esteem or

a feeling of rejection may assume a slumped, careless, and apathetic pose. Likewise, a child with confidence, a feeling of self-worth, and a sense of security usually demonstrates a tall, straight, well-balanced posture. While observing such body language, the nurse should not interpret too freely but rather record objectively.

The child's hygiene is noted in terms of cleanliness; unusual body odour; the condition of the hair, neck, nails, teeth, and feet; and the condition of the clothing. Such observations are excellent clues to possible instances of neglect, inadequate financial resources for childcare, housing difficulties (e.g., no running water), or lack of knowledge concerning children's needs.

Behaviour includes the child's personality, activity level, reaction to stress, requests, frustration, interactions with others (primarily the parent and nurse), degree of alertness, and response to stimuli. Some questions the nurse can keep in mind that serve as reminders for observing behaviour include the following:

- What is the child's overall personality?
- Does the child have a long attention span, or are they easily distracted?
- Can the child follow two or three commands in succession without the need for repetition?
- What is the child's response to delayed gratification or frustration?
- Does the child use eye contact during conversation?
- What is the child's reaction to the nurse and family members?
- Is the child quick or slow to grasp explanations?

Skin

Skin is assessed for colour, texture, temperature, moisture, turgor, lesions, acne, and rashes. Examination of the skin and its accessory organs primarily involves inspection and palpation. Touch allows the nurse to assess the texture, turgor, and temperature of the skin. Several variations in skin colour can occur, some of which warrant further investigation. The types of colour change and their appearance in children with light or dark skin are summarized in Table 33.7.

Normally the skin texture of young children is smooth, slightly dry, and not oily or clammy. Skin temperature is evaluated by symmetrically feeling each part of the body and comparing upper areas with lower ones. Any difference in temperature should be noted.

Tissue turgor, or elasticity in the skin, can be determined by grasping the skin on the abdomen between the thumb and index finger, pulling it taut, and quickly releasing it. Elastic tissue immediately assumes its normal position without residual marks or creases. In children with poor skin turgor, the skin remains suspended or tented for a few seconds before slowly falling back on the abdomen. Skin turgor is one of the best estimates of adequate hydration and nutrition.

Accessory Structures. Inspection of the accessory structures of the skin may be performed while the skin is being examined or when the scalp and extremities are being assessed. The hair is inspected for colour, texture, quality, distribution, and elasticity. Children's scalp hair is usually lustrous, silky, strong, and elastic. Genetic factors affect the appearance of hair. Hair that is stringy, dull, brittle, dry, friable, and depigmented may suggest poor nutrition. The nurse should record any bald or thinning spots. Loss of hair in infants may indicate lying in the same position and may be a clue for counselling parents concerning the child's stimulation needs.

The hair and scalp are inspected for general cleanliness. Some people condition their hair with oils or lubricants that, if not thoroughly washed from the scalp, can clog the sebaceous glands, causing scalp infections. The area should also be examined for lesions; scaliness; evidence of infestation, such as lice or ticks; and signs of trauma, such as ecchymosis, masses, or scars.

In children who are approaching puberty, the nurse should look for growth of secondary hair as a sign of normally progressing pubertal changes. Precocious or delayed appearance of hair growth should be noted because, although not always suggestive of hormonal dysfunction, it may be of great concern to the early- or late-maturing adolescent.

TABLE 33.7 Differences in Colour Changes Based on Skin Colour

Description	Appearance in Light Skin	Appearance in Dark Skin
Cyanosis—Bluish tone through skin; reflects reduced (deoxygenated) hemoglobin	Bluish tinge, especially in palpebral conjunctiva (lower eyelid), nail beds, earlobes, lips, oral membranes, soles, and palms	Ashen grey lips and oral membranes
Pallor—Paleness; may be sign of anemia, chronic disease, edema, or shock	Loss of rosy glow in skin, especially face	Assess the palms, there is reduced darkness in the palmar creases; pale pink or white lower eyelid
		More yellowish brown colour in brown skin
Erythema—Redness; may be result of increased blood flow from climatic conditions, local inflammation, infection, skin irritation, allergy, or other dermatoses, or may be caused by increased numbers of red blood cells as compensatory response to chronic hypoxia	Redness easily seen anywhere on body	Much more difficult to assess; rely on palpation for warmth or edema; shiny, smooth appearance with burgundy undertone
Ecchymosis—Large, diffuse areas, usually black and blue, caused by hemorrhage of blood into skin; typically result of injuries	Purplish to yellow-green areas; may be seen anywhere on skin	Purple or dark-brown; more difficult to assess; compare both sides of body
Petechiae—Same as ecchymosis except for size: small, distinct, pinpoint hemorrhages $\leq$2 mm in size; can denote some type of blood disorder, such as leukemia	Purplish pinpoints most easily seen on buttocks, abdomen, and inner surfaces of arms or legs	Usually invisible except in oral mucosa, conjunctiva of eyelids, and conjunctiva covering eyeball
Jaundice—Yellow staining of skin usually caused by bile pigments	Yellow staining seen in sclerae of eyes, skin, fingernails, soles, palms, and oral mucosa	Most reliably assessed in sclerae, hard palate, palms, and soles; often very subtle yellow colour

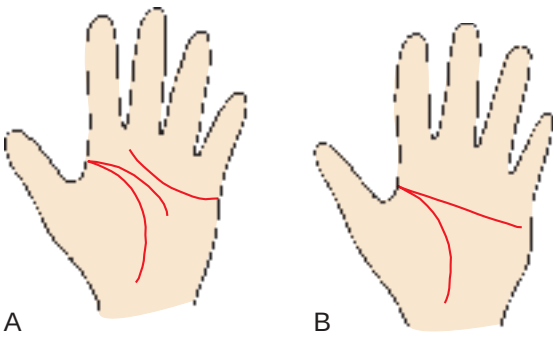

Fig. 33.9 Examples of flexion creases on palm. **A:** Normal. **B:** Transpalmar crease.

The nails are inspected for colour, shape, texture, and quality. Normally the nails are pink, convex, smooth, and hard but flexible (not brittle). The edges, which are usually white, should extend over the fingers. Dark-skinned individuals may have more deeply pigmented nail beds. Short, ragged nails are typical of habitual biting.

The palm normally shows three flexion creases (Figure 33.9, *A*). In some situations, such as Down syndrome, the two distal horizontal creases are fused to form a single horizontal crease (the single transverse palmar crease, or transpalmar crease) (see Figure 33.9, *B*). If grossly abnormal lines or folds are observed, the nurse should sketch a picture to describe them and refer the finding to a specialist for further investigation.

Lymph Nodes

Lymph nodes are usually assessed when the part of the body in which they are located is examined. The body's lymphatic drainage system is extensive; the usual sites for palpating accessible lymph nodes are shown in Figure 33.10.

Nodes are palpated using the distal portion of the fingers and gently but firmly pressing in a circular motion along the regions where nodes are normally present. During assessment of the nodes in the head and neck, the child's head is tilted upward slightly but without tensing the sternocleidomastoid or trapezius muscles. This position facilitates palpation of the submental, submandibular, tonsillar, and cervical nodes. The nurse should palpate the axillary nodes with the child's arms relaxed at the sides but slightly abducted. The inguinal nodes are assessed with the child in the supine position. The nurse needs to note size, mobility, temperature, and tenderness, as well as reports by the parents regarding any visible change of enlarged nodes. In children, small, nontender, movable nodes are usually normal. Tender, enlarged, warm lymph nodes generally indicate infection or inflammation close to their location. Such findings need to be reported for further investigation.

Head and Neck

The head is observed for general shape and symmetry. A flattening of one part of the head, such as the occiput, may indicate that the child continually lies in this position. Marked asymmetry is usually abnormal and may indicate premature closure of the sutures (craniosynostosis).

! NURSING ALERT

Significant head lag after 6 months of age strongly indicates cerebral injury and is referred for further evaluation.

The nurse should note head control in infants and head posture in older children. Most infants by 4 months of age should be able to hold the head erect and in midline when in a vertical position.

Range of motion is evaluated by asking the older child to look in each direction (to either side, up, and down) or by manually putting the younger child through each position. Limited range of motion may indicate wryneck, or torticollis, in which the child holds the head to one side with the chin pointing toward the opposite side as a result of injury to the sternocleidomastoid muscle.

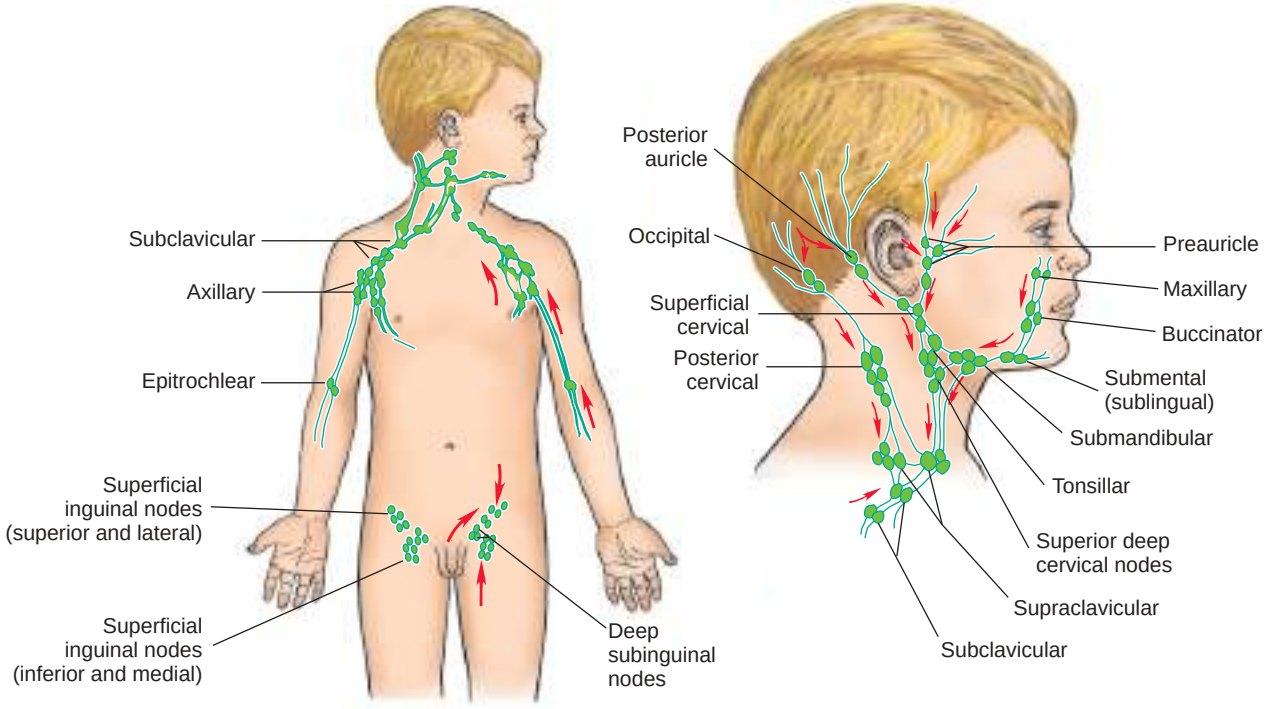

Fig. 33.10 Location of superficial lymph nodes. *Arrows* indicate directional flow of lymph.

! NURSING ALERT

Hyperextension of the head (opisthotonos) with pain on flexion is a serious indication of meningeal irritation and needs to be referred for immediate medical evaluation.

The skull is palpated for patent sutures, fontanels, fractures, and swellings. Normally the posterior fontanel closes by the second month of life, and the anterior fontanel fuses between 12 and 18 months of age. When lightly palpated, the fontanels normally feel firm and very slightly curved inward to the touch. The fontanels may look like they are bulging when an infant is crying or vomiting. However, they should return to normal when the infant is in a calm, head-up position. A tense or bulging fontanel occurs when fluid builds up in the brain or the brain swells, causing increased pressure inside the skull, and a depressed fontanel can indicate dehydration. Early or late closure should be noted, since either may be a sign of a pathological condition.

While examining the head, the nurse should observe the face for symmetry, movement, and general appearance. The nurse should ask the child to "make a face," to assess symmetrical movement and disclose any degree of paralysis. Any unusual facial proportion, such as an unusually high or low forehead, wide- or close-set eyes, or a small, receding chin needs to be noted.

In addition to assessment of the head and neck for movement, the neck is inspected for size and its associated structures palpated. The neck is normally short, with skin folds between the head and shoulders during infancy; however, it lengthens during the next 3 to 4 years.

! NURSING ALERT

If any masses are detected in the neck, report them for further investigation. Large masses can block the airway.

Eyes

Inspection of External Structures. The lids should be inspected for proper placement on the eye. When the eye is open, the upper lid should fall near the upper iris (Figure 33.11). When the eyes are closed, the lids should completely cover the cornea and sclera.

The general slant of the palpebral fissures or lids is determined by drawing an imaginary line through the two points of the medial canthus and across the outer orbit of the eyes and aligning each eye on the line. Usually the palpebral fissures lie horizontally. However, in Asians the slant is normally upward.

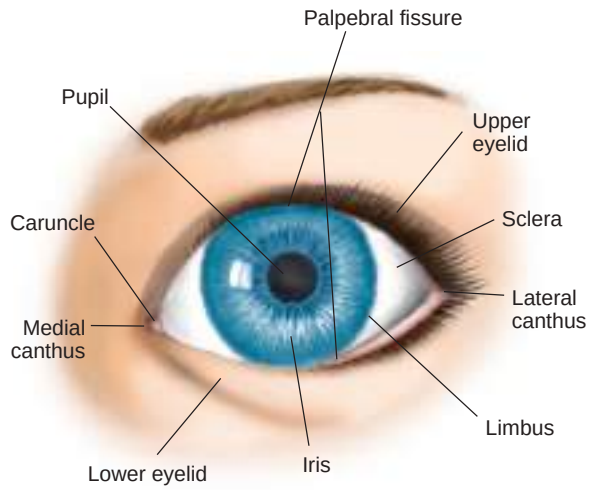

Fig. 33.11 External structures of the eye.

The inside lining of the lids, the *palpebral conjunctiva*, also needs to be inspected. To examine the lower conjunctival sac, the lid is pulled down while the patient looks up. To evert the upper lid, the nurse should hold the upper lashes and gently pull *down* and *forward* as the child looks down. Normally the conjunctiva appears pink and glossy. Vertical yellow striations along the edge are the *meibomian*, or *sebaceous*, glands near the hair follicle. Located in the inner or medial canthus and situated on the inner edge of the upper and lower lids is a tiny opening, the *lacrimal punctum*. Any excessive tearing, discharge, or inflammation of the lacrimal apparatus should be noted.

The *bulbar conjunctiva*, which covers the eye up to the limbus, or junction of the cornea and sclera, should be transparent. The *sclera*, or white covering of the eyeball, should be clear. Tiny black marks in the sclera of heavily pigmented individuals are normal.

The *cornea*, or covering of the iris and pupil, should be clear and transparent. The nurse needs to record opacities because they can be signs of scarring or ulceration, which can interfere with vision. The best way to test for opacities is to illuminate the eyeball by shining a light at an angle (obliquely) toward the cornea.

The pupils are compared for size, shape, and movement. They should be round, clear, and equal. Their reaction to light is tested by quickly shining a light toward the eye and removing it. As the light approaches, the pupils should constrict; as the light fades, the pupils should dilate. The pupil is tested for any response of accommodation by having the child look at a bright, shiny object at a distance and quickly moving the object toward the face. The pupils should constrict as the object is brought near the eye. Normal findings on examination of the pupils may be recorded as *PERRLA*, which stands for "*P*upils *E*qual, *R*ound, *R*eact to *L*ight, and *A*ccommodation."

The iris and pupil are inspected for colour, size, shape, and clarity. Permanent eye colour is usually established by 6 to 12 months of age. While inspecting the iris and pupil, the nurse should look for the lens. Normally the lens is not visible through the pupil.

Inspection of Internal Structures. The ophthalmoscope enables visualization of the interior of the eyeball with a system of lenses and a high-intensity light. The lenses permit clear visualization of eye structures at different distances from the nurse's eye and correct **visual acuity** differences in the examiner and child. Use of the ophthalmoscope requires practice to know which lens setting produces the clearest image.

The ophthalmic and otic heads are usually interchangeable on one "body" or handle, which encloses the power source, either disposable or rechargeable batteries. The nurse should practise changing the heads, which snap on and are secured with a quarter turn, and replacing the batteries and light bulbs. Nurses who are not directly involved in physical assessment are often responsible for ensuring that the equipment functions properly.

Preparing the child. The nurse can prepare the child for the ophthalmoscopic examination by showing the child the instrument, demonstrating the light source and how it shines in the eye, and explaining the reason for darkening the room. For infants and young children who do not respond to such explanations, it is best to use distraction to encourage them to keep their eyes open. Forcibly parting the lids results in a watery-eyed child who is even less likely able to comply with the examination. Usually, with some practice, the nurse can elicit a red reflex almost instantly while approaching the child and may also gain a momentary inspection of the blood vessels, macula, or optic disc.

Funduscopic examination. Figure 33.12 shows the structures of the back of the eyeball, or the *fundus*. The fundus is immediately apparent as the red reflex. The intensity of the colour increases in darkly pigmented individuals.

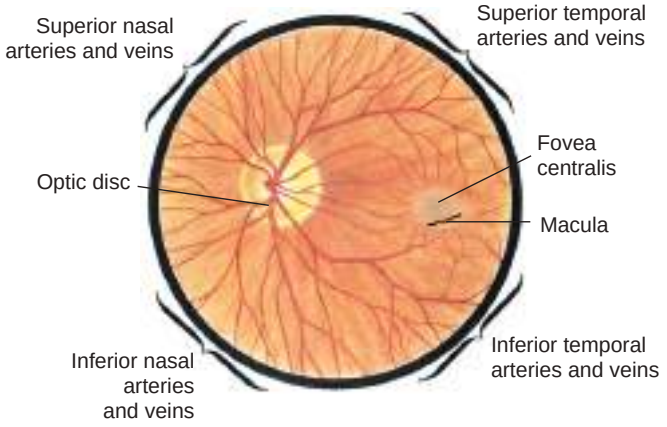

Fig. 33.12 Structures of the fundus. (From Ball, J. W., Dains, J. E., Flynn, J. A., et al. [2015]. *Seidel's guide to physical examination*, [8th ed.]. Mosby.)

! NURSING ALERT

A brilliant, uniform red reflex is an important sign because it rules out many serious defects of the cornea, aqueous chamber, lens, and vitreous chamber. Any dark shadows or opacities should be recorded because they indicate some abnormality in any of these structures.

As the ophthalmoscope is brought closer to the eye, the most conspicuous feature of the fundus is the optic disc, the area where the blood vessels and optic nerve fibres enter and exit from the eye. The colour of the disc is creamy pink; it is lighter in colour than the surrounding fundus. Normally it is round or vertically oval.

After the optic disc is located, the area is inspected for blood vessels. The central retinal artery and vein appear in the depths of the disc and emanate outward with visible branching. The veins are darker and about one fourth larger than the arteries. Normally the branches of the arteries and veins cross one another.

Other structures that may be seen are the *macula*, the area of the fundus with the greatest concentration of visual receptors, and, in the centre of the macula, a minute glistening spot of reflected light called the *fovea centralis*, which is the area of most perfect vision.

Vision Testing. Several tests are available for assessing vision. This discussion focuses on ocular alignment, visual acuity, peripheral vision, and colour vision. Vision screening should be performed at the earliest possible age and at regular intervals. Preschoolers should undergo at least one eye examination between the ages of 2 and 5 years. School-age children and adolescents should undergo an eye examination annually (Canadian Association of Optometrists, 2020). It has been estimated that about 25% of school-age children have vision challenges. Behavioural and physical signs of visual impairment are discussed in Chapter 42.

Ocular alignment. Normally, by the age of 3 to 4 months, children are able to fixate on one visual field with both eyes simultaneously (binocularity). One of the most important tests for binocularity is alignment of the eyes to detect nonbinocular vision, or strabismus. In **strabismus**, or cross-eye, one eye deviates from the point of fixation. If the misalignment is constant, the weak eye becomes "lazy," and the brain eventually suppresses the image produced by that eye. If strabismus is not detected and corrected by ages 4 to 6 years, blindness from disuse, known as **amblyopia**, may result.

Tests commonly used to detect misalignment are the corneal light reflex and the cover tests. To perform the corneal light reflex test, or Hirschberg test, the examiner shines a flashlight or the light of the ophthalmoscope directly into the patient's eyes from a distance of about 40.5 cm. If the eyes are *orthophoric*, or aligned, the light falls symmetrically within each pupil (Figure 33.13, *A*). If the light falls off centre in one eye, the eyes are misaligned. *Epicanthal folds*, excess folds of skin that extend from the roof of the nose to the inner termination of the eyebrow and that partially or completely overlap the inner canthus of the eye, may give a false impression of misalignment (*pseudostrabismus*) (see Figure 33.13, *B*). Epicanthal folds are often found in Asian children.

In the cover test, one eye is covered, and the movement of the *uncovered* eye is observed while the child looks at a near (33 cm) or distant (6 m) object. If the uncovered eye does not move, it is aligned. If the uncovered eye moves, a misalignment is present because, when the stronger eye is temporarily covered, the misaligned eye attempts to fixate on the object.

In the alternate cover test, occlusion shifts back and forth from one eye to the other, and movement of the eye that was covered is observed as soon as the occluder is removed while the child focuses on a point in front of them (Figure 33.14). If normal alignment is present, shifting the cover from one eye to the other will not cause the eye to move. If misalignment is present, eye movement will occur when the cover is moved. This test takes more practice to perform than the other cover test because the occluder must be moved back and forth quickly and accurately to see the eye move. Because deviations can occur at different ranges, it is important to perform the cover tests at both close and far distances.

Fig. 33.13 **A:** Corneal light reflex test demonstrating orthophoric eyes. **B:** Pseudostrabismus. Inner epicanthal folds cause eyes to appear misaligned; however, corneal light reflexes fall perfectly symmetrically.

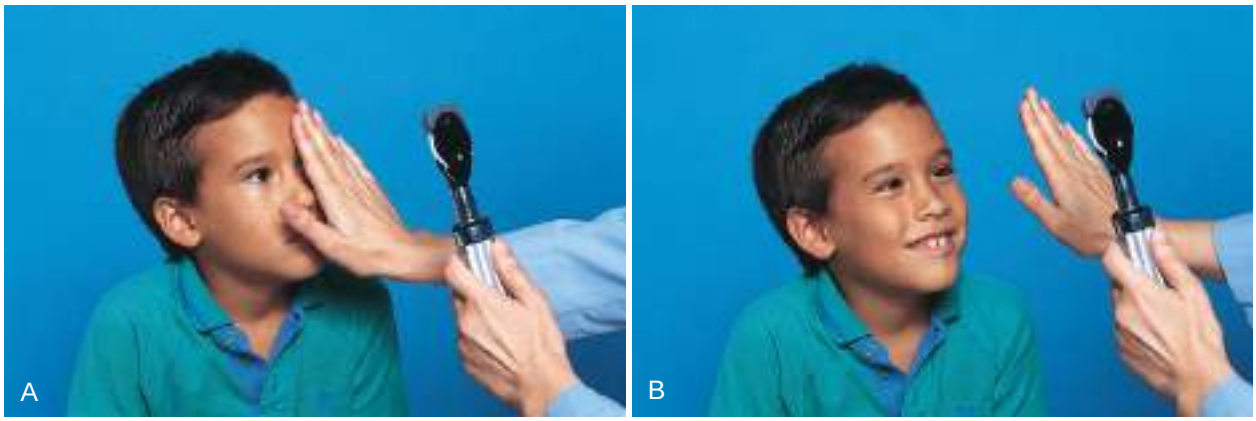

Fig. 33.14 Cover–Uncover test to detect amblyopia in patient with strabismus. **A:** Eye is occluded, and child is fixating on light source. **B:** If eye does not move when uncovered, eyes are aligned.

! NURSING ALERT

The cover test is usually easier to perform if the examiner uses their own hand rather than a card-type occluder (see Figure 33.14). Attractive occluders fashioned like an ice cream cone or happy-face lollipop cut from cardboard are also well received by young children.

Photoscreening is a technique used to screen for amblyopia, refractive disorders, and media opacities. Using a camera, the examiner obtains images of the pupillary reflexes (reflections) and red reflexes (Bruckner test). Photoscreening offers an effective way to screen infants, preverbal children, and those with developmental delays who are difficult to screen. The CPS (Amit & CPS Community Paediatrics Committee, 2009/2018) recommends photoscreening but states that is not practical for office-based primary care of children.

Visual acuity testing in children beyond infancy. Table 33.8 provides a list of visual screening tests for children and guidelines for referral. The CPS (Amit et al., 2009/2018) recommends that vision testing be done during periodic health review and when concerns are noted.

The most common test for measuring visual acuity is the Snellen letter chart, which consists of lines of letters of decreasing size (see Additional Resources at the end of this chapter). The child stands 3 metres from the chart with their heels at the 3-metre line. When screening for visual acuity in children, the right eye is tested first by covering the left eye. Children who wear glasses should be screened with them on. The child needs to keep both eyes open during the examination. The child begins moving down the chart until they fail to read the line. To pass each line, the child must correctly identify four of six symbols on the line. The procedure is repeated, with the child covering the right eye.

For children unable to read letters and numbers, the tumbling E or HOTV test is useful. The tumbling E test uses the capital letter *E* pointing in four different directions. The child is asked to point in the direction that the E is facing. The HOTV test consists of a wall chart composed of the letters *H, O, T*, and *V*. The child is given a board containing a large H, O, T, and V. The examiner points to a letter on the wall chart, and the child matches the correct letter on the board held in their hand. The tumbling E and HOTV tests are excellent tests for preschool-age children.

When a child is unable to perform the tumbling E or HOTV test, the LEA symbol or Allen card test may be used. The Allen card test uses common figures to test the child's vision. It is important to assess whether the child is able to identify the pictures before actual vision testing. The examiner walks backward slowly, flipping through the cards and presenting different pictures to the child. The examiner continues to move backward as the child correctly calls out the figures. When the child begins to miss the figure on the cards, the examiner moves forward to confirm that the child is able to identify the figures at that point. All Allen card figures are 20/30 in size. The farthest distance at which the child is able to accurately identify the pictures becomes the numerator, and 30 becomes the denominator. For example, if the child is able to identify the pictures accurately at 4.5 metres, the visual acuity is recorded as 15/30. This is equivalent to 20/40 or 10/20 visual acuity.

Visual acuity testing in infants and difficult-to-test children. In newborns, vision is tested mainly by checking for light perception by shining a light into the eyes and noting responses such as pupillary constriction, blinking, following the light to midline, increased alertness, or refusal to open the eyes after exposure to the light. Although the simple manoeuvre of checking light perception and eliciting the pupillary light reflex indicates that the anterior half of the visual apparatus is intact, it does not confirm that the newborn can see. In other words, this test does not assess whether the brain receives the visual message and interprets the signals.

Another test of visual acuity is the infant's ability to fix on and follow a target. Although any brightly coloured or patterned object can be used, the human face is excellent. The infant is held upright while the examiner moves their face slowly from side to side. Other signs that may indicate visual impairment or other serious eye conditions include fixed pupils, strabismus, constant nystagmus, the setting-sun sign, and slow lateral movements. Unfortunately, it is difficult to test each eye separately; the presence of such signs in one eye could indicate unilateral blindness.

Special tests are available for testing infants and other difficult-to-test children to assess acuity or confirm blindness. For example, in visually evoked potentials, the eyes are stimulated with a bright light or pattern, and electrical activity to the visual cortex is recorded through scalp electrodes. Acuity is assessed by using progressively smaller patterns.

! NURSING ALERT

If visual fixation and following are not present by 3 to 4 months of age, further ophthalmological evaluation is needed.

Peripheral vision. In children who are old enough to assist, peripheral vision, or the visual field of each eye, can be estimated by having children fixate on a specific point directly in front of them as an object,

TABLE 33.8 Eye Examination Guidelines*

Function	Recommended Tests	Referral Criteria	Comments
Ages 3–5 Years			
Distance visual acuity	Snellen letters Snellen numbers Tumbling E HOTV test Picture test • Allen figures • LEA symbols	1. Fewer than 4 of 6 correct on 6-m line with either eye tested at 3 m monocularly (i.e., <10/20 or 20/40) *or* 2. Two-line difference between eyes, even within passing range (i.e., 10/12.5 and 10/20 or 20/25 and 20/40)	1. Tests are listed in decreasing order of cognitive difficulty; highest test that child is capable of performing should be used; in general, tumbling E or HOTV test should be used for children 3–5 years of age and Snellen letters or numbers for children 6 years and older. 2. Testing distance of 3 m is recommended for all visual acuity tests. 3. Line of figures is preferred over single figures. 4. Nontested eye should be covered by occluder held by examiner or by adhesive occluder patch applied to eye; examiner must ensure that it is not possible to peek with nontested eye.
Ocular alignment	Cover-uncover test at 3 m Random dot E stereo test at 40 cm Simultaneous red reflex test (Bruckner test)	Any eye movement Fewer than 4 of 6 correct Any asymmetry of pupil colour, size, brightness	Child must be fixing on a target while cover-uncover test is performed. Use direct ophthalmoscope to view both red reflexes simultaneously in a darkened room from 60–90 cm away; detects asymmetrical refractive errors as well.
Ocular media clarity (cataracts, tumours, etc.)	Red reflex	White pupil, dark spots, absent reflex	Use direct ophthalmoscope in a darkened room. View eyes separately at 30–45 cm; white reflex indicates possible retinoblastoma.

*The Canadian Paediatric Society has adapted these guidelines to be used by physicians, nurses, educational institutions, public health departments, and other health care providers who perform vision evaluation services.

From American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, Section on Ophthalmology. (2003). Eye examination in infants, children, and young adults. Reproduced with permission from *Pediatrics, 111*(4), 902–907. Copyright © 2003 by the AAP.

such as a finger or a pencil, is moved from beyond the field of vision into the range of peripheral vision. As soon as children see the object, they should say "stop." At that point, the examiner measures the angle from the anteroposterior axis of the eye (straight line of vision) to the peripheral axis (point at which the object is first seen). Each eye is checked separately and for each quadrant of vision. Normally, children see about 50 degrees upward, 70 degrees downward, 60 degrees nasalward, and 90 degrees temporally. Limitations in peripheral vision may indicate blindness from damage to structures within the eye or to any of the visual pathways.

Colour vision. Another important test is for colour vision. It is estimated that 8 to 10% of White males and less than half that percentage of Black males inherit the X-linked disorder known as *colour vision deficit*. From 0.5 to 1% of White females are affected. Although the severity of impaired perception of colour varies considerably, the two most common types are *protanomaly*, in which the child confuses grey with pink or pale blue with green, and *deuteranomaly*, in which the child confuses grey with pale purple or green. In most of these individuals the colour vision deficit causes no major concerns. However, some individuals with more severe deficits may be unable to distinguish amber or red traffic lights, fail to see a red brake light on the rear of a car, have difficulty distinguishing green traffic lights from certain types of incandescent street lamps, and have a poor sense of colour coordination of clothing.

The tests available for colour vision include the Ishihara test and the Hardy-Rand-Rittler test. Each consists of a series of cards (pseudoisochromatic) on which is printed a colour field composed of spots of a certain "confusion" colour. Against the field is a number or symbol similarly printed in dots but of a colour likely to be confused with the field colour by the person with a colour vision deficit. As a result, the figure or letter is invisible to an affected individual but is clearly seen by a person with vision that is not impaired.

Ears

Inspection of External Structures. The entire external earlobe is called the *pinna*, or *auricle*; one is located on each side of the head.

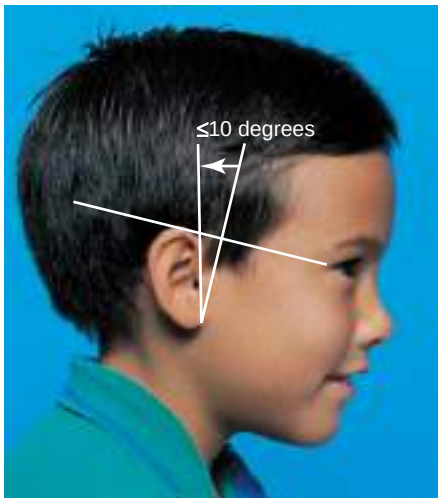

Fig. 33.15 Ear alignment.

The height alignment of the pinna is measured by drawing an imaginary line from the outer orbit of the eye to the occiput, or most prominent protuberance of the skull. The top of the pinna should meet or cross this line. Low-set ears are commonly associated with renal anomalies or cognitive impairment. The angle of the pinna is measured by drawing a perpendicular line from the imaginary horizontal line and aligning the pinna next to this mark. Normally the pinna lies within a 10-degree angle of the vertical line (Figure 33.15). If it falls outside this area, the nurse should record the deviation and look for other anomalies.

Normally the pinnae extend slightly outward from the skull. Except in newborn infants, ears that are flat against the head or protruding away from the scalp may indicate health concerns. Flattened ears in an infant may suggest a frequent side-lying position and, just as with isolated areas of hair loss, may indicate a need to investigate parents' understanding of the child's stimulation needs.

The skin surface around the ear should be inspected for small openings, extra tags of skin, sinuses, or earlobe creases. If a sinus is found, this should be noted because it may represent a fistula that drains into some area of the neck or ear. The nurse should note if an earlobe crease is found, because it may be associated with a rare, inherited syndrome. However, having one small abnormality is not uncommon and is often not associated with a serious condition. Cutaneous tags represent no pathological process but may cause parents concern in terms of the child's appearance.

The ear should also be assessed for hygiene. An otoscope is not necessary for looking into the external canal to note the presence of *cerumen*, a waxy substance produced by the ceruminous glands in the outer portion of the canal. Cerumen is usually yellow-brown and soft. If an otoscope is used and any discharge is seen, its colour and odour are noted. The nurse can prevent transmission of potentially infectious material to the other ear or to another child through hand hygiene and using disposable specula or sterilizing reusable specula between each examination.

Inspection of Internal Structures. The head of the otoscope enables visualization of the tympanic membrane by use of a bright light, a magnifying glass, and a speculum. Some otoscopes have an attachment for a pneumonic device to insert air into the canal to determine membrane compliance (movement). The speculum, which is inserted into the external canal, comes in a variety of sizes to accommodate different canal widths. The largest speculum that fits comfortably into the ear is used to achieve the greatest area of visualization. The lens, or magnifying glass, is movable, allowing the examiner to insert an object, such as a curette, into the ear canal through the speculum while still viewing the structures through the lens.

Positioning the child. Before beginning the otoscopic examination, the child should be properly positioned and gently restrained (the child can sit on the parent's lap and hold the parent's hand), if necessary. Older children are usually able to assist. However, the nurse should prepare them for the procedure by encouraging them to play with the instrument, demonstrating how it works, and stressing the importance of remaining still. It may be helpful to have them observe the nurse examining the parent's ear. Restraint may be needed for younger children because the ear examination can upset them (see Atraumatic Care box: Reducing Distress From Otoscopy in Young Children).

ATRAUMATIC CARE

Reducing Distress From Otoscopy in Young Children

Make examining the ear a game by explaining that you are looking for a "big elephant" in the ear. This kind of make-believe is an absorbing distraction and usually elicits cooperation. After examining the ear, clarify that "looking for elephants" was only pretend and thank the child for letting you look in their ear. Another great distraction technique is asking the child to put a finger on the opposite ear to keep the light from getting out.

As the speculum is inserted into the meatus, the examiner moves it around the outer rim to accustom the child to the feel of something entering the ear. If examining a painful ear, the examiner can touch a nonpainful part of the affected ear, then examine the unaffected ear, and finally return to the painful ear. By this time the child is usually less fearful of anything causing discomfort to the ear and will be more helpful.

For their protection and safety, infants and toddlers may need to be restrained for the otoscopic examination. There are two general positions of restraint. In one, the child is seated sideways in the parent's lap with one arm hugging the parent and the other arm at the side. The ear to be examined is toward the nurse. With one arm, the parent holds the child's head firmly against their chest, and with the other arm hugs the child, thereby securing the child's free arm (Figure 33.16, *A*). The ear is examined using the same procedure for holding the otoscope as described in the discussion that follows.

The other position involves placing the child on the side, back, or abdomen with the arms at the side and the head turned so that the ear to be examined points toward the ceiling. The examiner leans over the child, uses the upper part of the body to restrain the arms and upper trunk movements, and uses the examining hand to stabilize the head. This position is practical for young infants or for older children who need minimum restraint, but it may not be feasible for other children who protest vigorously. For safety, the examiner can enlist the parent's or an assistant's help in immobilizing the head by firmly placing one hand above the ear and the other on the child's side, abdomen, or back (see Figure 33.16, *B*).

With children who are able to help, the ear is examined with the child in a side-lying, sitting, or standing position. One disadvantage to standing is that the child may "walk away" as the otoscope enters the canal. If the child is standing or sitting, the head should be tilted slightly toward the child's opposite shoulder to achieve a better view of the eardrum (Figure 33.17).

With the thumb and forefinger of the free (usually nondominant) hand, the examiner grasps the auricle. For the two positions of restraint,

Fig. 33.16 Position for restraining child **(A)** and infant **(B)** during otoscopic examination.

Fig. 33.17 Positioning head by tilting it toward opposite shoulder for full view of tympanic membrane.

the otoscope is held upside down at the junction of its head and handle with the thumb and index finger. The other fingers are placed against the skull to allow the otoscope to move with the child in case of sudden movement. In examining a child who is helpful, the examiner can hold the handle with the otic head upright or upside down. The examiner can use the dominant hand to examine both ears or reverse hands for each ear, whichever is more comfortable.

Before using the otoscope, the examiner needs to visualize the external ear and the tympanic membrane as being superimposed on a clock (Figure 33.18). The numbers become important geographic landmarks. The speculum is introduced into the meatus between the 3 and 9 o'clock positions in a *downward* and *forward* position. Because the canal is curved, the speculum does not permit a panoramic view of the tympanic membrane unless the canal is straightened. In infants the canal curves upward. Therefore, the pinna is pulled *down* and *back* to the 6 to 9 o'clock range to straighten the canal (Figure 33.19, *A*). With older children, usually those older than 3 years of age, the canal curves downward and forward. Therefore, the examiner should pull the pinna *up* and *back* toward a 10 o'clock position (see Figure 33.19, *B*). If there is difficulty in visualizing the membrane, the head can be repositioned, introducing the speculum at a different angle, and pulling the pinna in a slightly different direction. The speculum should not be inserted past the cartilaginous (outermost) portion of the canal, usually a distance of 0.60 to 1.25 cm in older children. Insertion of the speculum into the posterior or bony portion of the canal causes pain.

In newborns and young infants, the walls of the canal are pliable and floppy because of the underdeveloped cartilaginous and bony structures. Therefore, the very small 2-mm speculum usually needs to be inserted deeper into the canal than in older children. Great care must be exercised not to damage the walls or drum. For this reason, only an experienced examiner should insert an otoscope into the ears of newborns.

Otoscopic examination. As the speculum is introduced into the external canal, the examiner inspects the walls of the canal, the colour of the tympanic membrane, the light reflex, and the usual landmarks of the bony prominences of the middle ear. The walls of the external auditory canal are pink, although they are more pigmented in dark-skinned children. Minute hairs are evident in the outermost portion, where cerumen is produced. Signs of irritation, foreign bodies, or infection should be noted.

Foreign bodies in the ear are not uncommon in children and range from erasers to beans. Symptoms may include pain, discharge, and affected hearing. Soft objects, such as paper or insects, can be removed with forceps. Small, hard objects, such as pebbles, can be removed with a suction tip, a hook, or irrigation. However, irrigation is contraindicated if the object is vegetative matter, such as beans or pasta, which swells when in contact with fluid.

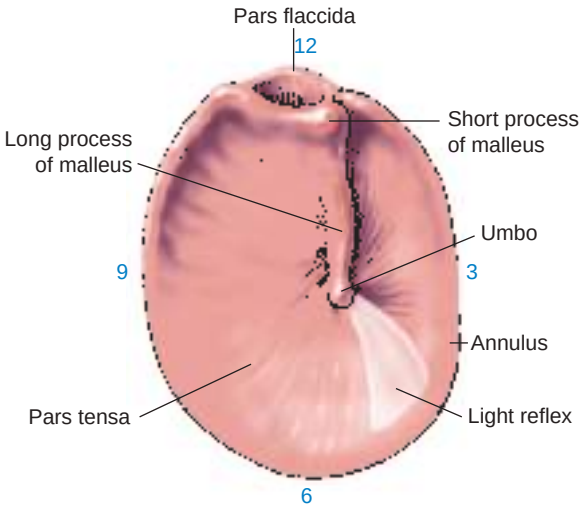

Fig. 33.18 Landmarks of tympanic membrane with "clock" superimposed. (Adapted from Rothrock, J. C. [2015]. *Alexander's care of the patient in surgery* [15th ed.]. Mosby.)

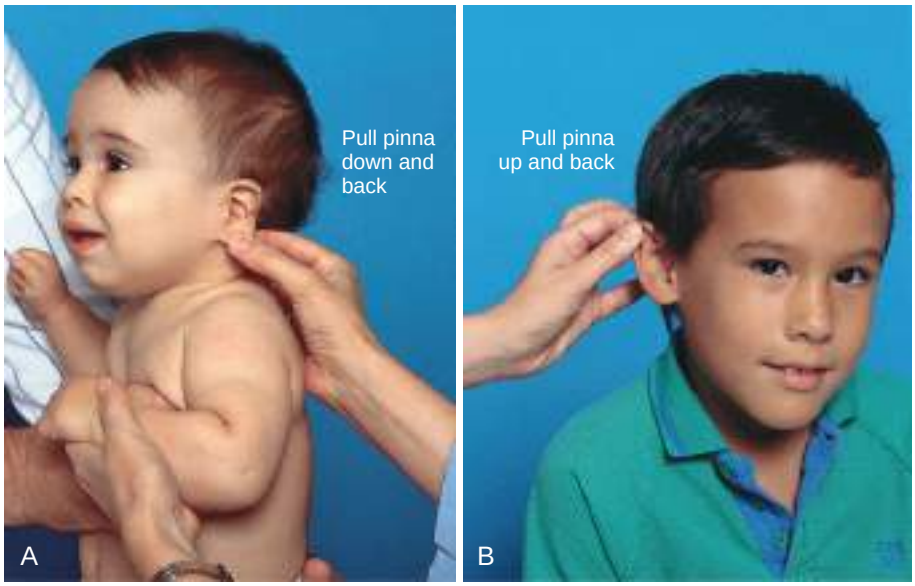

Fig. 33.19 Positioning for visualizing eardrum in infant **(A)** and in child older than 3 years of age **(B)**.

! NURSING ALERT

If there is any doubt about the type of object in the ear and the appropriate method to remove it, refer the child to the appropriate practitioner.

The *tympanic membrane* is a translucent, light pearly pink or grey. Marked erythema (which may indicate suppurative otitis media), a dull nontransparent greyish colour (sometimes suggestive of serous otitis media), or ashen grey areas (signs of scarring from a previous perforation) should be noted. A black area usually suggests a perforation of the membrane that has not healed.

The characteristic tenseness and slope of the tympanic membrane cause the light of the otoscope to reflect at about the 5 or 7 o'clock position. The light reflex is a fairly well-defined, cone-shaped reflection, which normally points away from the face.

The bony landmarks of the drum are formed by the *umbo*, or tip of the malleus. It appears as a small, round, opaque, concave spot near the centre of the drum. The *manubrium* (long process or handle) of the malleus appears as a whitish line extending from the umbo upward to the margin of the membrane. At the upper end of the long process near the 1 o'clock position (in the right ear) is a sharp, knoblike protuberance, representing the short process of the malleus. Absence of the light reflex or loss or abnormal prominence of any of these landmarks should be noted.

Auditory Testing. Several types of hearing tests are available and recommended for screening in infants and children (Patel et al., 2011/2018) (Table 33.9). Many provinces and territories have mandatory hearing screening for newborns before discharge in order to detect hearing impairment (see Newborn Hearing Screening, Chapter 26). The nurse must have a high index of suspicion for those children who appear to have conditions associated with hearing impairment and who may have developed behaviours that indicate auditory impairment. Chapter 42 has more information on hearing impairment.

TABLE 33.9 Audiological Tests for Infants and Children

Age	Auditory Test and Average Time	Type of Measurement	Procedure
Newborns	Auditory brainstem response (ABR)	Electrophysiological measurement of activity in auditory nerve and brainstem pathways	Placement of electrodes on the newborn's head detects auditory stimuli presented though earphones one ear at a time.
Infants	Behavioural audiometry	Used to observe their behaviour in response to certain sounds heard through speakers or earphones	The infant's responses are observed to the sounds heard.
Toddlers	Play audiometry	Uses an audiometer to transmit sounds at different volumes and pitches	The toddler is asked to do something with a toy (i.e., touch a toy, move a toy) every time the sound is heard.
Children and adolescents	Pure tone audiometry	Uses an audiometer that produces sounds at different volumes and pitches in the child's ears	The child is asked to respond in some way when the tone is heard in the earphone.
	Tympanometry (also called *impedance* or *admittance*)	Determines how the middle ear is functioning and detects any changes in pressure in the middle ear	A soft plastic tip is placed over the ear canal and the tympanometer measures eardrum movement when the pressure changes.
All ages	Evoked optoacoustic emissions (EOAE)	Physiological test specifically measuring cochlear (outer hair cell) response to presentation of stimulus	A small probe containing a sensitive microphone is placed in the ear canal for stimulus delivery and response detection.

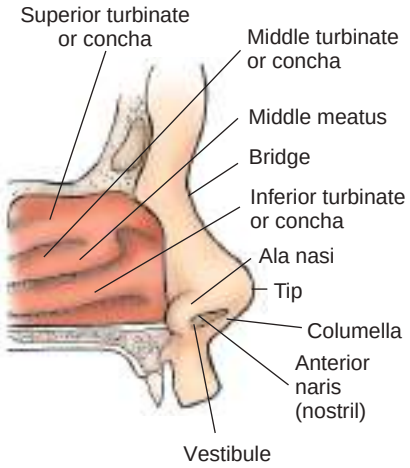

Fig. 33.20 External landmarks and internal structures of the nose.

Nose

Inspection of External Structures. The nose is located in the middle of the face just below the eyes and above the lips. Its placement and alignment are compared by drawing an imaginary vertical line from the centre point between the eyes down to the notch of the upper lip. The nose should be directly centred on this line, with each side exactly symmetrical. Its location, any deviation to one side, and asymmetry in overall size and in diameter of the nares (nostrils) should be noted. The bridge of the nose is flat in children of some ethnicities. The nurse should observe the alae nasi for any sign of flaring, which indicates respiratory difficulty; any flaring of the alae nasi should be reported. Figure 33.20 illustrates the landmarks used in describing the external structures of the nose.

Inspection of Internal Structures. The anterior vestibule of the nose is inspected by pushing the tip upward, tilting the head backward, and illuminating the cavity with a flashlight or otoscope without the attached ear speculum. The colour of the mucosal lining should be noted, which is normally redder than the oral membranes, as well as any swelling, discharge, dryness, or bleeding. There should be no discharge from the nose.

On looking deeper into the nose, the nurse should inspect the *turbinates*, or concha, plates of bone that jut into the nasal cavity and are enveloped by mucous membrane. The turbinates greatly increase the surface area of the nasal cavity as air is inhaled. The spaces or channels between the turbinates are called the *meatus* and correspond to each of the three turbinates. Normally the front end of the inferior and middle turbinate and the middle meatus are seen. They should be the same colour as the lining of the vestibule.

The septum is also inspected, which should divide the vestibules equally. Any deviation should be noted, especially if it causes an occlusion of one side of the nose. A perforation may be evident within the septum. If this is suspected, the examiner should shine the light of the otoscope into one naris and look for admittance of light to the other. Because olfaction is an important function of the nose, testing for smell may be done at this point or as part of the cranial nerve assessment (see Table 33.12).

Mouth and Throat

With a child who is helpful, almost the entire examination of the mouth and throat can be accomplished without the use of a tongue blade. The nurse can ask the child to open the mouth wide; to move the tongue in different directions for full visualization; and to say "ahh," which depresses the tongue for full view of the back of the mouth (tonsils, uvula, and oropharynx) (Figure 33.21, *B*). For a closer look at the buccal mucosa, or lining of the cheeks, children can be asked to use their fingers to move the outer lip and cheek to one side (see Atraumatic Care box: Encouraging Opening the Mouth for Examination).

ATRAUMATIC CARE

Encouraging Opening the Mouth for Examination

- Perform the examination in front of a mirror.
- Let the child first examine someone else's mouth, such as in the parent, the nurse, or a puppet (see Figure 33.21, *A*), and then examine the child's mouth.
- Instruct the child to tilt the head back slightly, breathe deeply through the mouth, and hold the breath; this action lowers the tongue to the floor of the mouth without the use of a tongue blade.
- Lightly brushing the palate with a cotton swab also may open the mouth for assessment.

Infants and toddlers usually resist attempts to keep their mouth open. Because inspection of the mouth is upsetting, it should be left for the end of the physical examination (along with examination of the ears) or done during episodes of crying. However, the use of a tongue blade (preferably flavoured) to depress the tongue is necessary. The tongue blade is placed along the *side* of the tongue, not in the centre back area where the gag reflex is elicited. Figure 33.21, *B* illustrates proper positioning of the child for the oral examination.

The major structure of the exterior of the mouth is the lips. The lips should be moist, soft, smooth, and pink, or a deeper hue than the surrounding skin. The lips should be symmetrical when relaxed or tensed. The nurse can assess symmetry when the child talks or cries.

Inspection of Internal Structures. The major structures visible within the oral cavity and oropharynx are the mucosal lining of the lips and cheeks, gums (or gingiva), teeth, tongue, palate, uvula, tonsils, and posterior oropharynx (Figure 33.22). The nurse needs to inspect all areas lined with mucous membranes (inside the lips and cheeks, gingiva, underside of the tongue, palate, and back of the pharynx) for colour, areas of white patches or ulceration, bleeding, sensitivity, and moisture. The membranes should be bright pink, smooth, glistening, uniform, and moist.

The teeth are inspected for number in each dental arch, for hygiene, and for occlusion or bite. Discoloration of tooth enamel with obvious plaque (whitish coating on the surface of the teeth) is a sign of poor dental hygiene and indicates a need for counselling. Brown spots in the crevices of the crown of the tooth or between the teeth may be **caries** (cavities). Chalky white to yellow or brown areas on the enamel may indicate fluorosis (excessive fluoride ingestion). Teeth that appear greenish black may be stained temporarily from ingestion of supplemental iron.

The gums (gingiva) surrounding the teeth should also be examined. The colour is normally coral pink, and the surface texture is stippled, similar to the appearance of an orange peel, in lighter coloured–skinned children. In dark-skinned children, the gums are more deeply coloured and a brownish area is often observed along the gum line.

The tongue is inspected for *papillae*, small projections that contain several taste buds and give the tongue its characteristic rough appearance. The size and mobility of the tongue should be noted. Normally the tip of the tongue should extend to the lips or beyond.

The roof of the mouth consists of the *hard palate*, which is located near the front of the oral cavity, and the *soft palate*, which is located toward the back of the pharynx and has a small midline protrusion called the *uvula*. The nurse should carefully inspect the palates to ensure that they are intact. The arch of the palate should be dome shaped. A narrow, flat roof or a high, arched palate affects the placement of the

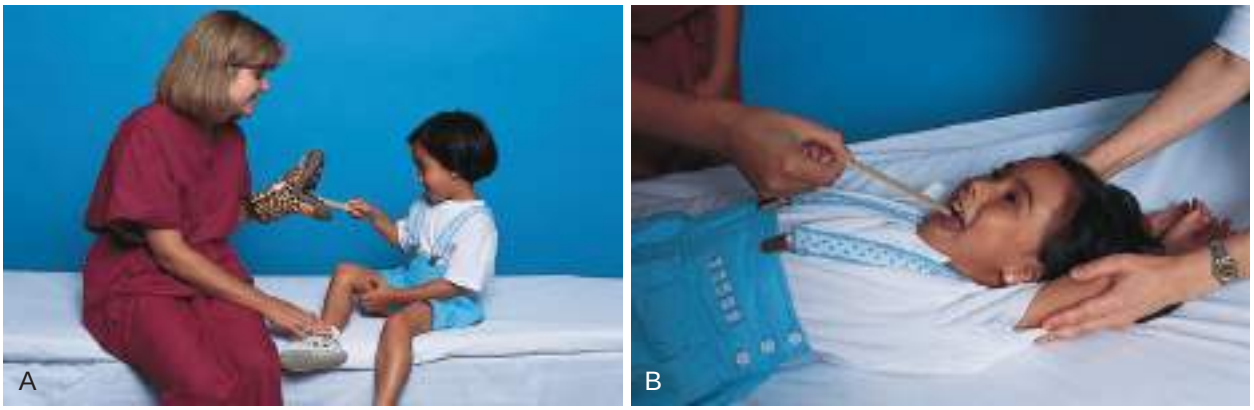

Fig. 33.21 **A:** Encouraging child to assist. **B:** Positioning child for examination of the mouth.

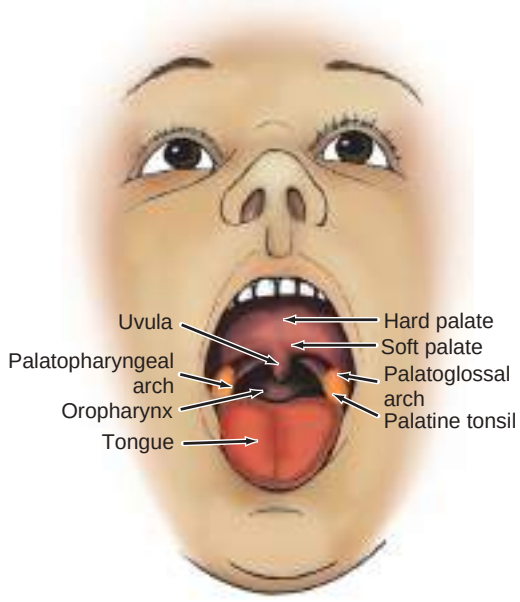

Fig. 33.22 Interior structures of the mouth.

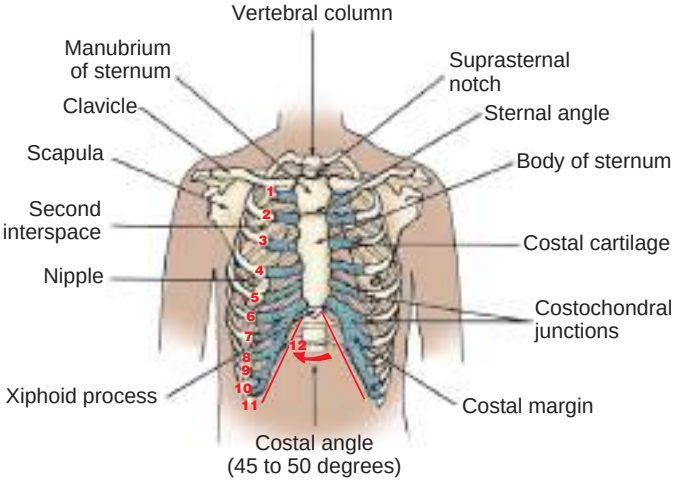

Fig. 33.23 Rib cage.

tongue and can cause feeding and speech difficulties. Movement of the uvula is tested by eliciting a gag reflex. The uvula should move upward to close off the nasopharynx from the oropharynx.

The nurse should examine the oropharynx and note the size and colour of the palatine tonsils. They are normally the same colour as the surrounding mucosa; glandular, rather than smooth in appearance; and barely visible over the edge of the palatoglossal arches. The size of the tonsils varies considerably during childhood. However, any swelling, redness, or white areas on the tonsils should be reported.

Chest

The chest is inspected for size, shape, symmetry, movement, breast development, and the bony landmarks formed by the ribs and sternum. The rib cage consists of 12 ribs on each side and the *sternum*, or breast bone, located in the midline of the trunk (Figure 33.23). The sternum is composed of three main parts. The *manubrium*, the uppermost portion, can be felt at the base of the neck at the suprasternal notch. The largest segment of the sternum is the *body*, which forms the sternal angle (angle of Louis) as it articulates with the manubrium. At the end of the body is a small, movable process called the *xiphoid*. The angle of the costal margin as it attaches to the sternum is called the *costal angle* and is normally about 45 to 50 degrees. These bony structures are important landmarks in the location of ribs and *intercostal spaces* (ICSs), which are the spaces between the ribs. They are numbered according to the rib directly above the space. For example, the space immediately below the second rib is the second ICS.

The thoracic cavity is also divided into segments by drawing imaginary lines on the chest and back. Figure 33.24 illustrates the anterior, right lateral, and posterior divisions.

The size of the chest is measured by placing the measuring tape around the rib cage at the nipple line. For greatest accuracy, the nurse should take two measurements (one during inspiration and the other during expiration) and record the average. Chest size is important mainly in relation to head circumference. Marked disproportions need to be reported because most are caused by abnormal head growth, although some may be a result of altered chest shape, such as barrel chest (chest is round), pectus excavatum (sternum is depressed), or pectus carinatum (sternum protrudes outward).

During infancy, the chest's shape is almost circular, with the anteroposterior (front-to-back) diameter equalling the transverse, or lateral (side-to-side), diameter. As the child grows, the chest normally increases in the transverse direction, causing the anteroposterior diameter to be less than the lateral diameter. The nurse should note the angle made by the lower costal margin and the sternum and palpate the junction of the ribs with the costal cartilage (costochondral junction) and sternum, which should be fairly smooth.

Movement of the chest wall should be symmetrical bilaterally and coordinated with breathing. During inspiration, the chest rises and expands, the diaphragm descends, and the costal angle increases. During expiration, the chest falls and decreases in size, the diaphragm rises, and the costal angle narrows (Figure 33.25). In children younger than 6 or 7 years of age, respiratory movement is principally abdominal or

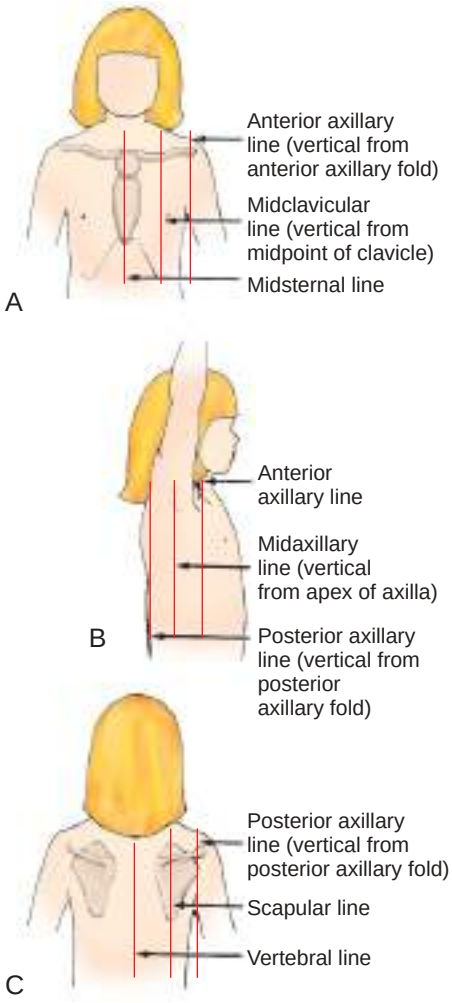

Fig. 33.24 Imaginary landmarks of the chest. **A:** Anterior. **B:** Right lateral. **C:** Posterior.

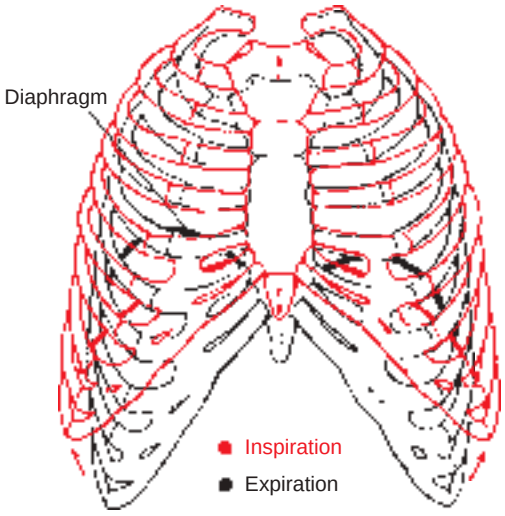

Fig. 33.25 Movement of chest during respiration.

diaphragmatic. In older children, particularly girls, respirations are chiefly thoracic. In either type the chest and abdomen should rise and fall together. Any asymmetry of movement must be reported.

While inspecting the skin surface of the chest, the nurse should observe the position of the nipples and any evidence of breast development. Normally the nipples are located slightly lateral to the midclavicular line, between the fourth and fifth ribs. Symmetry of nipple placement should be noted as well as normal configuration of a darker pigmented areola surrounding a flat nipple in the prepubertal child.

Pubertal breast development usually begins in girls between 10 and 14 years of age. Early (precocious) or delayed breast development should be recorded, as well as evidence of any other secondary sexual characteristics. In males, breast enlargement (**gynecomastia**) may be caused by hormonal or systemic disorders, but more commonly it is a result of adipose tissue from obesity or a transitory body change during early puberty. In either situation, the nurse should investigate the child's feelings regarding breast enlargement.

In adolescent girls who have achieved sexual maturity, the breasts need to be palpated for evidence of any masses or hard nodules. Most palpable masses are benign, thus it is important to convey this tendency, to decrease any fear or concern that results when a mass is felt.

The stages of development of secondary sex characteristics and genital development have been defined as a guide for estimating sexual maturity and are referred to as the *Tanner stages*. Details on assessing Tanner stages in adolescents are found in Chapter 40.

Lungs

The lungs are situated inside the thoracic cavity, with one lung on each side of the sternum. Each lung is divided into an *apex*, which is slightly pointed and rises above the first rib; a *base*, which is wide and concave and rides on the dome-shaped diaphragm; and a *body*, which is divided into lobes. The right lung has three lobes: the upper, middle, and lower. The left lung has only two lobes, the upper and lower, because of the space occupied by the heart (Figure 33.26).

Inspection of the lungs primarily involves observation of respiratory movements, which were discussed previously. Respirations are evaluated for rate (number per minute), rhythm (regular, irregular, or periodic), depth (deep or shallow), and quality (effortless, automatic, difficult, or laboured). The nurse should note the character of breath sounds, such as noisy, grunting, snoring, or heavy.

Respiratory movements are evaluated by placing each hand flat against the back or chest with the thumbs in midline along the lower costal margin of the lungs. The child should be sitting during this procedure and should take several deep breaths. During respiration, the examiner's hands will move with the chest wall. The amount and speed of respiratory excursion should be assessed and any asymmetry of movement noted.

Experienced examiners may **percuss** the lungs. The anterior lung is percussed from apex to base, usually with the child in the supine or sitting position. Each side of the chest is percussed in sequence to compare the sounds. When the posterior lung is percussed, the procedure and sequence are the same, although the child should be sitting. Resonance is heard over all the lobes of the lungs that are not adjacent to other organs. Any deviation from the expected sound should be recorded and reported.

Auscultation. Auscultation involves using the stethoscope to evaluate breath sounds (see Guidelines box: Effective Auscultation). Breath sounds are best heard if the child inspires deeply (see Atraumatic Care box: Encouraging Deep Breaths). In the lungs, breath sounds are classified as *vesicular, bronchovesicular,* or *bronchial* (Box 33.8).

GUIDELINES

Effective Auscultation

- Make certain the child is relaxed and not crying, talking, or laughing. Record if the child is crying.
- Check that the room is comfortable and quiet.

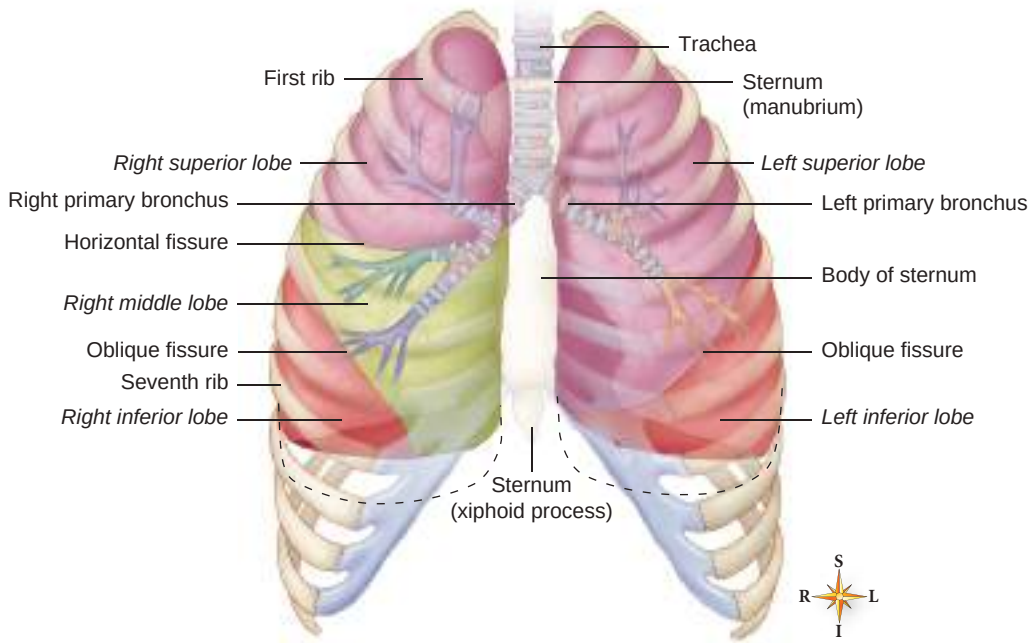

Fig. 33.26 Location of lobes of lungs within thoracic cavity. (From Patton, K. T. [2013]. *Anatomy and physiology* [8th ed.]. Mosby.)

BOX 33.8 Classification of Normal Breath Sounds

Vesicular Breath Sounds

These sounds are heard over the entire surface of the lungs, with the exception of the upper intrascapular area and area beneath the manubrium.
Inspiration is louder, longer, and higher pitched than expiration.
Sound is a soft, swishing noise.

Bronchovesicular Breath Sounds

These sounds are heard over the manubrium and in the upper intrascapular regions where the trachea and bronchi bifurcate.
Inspiration is louder and higher pitched than in vesicular breathing.

Bronchial Breath Sounds

These sounds are heard only over the trachea near the suprasternal notch.
The inspiratory phase is short, and expiratory phase is long.

- Warm the stethoscope before placing it against the skin.
- Apply firm pressure on chest piece but not enough to prevent vibrations and transmission of sound.
- Avoid placing the stethoscope over hair or clothing, moving it against skin, breathing on tubing, or sliding fingers over chest piece, which may cause sounds that falsely resemble pathological findings.
- Use a symmetrical and orderly approach for comparing sounds.

ATRAUMATIC CARE

Encouraging Deep Breaths

- Ask the child to "blow out" the light on an otoscope or pocket flashlight; discreetly turn off the light on the last try so that the child feels successful.
- Place a cotton ball in the child's palm; ask the child to blow the ball into the air and have the parent catch it.
- Place a small tissue on the top of a pencil and ask the child to blow the tissue off.
- Have the child blow a pinwheel, a party horn, or bubbles.

Absent or diminished breath sounds are always an abnormal finding warranting investigation. Fluid, air, or solid masses in the pleural space all interfere with the conduction of breath sounds. Diminished breath sounds in certain segments of the lung can alert the nurse to pulmonary areas that may benefit from chest physiotherapy. Increased breath sounds after pulmonary therapy indicate improved passage of air through the respiratory tract. Box 33.9 lists terms used to describe various respiration patterns. See Appendix C for normal pediatric respiratory rates.

Various pulmonary abnormalities produce adventitious sounds that are not normally heard over the chest. These sounds occur in addition

BOX 33.9 Various Patterns of Respiration

Tachypnea: Increased rate
Bradypnea: Decreased rate
Dyspnea: Distress during breathing
Apnea: Cessation of breathing
Hyperpnea: Increased depth
Hypoventilation: Decreased depth (shallow) and irregular rhythm
Hyperventilation: Increased rate and depth
Kussmaul respiration: Hyperventilation, gasping and laboured respiration; usually seen in diabetic coma or other states of respiratory acidosis
Cheyne-Stokes respiration: Gradually increasing rate and depth with periods of apnea
Biot respiration: Periods of hyperpnea alternating with apnea (similar to Cheyne-Stokes except that depth remains constant)
Seesaw (paradoxic) respirations: Chest falls on inspiration and rises on expiration
Agonal: Last gasping breaths before death

to normal or abnormal breath sounds. They are classified into two main groups: (1) **crackles**, which result from the passage of air through fluid or moisture, and (2) **wheezes**, which are produced as air passes through narrowed passageways, regardless of the cause, such as exudate, inflammation, spasm, or tumour. Abnormal sounds need to be reported for further evaluation.

Heart

The heart is situated in the thoracic cavity between the lungs in the mediastinum and above the diaphragm (Figure 33.27). About two thirds of the heart lies within the left side of the rib cage, with the other third on the right side as it crosses the sternum. The heart is positioned in the thorax like a trapezoid:

- *Vertically* along the right sternal border (RSB) from the second to the fifth rib
- *Horizontally* (long side) from the lower right sternum to the fifth rib at the left midclavicular line (LMCL)
- *Diagonally* from the left sternal border (LSB) at the second rib to the LMCL at the fifth rib
- *Horizontally* (short side) from the RSB and LSB at the second ICS—base of the heart

Inspection is easiest when the child sitting in a semi-Fowler position. The anterior chest wall is assessed from an angle, comparing both sides of the rib cage with each other. Normally they should be symmetrical. In children with thin chest walls, a pulsation may be visible. Because comprehensive evaluation of cardiac function is not limited to the heart, other findings such as the presence of all pulses (especially the femoral pulses) (Figure 33.28), distended neck veins, clubbing of the fingers, peripheral cyanosis, edema, BP, and respiratory status need to be considered.

Palpation is used to determine the location of the apical impulse (AI), the most lateral cardiac impulse that may correspond to the apex. The AI is found:

- Just lateral to the LMCL and fourth ICS in children over 7 years of age.
- At the LMCL and fifth ICS in children less than 7 years of age.

Although the AI gives a general idea of the size of the heart (with enlargement, the apex is lower and more lateral), its normal location is variable, making it an unreliable indicator of heart size.

The **point of maximum impulse (PMI)**, as the name implies, is the area of most intense pulsation. Usually the PMI is located at the same site as the AI, but it can occur elsewhere. For this reason, the two terms should not be used synonymously.

Capillary refill time, an important test for peripheral circulation, is assessed by pressing the skin lightly on a central site, such as the forehead, or a peripheral site, such as the top of the hand, to produce a slight blanching. The time it takes for the blanched area to return to its original colour is the capillary refill time.

! NURSING ALERT

Capillary refill should be brisk—less than 2 seconds; prolonged refill may be associated with poor systemic perfusion or a cool ambient temperature.

Auscultation.

Origin of heart sounds. The heart sounds are produced by the opening and closing of the valves and the vibration of blood against the walls of the heart and vessels. Normally two sounds—S_1 and S_2—are heard, which correspond, respectively, to the familiar "lub dub" often used to describe the sounds. S_1 is caused by closure of the tricuspid and mitral valves (sometimes called the *atrioventricular valves*). S_2 is the result of closure of the pulmonic and aortic valves (sometimes called *semilunar valves*). Normally the split of the two sounds in S_2 is distinguishable and widens during inspiration. Physiological splitting is a significant normal finding.

! NURSING ALERT

Fixed splitting, in which the split in S_2 does not change during inspiration, is an important diagnostic sign of atrial septal defect.

Two other heart sounds—S_3 and S_4—may be produced. S_3 is normally heard in some children; S_4 is rarely heard as a normal heart sound; it usually indicates the need for further cardiac evaluation.

Differentiating normal heart sounds. Figure 33.29 illustrates the approximate anatomical position of the valves within the heart chambers. The anatomical location of valves does not correspond to the area where the sounds are heard best. The auscultatory sites are located in the direction of the blood flow through the valves.

Normally S_1 is louder at the apex of the heart in the mitral and tricuspid area, and S_2 is louder near the base of the heart in the pulmonic and aortic area (Table 33.10). The nurse should listen to each sound by inching down the chest. The following areas are auscultated for sounds, such as murmurs, which may radiate to these sites: sternoclavicular area above the clavicles and manubrium, area along the sternal border, area along the left midaxillary line, and area below the scapulae.

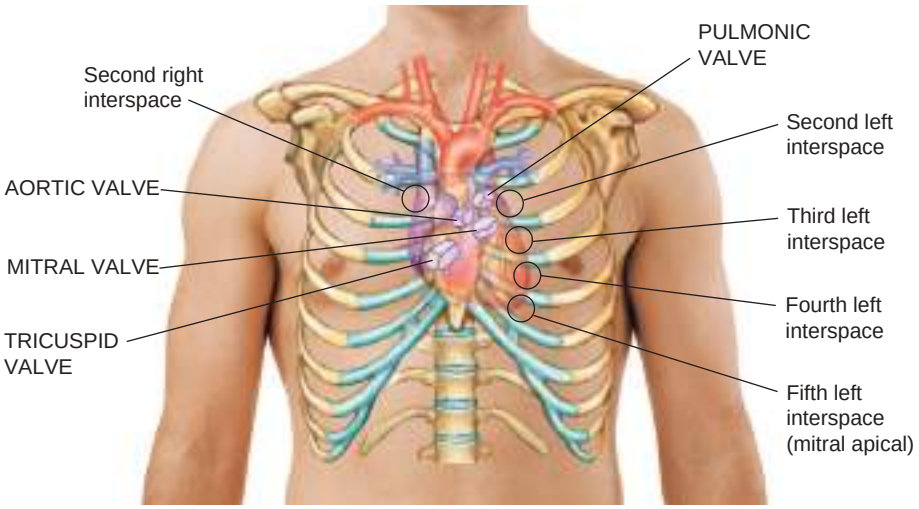

Fig. 33.27 Position of heart within thorax. (From Seidel, H. M., Dains, J. E., Ball, J. W., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. Mosby.)

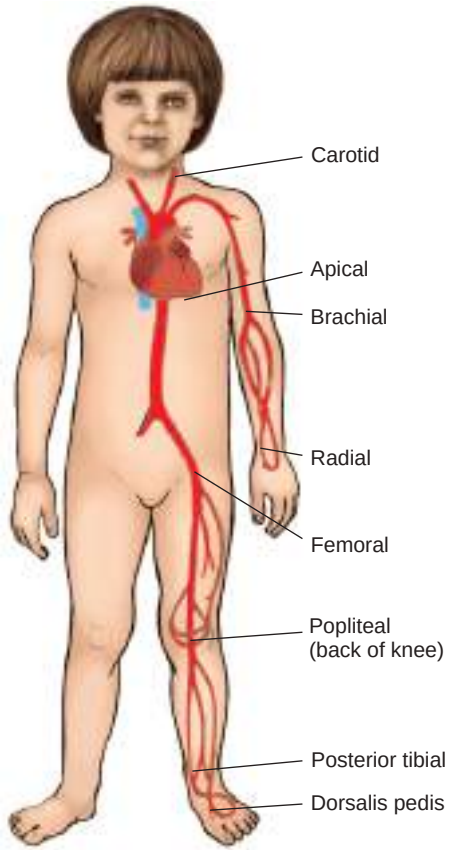

Fig. 33.28 Location of pulses.

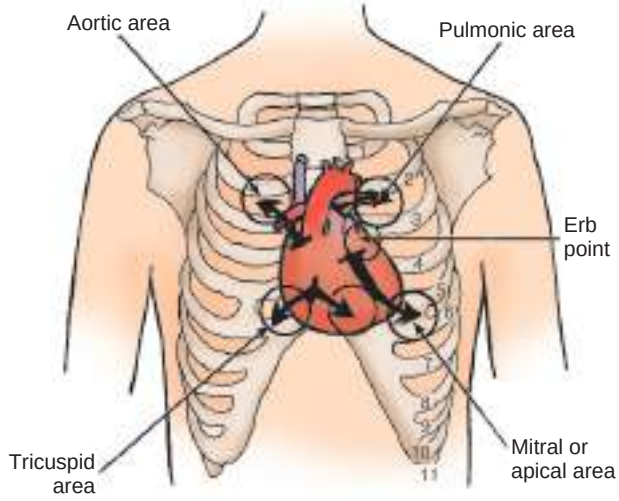

Fig. 33.29 Direction of heart sounds for anatomical valve sites and areas (circled) for auscultation.

! NURSING ALERT

To distinguish between S_1 and S_2 heart sounds, simultaneously palpate the carotid pulse with the index and middle fingers and listen to the heart sounds; S_1 is synchronous with the carotid pulse.

The nurse should auscultate the heart with the child in at least two positions: sitting and reclining. If adventitious sounds are detected, they should be further evaluated with the child standing, sitting and leaning forward, and lying on the left side. For example, atrial sounds such as S_4 are heard best with the person in a recumbent position and usually fade if the person sits or stands.

Heart sounds are evaluated for (1) quality (they should be clear and distinct, not muffled, diffuse, or distant); (2) intensity, especially in relation to the location or auscultatory site (they should not be weak or pounding); (3) rate (they should have the same rate as the radial pulse); and (4) rhythm (they should be regular and even). A particular arrhythmia that occurs normally in many children is *sinus arrhythmia*, in which the heart rate increases with inspiration and decreases with expiration. This rhythm is differentiated from a truly abnormal arrhythmia by having children hold their breath. In sinus arrhythmia, cessation of breathing causes the heart rate to remain steady.

Heart murmurs. Another important category of the heart sounds is *murmurs*, which are produced by vibrations within the heart chambers or in the major arteries from the back-and-forth flow of blood. Murmurs are classified as follows:

Innocent—No anatomical or physiological abnormality exists.

Functional—No automatic cardiac defect exists, but a physiological abnormality such as anemia is present.

Organic—A cardiac defect with or without a physiological abnormality exists.

The description and classification of murmurs are skills that require considerable practice and training. In general, the nurse should recognize murmurs as distinct swishing sounds that occur in addition to the normal heart sounds and record the (1) location, or the area of the heart in which the murmur is heard best; (2) time of the occurrence of the murmur within the S_1–S_2 cycle; (3) intensity (evaluate in relationship to the child's position); and (4) loudness. The usual subjective method of grading the loudness or intensity of a murmur is listed in Table 33.11.

Abdomen

Examination of the abdomen involves inspection, followed by auscultation and then palpation. Experienced examiners may also percuss the abdomen to assess for organomegaly, masses, fluid, and flatus. Palpation should be performed last because it may distort the normal abdominal sounds, assessed during auscultation. Knowledge of the anatomical placement of the abdominal organs is essential to differentiate normal, expected findings from abnormal ones (Figure 33.30).

For descriptive purposes, the abdominal cavity is divided into four quadrants by drawing a vertical line midway from the sternum to the symphysis pubis and a horizontal line across the abdomen through the umbilicus. The sections are named:

- Left upper quadrant
- Left lower quadrant
- Right upper quadrant
- Right lower quadrant

Inspection. The contour of the abdomen is inspected with the child erect and supine. Normally the abdomen of infants and young children is cylindrical and, in the erect position, fairly prominent because of the physiological lordosis of the spine. In the supine position, the abdomen appears flat. A midline protrusion from the xiphoid to the umbilicus or symphysis pubis is usually diastasis recti, or failure of the rectus abdominis muscles to join in utero. In a healthy child, a midline protrusion is usually a variation of normal muscular development.

! NURSING ALERT

A tense, boardlike abdomen is a serious sign of paralytic ileus and intestinal obstruction.

TABLE 33.10 Sequence of Auscultating Heart Sounds*

Auscultatory Site	Chest Location	Characteristics of Heart Sounds
Aortic area	Second right intercostal space close to sternum	S_2 heard louder than S_1; aortic closure heard loudest
Pulmonic area	Second left intercostal space close to sternum	Splitting of S_2 heard best, normally widens on inspiration; pulmonic closure heard best
Erb's point	Second and third left intercostal spaces close to sternum	Frequent site of innocent murmurs and those of aortic or pulmonic origin
Tricuspid area	Fifth right and left intercostal spaces close to sternum	S_1 heard as louder sound preceding S_2 (S_1 synchronous with carotid pulse)
Mitral or apical area	Fifth intercostal space, left midclavicular line (third to fourth intercostal space and lateral to left midclavicular line in infants)	S_1 heard loudest; splitting of S_1 may be audible because mitral closure is louder than tricuspid closure
		S_1 heard best at beginning of expiration with child in recumbent or left side-lying position; occurs immediately after S_2; sounds like word S_1 S_2 S_3: "Ken-tuc-ky"
		S_4 heard best during expiration with child in recumbent position (left side-lying position decreases sound); occurs immediately before S_1; sounds like word S_4 S_1 S_2: "Ten-nes-see"

*Use both diaphragm and bell chest pieces when auscultating heart sounds. Bell chest piece is necessary for low-pitched sounds of murmurs, S_3, and S_4. See Figure 33.29 for sites.

TABLE 33.11 Grading of Intensity of Heart Murmurs

Grade	Description
I	Very faint; often not heard if child sits up
II	Usually readily heard; slightly louder than grade I; audible in all positions
III	Loud, but not accompanied by a thrill
IV	Loud, accompanied by a thrill
V	Loud enough to be heard with a stethoscope barely touching the chest; accompanied by a thrill
VI	Loud enough to be heard with a stethoscope not touching the chest; often heard with the human ear close to the chest; accompanied by a thrill

The skin covering the abdomen should be uniformly taut, without wrinkles or creases. Sometimes silvery, whitish striae ("stretch marks") are seen, especially if the skin has been stretched, as in obesity. Superficial veins are usually visible in light-skinned, thin infants, but distended veins are an abnormal finding.

The nurse should observe movement of the abdomen. Normally, chest and abdominal movements are synchronous. In infants and thin children, peristaltic waves may be visible through the abdominal wall; they are best observed by standing at eye level to and across from the abdomen. This finding should always be reported.

The umbilicus is examined for size, hygiene, and evidence of any abnormalities, such as hernias. The umbilicus should be flat or only slightly protruding. If a herniation is present, the nurse should palpate the sac for abdominal contents and estimate the approximate size of the opening. Umbilical hernias are common in infants, especially in Black children.

Hernias may exist elsewhere on the abdominal wall (Figure 33.31). An *inguinal hernia* is a protrusion of peritoneum through the abdominal wall in the inguinal canal. It occurs mostly in males, is frequently bilateral, and may be visible as a mass in the scrotum. To locate a hernia, the examiner slides the little finger into the external inguinal ring at the base of the scrotum and asks the child to cough. If a hernia is present, it will hit the tip of the finger.

A *femoral hernia*, which occurs more frequently in girls, is felt or seen as a small mass on the anterior surface of the thigh just below the inguinal ligament in the femoral canal (a potential space medial to the femoral artery). To feel for a hernia, the examiner places the index finger of their right hand on the child's right femoral pulse (left hand for left pulse) and the middle finger flat against the skin toward the midline. The ring finger lies over the femoral canal, where the herniation occurs. Palpation of hernias in the pelvic region is often part of the genital examination.

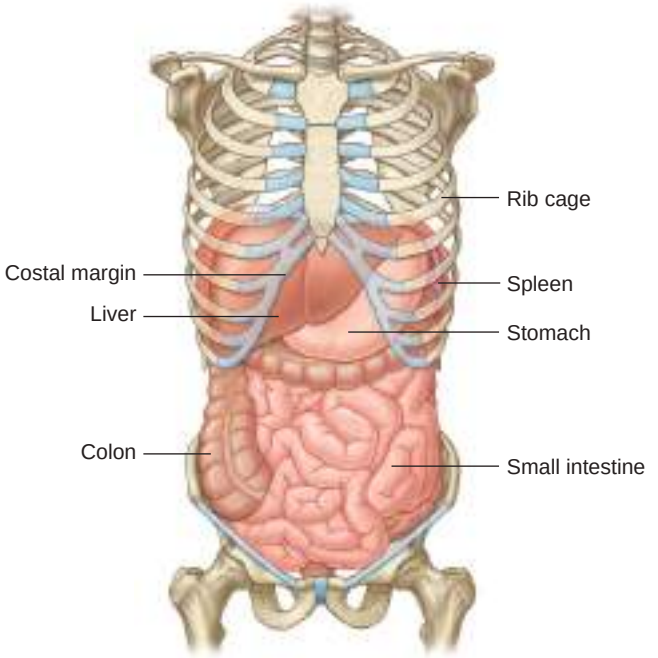

Fig. 33.30 Location of structures in the abdomen. (From Drake, R. L., Vogl, W., & Mitchell, A. W. M. [2005]. *Gray's anatomy for students*. Churchill Livingstone.)

Auscultation. The most important finding to listen for is *peristalsis*, or bowel sounds, which sound like short metallic clicks and gurgles. Their frequency per minute should be recorded (e.g., 5 sounds/min). Bowel sounds may be stimulated by stroking the abdominal surface with a fingernail. Absence of bowel sounds or hyperperistalsis should be reported, since either usually denotes an abdominal disorder.

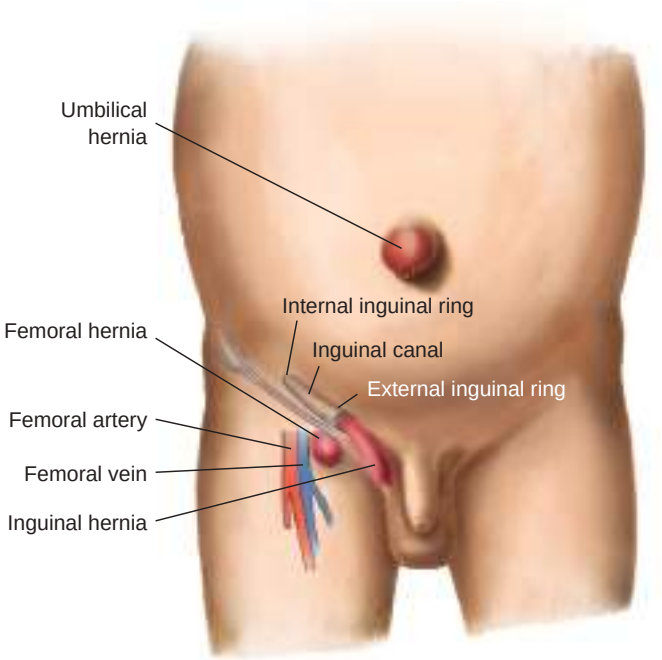

Fig. 33.31 Location of hernias.

Palpation. Two types of palpation are performed: superficial and deep. For superficial palpation, the examiner should lightly place their hand against the skin and feel each quadrant, noting any areas of tenderness, muscle tone, and superficial lesions such as cysts. Because superficial palpation is often perceived as tickling, several techniques can be used to minimize this sensation and relax the child (see Atraumatic Care box: Promoting Relaxation During Abdominal Palpation). Admonishing the child to stop laughing only draws attention to the sensation and may make it more difficult to complete the assessment.

ATRAUMATIC CARE

Promoting Relaxation During Abdominal Palpation

- Position the child comfortably, such as in a semi-reclining position in the parent's lap, with knees flexed.
- Warm your hands before touching the skin.
- Use distraction, such as telling stories or talking to the child.
- Teach the child to use deep breathing and to concentrate on an object.
- Give infants a bottle (if being bottle-fed) or pacifier (if agreed to by parents).
- Begin with light, superficial palpation and gradually progress to deeper palpation.
- Palpate any tender or painful areas last.
- Have the child hold the parent's or caregiver's hand and squeeze it if palpation is uncomfortable.
- Use the nonpalpating hand to comfort the child, such as placing the free hand on the child's shoulder while palpating the abdomen.
- To minimize sensation of tickling during palpation:
  - Have children "help" with palpation by placing a hand over the palpating hand.
  - Have them place a hand on the abdomen with the fingers spread wide apart, and palpate between their fingers.

Deep palpation is used for palpating organs and large blood vessels and for detecting masses and tenderness that were not discovered during superficial palpation. Palpation usually begins in the lower quadrants and proceeds upward to avoid missing the edge of an enlarged liver or spleen. Except for palpating the liver, successful identification of other organs, such as the spleen, kidney, and part of the colon, requires considerable practice with tutored supervision. Any questionable mass should be reported. The lower edge of the liver is sometimes felt in infants and young children as a superficial mass 1 to 2 cm below the right costal margin (the distance is sometimes measured in fingerbreadths). Normally, the liver descends during inspiration as the diaphragm moves downward. This downward displacement should not be mistaken as a sign of liver enlargement.

! NURSING ALERT

If the liver is palpable 3 cm below the right costal margin or the spleen is palpable more than 2 cm below the left costal margin, these organs are enlarged—a finding that is always reported for further medical investigation.

The femoral pulses are palpated by placing the tips of two or three fingers (index, middle, or ring) along the inguinal ligament about midway between the iliac crest and symphysis pubis. Both pulses should be felt simultaneously to make certain that they are equal and strong (Figure 33.32).

! NURSING ALERT

Absence of femoral pulses is a significant sign of coarctation of the aorta and needs to be referred for medical evaluation.

Genitalia

Examination of genitalia conveniently follows assessment of the abdomen while the child is still supine. In adolescents, inspection of the genitalia may be left to the end of the examination. The best approach is to examine the genitalia matter-of-factly, placing no more emphasis on this part of the assessment than on any other segment. It helps to relieve children's and parents' anxiety by telling them the results of the findings; for example, the nurse might say, "Everything looks fine here."

If it is necessary to ask questions, such as about discharge or difficulty urinating, the child's privacy can be respected by covering the lower abdomen with the gown or underpants. To prevent embarrassing interruptions, the door or curtain should be closed and a "do not disturb" sign posted. The nurse should have a drape ready to cover the genitalia if someone enters the room.

In examining the genitalia, gloves should be worn when touching body substances. It might be helpful for the adolescent to know that wearing gloves also prevents skin-to-skin contact.

The genital examination is an excellent time for eliciting questions or concerns about body function or sexual activity. The nurse can also use this opportunity to increase or reinforce the child's knowledge of reproductive anatomy by naming each body part and explaining its

Fig. 33.32 Palpating femoral pulses.

function. This is a good time to discuss testicular cancer; although testicular self-examination is not recommended, it is important for the male to know what is normal.

Male Genitalia. In examining the male genitalia, the nurse should note the external appearance of the glans and shaft of the penis, the prepuce, the urethral meatus, and the scrotum (Figure 33.33). The penis is generally small in infants and young boys until puberty, when it begins to increase in both length and width. In an obese child, the penis often looks abnormally small because of the folds of skin partially covering it at the base. It is important to be familiar with normal pubertal growth of the external male genitalia in order to compare the findings with the expected sequence of maturation.

The glans (head of the penis) and shaft (portion between the perineum and prepuce) are examined for signs of swelling, skin lesions, inflammation, or other irregularities. Any of these signs may indicate underlying disorders, especially STIs.

The urethral meatus is carefully inspected for location and evidence of discharge. Normally it is centred at the tip of the glans. Hair distribution should also be noted. Normally, before puberty, no pubic hair is present. Soft, downy hair at the base of the penis is an early sign of pubertal maturation. In older adolescents, hair distribution is diamond shaped from the umbilicus to the anus.

The location and size of the scrotum should be noted. The scrota hang freely from the perineum behind the penis, and the left scrotum normally hangs lower than the right. In infants, the scrota appear large in relation to the rest of the genitalia. The skin of the scrotum is loose and highly rugated (wrinkled). During early adolescence, the skin normally becomes redder and coarser. In dark-skinned children, the scrota are usually more deeply pigmented.

Palpation of the scrotum includes identification of the testes, epididymis, and, if present, inguinal hernias. The two testes are felt as small, ovoid bodies about 1.5 to 2 cm long—one in each scrotal sac. They do not enlarge until puberty, when they approximately double in size.

When palpating for the presence of the testes, the nurse should avoid stimulating the cremasteric reflex, which is stimulated by cold, touch, emotional excitement, or exercise. This reflex pulls the testes higher into the pelvic cavity. Several measures are useful in preventing the cremasteric reflex during palpation of the scrotum. First, the hands should be warmed. Second, if the child is old enough, he should be examined in a "tailor" position, which stretches the muscle, preventing its contraction (Figure 33.34, *A*). Third, the examiner can block the normal pathway of ascent of the testes by placing the thumb and index finger over the upper part of the scrotal sac along the inguinal canal (see Figure 33.34, *B*). If there is any question concerning the existence of two testes, the index and middle fingers can be placed in a scissors fashion to separate the right and left scrota. If, after using these techniques, the testes have not been palpated, the examiner should feel along the inguinal canal and perineum to locate masses that may be undescended testes. Although undescended testes may descend at any time during childhood and are checked at each visit, failure to palpate testes should be reported.

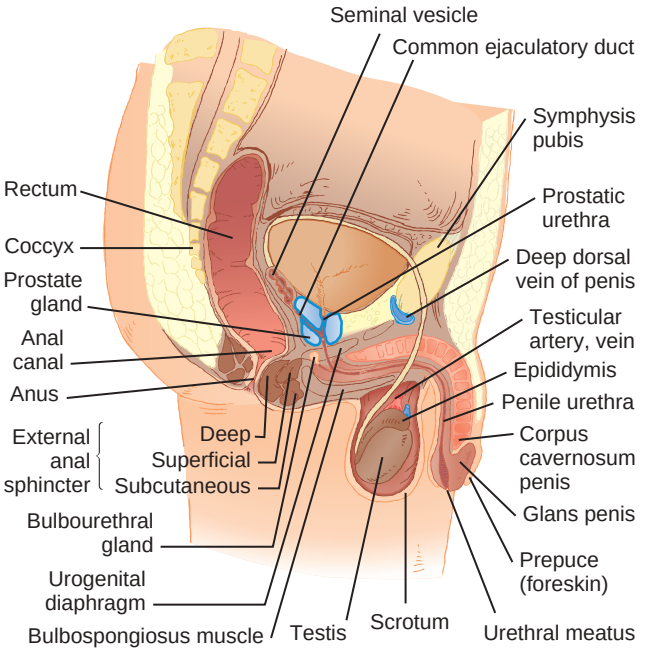

Fig. 33.33 Major structures of genitalia in uncircumcised postpubertal male. (From Black, J. M. [2008]. *Medical-surgical nursing: Clinical management for positive outcomes* [8th ed.]. Saunders.)

Female Genitalia. The examination of female genitalia is limited to inspection and palpation of external structures. If a vaginal examination is required, an appropriate referral is made unless the nurse is qualified to perform the procedure.

A convenient position for examination of the genitalia involves placing the young child supine on the examining table or in a semireclining position on the parent's lap with the feet supported on the nurse's knees as the nurse sits facing the child. The child's attention can be diverted from the examination by instructing her to try to keep the soles of her feet pressed against each other. The nurse should separate the labia majora with the thumb and index finger and retract outward to expose the labia minora, urethral meatus, and vaginal orifice.

The female genitalia are examined for size and location of the structures of the vulva, or pudendum (Figure 33.35). The *mons pubis* is a pad of adipose tissue over the symphysis pubis. At puberty, the mons is covered with hair, which extends along the labia. The usual pattern of female hair distribution is an inverted triangle. The appearance of soft, downy hair along the labia majora is an early sign of sexual maturation. The nurse should note the size and location of the *clitoris*, a small,

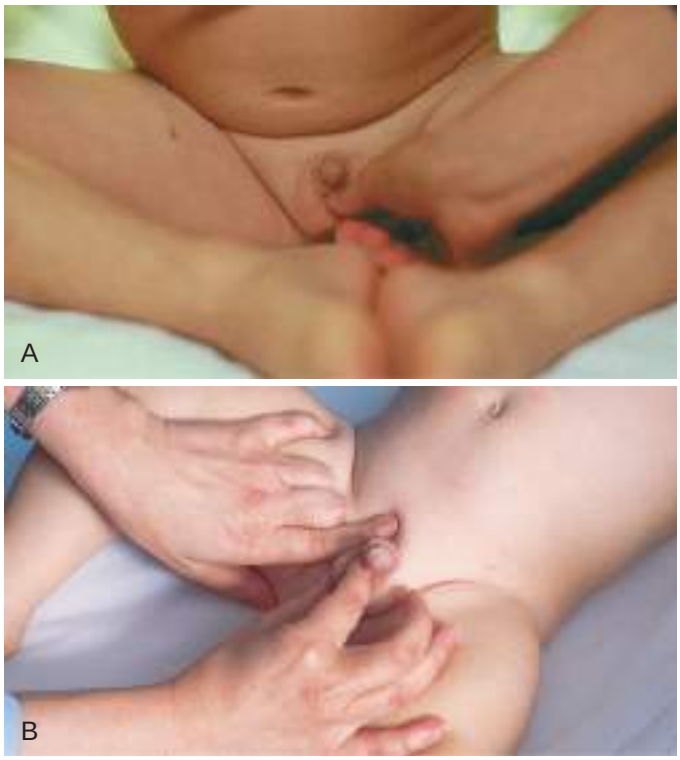

Fig. 33.34 **A:** Preventing cremasteric reflex by having child sit in "tailor" position. **B:** Blocking inguinal canal during palpation of scrotum for descended testes.

erectile organ located at the anterior end of the labia minora. It is covered by a small flap of skin, the *prepuce*.

The *labia majora* are two thick folds of skin running posteriorly from the mons to the posterior commissure of the vagina. Internal to the labia majora are two folds of skin called the *labia minora*. Although the labia minora are usually prominent in the newborn, they gradually atrophy, which makes them almost invisible until their enlargement during puberty. The inner surface of the labia should be pink and moist. The size of the labia should be noted as well as any evidence of fusion, which may suggest male scrota. Normally, no masses are palpable within the labia.

The urethral meatus is located posterior to the clitoris and is surrounded by Skene's glands and ducts. Although not a prominent structure, the meatus appears as a small, V-shaped slit. Its location should be noted, especially if it opens from the clitoris or inside the vagina. The glands should be gently palpated, as they are common sites of cysts and sexually transmitted lesions.

The vaginal orifice is located posterior to the urethral meatus. Its appearance varies depending on individual anatomy and sexual activity. Ordinarily, examination of the vagina is limited to inspection. In virgins, a thin, crescent-shaped or circular membrane, called the *hymen*, may cover part of the vaginal opening. In some instances it completely occludes the orifice. After rupture, small, rounded pieces of tissue called *caruncles* remain. Although an imperforate hymen denotes lack of penile intercourse, a perforate one does not necessarily indicate sexual activity.

! NURSING ALERT

In girls who have undergone female genital cutting (FGC) the genitalia will appear different. Do not show surprise or disgust, but note the appearance and discuss the procedure with the young woman (see Chapter 5, Female Genital Cutting).

Surrounding the vaginal opening are Bartholin's glands, which secrete a clear, mucoid fluid into the vagina for lubrication during intercourse. The ducts should be palpated for cysts. The nurse should also note the discharge from the vagina, which is usually clear or white.

Anus

After examination of the genitalia, the anal area is easily examined, although the child should be placed on the abdomen. The general firmness of the buttocks and symmetry of the gluteal folds should be noted. The tone of the anal sphincter can be assessed by eliciting the anal reflex. Gently scratching the anal area results in an obvious quick contraction of the external anal sphincter.

Back and Extremities

Spine. The general curvature of the spine is noted. Normally, the back of a newborn is rounded or C-shaped from the thoracic and pelvic curves. The development of the cervical and lumbar curves approximates development of various motor skills, such as cervical curvature with head control, and gives the older child the typical double S curve.

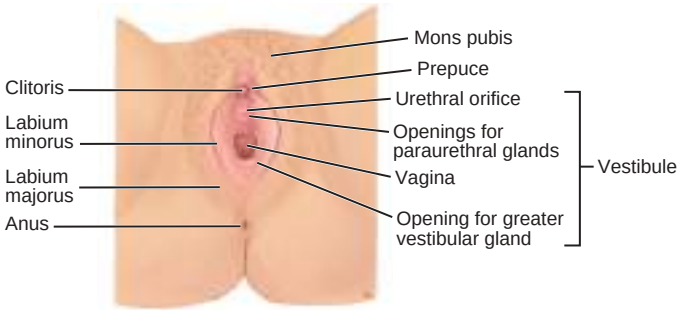

Fig. 33.35 External structures of genitalia in postpubertal female. Labia are spread to reveal deeper structures. (From Applegate, E. [2006]. *The anatomy and physiology learning system* [3rd ed.]. Mosby.)

Marked curvatures in posture are abnormal. *Scoliosis*, lateral curvature of the spine, is an important childhood condition, especially in girls. Although scoliosis may be identified by observing and palpating the spine and noting a sideways displacement, more objective tests include the following:

- With the child standing erect, clothed only in underpants (and bra if older girl), observe from behind, noting asymmetry of the shoulders and hips.
- With the child bending forward so that the back is parallel to the floor, observe from the side, noting asymmetry or prominence of the rib cage.

A slight limp, a crooked hemline, or concerns related to a sore back are other signs and symptoms of scoliosis (see Chapter 53, Scoliosis—Diagnostic Evaluation for further discussion).

The back should be inspected, especially along the spine, for any tufts of hair, dimples, or discoloration. Mobility of the vertebral column is easily assessed in most children because of their propensity for constant motion during the examination. However, mobility can be tested by asking the child to sit up from a prone position or to do a modified sit-up exercise.

Movement of the cervical spine is an important diagnostic sign of neurological disorders, such as meningitis. Normally, movement of the head in all directions is effortless.

! NURSING ALERT

Hyperextension of the neck and spine, or *opisthotonos*, which is accompanied by pain when the head is flexed, is always referred for immediate medical evaluation.

Extremities. Each extremity needs to be inspected for symmetry of length and size; any deviation should be referred for orthopedic evaluation. The nurse should count the fingers and toes to be certain of the normal number. This is so often taken for granted that an extra digit (*polydactyly*) or fusion of digits (*syndactyly*) may go unnoticed.

The arms and legs are inspected for temperature and colour, which should be equal in each extremity, although the feet may normally be colder than the hands.

The shape of bones should also be assessed. Several variations of bone shape may be observed in children. Although many of them cause parents concern, most are benign and require no treatment. *Bowleg*, or genu varum, is lateral bowing of the tibia. It is clinically present when the child stands with the medial malleoli (rounded prominence on either side of the ankle) opposite each other and the space between the knees is greater than approximately 5 cm (Figure 33.36). Toddlers are usually bowlegged after beginning to walk until all of their lower back and leg muscles are well developed. Unilateral or asymmetrical bowlegs that are present beyond the age of 2 to 3 years, may represent pathological conditions requiring further investigation.

Knock-knee, or genu valgum, appears as the opposite of bowleg, in that the knees are close together but the feet are spread apart. It is determined clinically by using the same method as for genu varum but by measuring the distance between the malleoli, which normally should be less than 7.5 cm (Figure 33.37). Knock-knee is normally present in children from about 2 to 7 years of age. Knock-knee that is excessive, asymmetrical, accompanied by short stature, or evident in a child nearing puberty requires further evaluation.

Next, the feet are inspected. Infants' and toddlers' feet appear flat because the foot is normally wide and the arch is covered by a fat

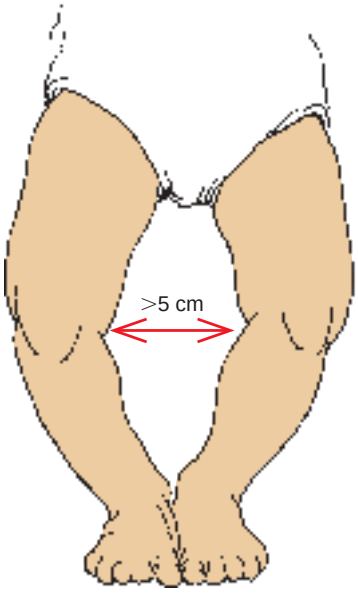

Fig. 33.36 Bowleg.

pad. Development of the arch occurs naturally from the action of walking. Normally, at birth the feet are held in a valgus (outward) or varus (inward) position. To determine whether a foot deformity at birth is a result of intrauterine position or development, the examiner scratches the outer, then inner, side of the sole. (See Chapter 53 for a discussion of clubfoot and Figure 53.14.) If the foot position is self-correctable, it will assume a right angle to the leg. As the child begins to walk, the feet turn outward less than 30 degrees and inward less than 10 degrees.

Toddlers have a "toddling" or broad-based gait, which facilitates walking by lowering the centre of gravity. As the child reaches preschool age, the legs are brought closer together. By school age the walking posture is much more graceful and balanced.

The most common gait issue in young children is *pigeon toe*, or toeing in, which usually results from torsional deformities, such as internal tibial torsion (abnormal rotation or bowing of the tibia). Tests for tibial torsion include measuring the thigh–foot angle, which requires considerable practice for accuracy.

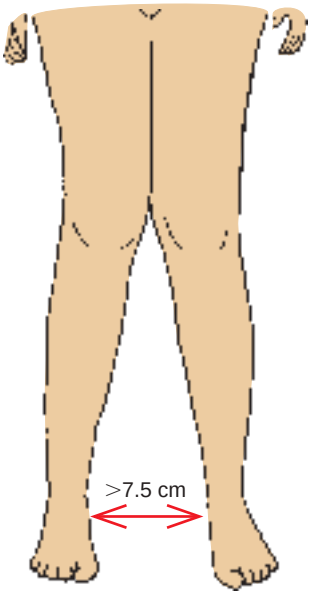

Fig. 33.37 Knock-knee.

The plantar or grasp reflex can be elicited by exerting firm but gentle pressure with the tip of the thumb against the lateral sole of the foot from the heel upward to the little toe and then across to the big toe (see Table 26.3, Assessment of Newborn Reflexes). The normal response in children who are walking is flexion of the toes. *Babinski sign*, dorsiflexion of the big toe and fanning of the other toes, is normal during infancy but abnormal after about 1 year of age or when locomotion begins.

Joints. The joints are evaluated for range of motion. Normally this requires no specific testing if the nurse has observed the child's movements during the examination. However, the hips should be routinely investigated in infants for developmental dysplasia by a qualified health care provider (physician or nurse practitioner) (see Figure 25.13 and Chapter 53). Any evidence of joint immobility or hyperflexibility needs to be reported.

The joints are palpated for heat, tenderness, and swelling. These signs, as well as redness over the joint, warrant further investigation.

Muscles. The symmetry and quality of muscle development, tone, and strength should be noted. Development is observed by looking at the shape and contour of the body in both a relaxed and a tensed state. Tone is estimated by grasping the muscle and feeling its firmness when it is relaxed and contracted. A common site for testing tone is the biceps muscle of the arm. Children are usually willing to "make a muscle" by clenching their fist.

Strength can be estimated by having the child use an extremity to push or pull against resistance, as in the following examples:

Arm strength—Child holds the arms outstretched in front of the body and tries to raise the arms while downward pressure is applied.

Hand strength—Child shakes hands with nurse and squeezes one or two fingers of the nurse's hand.

Leg strength—Child sits on a table or chair with the legs dangling and tries to raise the legs while downward pressure is applied.

Symmetry of strength in the extremities, hands, and fingers should be noted and evidence of paresis, or weakness, needs to be reported.

Neurological Assessment

The assessment of the nervous system is the broadest and most diverse part of the examination process, since every human function, both physical and emotional, is controlled by neurological impulses. Much of the neurological examination has already been discussed, such as assessment of behaviour, sensory testing, and motor function. The following discussion focuses on a general appraisal of cerebellar function, deep tendon reflexes, and the cranial nerves. See Chapter 50, Neurological Assessment for further discussion.

Cerebellar Function. The cerebellum controls balance and coordination. Much of the assessment of cerebellar function is included in observing the child's posture, body movements, gait, and development of fine and gross motor skills. Tests such as balancing on one foot and the heel-to-toe walk assess balance. Coordination is tested by asking the child to reach for a toy, button clothes, tie shoes, or draw a straight line on a piece of paper (provided the child is old enough to do these activities). Coordination can also be tested by any sequence of rapid, successive movements, such as quickly touching each finger with the thumb of the same hand.

Several tests for cerebellar function can be performed as games (Box 33.10). When a Romberg test is done, the nurse stays beside the child if there is a possibility that the child may fall. School-age children should be able to perform these tests, although in the finger-to-nose test, preschoolers normally can only bring the finger within 5 to 7.5 cm of the nose. Difficulty in performing these exercises indicates

BOX 33.10 Tests for Cerebellar Function

Finger-to-nose test—With the child's arm extended, ask the child to touch the nose with the index finger with eyes open and then closed.

Heel-to-shin test—Have the child stand and run the heel of one foot down the shin or anterior aspect of the tibia of the other leg, both with eyes opened and then closed.

Romberg test—Have the child stand with eyes closed and heels together; falling or leaning to one side is abnormal and is called the *Romberg sign*.

poor sense of position (especially with the eyes closed) and incoordination (especially with the eyes opened).

Reflexes. Testing reflexes is an important part of the neurological examination. Persistence of primitive reflexes, loss of reflexes, or hyperactivity of deep tendon reflexes is usually a result of a cerebral insult.

Reflexes can be elicited by using the rubber head of the reflex hammer, flat of the finger, or side of the hand. If the child is easily frightened by equipment, a hand or finger can be used. Although testing reflexes is a simple procedure, the child may inhibit the reflex by unconsciously tensing the muscle. To avoid tensing, younger children can be distracted with toys or talk to them. Older children can concentrate on the exercise of grasping their two hands in front of them and trying to pull them apart. This diverts their attention from the testing and causes involuntary relaxation of the muscles.

Deep tendon reflexes are stretch reflexes of a muscle. The most common deep tendon reflex is the knee jerk, or patellar reflex (sometimes called the *quadriceps reflex*). The reflexes normally elicited are described in Figures 33.38 and 33.39. Any diminished or hyperreflexive response should be reported for further evaluation.

Cranial Nerves. Assessment of the cranial nerves (Figure 33.40) is an important area of neurological assessment (Table 33.12). With young children, the nurse can present the tests as games to foster **trust** and

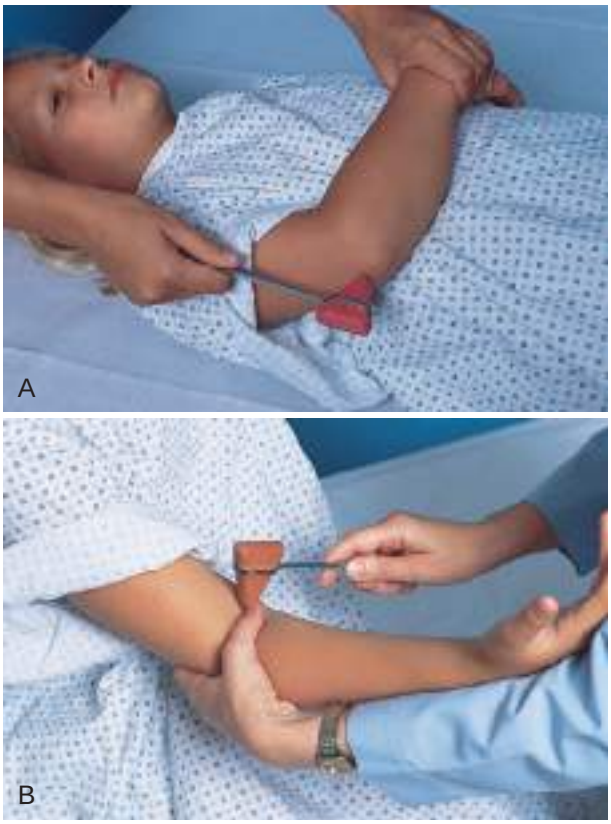

Fig. 33.38 **A:** Testing for triceps reflex. The child is placed supine, with forearm resting over chest, and triceps tendon is struck. Alternative procedure: child's arm is abducted, with upper arm supported and forearm allowed to hang freely. Triceps tendon is struck. Normal response is partial extension of the forearm. **B:** Testing for biceps reflex. The child's arm is held by placing the partially flexed elbow in the examiner's hand with thumb over antecubital space. The examiner's thumbnail is struck with a hammer. Normal response is partial flexion of the forearm.

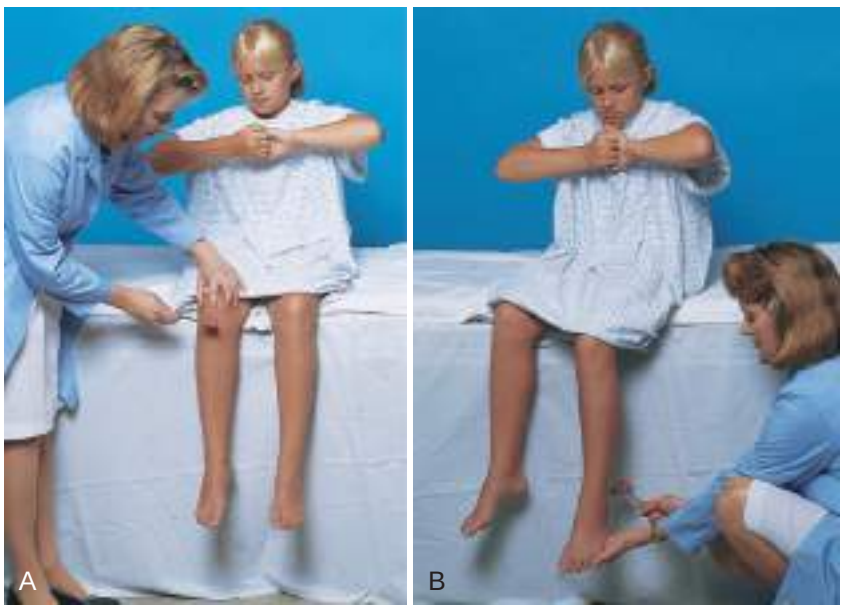

Fig. 33.39 **A:** Testing for patellar, or knee jerk, reflex, using distraction. The child sits on edge of the examining table (or on parent's lap) with lower legs flexed at the knee and dangling freely. The patellar tendon is tapped just below the kneecap. Normal response is partial extension of the lower leg. **B:** Testing for Achilles reflex. The child should be in the same position as for knee jerk reflex. The foot is supported lightly in the examiner's hand, and the Achilles tendon is struck. Normal response is plantar flexion of the foot (foot pointing downward).

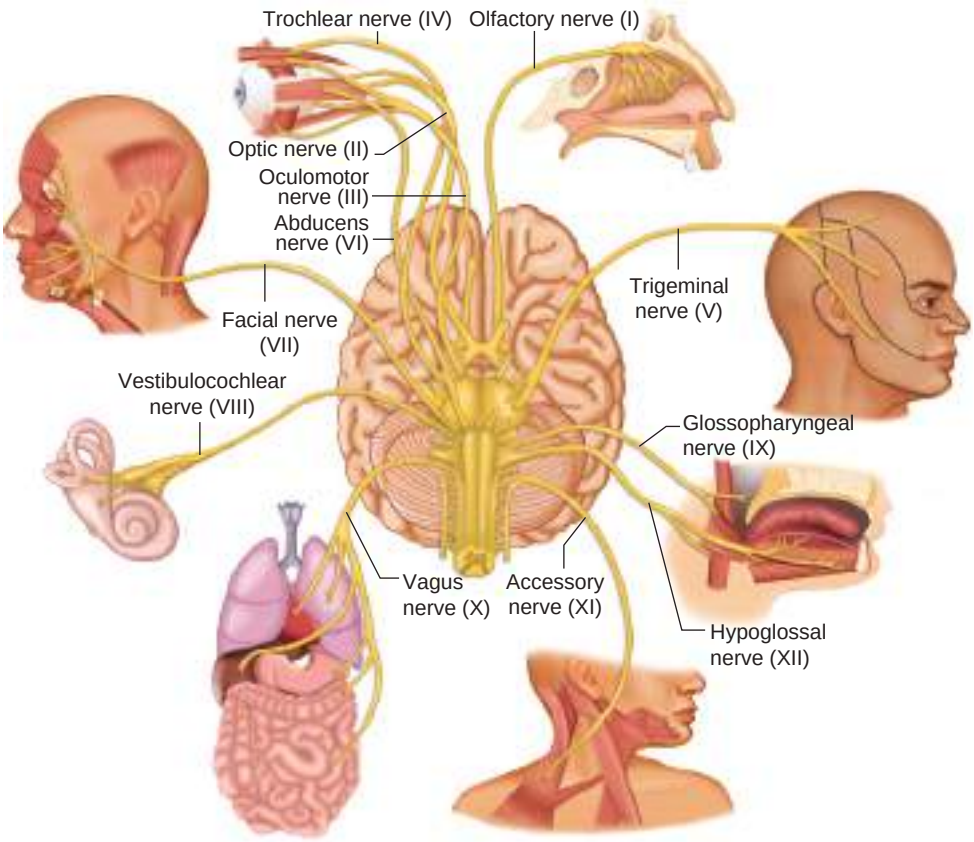

Fig. 33.40 Cranial nerves. (From Patton, K. T., & Thibodeau, G. A. [2013]. *Anatomy & physiology* [8th ed.]. Mosby.)

TABLE 33.12 Assessment of Cranial Nerves

Description and Function	Tests
I—Olfactory Nerve	
Olfactory mucosa of nasal cavity Smell	With eyes closed, have child identify odours such as coffee, alcohol from a swab, or other smells; test each nostril separately.
II—Optic Nerve	
Rods and cones of retina, optic nerve	Check for perception of light, visual acuity, peripheral vision, colour vision, and normal optic disc.
Vision	
III—Oculomotor Nerve	
Extraocular muscles of the eye:	Have child follow an object (toy) or light in six cardinal positions of gaze (see Figure 33.41).
Superior rectus (SR)—moves eyeball up and in	
Inferior rectus (IR)—moves eyeball down and in	
Medial rectus (MR)—moves eyeball nasally	
Inferior oblique (IO)—moves eyeball up and out	
Pupil constriction and accommodation	Perform PERRLA (*P*upils *E*qual, *R*ound, *R*eact to *L*ight, and *A*ccommodation).
Eyelid closing	Check for proper placement of lid.
IV—Trochlear Nerve	
Superior oblique muscle (SO)—moves eye down and out	Have child look down and in (see Figure 33.41).
V—Trigeminal Nerve	
Muscles of mastication	Have child bite down hard and open jaw; test symmetry and strength.
Sensory—face, scalp, nasal and buccal mucosa	With child's eyes closed, see if child can detect light touch in mandibular and maxillary regions.
	Test corneal and blink reflex by touching cornea lightly (approach from the side so that child does not blink before cornea is touched).

Continued

TABLE 33.12 Assessment of Cranial Nerves—cont'd

Description and Function	Tests
VI—Abducens Nerve	
Lateral rectus (LR) muscle—moves eye temporally	Have child look toward temporal side (see Figure 33.41).
VII—Facial Nerve	
Muscles for facial expression	Have child smile, make a funny face, or show teeth to see symmetry of expression.
Anterior two thirds of tongue (sensory)	Have child identify sweet or salty solution; place each taste on anterior section and sides of protruding tongue; if child retracts tongue, solution will dissolve toward posterior part of tongue.
VIII—Auditory, Acoustic, or Vestibulocochlear Nerve	
Internal ear	Test hearing; note any loss of equilibrium or presence of vertigo.
Hearing and balance	
IX—Glossopharyngeal Nerve	
Pharynx, tongue	Stimulate posterior pharynx with a tongue blade; child should gag.
Posterior third of tongue	Test sense of sour or bitter taste on posterior segment of tongue.
Sensory	
X—Vagus Nerve	
Muscles of the larynx, pharynx, some organs of gastrointestinal system, sensory fibres of root of tongue, heart, and lung	Note hoarseness of voice, gag reflex, and ability to swallow.
	Check that uvula is in midline; when stimulated with tongue blade, it should deviate upward and to stimulated side.
XI—Accessory Nerve	
Sternocleidomastoid and trapezius muscles of the shoulder	Have child shrug shoulders while applying mild pressure; with examiner's hands placed on shoulders, have child turn head against opposing pressure on either side; note symmetry and strength.
XII—Hypoglossal Nerve	
Muscles of the tongue	Have child move tongue in all directions; have child protrude tongue as far as possible; note any midline deviation.
	Test strength by placing tongue blade on one side of tongue and having child move it away.

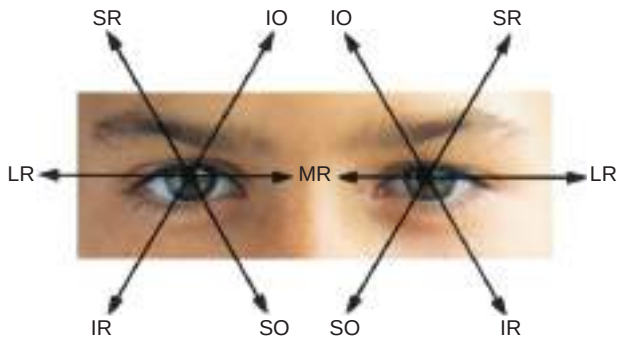

Fig. 33.41 Testing cardinal positions of gaze. Muscles responsible for movement: *SR*, superior rectus; *IR*, inferior rectus; *MR*, medial rectus; *IO*, inferior oblique; *SO*, superior oblique; *LR*, lateral rectus.

security at the beginning of the examination. Alternatively, the cranial nerve test can be included when each system is examined, such as tongue movement and strength, gag reflex, swallowing, cardinal positions of gaze (Figure 33.41), and position of the uvula during examination of the mouth.

KEY POINTS

- The objectives of performing a health history are to identify pertinent information, determine the chief health concern, analyze the present illness, secure the patient's health history, review biological systems, and record a family medical history and child psychosocial and sexual history.
- Family assessment is the collection of data about family composition and relationships among its members; it also focuses on home and community environment, parents' occupation and education, and cultural and religious traditions.
- Nutritional assessment is performed by determination of dietary intake, clinical examination, and biochemical analysis.
- Developmental screening tools are valuable in identifying infants and children who are at risk for developmental delays.
- Growth measurements during the physical examination focus on length or height, weight, skin fold thickness, and arm and head circumference. Assessment of growth is measured against standard growth charts to determine a child's status in comparison with that of other children the same age.
- Measurements of temperature, pulse, respiration, and BP constitute the physiological approach to assessment.
- The child's general appearance is a cumulative, subjective impression of physical appearance, state of nutrition, behaviour, personality, interactions with parents and nurse, posture, development, and speech.
- Assessment of the skin, which primarily involves inspection and palpation, focuses on colour, texture, temperature, moisture, and turgor. The nurse needs to be aware of both physiological and ethnic factors that may affect these areas.
- In assessment of the lymph nodes, the nurse examines, by palpation, the part of the body in which the glands are located.
- The head is inspected for shape, symmetry, mobility, and muscle control.
- Examination of the eyes includes placement and alignment, inspection of external and internal structures, and vision testing.

- The ear examination encompasses placement and alignment, external and internal structures, and auditory testing.
- The lungs are examined by inspection, palpation, percussion, and auscultation.
- Auscultation is the most important procedure for examining the heart.
- Abdominal assessment follows an orderly sequence of inspection, auscultation, percussion, and, finally, palpation, since palpation may distort normal abdominal sounds assessed during auscultation.
- Examination of the genitalia may provoke anxiety in the child, and the nurse must avoid any transference of anxiety.
- Neurological assessment addresses behaviour; motor, sensory, and cerebellar function; reflexes; and cranial nerves.

Pain Assessment and Management

Jennifer Tyrrell and Lorraine Bird
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify and use measures to assess pain in infants and children.
2. List various types of pain assessment tools that are used with infants and children.
3. Outline essential pain management strategies of reducing pain in infants and children.
4. Review common types of pain experienced by infants, children, and adolescents.
5. Discuss evidence supporting specific pain management strategies.

The evidence-informed literature on pediatric pain assessment and management grows considerably each year. Treatment options for pediatric acute and chronic (persistent) pain are continually being evaluated, and new technologies and administration options have become available (Tobias, 2014a). Unfortunately, despite advances in management of acute and chronic pediatric pain, many children and adolescents continue to suffer from inadequately treated pain of all types. Pain is a frequent occurrence in children, with more than 25% of children experiencing pain during hospitalization (Harrison et al., 2014; Kozlowski et al., 2014; Stevens et al., 2012). Optimal pain management begins with systematic and consistent assessment and reassessment following pain treatment and painful procedures to guide the selection of treatments and allow evaluation of the effectiveness or ineffectiveness of pain treatments (Freund & Bolick, 2019; Registered Nurses Association of Ontario [RNAO], 2013). Nurses play a major role as the member of an interprofessional team involved in managing pain in children. The best approach to providing pain management in children is to ensure that accurate assessments are done and a multimodal approach to management is employed. The term *the 3Ps of pain management* has been used to describe a mix of *p*sychological, *p*hysical, and *p*harmacological strategies, or methods, to treat and manage **pain**.

No one strategy on its own may be effective. Utilizing a multimodal and interprofessional approach can provide effective outcomes in pediatric pain management (Dancel et al., 2017).

PAIN ASSESSMENT

Although there are many different measures of pain for infants, children, and adolescents, pain assessment remains challenging, particularly for children with complex pain that may be chronic or recurrent (Manworren & Stinson, 2016; Stevens et al., 2012; Young, 2017). The number of pain measures available for use in infants and young children has increased dramatically and adds a layer of complexity to the assessment of pain in children.

The purpose of a pediatric pain assessment is to determine how much pain the child is feeling. Although pain assessment includes more than a number rating, understanding the intensity of the pain experienced by the child is essential for effective pain management. Numerous pediatric pain scales exist and are most commonly identified as behavioural pain measures, self-report pain rating scales, and multidimensional pain assessment tools.

Assessment of Acute Pain

Acute pain in children may have several causes, such as medical procedures (immunization, venipuncture, for blood tests or intravenous [IV] therapy, lumbar puncture for diagnosis or treatment, bone marrow aspiration, skin debridement for severe burns); surgical (appendectomy, tonsillectomy) and orthopedic (spinal fusion) procedures; medical treatments (chemotherapy-induced mucositis or peripheral neuropathy); injury (such as falls, burns, injury from motor vehicle

collisions, other traumatic injuries); infection; and exacerbation of disease-related pain, such as from arthritis, sickle cell disease, or cancer.

Behavioural Pain Measures. Behavioural measures of pain (for infants and children younger than 4 years; see Table 34.1) have been developed, validated, and widely used. These are used especially with young children under 3 years of age, who cannot self-report pain using a pain scale, as they lack the ability to quantify pain using self-report measures. Other reasons for inability to self-report include cognitive impairment, inability to communicate, and critical illness (Crellin et al., 2015; Quinn et al., 2018).

Distress behaviours such as crying, facial expression, and body movements occur in response to acute painful procedures and are associated with pain (see Figure 26.21) (Box 34.1). The facial expressions of brow bulge, eye squeeze, nasolabial furrow, and stretched open lips are the most frequently occurring and specific behavioural indicators of acute procedural pain in infants regardless of gestational age or severity of illness (Harrison et al., 2015). Behavioural indicators of pain are helpful in evaluating pain in infants and children with limited communication skills. However, discriminating between pain behaviours and reactions from other sources of distress, such as hunger, anxiety, or other types of discomfort, depends on the context of the situation and is not always easy (Harrison et al., 2018; Pillai Riddell et al., 2016).

Behaviour provides important information that cannot be obtained from self-report. Behavioural assessment may give a more complete picture of the total pain experience when done in conjunction with a subjective self-report measure. However, behavioural pain scales may be more time-consuming to conduct than obtaining self-reports. These

TABLE 34.1 Summary of Selected Behavioural Pain Measurement Scales for Infants and Young Children

Ages of Use	Purpose/Context	Items	Scoring Range
Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) (McGrath et al., 1985)			
1–7 years	Originally developed for measurement of postoperative pain Subsequently used to assess pain during brief pain episodes (e.g., vaccinations) and major procedural pain (e.g., bone marrow biopsies; severe pain (e.g., sickle cell)	Cry (1–3) Facial (0–2) Child verbal (0–2) Torso (1–2) Touch (1–2) Legs (1–2)	4 = no pain; 13 = worst pain
Modified Behavioural Pain Scale (MBPS) (Taddio et al., 1995)			
2–6 months	Modified from the Behavioural Pain Score (Robieux et al., 1991) Developed for measurement of vaccination pain	Facial expression (0–3) Cry (0–4) Movements (0, 2, 3)	0 = no pain; 10 = worst pain
Face, Legs, Activity, Cry, and Consolability (FLACC) (Merkel et al., 1997)			
2 months–7 years	Originally developed for measurement of postoperative pain Subsequently used to assess pain during brief pain episodes and in critically ill patients and for infants from 15 days of age through to adults	Face (0–2) Legs (0–2) Activity (0–2) Cry (0–2) Consolability (0–2)	0 = no pain; 10 = worst pain
FLACC Scale–Revised (Malviya et al., 2006)			
4–19 years	Originally developed for measurement of postoperative pain in children with cognitive impairment Subsequently used to assess pain during brief pain episodes and in critically ill patients Option of indicating individualized behaviours can be beneficial for children with atypical pain behaviours and lack of other typical features, which may result in a false low score on other tools	Same scale as for FLACC, however, further individual behaviour descriptors noted: Face 1: appears sad or worried Face 2: distressed-looking face; expression of fright or panic Legs 2: marked increase in spasticity, constant tremors, or jerking	0 = no pain; 10 = worst pain
Non-communicating Children's Pain Checklist (NCCPC) (Breau et al., 2002)			
5–29 years	Checklist to be used by primary caregivers to assess pain in children and young adults with severe cognitive impairment (see Figure 34.1)	27 items grouped into six subscales categories: Vocal; Social; Facial; Activity; Body and Limbs; Physiological, which are scored on the basis of number of times the items are observed over a 10-minute period (0 = not at all; 1 = just a little; 2 = fairly often; 3 = very often)	Moderate to severe pain determined at a cutoff of ≥11 of 81
Non-communicating Children's Pain Checklist–Revised (NCCPC-R)			
3–18 years	Nonverbal children with intellectual disabilities Revised from the NCCPC-PV (postoperative version)*	30-item pain-assessment tool	Moderate to severe pain determined at a cutoff of ≥7 of 90

BOX 34.1 Developmental Characteristics of Children's Responses to Pain

Young Infant

Generalized body response of rigidity or thrashing, possibly with local reflex withdrawal of stimulated area
Crying
Facial expression of pain (brows lowered and drawn together, eyes tightly closed, mouth stretched open and squarish)
No association demonstrated between approaching stimulus and subsequent pain

Older Infant

Localized body response with deliberate withdrawal of stimulated area
Loud crying
Facial expression of pain or anger
Physical resistance, especially pushing the stimulus away after it is applied

Young Child

Loud crying, screaming
Verbal expressions such as "Ow," "Ouch," "It hurts"
Thrashing of arms and legs
Attempts to push stimulus away before it is applied
Requests for termination of procedure
Clinging to parent, nurse, or other significant person
Requests for emotional support, such as hugs or other forms of physical comfort
Becoming restless and irritable with continuing pain
Behaviours occurring in anticipation of actual painful procedure

School-Age Child

May see all behaviours of young child, especially during actual painful procedure, but less in anticipatory period
Stalling behaviour, such as "Wait a minute" or "I'm not ready"
Muscular rigidity, such as clenched fists, white knuckles, gritted teeth, contracted limbs, body stiffness, closed eyes, wrinkled forehead

Adolescent

Less vocal protest
Less motor activity
More verbal expressions, such as "It hurts" or "You're hurting me"
Increased muscle tension and body control

Data from Craig, K. D., et al. (1984). Developmental changes in infant pain expression during immunization injections. *Social Science and Medicine, 19*(12), 1331–1337; Katz, E. R., Kellerman, J., & Siegel, S. E. (1980). Behavioral distress in children with cancer undergoing medical procedures: Developmental considerations. *Journal of Consulting and Clinical Psychology, 48*(3), 356–365.

measures depend on a trained observer to watch and record children's behaviours, such as vocalization, facial expression, and body movements that suggest discomfort. Caregiver or parental reports of a child's unique pain behaviours should be considered in a comprehensive behavioural pain assessment (Giordano et al., 2019).

Table 34.1 lists and summarizes a selection of validated behavioural pain measurement scales used to assess pain intensity in different contexts (such as procedural, postoperative) and different populations, such as infants, children, and children with cognitive disabilities (Giordano et al., 2019; Manworren & Stinson, 2016; Michaleff et al., 2017). The six behavioural pain measurement scales in Table 34.1 have undergone formal psychometric testing, and all have been used to various degrees in clinical care and research.

The *Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)* was developed in collaboration with experienced recovery room nurses to measure postoperative pain in children. The scale ranges from 4 ("no pain") to 13 ("worst pain") and includes indicators of cry, facial expressions, verbalization about pain, torso position and movements, touching (e.g., reaching, grabbing, need for restraint), and movement of legs.

The *Modified Behavioural Pain Scale (MBPS)* was specifically developed for measurement of vaccination pain in infants (Taddio et al., 1995). The 0–10 scale includes the items of cry, facial expressions, and body movements.

The *FLACC* has been used extensively in clinical practice (Crellin et al., 2015) and includes five categories of behaviour: *F*acial expression, *L*eg movement, *A*ctivity, *C*ry, and *C*onsolability. It is used to measure pain by quantifying pain behaviours with scores ranging from 0 (no pain behaviours) to 10 (most possible pain behaviours). The revised FLACC (r-FLACC) scale includes behaviours specific to individuals with cognitive impairment. The r-FLACC includes a section for open-ended descriptors of individual pain behaviours.

The *Non-communicating Children's Pain Checklist (NCCPC)* (Figure 34.1) and the revised postoperative version are used to measure pain in nonverbal children. A 10-minute observation period by caregivers is recommended to score 31 items in seven categories on the original scale and 29 items in six categories in the revised postoperative version. Such items include moaning, whining, crying (Vocal category); being irritable, withdrawn, difficult to distract (Social category); and furrowed brow and clenching or grinding teeth (Facial category) (Carter, 2020; Cascella et al., 2019).

In critical care settings the *COMFORT scale* (Ambuel et al., 1992; Ismail et al., 2019) or the revised modified COMFORT scale (Carnevale & Razack, 2002) is recommended (Maaskant et al., 2016). The modified COMFORT scale is a behavioural, unobtrusive method of measuring distress in unconscious and ventilated patients. It has six indicators: alertness, calmness/agitation, respiratory response, physical movement, muscle tone, and facial tension. Each indicator is scored between 1 and 5, based on the behaviours exhibited by the patient. Patients are observed unobtrusively for 2 minutes, and the total score is derived by adding the scores of each indicator. The total scores can range between 6 and 30, and scores of 11 generally indicate adequate sedation and pain control.

Self-Report Pain Rating Scales. Self-report measures are most often used for children older than 4 years of age (Table 34.2). Although children 4 or 5 years of age are able to use self-report measures, cognitive characteristics of the preoperational stage influence their ability to separate feelings of pain and mood. Smiling faces on pain assessment scales can result in inadequacies of the pain rating (Quinn et al., 2014). Simple, concrete anchor words, such as "no hurt" to "biggest hurt," are more appropriate than "least pain sensation" to "worst intense pain imaginable."

The ability to discriminate degrees of pain in facial expressions appears to be reasonably established by 3 years of age. There are many different "faces" scales for the measurement of pain intensity. Faces scales provide a series of facial expressions depicting gradations of pain. The faces are appealing because children can simply point to the face that represents how they feel.

The *Faces Pain Scale–Revised (FPS-R)* (Hicks et al., 2001) and the *Wong-Baker FACES Pain Rating Scale* (Wong & Baker, 1988) are the most widely used faces pain measurement tools. The scales range from 0 to 10. The FPS–R shows six faces depicting increasing gradation of

Non-communicating Children's Pain Checklist — Postoperative Version (NCCPC-PV)

NAME:_____ UNIT/FILE #: _____ DATE:_____ (dd/mm/yy)

OBSERVER:_____ START TIME:_____AM/PM STOP TIME:_____AM/PM

How often has this child shown these behaviours in the last 10 minutes? Please circle a number for each behaviour. If an item does not apply to this child (for example, this child cannot reach with their hands), then indicate "not applicable" for that item.

0 = NOT AT ALL	1 = JUST A LITTLE	2 = FAIRLY OFTEN	3 = VERY OFTEN	NA = NOT APPLICABLE

I. Vocal

USING THE NCCPC-PV

The NCCPC-PV was designed to be used for children age 3 to 18 years who are unable to speak because of cognitive (mental/intellectual) impairments or disabilities. It can be used *whether or not* a child has physical impairments or disabilities. Descriptions of the types of children used to validate the NCCPC-PV can be found in: Breau, L.M., Finley, G.A., McGrath, P.J., & Camfield, C.S. (2002). Validation of the Non-communicating Children's Pain Checklist — Postoperative Version. *Anesthesiology, 96* (3), 528-535. The NCCPC-PV was designed to be used without training by parents and caregivers (carers), or by other adults who are not familiar with a specific child (do not know them well).

The NCCPC-PV may be freely copied for clinical use or use in research funded by not-for-profit agencies. For-profit agencies should contact Lynn Breau: Pediatric Pain Research, IWK Health Centre, 5850 University Avenue, Halifax, Nova Scotia, Canada, B3J 3G9 (lbreau@ns.sympatico.ca).

The NCCPC-PV was intended for use for pain after surgery or due to other procedures conducted in hospital. If short- or long-term pain is suspected for a child at home or in a long-term residential setting, the **Non-communicating Children's Pain Checklist — Revised** may be used. It can be obtained by contacting Lynn Breau. Information regarding the NCCPC-R can be found in: Breau, L.M., McGrath, P.J., Camfield, C.S. & Finley, G.A. (2002). Psychometric Properties of the Non-communicating Children's Pain Checklist—Revised. *Pain, 99,* 349-357.

ADMINISTRATION

To complete the NCCPC-R, base your observations on the child's behaviour over **10 minutes**. ***It is not necessary to watch the child continuously for this period***. However, it is recommended that the observer be in the child's presence for the majority of this time (e.g., be in the same room with the child). Although shorter observation periods may be used, the cut-off scores described below may not apply.

At the end of the observation time, indicate how frequently (how often) each item was seen or heard. This should not be based on the child's typical behaviour or in relation to what he or she usually does. A guide for deciding the frequency of items is below:

0 = Not present at all during the observation period. (Note: If the item is not present because the child is not capable of performing that act, it should be scored as "NA").
1 = Seen or heard rarely (hardly at all), but is present.
2 = Seen or heard a number of times, but not continuous (not all the time).
3 = Seen or heard often, almost continuous (almost all the time); anyone would easily notice this if they saw the child for a few moments during the observation time.
NA = Not applicable. This child is not capable of performing this action.

SCORING

1. Add up the scores for each subscale and enter below that subscale number in the Score Summary at the bottom of the sheet. Items marked "NA" are scored as "0" (zero).
2. Add up all subscale scores for Total Score.
3. Check whether the child's score is greater than the cut-off score.

CUT-OFF SCORE

Based on the scores of 24 children age 3 to 18 (Breau, Finley, McGrath, & Camfield, 2002), a **Total Score of 11 or more** indicates a child has **moderate to severe pain**. Based on unpublished data from this same sample, a ***Total score of 6-10*** indicates a child has **mild pain**. When parents and caregivers completed the NCCPC-PV in hospital for the study group, this was accurate 88% of the time. When other observers completed the NCCPC-PV, this was accurate 75% of the time. A Total Score of 10 or less indicates less than moderate/severe pain. This was correct in the study group for parents and caregivers 81% of the time and for other observers 63% of the time.

USE OF CUT-OFF SCORES

As with all observational tools, caution should be taken in using cut-off scores, because they may not be 100% accurate. They should not be used as the only basis for deciding whether a child should be treated for pain. In some cases children may have lower scores when pain is present. For more detailed instructions for use of the NCCPC-PV in such situations, please refer to the full manual, available from Lynn Breau: Pediatric Pain Research, IWK Health Centre, 5850 University Avenue, Halifax, Nova Scotia, Canada, B3J 3G9 (lbreau@ns.sympatico.ca).

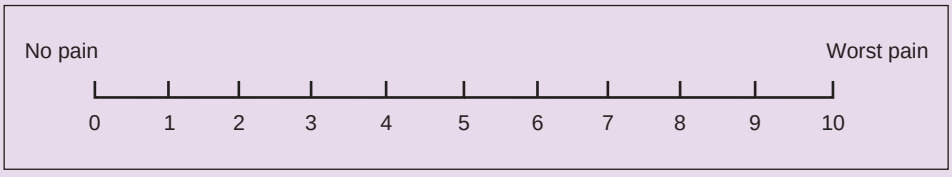
TABLE 34.2 Pain Rating Scales for Children*

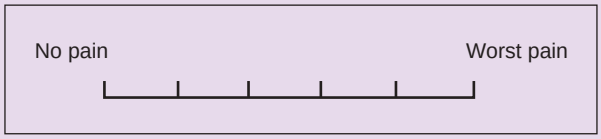
Pain Scale, Description	Instructions	Recommended Age, Comments
Wong-Baker FACES® Pain Rating Scale*		
Uses six cartoon faces ranging from smiling face for "no pain" to tearful face for "worst pain"	Explain to the child that each face represents a face of a person with no pain (hurt), some pain, or a lot of pain. Ask child to choose face that best describes their own pain and record appropriate number.	Children as young as 3 years. The numbers are for parents and health care providers to quantify the pain. The words are included as a guide to explain how to use the faces. The Wong-Baker FACES Pain Rating Scale provides three scales in one: facial expressions, numbers, and words. Research supports cultural sensitivity of faces for White, Black, Latin American, Thai, Chinese, and Japanese children.



Wong-Baker FACES Foundation (2020). *Wong-Baker FACES® Pain Rating Scale.* With permission from www.WongBakerFACES.org. Originally published in *Whaley & Wong's Nursing Care of Infants and Children.* © Elsevier Inc.

FACES Pain Scale-Revised (FPS-R)		
Made up of six faces depicting increasing gradation of pain severity, from 0 = "no pain" on the left face to 10 = "most pain possible" on the right face. The "no pain" anchor face is a neutral face.	These faces show how much something can hurt. This face [**point to left-most face**] shows no pain. The faces show more and more pain [**point to each from left to right**] up to this one [**point to right-most face**]. It shows very much pain. Point to the face that shows how much you hurt [**right now**] (International Association for the Study of Pain [IASP], 2001).	Well validated for children as young as 3 years. Do not use words like *happy* and *sad* when explaining tool to children. The scale is intended to measure how children feel, not how their face looks.

Faces Pain Scale–Revised (FPS-R). https://www.iasp-pain.org/resources/faces-pain-scale-revised/. Copyright © 2001, International Association for the Study of Pain®. Reproduced with permission.



Numeric Scale		
Uses straight line with end points identified as "no pain" and "worst pain" and sometimes "medium pain" in the middle; divisions along line marked in units from 0 to 10 (high number may vary)	Explain to child that at one end of the line is 0, which means that person feels no pain (hurt). At other end is usually 5 or 10, which means the person feels the worst pain imaginable. The numbers 1–5 or 1–10 are for very little pain to a whole lot of pain. Ask child to choose number that best describes their own pain.	Children as young as 5 years, as long as they can count and have some concept of numbers and their values in relation to other numbers. Scale may be used horizontally or vertically. Number coding should be the same as in other scales used in facility.

Continued

TABLE 34.2 Pain Rating Scales for Children—cont'd

Pain Scale, Description	Instructions	Recommended Age, Comments
Visual Analogue Scale (VAS) (Cline et al., 1992)		
A vertical or horizontal line is drawn to a certain length, such as 10 cm, and anchored by items that represent extremes of the subjective phenomenon, such as pain, that is measured.	Ask child to place mark on the line that best describes amount of their own pain. With centimetre ruler measure from "no pain" end to the mark and record this measurement as the pain score.	Children as young as 4 to 5, up to 7 years. Vertical or horizontal scale may be used. Research shows that children ages 3–18 years prefer VAS less than other scales (Luffy & Grove, 2003; Wong & Baker, 1988).

*Wong-Baker FACES Pain Rating Scale reference manual describing development and research of the scale is available from City of Hope Pain/Palliative Care Resource Center, 1500 East Duarte Road, Duarte, CA 91010; (626) 359-8111, ext. 3829; fax (626) 301-8941; http://www.elsevierhealth.com/WOW/. Use of FACES with children is demonstrated in *Whaley and Wong's Pediatric Nursing Video Series*, "Pain Assessment and Management," narrated by Donna Wong, PhD, RN. Available from Elsevier, 3251 Riverport Lane, Maryland Heights, MO, 63043; (800) 426-4545; fax (800) 535-9935; http://www.elsevierhealth.com.

pain severity, from 0 = "no pain" on the left face to 10 = "very much pain" on the right face. The "no pain" anchor face is a neutral face and does not depict the emotion of "happiness," and, similarly, none of the faces have tears, depicting the emotion of "sadness." The FPS-R has been translated for use in 69 languages (see Additional Resources). The Wong-Baker FACES Pain Rating Scale consists of six cartoon faces ranging from a smiling face for "no pain" to a tearful face for "worst pain." The child is asked to choose a face that describes their pain. The Wong-Baker FACES Pain Rating Scale can enable differentiating pain from fear in school-age children (Garra et al., 2013).

For children aged 8 years and older the *numeric rating scale (NRS)*, specifically the 0-to-10 scale, is most widely used in clinical practice because it is easy to use. The *visual analogue scale (VAS)*, a 10-centimetre line anchored by numbers or the words "no pain" on the left and "worst pain" on the right, is another well-established measure of pain intensity in normally developing children aged 8 years and older (von Baeyer, 2014).

It is important to select a pain assessment tool based on the context for which the tool was designed and for the population it was intended. For instance, research has demonstrated that the VAS, the Colour Analogue Scale (CAS), and the FPR-R are reliable tools for self-report of pain in children with acute pain (Birnie et al., 2019; Le May et al., 2018).

Scales for pain measurement instruments mostly consist of 0 for no pain and a variable top score anchor (most severe pain) ranging from 4 to 160. A pain score of 5 may mean a lot of pain (if a 0-to-5 scale is used) or very little (if a 0-to-100 scale is used). This highlights the need to clearly specify which score corresponds to which scale and, at an organizational level, making it clear which pain assessment measures have been adopted for which populations. A common metric, such as a 0-to-10 score, may facilitate using pain scores to guide treatment, as a certain score may be considered the point at which an intervention is required or a point at which pain may be considered to be well controlled. A 0-to-10 system was reported to be preferred by health care providers and would make pain scores easier to read, interpret, and integrate into research and practice.

Multidimensional Measures. Several cognitive skills, such as measurement, classification, and seriation (the ability to accurately place items in ascending or descending order), become explicit between approximately 7 and 10 years of age. Children in this age range are therefore usually able to use a 0-to-10 numeric rating scale, currently used with adolescents and adults. However, use of this scale is only an assessment of pain intensity, which may not change in some pain states. Other dimensions such as pain quality, pain location, and spatial distribution of pain may change without a change in pain intensity.

Two multidimensional pain assessment tools have been well validated in children 8 years and older (von Baeyer et al., 2011). Modelled after the McGill Pain Questionnaire (Melzack, 1975), the *Adolescent Pediatric Pain Tool (APPT)* is a multidimensional pain instrument for children and adolescents that is used to assess three dimensions of pain—location, intensity, and quality (Figure 34.2)—and has been used in children of different ages, in a variety of settings, and with different health conditions (Fernandes et al., 2014). The APPT is composed of

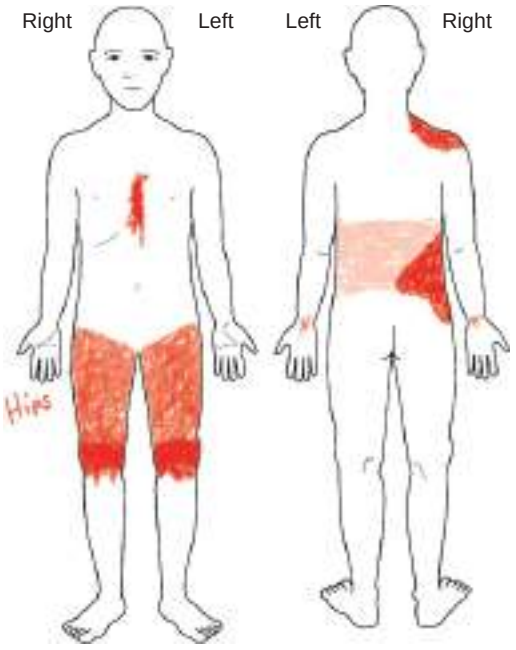


Fig. 34.2 Adolescent Pediatric Pain Tool (APPT): Body outlines for pain assessment. Instructions: "Colour in the areas on these drawings to show where you have pain. Make the marks as big or as small as the place where the pain is." (From Savedra, M. C., Tesler, M. D., Holzemer, W. L., & Ward, J. A. School of Nursing, University of California–San Francisco; copyright 1989, 1992.)

three independent measures: a front- and back-view body outline diagram, for children to mark the location of their pain; a 10-cm word-graphic pain intensity rating scale, anchored by "no pain" and "worst possible pain"; and a pain descriptor list that includes qualitative descriptors to assess three dimensions of pain: sensory (e.g., aching, burning), affective (e.g., sickening, terrifying), evaluative (e.g., uncomfortable), and temporal descriptors (e.g., off and on, steady). Each of the three components of the APPT is scored separately. The total number of words on the descriptor list is counted, with scores ranging from 0 to 56. The clinician then counts the number of words selected from the categories and calculates a percentage score for each one (Savedra et al., 1993).

An advantage to using the APPT is that in some pain states pain-intensity ratings do not change, but pain location and spatial distribution of pain may change over time, reflected in these ratings. The total surface area may decrease, but some children may perceive the remaining sites as equal in pain intensity. In addition to pain location, assessments of pain quality may be able to distinguish the presence of the different dimensions of pain (temporal, affective, evaluative, and sensory). Words may not be quantifiable on an NRS yet represent the pain experience, such as *horrible* and *terrible* from the evaluative dimension, *screaming* and *terrifying* from the affective dimension, or *sharp* and *stabbing* from the sensory dimension. The different qualities of pain may also represent whether pain is of an ischemic and inflammatory nature in the cutaneous, subcutaneous, and musculoskeletal tissues or pain that is more neuropathic, which may be described using words such as *shooting, burning,* or *shock-like*.

Assessment of Chronic (Persistent) and Recurrent Pain

It is estimated that, worldwide, 20 to 35% of children are affected by chronic pain (Friedrichsdorf et al., 2016). *Chronic pain* has been defined as pain that persists past normal healing time, lasting or recurring for more than 3 to 6 months (Nicholas et al., 2019). The term *chronic pain* has begun to be replaced in some literature with the term *persistent pain*. The reason for this is that people often think of chronic pain as something they need to cure and get over; persistent pain can indicate the need to learn to cope with the pain. Recently, members of the International Association for the Study of Pain (IASP), together with the World Health Organization (WHO), formed a task force to review this definition, as it did not reflect the nature of chronic pain beyond duration of pain. The new ICD (International Classification of Diseases), ICD-11, classifies the most common clinically relevant disorders. These disorders are divided into seven groups:

1. Chronic primary pain
2. Chronic cancer pain
3. Chronic posttraumatic and postsurgical pain
4. Chronic neuropathic pain,
5. Chronic headache and orofacial pain
6. Chronic visceral pain
7. Chronic musculoskeletal pain

These categories better reflect pain etiology, underlying pathophysiological mechanisms, and affected body site.

Pain that is episodic and recurs is defined as *recurrent pain*. The time frame within which episodes of pain recur is at least 3 months. Identified reasons for recurrent pain in children include headaches, migraine headaches, inflammatory bowel disease, sickle cell pain and sickle cell crisis, and rheumatoid arthritis, to name only a few (Friedrichsdorf et al., 2016). Chronic pain in children is the result of a dynamic interaction between biological processes, psychological factors, and sociocultural variables, considered within a developmental context. It can have a detrimental effect on the psychosocial and physical well-being of children and their families. Assessment of chronic or recurrent pain includes pain location and intensity; impact on physical and psychological functioning and on role functioning, such as school attendance and friendships; mood; impact on sleep; global judgement of satisfaction with treatment; and economic factors. Because the time course of chronic and recurrent pain is different from that of acute pain, measures used to assess the impact of chronic and recurrent pain must take into account timing and duration as key factors.

Pain diaries have been used to assess pain symptoms and response to treatment in children and adolescents with chronic and recurrent pain (Heath et al., 2017; Lewandowski et al., 2009; Stinson et al., 2008). Most pain diaries use an NRS or a VAS with faces or words. Children as young as 6 years have been included in pain diary studies. Conventional paper-and-pencil measures have been associated with several limitations, such as poor completion, missing data, hoarding responses, problems with recall, and back-and-forward filling (Stinson, 2009). Research has been conducted using electronic diaries with school-age children and adolescents with recurrent or chronic pain (Stinson, 2009; Stinson et al., 2014). Such diaries facilitate real-time data collection, therefore reducing the need for recall; better capture periods of "no pain"; allow for collection of longitudinal data and investigation of within-person variability; and may facilitate rapid and responsive follow-up, support, and treatment for episodes of exacerbation of pain or difficulties managing pain. Challenges and limitations to using electronic diaries for research and clinical practice include increased costs, training, technical skills, and risk of technical malfunction (Stinson, 2009; Stinson et al., 2011).

Chronic and recurrent pain can significantly interfere with the roles that children and adolescents perform, such as being a student, friend, and family member. School attendance can be used as a measure of role functioning in school-age children with chronic or recurrent pain. For children and adolescents with chronic pain, a measure such as the *Functional Disability Inventory* (FDI) (Walker & Greene, 1991) provides a more comprehensive evaluation of the influence of pain on physical functioning. The FDI is used to assess the child's ability to perform everyday physical activities and has established psychometric properties with different populations (Claar & Walker, 2006; Kashikar-Zuck et al., 2016).

The *Pediatric Pain Questionnaire (PPQ)* is a multidimensional pain instrument used to assess patient and parental perceptions of the pain experience in a manner appropriate for the cognitive-developmental level of children and adolescents (Lootens & Rapoff, 2011). The PPQ represents an attempt to assess the complexities of pediatric chronic, recurrent pain and targeted chronic musculoskeletal pain in children with juvenile rheumatoid arthritis. It consists of eight questions addressing the following areas: (1) pain history, (2) pain language, (3) colours that children associate with pain, (4) the emotions they experience, (5) their worst pain experiences, (6) ways in which they cope with pain, (7) the positive aspects of pain, and (8) the location of their current pain. The PPQ includes three components: (1) VAS; (2) colour-coded rating scales; and (3) verbal descriptors to provide information about the sensory, affective, and evaluative dimensions of chronic pain. It also has information about the child's and family's pain history, symptoms, pain-relief interventions, and socioenvironmental situations that may influence pain. The child, parent, and health care provider complete the form separately.

For children younger than 7 years of age, the *Pediatric Quality of Life Scale (PedsQL)*, developed by Varni and colleagues (1999), is a multidimensional scale with both parent and child versions that is recommended for assessing physical, emotional, social, and academic functioning as they relate to the child's pain. The PedsQL and the PedMIDAS (Gold et al., 2009; Hershey, 2001; Hershey et al., 2004) have been validated for measurement of role functioning in children with chronic or recurrent pain. The PedMIDAS is specifically designed to evaluate pain caused by migraines in children.

The *emotional functioning domain* usually refers to depression and anxiety, both of which are associated with chronic and recurrent pain

and can occur concurrently. Furthermore, poor functional outcomes in children with chronic pain are associated with pain catastrophizing, conceptualized as including rumination, magnification, and feelings of helplessness surrounding one's pain (Miller et al., 2018). The *Children's Depression Inventory* (Kovacs, 1981) and the revised child anxiety and depression scale (Chorpita et al., 2000) are person-centred measures used to evaluate and monitor physical, mental, and social health in adults and children. There are several pediatric-specific measures that can be used to assess anxiety and depression in children and adolescents with chronic or recurrent pain (Kashikar-Zuck et al., 2016).

Sleep disruption is also common in children with chronic or recurrent pain (Valrie et al., 2013). A sleep diary can be useful for keeping a record of activities surrounding sleep, including bedtime, time to fall asleep, number of night awakenings, waking in the morning, and especially any pain or other circumstance that interfere with sleeping. The *Sleep Habits Questionnaire*, which is useful for assessing sleep behaviours in school-age children with chronic or recurrent pain, has also been evaluated for use in preschool and toddlers, using parent proxy (Sneddon et al., 2013).

Global Judgement of Improvement and of Satisfaction With Treatment

Although pain intensity is the dimension that is most commonly assessed, patients or patient surrogates should also be asked to rate a global judgement of the pain and satisfaction with pain treatment. These ratings mean something different from one patient or surrogate to another. Some may focus on the relief of pain, whereas others may consider adverse effects of the treatment. The global question should be posed with indications of what should be considered in the answer, such as "Considering pain relief, adverse effects, physical recovery, and emotional recovery, how satisfied were you with the treatments your child is receiving for pain?" Children who are able to communicate verbally (using self-report methods) should be asked what they feel is a satisfactory pain relief goal or plan. Numbers may remain elevated despite treatment, but the child may feel their pain is well managed. As noted earlier, it is important to explore the meaning of pain in children who are able to able to report.

Pain Assessment in Specific Populations

Cultural Differences. While the experience of pain is universal, everyone has a unique experience with pain that is influenced by many dynamic factors, including family, community, and culture. Language and cultural differences between health care providers and the children they treat can make pain assessment and treatments more challenging. Several barriers to effective pain treatment that have been documented among non–English-speaking patients in general include inadequate assessment of pain, patient concern about adverse effects and tolerance of analgesics, patient and family reluctance to report pain, fear that pain means worse disease, reluctance to take pain medications, and lack of adherence to prescribed analgesics (Meints et al., 2019). One particular challenge in the assessment and management of pain in children is the cultural appropriateness of pain assessment tools that have been validated predominantly in White and English-speaking children. Observational scales and interview questionnaires for pain may not be as reliable for pain assessment as self-report scales in non-White and non–English-speaking children.

Indigenous children tend to have pronounced vulnerabilities related to pain due to (a) the high prevalence of painful conditions among these children, (b) potential cultural differences in how they express pain, (c) the lack of culturally relevant validated pain assessments, and (d) inadequate pain care resulting in persistent pain (Latimer et al., 2014, 2018). Westernized pain assessment tools may not accurately reflect the cultural differences in the pediatric Indigenous population, resulting in inaccurate pain assessment and inadequate pain management. Safe spaces must be created for Indigenous youth in order to provide culturally based understanding of pain and coping experiences from both an individual and community perspective. These engaging culturally sensitive methods could include Talking Circles and painting workshops and have been shown to provide a safe space for young people to share their perspectives related to both physical and emotional pain (Latimer et al., 2018).

Children With Communication or Cognitive Impairment. The IASP has noted that "the inability to communicate verbally does not negate the possibility that an individual is experiencing pain and is in need of appropriate pain-relieving treatment" (Treede, 2018). The assessment of pain in children with communication and cognitive impairment can be challenging. Children who have difficulties communicating with others about their pain include those with significant neurological impairments, such as cerebral palsy, cognitive impairment, metabolic disorders, autism, or severe brain injury, and those with communication barriers, such as critically ill children who are on ventilators, are heavily sedated, or have neuromuscular disorders or hearing or vision impairment. These children are at risk for their pain being underrecognized and undertreated because, in addition to potential communication difficulties, they have medical conditions that cause pain, and they may require repeated painful procedures. Pain may also occur during activities of daily living, such as assisted stretching and walking; independent standing; toileting; putting on splints; and doing occupational therapy, range-of-motion exercises, or physiotherapy. These children may experience spasticity, contractures, and orthopedic surgical treatment that can be painful (Hauer et al., 2017).

Parents and other primary caregivers are important aids in helping health care providers understand and identify pain behaviours and provide optimal pain care for children with cognitive impairments and communication challenges. Behaviours related to pain include crying, moaning, irritability, changes in facial expression, and changes in social behaviour such as cooperation, activity, play, eating and sleeping, and engagement with family, friends, and others (Breau, 2014; Hauer et al., 2017). See Table 34.1 for further discussion of the pain assessment tools that can be used.

Children With Chronic Illness and Complex Pain. Questionnaires and pain assessment scales do not always provide the most meaningful means of assessing pain in children, particularly for those with complex pain. Some children cannot relate to a face or a number that describes their pain and may not be able to isolate pain from other concurrent symptoms they are experiencing, for example, cancer. Experiencing multiple symptoms makes the task of having to isolate the pain symptom from other symptoms difficult for children with cancer. Rating the pain does not always accurately convey to others how they really feel (Loeffen et al., 2019).

In children with chronic illness, particularly those with complex pain, the most important aspect of the assessment is the relationship developed between the health care providers and the child and their family; this process facilitates an understanding of what the pain experience is like for the child and family. The pain may interfere with the child's ability to eat, sleep, and perform daily activities and routines and may be complicated by adverse effects of medical treatments and complications associated with disease management.

Other important components of assessment include the onset of pain; pain duration or pattern; the effectiveness of the current treatment; factors that aggravate or relieve the pain; other symptoms and complications concurrently felt; and interference with the child's mood,

function, and interactions with family. In addition to asking the child or parent when the pain started and how long the pain lasts, the nurse can assess variations and rhythms by asking whether the pain is better or worse at certain times of the day or night. If the child has had pain for an extended time, the child or parent may know which medications and doses are helpful. They may also have found some mind-body strategies methods that have helped. The nurse may ask the child or parent to keep a diary of activities, positions, and other events that may increase or decrease the pain. Pain may be accompanied by other symptoms (e.g., nausea and poor appetite) and it may interfere with sleep and other activities. A diary can help families identify triggers that may cause pain and interventions that work.

PAIN MANAGEMENT

Unrelieved pain may lead to potential long-term physiological, psychosocial, and behavioural consequences. It can also lead to longer hospitalizations, increased readmissions to the hospital, and more outpatient visits (Friedrichsdorf & Goubert, 2019; Twycross, 2017). These issues highlight the importance of a comprehensive pain assessment and management plan. See Nursing Skills on Evolve: Managing Pain.

Physical Recovery

Physical recovery, which includes aspects of physical functioning that are influenced by the procedure or injury, can cause acute pain. For example, swallowing 50 mL of water is important after tonsillectomy yet is painful. Sufficient preparation and instruction as well as appropriate analgesia are essential to facilitate activities that promote return to normal function. Possible assessments of the physical domain include the time taken to achieve sitting or ambulation, time to resume swallowing (post-tonsillectomy), and times to normal spirometry, oral intake, and full return to expected functioning. However, measures such as tolerance of physiotherapy may be inconsistent. One child may be intolerant of physiotherapy because they did not want to go when asked, whereas another might be considered intolerant to it if they cried and refused to continue with it. The use of preemptive pain management strategies before potentially painful activities should be considered. An example would be the use of analgesics before ambulation postoperatively or swallowing post-tonsillectomy. These measures of physical recovery should be assessed consistently and systematically to evaluate pain treatment interventions prior to, during, and following procedures and injuries that have specific effects on physical functioning.

Mind–Body Pain Management Strategies

Pain is often associated with fear, anxiety, and stress. A number of nonpharmacological techniques, such as distraction, relaxation, guided imagery, and cutaneous stimulation, provide coping strategies that may help reduce **pain perception**, make pain more tolerable, decrease anxiety, and enhance the effectiveness of pharmacological treatments (**analgesics**) or reduce the dosage required (see Guidelines box: Mind–Body Strategies for Pain Management). In addition, these techniques decrease the perceived threat of pain, provide a sense of control, enhance comfort, and promote rest and sleep. Although there is limited rigorous research on the effectiveness of many of these interventions, the strategies are safe, noninvasive, inexpensive, simple, and feasible to use. Environmental and psychological factors may play a large role in children's pain perceptions and may be modified by using psychosocial strategies, education, parental support, and cognitive-behavioural interventions (Ruskin et al., 2017). For children undergoing repeated painful procedures, cognitive-behavioural interventions are effective for decreasing anxiety and distress.

GUIDELINES

Mind–Body Strategies for Pain Management

General Strategies

- Use mind–body and physical interventions to supplement, not replace, pharmacological interventions.
- Consult with members of the interprofessional team (child life, psychology, social worker) to assist with strategies.
- Form a trusting relationship with the child and their family.
- Express concern regarding their reports of pain, and intervene appropriately.
- Take an active role in seeking effective pain management strategies.
- Use general guidelines to prepare the child for a procedure.
- Prepare the child before conducting potentially painful procedures but avoid "planting" the idea of pain.
  - For example, instead of saying, "This is going to (or may) hurt," say, "Sometimes this feels like pushing, sticking, or pinching, and sometimes it doesn't bother people. Tell me what it feels like to you."
  - Use "nonpain" descriptors when possible (e.g., "It feels like heat" rather than "It's a burning pain"). This allows for variation in sensory perception, avoids suggesting pain, and gives the child control in describing reactions.
  - Avoid evaluative statements or descriptions (e.g., "This is a terrible procedure" or "It really will hurt a lot").
- Stay with the child during a painful procedure.
- Support parents to stay with the child whenever possible; support and encourage the parent to breastfeed or hold their baby skin-to-skin if possible, comfort the child, hold the child if possible and feasible, talk softly to the child, and remain near the child's head.
- Educate the child about the pain, especially when explanation may lessen anxiety (e.g., that pain may occur after surgery and does not indicate that something is wrong); reassure the child that they are not responsible for the pain.
- It may help to give the child a medical play doll, which represents "the patient," and allow the child to first do the procedures on the doll. Pain treatment can be emphasized through the doll by stating, "Dolly feels better after the medicine."

Specific Strategies

Distraction

- Involve the parent and child in identifying their preferred distracters.
- Involve the child in play; music, electronic tablet, or computer games; have the child sing or use rhythmic breathing.
- Have the child take a deep breath and blow it out until told to stop.
- Have the child blow bubbles to "blow the hurt away."
- Have the child concentrate on yelling or saying "ouch," with instructions to "yell as loud or soft as you feel it hurt; that way I know what's happening."
- Have the child look through a kaleidoscope (one with glitter suspended in fluid-filled tube) and encourage them to concentrate, by asking, "Do you see the different designs?"
- Use humour, such as watching cartoons, telling jokes or funny stories, or acting silly with the child.
- Have the child read, play games, or visit with friends.

Relaxation

With an infant or a young child:

- Hold the child in a comfortable, well-supported position, such as vertically against the chest and shoulder.
- Rock the child in a wide, rhythmic arc in a rocking chair or sway back and forth, rather than bouncing the child.

- Repeat one or two words softly, such as "Mommy's here."

With a slightly older child:

- Ask the child to take a deep breath and "go limp as a rag doll" while exhaling slowly; then ask the child to yawn (demonstrate if needed).
- Help the child assume a comfortable position (e.g., pillow under neck and knees).
- Begin progressive relaxation: starting with the toes, systematically instruct the child to let each body part "go limp" or "feel heavy"; if the child has difficulty relaxing, instruct the child to tense or tighten each body part and then relax it.
- Allow the child to keep their eyes open, since children may respond better if eyes are open rather than closed during relaxation.

Guided Imagery

- Have the child identify some highly pleasurable real or imaginary experience.
- Have the child describe details of the event, including as many senses as possible (e.g., "feel the cool breezes," "see the beautiful colours," "hear the pleasant music").
- Have the child write down or record the script.
- Encourage the child to concentrate only on the pleasurable event during the painful time; enhance the image by recalling specific details through reading the script or playing the recording.
- Combine imagery with relaxation and rhythmic breathing.
- Older children and adolescents may want to use an app on their mobile device that supports guided imagery.

Positive Self-Talk

- Teach the child positive statements to say when in pain (e.g., "I will be feeling better soon," "When I go home, I will feel better, and we will eat ice cream").

Thought Stopping

- Identify positive facts about the painful event (e.g., "It does not last long").
- Identify reassuring information (e.g., "If I think about something else, it does not hurt as much").
- Condense positive and reassuring facts into a set of brief statements and have the child memorize them (e.g., "short procedure, good veins, little hurt, go home").
- Have the child repeat the memorized statements whenever thinking about or experiencing the painful event.

Behavioural Contracting

Informal—May be used with children as young as 4 or 5 years of age:

- Use stars, tokens, or cartoon character stickers as rewards.
- Give a child who has difficulty assisting or is procrastinating during a procedure a limited time (measured by a visible timer) to complete the procedure.
- Reinforce assistance with a reward if the procedure is accomplished within a specified time.

Formal—Use a written contract, which includes:

- Realistic (seems possible) goal or desired behaviour
- Measurable behaviour (e.g., agreeing not to hit anyone during procedures)
- Date and signature of all persons involved in any of the agreements
- Identified rewards or consequences that are reinforcing
- Goals that can be evaluated
- Commitment and compromise requirements for both parties (e.g., while timer is used, the nurse will not nag or prod the child to complete the procedure)

Mindfulness-based stress reduction (MBSR)

A mind–body intervention that can help children with chronic pain, and their parents, cope more effectively. It requires training from a practitioner trained in MBSR (Khoo et al., 2019)

Cognitive behavioural therapy (CBT)

If the child cannot identify a familiar coping technique, the nurse can describe several strategies (e.g., distraction, breathing, guided imagery) and let the child select the most appealing one. Experimentation with several strategies that are suitable to the child's age, pain intensity, and abilities is often necessary to determine the most effective approach. Parents should be involved in the selection process; they may be familiar with the child's usual coping skills and can help identify potentially successful coping strategies. Involving parents also encourages their participation in learning the relevant skill with the child and acting as coach. If the parent cannot assist the child, other appropriate persons may include a grandparent, older sibling, nurse, or child life specialist.

Children should learn to use a specific strategy before pain occurs or before it becomes severe. To reduce the child's effort, instructions for a strategy, such as distraction or relaxation, can be recorded and played during a period of comfort. However, even after they have learned an intervention, children often need help using it during a painful procedure. The intervention can also be used after the procedure. This gives the child a chance to recover, feel mastery, and cope more effectively.

For newborns, the administration of concentrated sucrose or glucose, with or without non-nutritive sucking, has been extensively shown to have calming and analgesic effects for painful invasive procedures (Stevens et al., 2016) (Figure 34.3). A small volume (0.1 mL), the minimally effective dose, of a sucrose or glucose solution (24%) given prior to and throughout the procedure has been reported to consistently reduce crying time, facial expression scores, and pain scores during a heel lance, venipuncture, or intramuscular (IM) injection (Stevens et al., 2018). For more major and invasive procedures, such as circumcision, the use of multimodal therapy, such as sucrose in combination with swaddling or non-nutritive sucking, as well as pharmacological strategies, such as topical anaesthetics and a penile nerve block, are recommended for effective prevention and treatment of pain.

Fig. 34.3 Oral sweet solutions (sucrose or glucose), with or without non-nutritive sucking, effectively reduce pain during a heel stick in a preterm infant.

High-quality evidence also supports the analgesic effects of breastfeeding and kangaroo (skin-to-skin) holding, with or without non-nutritive sucking, during painful procedures (Harrison et al., 2015). *Kangaroo care* is skin-to-skin holding of infants, dressed only in diapers, against their parent's chest (Johnston et al., 2017) (see Chapter 27,

Fig. 34.4 Mother using kangaroo hold with her newborn. Note placement of the infant directly on the mother's skin.

Evidence-Informed Practice box). Skin-to-skin care, when commenced before a painful procedure and continued throughout and following the procedure, reduces behavioural responses to pain (crying, facial expressions, and pain scores) (Figure 34.4) (Johnston et al., 2017).

Breastfeeding, when feasible and possible, during heel lance, venipuncture, or intramuscular injection is a simple and easy method of effective pain treatment for term newborn and young infants (Harrison et al., 2016; Shah et al., 2012). Supporting and facilitating mothers to breastfeed during administration of minor painful procedures to an infant, for example, vaccinations, and other family members to hold babies skin-to-skin, when feasible, during painful procedures, are strategies that not only effectively reduce pain in infants but can also help empower the parents in caring for their infant.

When it is not possible or feasible to use these strategies, facilitated tucking can help the infant return to a calm state following a painful procedure (Pillai Riddell et al., 2015). *Facilitated tucking*, which is holding the infant's extremities flexed and contained close to the trunk during heel lance procedures, has been demonstrated to decrease heart rate, decrease crying time, and promote stability in the sleep–wake cycles after the lance (Perroteaua et al., 2018). See Chapter 26, Pain in the Newborn, and Evidence-Informed Practice box: Nonpharmacological Pain Relief for Newborns, for further information, as well as Additional Resources (CHEO) at the end of this chapter.

Complementary and Alternative Medicine (CAM)

Many terms are used to describe approaches to health care that are outside the realm of conventional medicine as practised in Canada. Such terms may include complementary, alternative, and integrative health practices, and some of these are used to manage children's pain.

Kalaichandran et al. (2018) reported an increase in CAM use in Canada, with over half of the participants in their study using some form of CAM. The most common CAM products used are vitamins and minerals, followed by homeopathic therapies, and probiotics. Other practices include massage, homeopathy, and relaxation techniques. Homeopathy is one of the more popular alternative therapies used in children for dermatological; ear, nose, and throat; respiratory; and emotional disorders (Spigelblatt & Canadian Paediatric Society [CPS] Community Paediatrics Committee, 2005/2018). Some of the factors that may affect the use of CAM are health care insurance benefits, access, regulations, and parental perceptions and attitudes.

Questions about the use of any CAM therapies or products should be a routine part of the pediatric history, especially for children with chronic health conditions. As with all CAM therapies, health care providers should be prepared to respond to parents' questions on homeopathy in an informed and nonjudgemental manner (Cirik & Efe, 2018; Spigelblatt & CPS Community Paediatrics Committee, 2005/2018). Although some scientific evidence exists regarding the efficacy of some CAM therapies, questions remain to be answered through well-designed scientific studies, such as whether these therapies are safe and whether they work for the diseases or medical conditions for which they are used.

CAM therapies may be grouped into five classes:

1. **Biologically based**—Foods, special diets, herbal or plant preparations, vitamins, other supplements
2. **Manipulative treatments**—Chiropractic, osteopathy, massage
3. **Energy based**—Reiki, bioelectric or magnetic treatments, pulsed fields, alternating and direct currents
4. **Mind–body techniques**—Mental healing, expressive treatments, spiritual healing, hypnosis, relaxation
5. **Alternative medical systems**—Homeopathy; naturopathy; ayurvedic; and traditional Chinese medicine, including acupuncture and moxibustion

Pharmacological Management

The interprofessional care team must develop appropriate pain management interventions that are individualized for each child. This strategy consists of a choice of the appropriate analgesic medication, according to the child's level of pain severity. The effectiveness of analgesics can be enhanced by a supportive attitude toward the child. By reinforcing the cause and effects of the medication and analgesia, the nurse, in partnership with the family and interprofessional health care team, can help the child understand what to expect and ways to optimize effectiveness of analgesics in conjunction with nonpharmacological measures. A pain scale or periodic ratings of pain intensity should be used for evaluation of effectiveness of pain regimens.

The response to therapy should be evaluated 30 to 60 minutes after each analgesic dose, and titration should continue to the point of highest achievable amount of relief (Turner, 2015).

For children with mild pain, a nonopioid (e.g., acetaminophen, ibuprofen) is frequently used and effective for this level of pain. A strong opioid is usually administered to infants and children with moderate or severe pain. Morphine is the medicine of choice for moderate to severe pain, although other opioids may be considered. The following sections discuss the most common pain medications used in children, in the nonopioid and opioid categories.

Nonopioids. Acetaminophen can be given alone or in combination with other pharmacological pain medications, together with mind–body strategies, for the relief of mild (<3/10) to moderate (4–6/10) pain (Table 34.3). It can also be used in combination with opioids in the treatment of severe pain (7–10/10). Acetaminophen has both analgesic and antipyretic effects but has no anti-inflammatory effects. It is primarily metabolized by the liver so should be dosed with caution in children with impaired liver function. Acetaminophen can be given together with opioids and nonsteroidal anti-inflammatory drugs (NSAIDS) and should be timed appropriately for optimal effect (e.g., 1 hour prior to physiotherapy). (See Table 34.3.)

TABLE 34.3 Nonopioid Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) Approved for Use in Children

Medication	Dosage	Comments
Nonopioids		
Acetaminophen (Tylenol)	Oral: 10–15 mg/kg/dose q4–6h prn **Dose limit:** 75 mg/kg/day or 4 g/day, whichever is less	Available in numerous preparations Nonprescription May be contraindicated in children with hepatic disease
	Rectal: 10–20 mg/kg/dose q4–6h prn **Dose limit:** 80 mg/kg/day or 4 g/day, whichever is less	
	Newborns Oral: GA 28–32 weeks: 10 to 12 mg/kg/dose q6–8h (max: 40 mg/kg/day) GA >32–37 weeks: 10 to 15 mg/kg/dose q6h (max: 60 mg/kg/day) >37 weeks: 10 to 15 mg/kg/dose q4–6h (max: 75 mg/kg/day) Rectal: GA 30–33 weeks: 20 mg/kg/dose q12h (max: 40 mg/kg/day) GA 34–39 weeks: 25 mg/kg/dose q8h (max: 75 mg/kg/day) GA ≥40 weeks: 30 mg/kg/dose q6h (max: 120 mg/kg/day)	
Nonsteroidal Anti-inflammatory Drugs (NSAIDS)		
Ibuprofen (children's Motrin, children's Advil)	Children 6 months to 12 years: 5–10 mg/kg/dose q6–8h; not to exceed: 40 mg/kg/day	Available in numerous preparations Available in suspension (100 mg/5 mL) and drops (100 mg/2.5 mL) Nonprescription Do not use in children with renal impairment.
Naproxen (Naprosyn) (125 mg, 250 mg, 375 mg, 500 mg)	Oral: 5–10 mg/kg/dose bid Rectal : 25–49 kg: 250 mg/dose ≥50 kg: 500 mg/dose **Dose limit:** 1 g/day Naprosyn not recommended for use in children under 2 years of age	Available in suspension (25 mg/mL) and several different dosages for tablets Nonprescription

bid, Twice daily; *GA,* gestational age; *PO,* orally; *q,* every.
Acetylsalicylic acid (Aspirin) is also an NSAID but is not recommended for children because of its possible association with Reye syndrome.
Adverse effects of ibuprofen and naproxen include nausea, vomiting, diarrhea, constipation, gastric ulceration, bleeding nephritis, and fluid retention.
Acetaminophen is well tolerated in the gastrointestinal tract and does not interfere with platelet function.
Dosages from Lau, E. (Ed.) (2020). 2020 SickKids Drug Handbook and Formulary. Wolters Klower Clinical Drug Information; The Hospital for Sick Children. (2020). *Pharmacy and Drug Formulary*. https://www.sickkids.ca/en/care-services/for-health-care-providers/pharmacy/; Canadian Pharmacists Association. (2020). *Compendium of Pharmaceuticals and Specialties* (CPS). Author Health Canada. (2015). *Drug product database online query*. https://health-products.canada.ca/dpd-bdpp/index-eng.jsp.

NSAIDS can be given alone or in combination with other pharmacological pain medications, together with mind–body strategies, for the relief of mild to moderate pain (see Table 34.3). NSAIDS can also be used in combination with opioids in the treatment of severe pain. These agents have antipyretic, anti-inflammatory, and analgesic actions. Nonopioids are usually the first analgesics for pain related to tissue injury, also known as *nociceptive pain*. NSAIDs can provide safe and effective pain relief when dosed at appropriate levels with adequate frequency. NSAIDS adverse effects are primarily gastrointestinal (GI), including GI ulceration and bleeding, so children and families should be educated to give NSAIDs with food.

Opioids. For moderate to severe pain, opioids are recommended. Morphine remains the standard agent used in comparison to other opioid medications. When morphine is not a suitable opioid, because of adverse effects or route availability, medications such as hydromorphone hydrochloride (Dilaudid), oxycodone, and fentanyl citrate (Sublimaze) are effective substitutes. Dilaudid is associated with less nausea and pruritus than morphine. Although fentanyl is used as an anaesthetic in the operating room, it is classified as an analgesic and is 100 times more potent than morphine (Tobias, 2014b). It can be administered by nurses by the IV, IM, transmucosal, transdermal, and intranasal routes. Fentanyl is a very short–acting medication and is often used to manage procedural pain or pain that will only be of short duration. It is most often used in the emergency department and critical care unit. Policies and procedures guiding the use of opioids and monitoring post-administration should be readily available to any care provider authorized to administer opioids.

Codeine, a once commonly used oral opiate analgesic, is a weak opioid and has well-known safety and efficacy problems related to genetic variability in biotransformation. For this reason, codeine is excluded as a recommendation for treatment of pain in children under 12 years of age (Government of Canada, 2016; Tobias et al., 2016).

The combination of acetaminophen or NSAIDs with opioids provides increased analgesia without increased adverse effects, as nonopioids act at the peripheral nervous system and opioids act at the central nervous system. Oxycodone is available as an immediate-release and controlled-release preparation. Oxycodone is also available in a combination product (Percocet, Oxycocet). Caution must be used with combination products. If acetaminophen is used as an adjunct for pain and has been prescribed with a combination product, the risk of exceeding the safe daily limit of acetaminophen could occur if not carefully monitored. When possible, each medication should be prescribed as a single pharmacological agent.

Adjunct Medications. Several medications known as *coanalgesics* or **adjunct** *analgesics* may be used alone or with opioids for pain management and to reduce opioid adverse effects (see Table 34.4). Medications

TABLE 34.4 Management of Opioid Adverse Effects

Adverse Effect	Treatment	Nonpharmacological Techniques
Constipation	**Senna and docusate sodium** *Tablet:* 2–6 yr: Start with 1/2 tablet once a day; maximum: 1 tablet twice a day 6–12 yr: Start with 1 tablet once a day; maximum: 2 tablets twice a day >12 yr: Start with 2 tablets once a day; maximum: 4 tablets twice a day *Liquid:* 1 mo–1 yr: 1.25–5 mL qhs 1–5 yr: 2.5–5 mL qhs 5–15 yr: 5–10 mL qhs >15 yr: 10–25 mL qhs **Polyethylene glycol-electrolyte solution** 100 mL/yr of age/hr PO/NG Dose limit: 1 L/hr (4 L total) Adolescents: 240 mL PO q10min **Bisacodyl:** PO or PR 3–12 yr: 5 mg/dose/day >12 yr: 5–10 mg/dose/day **Lactulose** 5–10 mL/day PO, double daily dose until stool produced Adult: 15–30 mL/day PO **Mineral oil:** 1–2 tsp/day PO **Magnesium citrate** <6 yr: 1–3 mL/kg PO OD 6–12 yr: 100–150 mL PO once/day >12 yr: 150–300 mL PO once/day follow with 250 mL water **Milk of Magnesia** <2 yr: 0.5 mL/kg/dose PO once/day 2–5 yr: 5–15 mL/day PO 6–12 yr: 15–30 mL PO once/day >12 yr: 30–60 mL PO once/day	Increase water intake. Prune juice, bran cereal, vegetables Increase ambulation.
Sedation* (without respiratory depression)	*Consider dose reduction and monitor analgesia closely; if analgesia is inadequate at reduced dose, consider opioid switch and continue to monitor analgesia and sedation closely.*	
Nausea, vomiting	**Dimenhydrinate** 1.25 mg/kg/dose q6h PO/IV/PR—prn maximum 50 mg/dose and 300 mg/day **Ondansetron:** 0.1–0.15 mg/kg IV or PO q4h; maximum: 8 mg/dose **Granisetron:** 10–40 mcg/kg q2–4h; maximum: 1 mg/dose	Imagery, relaxation Deep, slow breathing Small amounts of fluids frequently Dry foods—crackers, toast
Pruritus	**Diphenhydramine:** 1 mg/kg IV or PO q4–6h prn; max: 25 mg/dose **Hydroxyzine:** 0.6 mg/kg/dose PO q6h; maximum: 50 mg/dose **Naloxone:** 0.25–2 mcg/kg/hr, not to exceed upper dose recommendation or else analgesia may reverse	Oatmeal baths, good hygiene Exclude other causes of itching. Change opioids.
Respiratory depression: mild to moderate	Hold dose of opioid Reduce subsequent doses by 25%	Arouse gently, give oxygen, encourage to deep breathe.
Respiratory depression: severe	**Naloxone** *During disease pain management:* Administer in increments until breathing improves. Reduce opioid dose if possible. Consider opioid switch. *During sedation for procedures:* Administer until breathing improves. Reduce opioid dose if possible. Consider opioid switch.	Oxygen, bag and mask if indicated
Dysphoria, confusion, hallucinations	Evaluate medications, eliminate adjuvant medications with central nervous system effects as symptoms allow. Consider opioid switch if possible.	Rule out other physiological causes.
Urinary retention	Evaluate medications, eliminate adjuvant medications with anticholinergic effects (e.g., antihistamines, tricyclic antidepressants). Occurs more frequently with epidural analgesia than with systemic opioid use	Rule out other physiological causes. In/out or in-dwelling urinary catheter

hs, At bedtime; *IV,* intravenously; *PO,* by mouth; *PR,* by rectum; *prn,* as needed; *q,* every.

*Although pharmacological treatment options for sedation do exist as noted in this table, in the pediatric population this is not the recommended treatment approach. For patients with mild sedation but adequately controlled pain, consider a dose reduction. If pain is not well controlled and the patient is sedated, consider changing to a different opioid and ensuring maximal use of adjuvants that are nonsedating are being used.

Sources: Lau, E. (Ed.). (2020). *2020 SickKids drug handbook and formulary*. The Hospital for Sick Children; Canadian Pharmacists Association. (2020). *Compendium of Pharmaceuticals and Specialties (CPS)*. Author.

frequently used to relieve anxiety, cause sedation, and provide amnesia are diazepam (Valium) and midazolam (Versed). However, these medications are not analgesics and should be used to enhance the effects of analgesics, not as a substitute for analgesics. Other adjuvants include tricyclic antidepressants, such as amitriptyline, nortriptyline, imipramine; antiepileptics, such as gabapentin, pregabalin, carbamazepine; ketamine for neuropathic pain; stool softeners and laxatives for constipation; antiemetics for nausea and vomiting; diphenhydramine for itching; and steroids for inflammation and bone pain.

! NURSING ALERT

The optimum dosage of an analgesic is one that controls pain without causing adverse effects. This usually requires *titration*, the gradual adjustment of medication dosage (usually by increasing the dose), until optimum pain relief, without excessive sedation or adverse effects, is achieved. It is imperative to follow monitoring guidelines as directed by an organization's policy and procedure statements. The accessibility of a valid medication reference or formulary is required for review of opioid doses and dose ranges.

It is also imperative that for a child who is discharged home on opioids the child and family are provided with verbal and written education on dosing instructions, potential adverse effects, safe storage and disposal, safe prescribing (only one licensed prescriber), and emergency instructions (e.g., contact information, when to seek urgent medical attention, such as depressed breathing). The provision of a naloxone kit for accidental overdose should be considered.

Choosing the Pain Medication Dose. Children (except infants younger than about 3 to 6 months) metabolize medications more rapidly than adults and show great variability in medication elimination and adverse effects. Younger children may require higher doses of opioids to achieve the same analgesic effect. Therefore, the therapeutic effect and duration of analgesia vary. Children's dosages are usually calculated according to body weight, except in children with a weight greater than 50 kg, where the weight formula may exceed the average adult dosage. In this case, the adult dosage may be considered.

Conversion factors for selected opioids must be used when a change is made from IV (preferred) or IM to oral. Immediate conversion from IM or IV to the suggested equianalgesic oral dose may result in a substantial error. For example, the dose may be significantly more or less than that which the child requires. Opioid rotation is used when one opioid must be switched to another in an effort to improve clinical outcomes (benefits or harms). It begins with the selection of a new medication at a starting dose that minimizes potential risks while ideally maintaining analgesic efficacy. The selection of a starting dose must be informed by an estimate of the relative potency between the existing opioid and the new one (Fine & Porenoy, 2009; Lau & Hall, 2017). Opioid rotation is not an exact science and should be done in consultation with a pain specialist or pharmacist. Guidelines are available but should be combined with an individualized pain assessment and close monitoring (Rennick et al., 2016).

Several routes of analgesic administration can be used (Box 34.2); the most effective and least traumatic route should be selected.

BOX 34.2 Routes and Methods of Analgesic Medication Administration

Oral

Oral route preferred because of convenience, cost, and relatively steady blood levels

Higher dosages of oral form of opioids required for equivalent parenteral analgesia

Peak medication effect after 1 to 2 hours for most analgesics

Delay in onset is a disadvantage when rapid control of severe pain or of fluctuating pain is desired.

Sublingual, Buccal, or Transmucosal

Tablet or liquid placed under tongue (sublingual), between cheek and gum (buccal), or through the mucous membrane (transmucosal)

Highly desirable because more rapid onset than with oral route

- Produces less first-pass effect through liver than with oral route, which normally reduces analgesia from oral opioids (unless sublingual or buccal form is swallowed, which occurs often in children)

Few medications are commercially available in this form.

Many medications can be compounded into sublingual troche or lozenge.

- Actiq—Oral transmucosal fentanyl citrate in hard confection base on a plastic holder; indicated only for management of breakthrough cancer pain in patients with malignancies who are already receiving and are tolerant of opioid therapy, but can be used for preoperative or preprocedural sedation and analgesia

Intravenous (IV) (Bolus)

Preferred for rapid control of severe pain

Provides most rapid onset of effect, usually in about 5 minutes

Advantage for acute pain, procedural pain, and breakthrough pain

Not recommended if continuous pain control is required

Preferable for medications with short half-life (morphine, fentanyl, hydromorphone) to avoid toxic accumulation of medication

Intravenous (Continuous)

Preferred over bolus and intramuscular injection for maintaining control of pain

Provides steady blood levels

Easy to titrate dosage

Subcutaneous (Continuous)

Used when oral and IV routes not available

Provides equivalent blood levels to continuous IV infusion

Suggested initial bolus dose to equal 2-hour IV dose; total 24-hour dose usually requires concentrated opioid solution to minimize infused volume; use smallest-gauge needle that accommodates infusion rate.

Teflon subcutaneous catheters are available for continuous infusion. These materials tend to cause less inflammation than metal needles.

Policies should be followed regarding cannula changes.

Patient-Controlled Analgesia (PCA)

Generally refers to self-administration of medications, regardless of route

Typically involves programmable infusion pump (IV, epidural, subcutaneous) that permits self-administration of boluses of medication at preset dose and time interval (lockout interval is time between doses)

PCA bolus administration can be combined with bolus and continuous (basal or background) infusion of opioid.

Lockout interval is based on dose and indication for the therapy

- Should effectively control pain during movement or procedures
- Longer lockout requires larger dose monitoring of dose; effectiveness is key.

Policies and procedures should be available for PCA administration.

PCA by Proxy

PCA by proxy describes administration of a medication via PCA pump by someone other than the patient. There is controversy over this practice and inherent risks.

Continued

BOX 34.2 Routes and Methods of Analgesic Medication Administration—cont'd

Family-Controlled Analgesia

One family member (usually a parent) or other caregiver is designated as child's primary pain manager with responsibility for pressing PCA button

Guidelines for selecting a primary pain manager for family-controlled analgesia:

- Spends a significant amount of time with the patient
- Is willing to assume responsibility of being primary pain manager
- Is willing to accept and respect patient's reports of pain (if able to provide) as best indicator of how much pain the patient is experiencing; knows how to use and interpret a pain rating scale
- Understands the purpose and goals of patient's pain management plan
- Understands concept of maintaining a steady analgesic blood level
- Recognizes signs of pain and adverse reactions to opioid

Nurse-Activated Analgesia/Nurse-Controlled Analgesia (NCA)

Child's primary nurse is designated as primary pain manager and is the only person who presses PCA button during that nurse's shift.

Guidelines for selecting primary pain manager for family-controlled analgesia are also applicable to nurse-activated analgesia.

May be used in addition to a basal rate to treat breakthrough pain with bolus doses; patients need to be assessed regularly for need of a bolus dose

May be used without a basal rate as a means of providing rapid analgesic for sudden painful episodes or care procedures

Intramuscular

Not recommended for pain control; not current standard of care

Painful administration (feared by children)

Tissue and nerve damage possible with some medications

Wide fluctuation in absorption of medication from muscle

Faster absorption from deltoid than from gluteal sites

Shorter duration and more expensive than oral medications

Time-consuming for staff and unnecessary delay for child

Intranasal

Used for rapid access of medication for pain

Commonly used in emergency departments and critical care units for rapid relief of pain related to procedures

Can be used to effectively manage pain without an IV cannula being in place

Intradermal

Used primarily for skin anaesthesia (e.g., before lumbar puncture, bone marrow aspiration, arterial puncture, skin biopsy)

Local anaesthetics (e.g., lidocaine) cause stinging, burning sensation

Duration of stinging depends on type of "caine" used

To avoid stinging sensation associated with lidocaine:

- Buffer the solution by adding 1 part sodium bicarbonate (1 mmol/mL) to 9 or 10 parts 1% or 2% lidocaine with or without epinephrine.

Normal saline with preservative, benzyl alcohol, used to anaesthetize venipuncture site

- Use same dose as for buffered lidocaine.

Topical or Transdermal

EMLA (eutectic mixture of local anaesthetics [lidocaine and prilocaine]) cream and anaesthetic disk or LMX4 (4% lidocaine cream)

- Eliminates or reduces pain from most procedures involving skin puncture
- Must be placed on intact skin over puncture site and covered by occlusive dressing or applied as anaesthetic disk for 30 to 60 minutes (product dependent) before procedure
- May cause skin blanching and vasoconstriction, therefore may make venous access slightly more challenging

AMETOP (4% tetracaine) Maxiline (lidocaine)

- Eliminates or reduces pain from most procedures involving skin puncture
- Must be placed on intact skin over puncture site and covered by occlusive dressing or for 30 minutes or more before procedure
- May cause vasodilation, therefore may make venous access easier

LAT (lidocaine-adrenaline-tetracaine), LET (lidocaine-epinephrine-tetracaine) or tetracaine-phenylephrine (tetraphen)

- Provides skin anaesthesia about 15 minutes after application on nonintact skin
- Gel (preferable) or liquid placed on wounds for suturing
- Adrenaline not for use on end arterioles (fingers, toes, tip of nose, penis, earlobes) because of vasoconstriction

Transdermal fentanyl (Duragesic)

- Available as patch for continuous pain control
- Safety and efficacy not established in children younger than 12 years of age (used at the discretion of the care team; palliative care use is often the circumstance)
- Not appropriate for initial relief of acute pain because of long interval to peak effect (12 to 24 hours); for rapid onset of pain relief, an immediate-release opioid is given.
- Orders for "rescue doses" of an immediate-release opioid recommended for breakthrough pain (a flare of severe pain that breaks through the medication being administered at regular intervals for persistent pain)
- Has duration of up to 72 hours for prolonged pain relief
- If respiratory depression occurs, possible need for several doses of naloxone
- Patch should not be cut or modified in any way. Gloves are needed to handle. Soap, alcohol, or any other solvent should not be used on the skin before application as this may affect medication absorption. Patch should be applied only to intact skin. Patch should not be exposed to external heat sources as this may increase medication release and has resulted in fatalities. Must be removed before magnetic resonance imaging (MRI).

Vapocoolant

- Use of prescription spray coolant, such as Fluori-Methane (Spray and Stretch) or ethyl chloride (Pain Ease™)
- Applied to the skin for 10 to 15 seconds immediately before the needle puncture; anaesthesia lasts about 15 seconds
- Cold disliked by some children
- Child must be able to describe the degree of cold sensation to avoid tissue damage.
- Application of ice to the skin for 30 seconds found to be ineffective

Rectal*

Alternative to oral or parenteral routes

Variable absorption rate

Generally disliked by children

Regional Techniques/Peripheral Nerve Blocks

Use of long-acting local anaesthetic (bupivacaine or ropivacaine) injected into tissue surrounding nerves to block pain at site of injury or surgery. A nerve block is a deliberate interruption of signals that travel along a nerve pathway for the purpose of pain control. A peripheral nerve block can last hours to days depending on the medication and modality being used (e.g., a single shot or continuous infusion of an anaesthetic agent).

Peripheral nerve block infusions are used as a postoperative pain management modality. A single injection intraoperatively can be used to provide longer pain control in the postoperative phase of care. Nerve blocks are inserted at the site where the nerve roots are innervated around a surgical site and administered

Continued

BOX 34.2 Routes and Methods of Analgesic Medication Administration—cont'd

as an infusion. Common peripheral nerve blocks include femoral, fascia iliaca, popliteal, intercostal, and paravertebral (Roberts et al., 2019).

Inhalation

Use of anaesthetics, such as nitrous oxide, to produce partial or complete analgesia for painful procedures

Adverse effects (e.g., headache) possible from occupational exposure to high levels of nitrous oxide

Epidural or Intrathecal

Involves a catheter placed into epidural or intrathecal space for continuous infusion or single or intermittent administration of opioid with or without a long-acting local anaesthetic (e.g., bupivacaine, ropivacaine)

Analgesia primarily from medication's direct effect on opioid receptors in spinal cord and from action of local anaesthetic on spinal nerves

Respiratory depression is rare but may have slow and delayed onset; can be prevented by checking level of sedation and respiratory rate and depth hourly for initial 24 hours and decreasing dose when excessive sedation is detected

Nausea, itching, and urinary retention are common dose-related adverse effects from the epidural opioid.

Mild hypotension, urinary retention, and temporary motor or sensory deficits are common unwanted effects of epidural local anaesthetic.

Catheter for urinary retention is inserted during surgery to decrease trauma to child; if inserted when child is awake, anaesthetize urethra with lidocaine.

*Many medications can be compounded into rectal suppositories. For further information about compounding medications in troche or suppository form, contact Professional Compounding Centers of America (PCCA), Canada, 744 Third Street, London, ON, N5V 5J2, 800.668.9453, http://www.pccarx.ca/.

Timing of Analgesia. The right timing for administering analgesics depends on the type of pain. For continuous pain control, such as for postoperative or cancer pain, a preventive schedule of medication around the clock (ATC) is effective. The ATC schedule avoids the low concentrations of medications in plasma that permit breakthrough pain. If analgesics are administered only when pain returns (a typical use of the prn, or "as needed," order), pain relief may take several hours. The patient may then require higher doses, leading to a cycle of undermedication of pain, alternating with periods of overmedication and medication toxicity. This cycle of erratic pain control also promotes "clock watching," which may be erroneously equated with addiction. Nurses can effectively use prn (as needed) orders by giving the medication at regular intervals, since "as needed" should be interpreted as "as needed to prevent pain," not "as little as possible."

Continuous oral doses of an opioid ATC can be as effective as an IV infusion and potentially have fewer adverse effects. Breakthrough medication can be administered intravenously or orally as ordered but not exceeding the timing of the medication's expectation of effectiveness. If many breakthrough doses are required, the scheduled dose of the medication should be re-evaluated or a different opioid administered for better efficacy.

For extended pain control with fewer administration times for a child with complex pain, medications that provide longer duration of action (e.g., some NSAIDs, time-released/controlled release morphine, hydromorphone, oxycodone, or methadone) can be used. The challenge with controlled-release medications can be the dose availability for the pediatric patient.

Continuous analgesia is not always appropriate, since not all pain is continuous. Frequently, temporary pain control or conscious sedation is needed to provide analgesia or anti-anxiety effects before a scheduled procedure. When pain can be predicted, the medication's peak effect should be timed to coincide with the painful event. For example, with opioids the peak effect is approximately a half-hour for the IV route; with nonopioids the peak effect occurs about 2 hours after oral administration. For rapid onset and peak of action, opioids that quickly penetrate the blood–brain barrier (e.g., IV fentanyl) provide excellent pain control.

Patient-Controlled Analgesia. A significant advance in the administration of IV, epidural, or subcutaneous analgesics is the use of patient-controlled analgesia (PCA). As the name implies, the patient controls the amount and frequency of the analgesic, which is typically delivered through a special infusion device. Children who are physically able to "push a button" and who can understand the concept of pushing a button to obtain pain relief can use PCA, that is, children over 6 years of age (DiGiusto et al., 2014). Although controversial, the IV PCA system for children has been used by parents and nurses (see Box 34.2). Children can use the IV PCA system if they are old enough and capable of effectively managing their own pain. Nurses can efficiently use the PCA device on a child of any age to administer analgesics to avoid signing for and preparing opioid injections every time one is needed (Figure 34.5). When PCA is used "by proxy" (administered by a nurse or parent), the concept of patient control is negated, and the inherent safety of PCA needs to be monitored. Human error can occur in this situation, and education is key (Ocay et al., 2018).

Fig. 34.5 Nurse programming a patient-controlled analgesia pump to administer analgesic.

PCA infusion devices typically allow for three methods or modes of medication administration to be used alone or in combination:

1. Patient-administered boluses that can only be infused according to the preset amount and *lockout interval* (time between doses). More frequent attempts at self-administration usually mean that the patient may need the dose and time adjusted for better pain control. Patient understanding of how to use the device should be evaluated and further education may be required.
2. Nurse-controlled analgesia (NCA) using a PCA device is often used for rapid administration of an opioid. The nurse makes the assessment that the child is in pain and can press the button without leaving the patient's beside to access pain medication. The child is often too young or unable to understand the concept of pressing the button. The nurse can also use the button for preemptive pain management if a care process will be painful for the child (e.g., diaper change for a child with severe mucositis affecting the rectal mucosa). Dose and lockout periods maybe altered (generally longer) for safety according to organizational policy and patient care requirements. Clear documentation and assessment parameters for using an NCA should be in place.
3. Continuous basal rate infusion that delivers a constant amount of analgesic and prevents pain from intensifying during times when the patient cannot control the amount of analgesic they receive, such as during sleep. A PCA may have the capability to have a continuous basal infusion as well as bolus dosing capabilities.

As with any type of analgesic management plan, continued assessment of the child's pain relief is essential for the greatest benefit from PCA. Typical uses of PCA are for controlling pain from surgery, sickle cell crisis, trauma, and cancer. Morphine is the medication of choice for PCA and standard concentrations are used for safety. Hydromorphone is often used when patients are not able to tolerate morphine because of the adverse effects, such as pruritus and nausea, from the morphine PCA.

! NURSING ALERT

Close attention must be paid to programming a PCA device. The medication, dose, modality (bolus only, bolus and continuous infusion), lockout parameters, and maximum time-limited dose (1 hour, 2 hours, 4 hours) should be checked against the health care provider orders to avoid any programming errors. Standardized concentrations of opioids limit the potential for errors (Institute for Safe Medication Practices Canada, 2014).

Epidural Analgesia. Epidural analgesia may be used to manage pain intraoperatively and postoperatively, in selected cases. An epidural catheter is placed into the **epidural space** of the spinal column at the lumbar, thoracic, or caudal level (Figure 34.6). The direct thoracic level is most often used for older children or adolescents who have had an upper abdominal or thoracic procedure, such as a lung transplant. It is important to understand where the catheter is placed, as it has implications for assessment. An opioid (usually fentanyl, hydromorphone, or preservative-free morphine, which is often combined with a long-acting local anaesthetic such as bupivacaine or ropivacaine) is instilled via single or intermittent bolus, continuous infusion, or patient-controlled epidural analgesia. Analgesia results from the medication's effect on opiate receptors in the dorsal horn of the spinal cord, rather than the brain. As a result, respiratory depression is rare, but if it occurs, it develops slowly, typically 6 to 8 hours after administration.

Fig. 34.6 Epidural analgesia catheter placement.

Careful securing of the epidural catheter with an occlusive dressing decreases the possibility of soiling or inadvertently displacing the catheter. Careful monitoring of sedation level and respiratory status is critical to prevent opioid-induced respiratory depression. Assessment of pain, sensory and motor block, as well as the skin condition around the catheter site is an important aspect of related nursing care. Proper positioning and change of position should occur for any child with an epidural in place. Close monitoring of urinary output and function is important if the child has a lumbar epidural infusion. Depending on the level of the epidural, catheter urinary retention may occur, as the epidural may affect the motor and sensory nerve fibres of the pelvis and may interfere with the function of the bladder. A urinary catheter is often placed intraoperatively to avoid this issue.

Transmucosal and Transdermal Analgesia. Oral transmucosal fentanyl (Oralet) provides nontraumatic preoperative and preprocedural analgesia and sedation. Fentanyl is also available as a transdermal patch (Duragesic). Although contraindicated for acute pain management, it may be used for children and adolescents who have cancer pain or for palliative pain management.

One of the most significant pain management improvements in the ability to provide atraumatic needle stick care to children is with an anaesthetic cream, which is a 4% liposomal lidocaine preparation (Maxilene, Ametop) or EMLA (a eutectic mixture of local anaesthetics). The eutectic mixture (lidocaine 2.5% and prilocaine 2.5%), whose melting point is lower than that of the two anaesthetics alone, permits effective concentrations of the medication to penetrate intact skin (Figure 34.7).

In some situations, refrigerant sprays such as ethyl chloride and fluoromethane can be used. When sprayed on the skin, these sprays vaporize, rapidly cooling the area and providing superficial **anaesthesia**. Hospital formularies may have other products with lidocaine, prilocaine, or amethocaine topical preparations that require less time for application.

The intradermal route is sometimes used to inject a local anaesthetic, typically lidocaine, into the skin to reduce the pain from a lumbar puncture, bone marrow aspiration, or venous or arterial access. One concern with the use of lidocaine is the stinging and burning that initially occurs. However, the use of buffered lidocaine with sodium bicarbonate reduces the stinging sensation.

Fig. 34.7 LMX is an effective analgesic before intravenous insertion or blood draw.

Intranasal Route. The intranasal route is another option in the delivery of medication. The nasal mucosa are highly vascularized and provide rapid absorption in the central nervous system. The onset of action is similar to the IV route as it avoids first-pass metabolism. A *first-pass effect* or *metabolism* is a phenomenon whereby the concentration of a medication that is administered enterally is reduced and only a proportion of the medication reaches the systemic circulation. *Bioavailability* is the term used to describe the amount of a medication that remains unchanged after first-pass metabolism. It is important to note many factors can affect bioavailability. The intranasal route is used most often in the emergency department when rapid access to medication is required and vascular access has not been established. A number of medications can be administered via the intranasal route, including opioids and benzodiazepines (e.g., fentanyl, midazolam, lorazepam). An atomization device can be used as it breaks down the medications into a fine mist and is easily inhaled and well tolerated (Baily et al., 2017).

Cannabinoids. Cannabinoids are derived from the cannabis plant. Cannabidiol and tetrahydrocannabinol (THC) are the most studied chemical agents. These chemicals interact with receptors in the endocannabinoid system, which moderates functions such as neurodevelopment, cognition, and motor control (Libzon et al., 2018). There are two cannabinoid receptors, CB1 and CB2. CB1 is believed to be responsible for psychological effects on pleasure, memory, thought, concentration, sensory and time perceptions, and coordinated movement. CB2 is thought to play an anti-inflammatory and immunosuppressive role (Campbell et al., 2017). THC is a partial agonist at both CB1 and CB2 receptors and achieves its psychoactive properties likely through modulation of gamma-aminobutyric acid (GABA) and glutamine, two neurotransmitters within the central nervous system that have significant neurodevelopmental effects on the brain (Marzo et al., 2004). The frontal cortex, responsible for higher-order cognitive processes such as judgement and decision making, is undergoing rapid change during adolescence and, as such, is more susceptible to THC (Blakemore, 2013). Conversely, cannabidiol does not appear to bind to either CB1 or CB2 but does possess neuroprotective and anti-inflammatory effects, the exact mechanism of which is unknown and the subject of recent debate and clinical trials.

Since the legalization of cannabis in Canada, many patients and families are requesting medical cannabis for a variety of conditions. It is important that patients and families are provided with up-to-date, unbiased information to allow for informed decision making. Wong and Wilens (2017) completed a systematic review on the use of medical cannabinoids in children and adolescents and found evidence for benefit was strongest for chemotherapy-induced nausea and vomiting, with increasing evidence of benefit for treating epilepsy. However, they found insufficient evidence to support its use for neuropathic pain, as well as for spasticity, post-traumatic stress disorder, and Tourette syndrome. Additional research is needed to evaluate the potential role of medical cannabinoids in treating children and adolescents, especially given the increasing accessibility and the potential psychiatric and neurocognitive adverse effects identified from studies of recreational cannabis use (Wong & Wilens, 2017). In addition, a recent study by Gobbi et al. (2019) found that adolescent cannabis consumption was associated with increased risk of developing depression and suicidal behaviour later in life, even in the absence of a premorbid condition. Given what is known about the ongoing development of the brain throughout childhood and adolescence, caution should be used when introducing cannabis in this age group, and only when supported by research-based evidence (Grant & Bélanger, 2017; Lisdahl et al., 2014).

As this area of treatment continues to move forward, policies and procedures must be in place to address the prescribing, dispensing, administration, monitoring, and storage of cannabinoids. It is imperative that high-quality studies be done to understand the indications and risks for the use of cannabinoids in pediatrics.

Monitoring Adverse Effects of Analgesic Management. Anticipation and early management of adverse effects of pharmacological interventions is an important and vital aspect of pain treatment (RNAO, 2013). Commonly occurring adverse events anticipated with the use of NSAIDs include nausea, vomiting, and constipation but can also include GI bleeding. The use of Aspirin in children with chickenpox or influenza is associated with Reye syndrome, thus alternatives should be used. Commonly occurring adverse effects anticipated with use of opioids include sedation, nausea, vomiting, constipation, and itching (Box 34.3). Nurses, in partnership with the interprofessional health team, the family and caregivers, and the child if the child is able to contribute information, need to judiciously monitor the effectiveness of the treatment and anticipate and monitor adverse effects of treatment (Table 34.4).

Respiratory depression is the most serious complication and poses increased risk in sedated children and infants. The respiratory rate may decrease gradually, or respirations may cease abruptly and thus must be monitored closely. Any significant change from a previous rate calls for increased vigilance. A slower respiratory rate does not necessarily reflect decreased arterial oxygenation; an increased depth of ventilation may compensate for the altered rate. If respiratory depression or arrest occurs, the nurse must be prepared to intervene quickly (see Guidelines box: Managing Opioid-Induced Respiratory Depression).

BOX 34.3 Adverse Effects of Opioids

General
Constipation (possibly severe)
Respiratory depression
Sedation
Nausea and vomiting
Agitation, euphoria
Confusion
Hallucinations
Orthostatic hypotension
Pruritus
Urticaria
Sweating
Miosis (may be sign of toxicity)
Anaphylaxis (rare)

Signs of Tolerance
Decreasing pain relief
Decreasing duration of pain relief

Signs of Withdrawal Syndrome in Patients With Physical Dependence
The use of a withdrawal assessment tool to identify signs and symptoms of withdrawal is important if opioids or benzodiazepines are being decreased.

Initial Signs of Withdrawal
Lacrimation
Rhinorrhea
Yawning
Sweating

Later Signs of Withdrawal
Restlessness
Irritability
Tremors
Anorexia
Dilated pupils
Gooseflesh
Nausea, vomiting

GUIDELINES

Managing Opioid-Induced Respiratory Depression

If Respirations Are Depressed
- Assess sedation level.
- Reduce infusion by decrements (25% reduction when possible).
- Stimulate patient (shake shoulder gently, call by name, ask to breathe).
- Administer oxygen.

If Patient Cannot Be Aroused or Is Apneic
Administer naloxone (Narcan)
For resuscitation:
- Titrate to achieve a positive response with 0.01 mg/kg/dose increments intravenously (IV) or via endotracheal tube (ETT) or 0.1 mg/kg/dose IV/ETT repeat prn. Dose limit is 2 mg/dose.
- Administer bolus by slow IV push every 2 minutes until effect is obtained.
- Naloxone's duration of antagonist action may be shorter than that of opioid, requiring repeated doses of naloxone.

Management of adverse opioid effects:
- Administer 0.001–0.01 mg/kg IV dose; observe and repeat every 10 minutes prn to a maximum total dose of 0.1 mg/kg or continuous infusion 0.5 to 1 mcg/kg/hr starting dose range (0.25–2 mcg/kg/hr).

Following the administration of naloxone, the patient must be monitored with constant care and discharged only when they are fully awake and a minimum of 3 hours from the last dose has elapsed.

Note: Respiratory depression caused by benzodiazepines (e.g., diazepam [Valium] or midazolam [Versed]) can be reversed with flumazenil (Romazicon), a benzodiazepine antagonist: use dose of 0.01 mg/kg (10 mcg/kg) over 15 seconds; if there is no (or inadequate) response after 1 to 3 minutes repeat dose; if necessary, dose may be repeated up to 4 times at 1- to 3-minute intervals to a total dose of 50 mcg/kg. Dose limit is 1 000 mcg/dose, total dose 3 000 mcg.

Adapted from Lau, E. (Ed.). (2016). *2016 SickKids drug handbook and formulary*. The Hospital for Sick Children.

Although respiratory depression is the most feared adverse effect, constipation is a common, and sometimes serious, adverse effect of opioids. If ongoing use of opioids is expected, prevention with stool softeners and laxatives is more effective than treatment once constipation occurs. Dietary treatment, such as increased fibre, is usually not sufficient to promote regular bowel evacuation. However, dietary measures, such as greater fluid and fruit intake, and physical activity are encouraged. Another common adverse effect is pruritus from epidural or IV infusion. Pruritus can be treated with low doses of IV naloxone most often in the form of an infusion, nalbuphine, or diphenhydramine. Nausea and vomiting usually subside after 2 days of opioid administration; however, oral or rectal antiemetics may be necessary. Opioid rotation may be helpful with any unwanted effects from opioids.

Tolerance and physical dependence. Tolerance occurs when the dose of an opioid needs to be increased to achieve the same analgesic effect that was previously achieved at a lower dose (see Family-Centred Care box: Fear of Opioid Addiction). Tolerance may develop after only a few days of therapy; physiological response and genetic factors can affect the time for someone to become tolerant to a medication. Treatment of tolerance involves increasing the dose or decreasing the duration between doses.

Physical dependence is a normal, natural, physiological state of "neuroadaptation." When opioids are abruptly discontinued without weaning, withdrawal symptoms occur. *Withdrawal* is the physical signs and symptoms that occur after an opioid or benzodiazepine is stopped abruptly or weaned too quickly after continuous use. Withdrawal may occur after 5 consecutive days of use or occasionally as short as 3 days and is more common in critically ill children. Treatment of physical dependence involves gradually reducing the medication to prevent withdrawal (Kanwaljeet et al., 2010).

Medications known to cause withdrawal symptoms include opioids, benzodiazepines, clonidine, dexmedetomidine, barbiturates, and chloral hydrate. Risk factors for withdrawal from analgesia and sedation agents include newborns, children, and adolescents who (SickKids, 2018):
- Have required analgesia or sedation for greater than 5 days
- Require high doses of multiple agents
- Have had previous experience of withdrawal
- Are less than 6 months of age

The use of a withdrawal assessment tool should be considered if an infant or child has been on opioids or benzodiazepines for 5 days or more and is being tapered from their use. The *Withdrawal Assessment Tool–1 (WAT-1)* is one example and may be used to assess and monitor withdrawal symptoms in children (Franck et al., 2008) (Figure 34.8). See Chapter 29 for more information on care of the drug-exposed newborn.

FAMILY-CENTRED CARE

Fear of Opioid Addiction

One of the reasons for the unfounded but prevalent fear of addiction from opioids used to relieve pain is a misunderstanding of the differences between physical dependence, tolerance, and addiction. Health care providers and community members often confuse addiction with the physiological effects of opioids, when, in reality physical dependence, tolerance, and addiction differ in important ways. The Canadian Pain Society defines these terms as follows:

Physical dependence is a state of adaptation that often includes tolerance and is manifested by a medication class–specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the medication, or administration of an antagonist. It is not the same thing as addiction. The symptoms of withdrawal include signs of neurological excitability (irritability, tremors, seizures, increased motor tone, insomnia), gastrointestinal dysfunction (nausea, vomiting, diarrhea, abdominal cramps), autonomic dysfunction (sweating, fever, chills, tachypnea, nasal congestion, rhinitis), hypertension, and muscle aches. These symptoms can be minimized by slowly decreasing the dose of opioids. Weaning should be planned for any patient who has been taking opioids for more than 5 to 7 days.

Tolerance is a state of adaptation in which exposure to a medication induces changes that result in a diminution of one or more of the medication's effects over time. This is also not the same as addiction.

Addiction is a primary, chronic, neurobiological disease, with genetic, psychosocial, and environmental factors influencing its development and manifestations. Addiction is characterized by behaviours that include one or more of the following (4 C's):

- Impaired **C**ontrol over drug use
- **C**ompulsive use
- **C**raving
- **C**ontinued use despite harm (Consequences)

Unfortunately, individuals who have severe, unrelieved pain may become intensely focused on finding relief. Sometimes behaviours such as "clock watching" make patients appear to others to be preoccupied with obtaining opioids. However, this preoccupation centres on finding relief of pain, not on using opioids for reasons other than pain control. This phenomenon has been termed *pseudoaddiction* and must not be confused with clinical addiction.

Nurses are in an ideal position to educate children, parents, and other health care providers about the risk of addiction (less than 1%) from the use of opioids to treat pain. Helping families and caregivers to understand that infants, young children, and comatose or terminally ill children have a low risk of addiction is integral to the role of the nurse caring for these children.

Data from The Canadian Pain Society. (2005). *Accreditation pain standard: Making it happen!* https://acclaimhealth.ca/wp-content/uploads/2019/01/Canadian-Pain-Society-Accreditation-Standards.pdf.

Patients requiring more than 5 to 7 days of opioids should have tapering doses to avoid the physiological symptoms of withdrawal (dysphoria, nasal congestion, diarrhea, nausea and vomiting, sweating, and seizures) (Figure 34.9). Appropriate weaning of the PCA schedules start with reduction of the continuous infusion rate before discontinuation while the patient continues to use demand doses for analgesia. Morphine-equivalent equianalgesic conversions may be used to convert continuous infusion rates to equivalent oral analgesics.

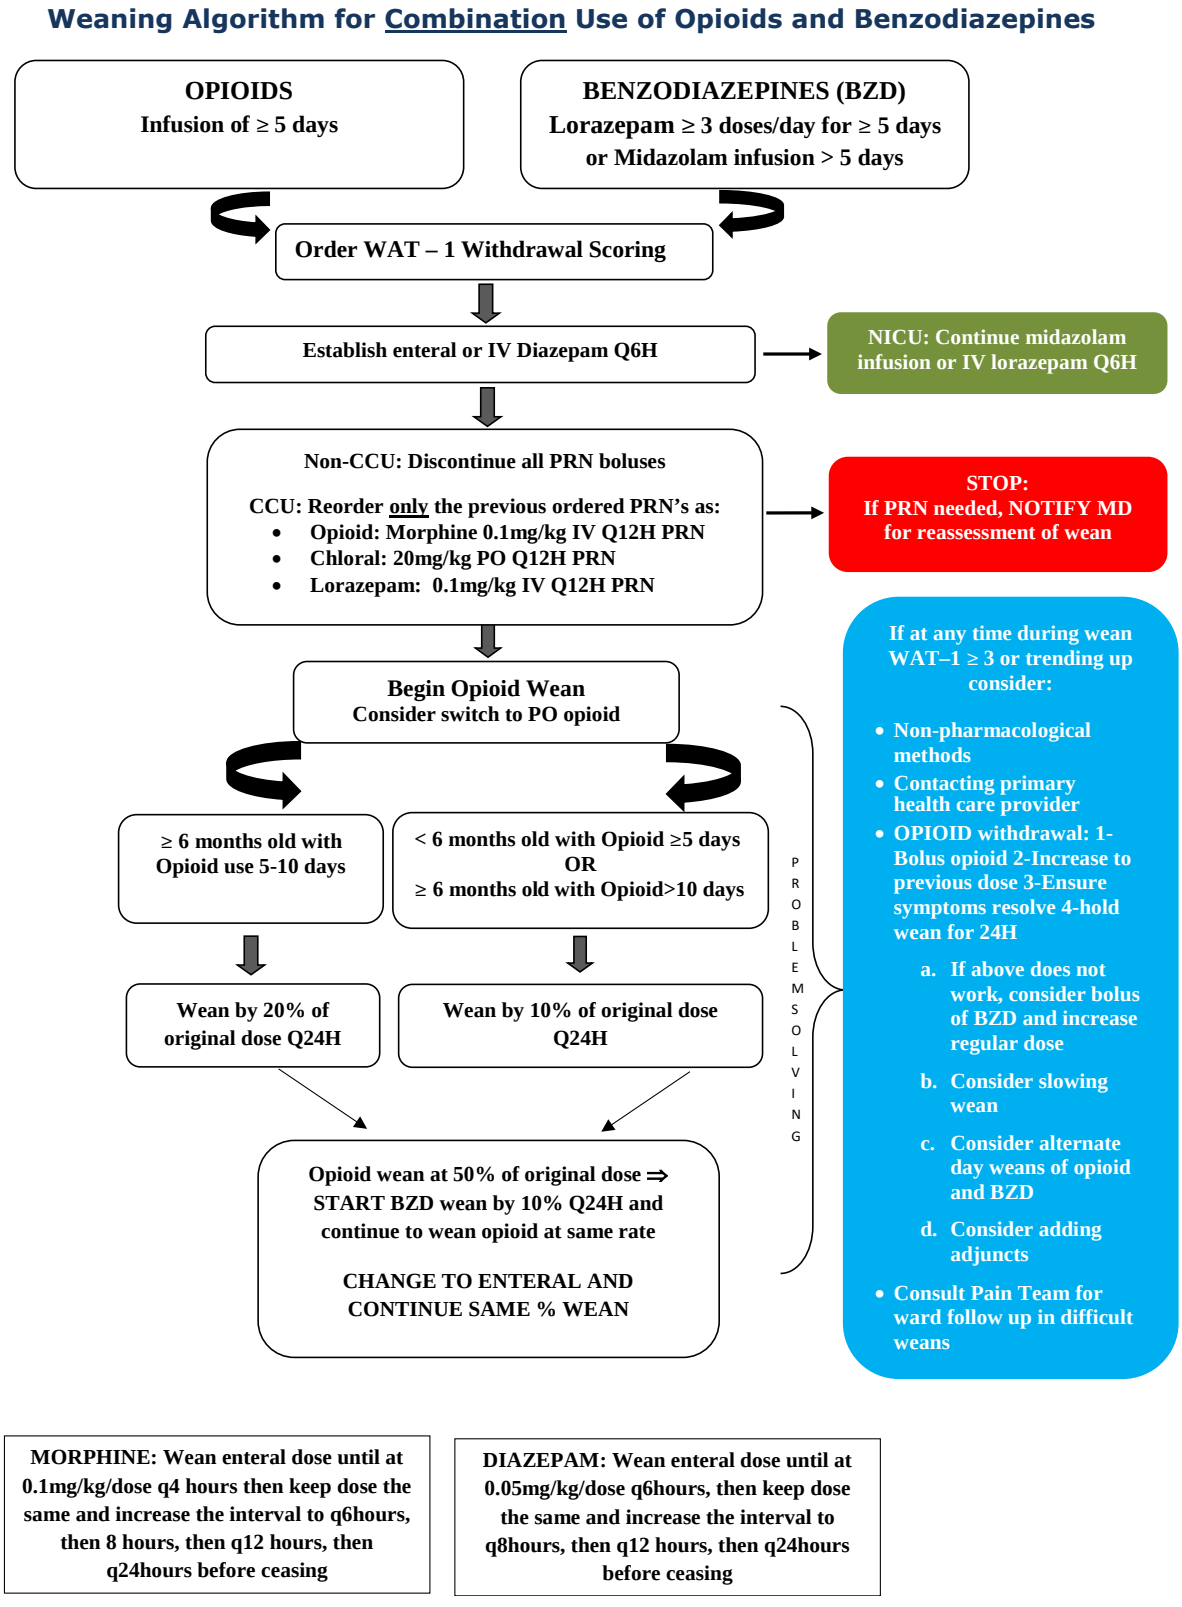

Fig. 34.9 Weaning algorithm. *CCU,* Critical care unit; *D/C,* discontinue; *IV,* intravenous; *NICU,* neonatal intensive care unit; *PO,* by mouth; *PRN,* as needed; *Q12/24H,* every 12/24 hours; *WAT-1,* Withdrawal Assessment Tool Version 1.

Doses of long-acting oral analgesics, such as sustained-release oral morphine, may also be used to replace continuous infusion dosing. The demand doses can be subsequently reduced if analgesia remains adequate.

Parents and older children may fear addiction when opioids are prescribed. The nurse should address these concerns with assurance that any such risk is extremely low. It may be helpful to ask the question, "If you did not have this pain, would you want to take this medicine?" The answer is invariably no, which reinforces the solely therapeutic nature of the medication. It is also important to avoid making statements to the family such as "We don't want you to get used to this medicine," or "By now you shouldn't need this medicine," which may reinforce the fear of becoming addicted. Whereas both physical dependence and tolerance are physiological states, *addiction* or *psychological dependence* is a psychological state and implies a "cause–effect" mode of thinking, such as "I need the drug because it makes me feel better." The use of opioid analgesics early in life has not been demonstrated to increase the risk for addiction later in life. Nurses need to explain to parents the differences between physical dependence, tolerance, and addiction and allow parents to express concerns about the use and duration of use of opioids. Infants, when treated appropriately with opioids, may be at risk for physical tolerance and physical dependence, but not psychological dependence or addiction.

COMMON PAIN STATES IN CHILDREN

Painful and Invasive Procedures

Procedures that infants and children must experience as part of routine medical care often cause pain and distress. For example, infants and children experience a substantial amount of pain due to routine immunizations.

Combining pharmacological and mind–body interventions provides the best approach for reducing pain. Local anaesthetic administration is crucial to minimize pain from the procedure and is discussed in the Transmucosal and Transdermal Analgesia section earlier in this chapter.

Procedural Sedation and Analgesia

Severe pain associated with invasive procedures and anxiety associated with diagnostic imaging can be managed with sedation and analgesia. Sedation involves a wide range of levels of consciousness (Box 34.4). A thorough patient assessment, including the child's history, is essential before procedural sedation.

BOX 34.5 Procedural Sedation and Analgesia Equipment Needs

- High-flow oxygen and delivery method
- Airway management materials: endotracheal tubes, bag valve masks, and laryngoscopes
- Pulse oximetry, blood pressure monitor, electrocardiography, capnography
- Suction and large-bore catheters
- Vascular access supplies
- Resuscitation drugs, intravenous (IV) fluids
- Reversal agents, including flumazenil and naloxone

Key components to include in the patient history include the following:

- Past medical history: major illnesses, previous hospitalizations or surgeries; history of previous anaesthesia or sedation
- Allergies assessment and an up-to-date medication reconciliation
- Current medications
- Illicit drug use: narcotics, benzodiazepines, barbiturates, drugs not prescribed by a health care provider, cannabis, cocaine, and alcohol
- Last oral intake and volume status

To provide a safe environment for procedural sedation and analgesia (PSA), equipment should be readily available to prevent or manage adverse events and complications (Box 34.5). The patient must have an IV access for titration of sedation and analgesic medications and for administration of possible antagonists and fluids. Trained personnel who are members of the interprofessional care team (physician, registered nurse, respiratory therapist) whose sole responsibility is to monitor the patient (rather than performing or assisting with the procedure) should be present to monitor for adverse events and complications.

Postoperative Pain

Surgery and traumatic injuries (fractures, dislocations, strains, sprains, lacerations, burns) generate a catabolic state as a result of increased secretion of catabolic hormones and lead to alterations in blood flow, coagulation, fibrinolysis, substrate metabolism, and water and electrolyte imbalance and increase the demands on the cardiovascular and respiratory systems. The major endocrine and metabolic changes occur during the first 48 hours after surgery or trauma. Local anaesthetics and opioid neural blockade may effectively mitigate the physiological responses to surgical injury.

Pain associated with surgery to the chest (e.g., repair of congenital heart defects, chest trauma) or abdominal regions (e.g., appendectomy, cholecystectomy, splenectomy) may result in pulmonary complications.

BOX 34.4 Levels of Sedation

Minimal Sedation (Anxiolysis)
Patient responds to verbal commands.
Cognitive function may be impaired.
Respiratory and cardiovascular systems are unaffected.

Moderate Sedation (Previously Conscious Sedation)
Patient responds to verbal commands but may not respond to light tactile stimulation.
Cognitive function is impaired.
Respiratory function is adequate; cardiovascular system is unaffected.

Deep Sedation
Patient cannot be easily aroused except with repeated or painful stimuli.
Ability to maintain airway may be impaired.
Spontaneous ventilation may be impaired; cardiovascular function is maintained.

General Anaesthesia
Loss of consciousness, patient cannot be aroused with painful stimuli.
Airway cannot be maintained adequately, and ventilation is impaired.
Cardiovascular function may be impaired.

From Meredith, J. R., O'Keefe, K. P., & Galwankar, S. (2008). Pediatric procedural sedation and analgesia. *Journal of Emergencies, Trauma and Shock, 1*(2), 88–96.

Pain leads to decreased muscle movement in the thorax and abdominal area and leads to decreased tidal volume, vital capacity, functional residual capacity, and alveolar ventilation. The patient is unable to cough and clear secretions, and the risk for complications (such as pneumonia and atelectasis) is high. Severe postoperative pain also results in sympathetic overactivity that leads to increases in heart rate, peripheral resistance, blood pressure, and cardiac output. The patient eventually experiences an increase in cardiac demand and myocardial oxygen consumption and a decrease in oxygen delivery to the tissues.

The basis for good postoperative pain control in children is preemptive analgesia (Michelet et al., 2012). Preemptive analgesia involves administration of medications (e.g., local and regional anaesthetics, analgesics) before the child experiences the pain or before surgery is performed so that the sensory activation and changes in the pain pathways of the peripheral and central nervous systems can be controlled. Preemptive analgesia lowers postoperative pain, decreases analgesic requirement, decreases length of hospital stay, results in fewer complications after surgery, and minimizes the risks for peripheral and central nervous system sensitization that can lead to persistent pain.

A combination of medications (multimodal or balanced analgesia) is used for postoperative pain and may include NSAIDs, local anaesthetics, nonopioids, and opioid analgesics to achieve optimum relief and minimize adverse effects. Opioids administered ATC during the first 48 hours or administered via PCA are commonly prescribed. Perioperative NSAID administration has been shown to reduce opioid consumption and postoperative nausea and vomiting in children (Michelet et al., 2012). Scheduled acetaminophen is supported as the preferred medication in children after tonsillectomy.

The combination of the IV NSAID ketorolac and morphine using a PCA device is frequently prescribed after thoracic surgery. Morphine delivered by PCA leads to a lower total dosage of opioid analgesia when compared with the administration of intermittent doses of analgesic as required. After bowel surgery, a mixture of a local anaesthetic (bupivacaine) and a low-dose opioid (fentanyl) delivered by epidural route improves the rate of recovery and minimizes the GI effects (e.g., bowel stasis, nausea, vomiting). In older children, once bowel function has been restored, oral opioids (e.g., immediate-release and controlled-release preparations) are preferred. Controlled-release opioids facilitate ATC dosing and improve sleep. They are also associated with a lower incidence of nausea, sedation, and breakthrough pain.

Burn Pain

Because burn pain has multiple components, involves repeated manipulations over the injured painful sites, and has changing patterns over time, it is difficult and challenging to control. Burn pain includes a constant background pain that is felt at the wound sites and surrounding areas. Burn pain is exacerbated (breakthrough pain) by movements, such as changing position, turning in bed, walking, or even breathing. Areas of normal skin that have been harvested for skin grafts (donor sites) also are painful. Pain is commonly experienced with intense tingling or itching sensations when skin grafting is required. During the healing process, when the tissue and nerves regenerate, the necrotic tissue (eschar) is excised until viable tissue is reached. The healing process may last for months to years. Pain or paresthetic sensations (itching, tingling, cold sensations) may persist. In addition, discomfort may be associated with immobilization of limbs in splints or garments, as well as multiple surgical interventions such as skin grafting and reconstructive surgery.

Multiple therapeutic procedures are carried out during the course of treatment. These procedures (dressing changes, wound débridement and cleansing, physiotherapy) occur daily or even several times per day (see Chapter 52). Providing proper analgesia without interfering with the patient's awareness during and after the procedure is the biggest challenge in the management of burn pain. Fentanyl or alfentanil has a major advantage over morphine because of the short duration. Fentanyl can prevent oversedation after the procedure. For less painful procedures, premedication with oral morphine, oral ketamine, or milder opioids 15 minutes before the procedure may be sufficient. Depending on the patient's anxiety level, a benzodiazepine (e.g., lorazepam) before the procedure may be beneficial. For longer procedures, morphine is the mainstay of treatment. Some patients may require moderate to deep sedation and analgesia. Oral oxycodone with midazolam and acetaminophen, in addition to nitrous oxide, may be needed. IV ketamine administered at subtherapeutic doses has been one of the most extensively used anaesthetics for burn patients. The dysphoria and unpleasant reactions associated with ketamine administration may be minimized with premedication with a benzodiazepine. If ketamine is used with either morphine or fentanyl, the regimen could have opioid-sparing actions and reduce the opioid-related adverse effects.

Mind–body strategies are helpful in the treatment of burn pain. These interventions include hypnosis, relaxation training (breathing exercises, progressive muscle relaxation), biofeedback, stress inoculation training, cognitive-behavioural strategies (guided imagery, distraction, coping skills), and group and individual psychotherapy. They can be used alone or in combination. All of these techniques can help the patient relax and maintain a sense of control. A major disadvantage of these interventions is that they require time and discipline, and often patients are too stressed, fatigued, disoriented, or sick to engage in them.

Recurrent Headaches in Children

Recurrent headaches in children can be caused by several factors, including tension, dental braces, imbalance or weakness of eye muscles causing deviation in alignment and refractive errors, sequelae to accidents, sinusitis and other cranial infection or inflammation, increased intracranial pressure, epileptic attacks, medications, obstructive sleep apnea, and, rarely, hypertension. Other causes may include arteriovenous malformations, disturbances in cerebrospinal fluid flow or absorption, intracranial hemorrhages, ocular and dental diseases, bacterial infections, and brain tumours.

Severe pain is the most disturbing symptom in migraine. Tension-type headache is usually mild or moderate, often producing a pressing feeling in the temples, like a "tight band around the head." Continuous, daily, or near-daily headache with no specific cause, or due to chronic daily use of simple analgesics such as acetaminophen and NSAIDS, occurs in a small subgroup of children. In epilepsy, headaches commonly occur immediately before, during, or after a seizure attack.

Treatment of recurrent headaches requires an understanding of the antecedents and consequences of headache pain. Using a headache diary, the child can record the time of onset, activities before the onset, any worries or concerns as far back as 24 hours before the onset, severity and duration of pain, pain medications taken, and activity pattern during headache episodes. The headache diary enables ongoing monitoring of headache activity, indicates the effects of interventions, and guides treatment planning.

Headache management involves two main behavioural approaches: (1) teaching patients self-control skills to prevent headache (biofeedback techniques and relaxation training), and (2) modifying behaviour patterns that increase the risk for headache occurrence or reinforce headache activity (cognitive-behavioural stress management techniques). Families may be able to identify factors that trigger the headache and avoid the triggers in the future. Biofeedback is a technology-based form of relaxation therapy that can be useful in assessing and

reinforcing learning of relaxation skills, such as progressive muscle relaxation, deep breathing, and imagery. Children as young as 7 years of age are able to learn these skills and with 2 to 3 weeks of practice are able to decrease the time needed to achieve relaxation.

Recurrent Abdominal Pain in Children

Recurrent abdominal pain (RAP) or *functional abdominal pain* is defined as pain that occurs at least once per month for 3 consecutive months, accompanied by pain-free periods, and is severe enough that it interferes with a child's normal activities. Management of RAP is highly individualized to reflect the causes of the pain and the psychosocial needs of the child and family. A clear understanding of the child's characteristics (anxiety, physical health, temperament, coping skills, experience, learned response, depression), the impact on the child's life (school attendance, activities with family, social interactions, pain behaviours), environmental factors (family attitudes and behavioural patterns, school environment, community, friendships), and the pain stimulus (disease, injury, stress) is important in planning management strategies (Oakes, 2011).

Before any workup of the pain, the nurse needs to inform the family that RAP is common in children and that only 10% of children with RAP have an identifiable organic cause for their pain symptom. Medical workup is determined by the child's symptoms and signs in combination with knowledge about common organic causes of RAP. If an organic cause is found, it will be treated appropriately. Even if no organic cause is found, the nurse needs to communicate to the child and family a belief that the pain is real. Usually the abdominal pain goes away, but even if problems are identified, they may not be the actual cause, and pain may persist, may be replaced by another symptom, or may go away on its own. The management plan includes regular follow-up at 3- to 4-month intervals, a list of symptoms that call for earlier contact, and biobehavioural pain management techniques. The goal is to minimize the impact of the pain on the child's activities and the family's life.

The use of cognitive behavioural therapy has been documented to reduce or eliminate pain in children with RAP and highlights the involvement of parents in supporting their child's self-management behaviour. Case reports have demonstrated the effectiveness of implementing a time-out procedure, token systems, and positive reinforcement based on operant theory treatment modalities. Stress-management strategies have also been successful. Parent training in how to avoid positive reinforcement of sick behaviours and focus on rewarding healthy behaviours is important. Over the course of several sessions, parents are educated about RAP, how to distinguish between sick and well behaviours, a reward system for well behaviours, and the importance of reinforcing relaxation and coping skills taught to children for pain management. Treatment may consist of a varying number of sessions over 1 to 6 months and may include various components, such as monitoring symptoms, limiting parent attention, relaxation training, increasing dietary fibre, and requiring school attendance.

Pain in Children With Sickle Cell Disease

A painful episode is the most frequent cause for emergency department visits and hospital admissions among children with sickle cell disease (see Chapter 48). The acute painful episode in sickle cell disease is the only pain syndrome in which opioids are considered the major therapy and are started in early childhood and continued throughout adult life. A source of frustration for patients and clinicians is that most current analgesic regimens are inadequate in controlling some of the most severe painful episodes. An interprofessional approach that involves both pharmacological and mind–body modalities (cognitive-behavioural intervention, heat, massage, physical therapy) is needed but not often implemented. The goals of treatment of the acute episode may not be to take all the pain away, which is usually impossible, but to make the pain tolerable to the patient until the episode resolves and to increase function and patient participation in activities of daily living.

Patients coming to an emergency department for acute painful episodes usually have exhausted all home care options or outpatient therapy. The nurse should ask patients what the usual medication, dosage, and adverse effects were in the past; the usual medication taken at home; and medication taken since the onset of present pain. The patient may be on long-term opioid therapy at home and therefore may have developed some degree of tolerance. A different potent opioid or a larger dose of the same medication may be indicated. Because mixed opioid-agonist-antagonists may precipitate withdrawal syndromes, these should be avoided if patients were taking long-term opioids at home. A "passport" card with patient information about the diagnosis, previous complications, suggested pain management regimen, and name and contact information of the primary hematologist is helpful for parents and can facilitate management of pain in the emergency department.

The patient is admitted for inpatient management of severe pain if adequate relief is not achieved in the emergency department. For severe pain, IV administration with bolus dosing and continuous infusion using a PCA device may be necessary.

Patients who are administered doses of opioids that are inadequate to relieve their pain or whose doses are not tapered after a course of treatment may develop iatrogenic pseudoaddiction, which resembles addiction. Pseudoaddiction or clock-watching behaviour may be resolved by communicating with patients to ensure accurate assessment, involving them in decisions about their pain management, and administering adequate opioid doses. See discussion above in Tolerance and Physical Dependence on how to wean opioid medication.

Cancer Pain in Children

Pain in children with cancer may be present before diagnosis and treatment and may resolve after initiation of anticancer therapy, although treatment-related pain is also common. Pain may be related to an operation, mucositis, a phantom limb, or infection. Pain can also be related to chemotherapy and procedures, such as bone marrow aspiration, needle puncture, and lumbar puncture. Tumour-related pain frequently occurs when the child relapses or when tumours become resistant to treatment. Intractable pain may occur in patients with solid tumours that metastasize to the central or peripheral nervous system. In young adult survivors of childhood cancer, chronic pain conditions may develop, including complex regional pain syndrome of the lower extremity, phantom limb pain, avascular necrosis, mechanical pain related to bone that failed to unite after tumour resection, and postherpetic neuralgia.

Oral mucositis (ulceration of the oral cavity and throat) may occur in patients undergoing chemotherapy or radiotherapy and in patients undergoing bone marrow transplant. No present therapy adequately relieves the pain of these lesions. Antihistamines, local anaesthetics, and opioids provide only temporary relief, may block taste perception, or may produce additional adverse effects, such as lethargy and constipation. Initial treatment includes single agents (saline, opioids, sodium bicarbonate, hydrogen peroxide, sucralfate suspension, clotrimazole, nystatin, viscous lidocaine, amphotericin B, dyclonine) or mouthwash mixtures using a combination of agents (lidocaine, diphenhydramine, Maalox or Mylanta, nystatin). The mucositis after bone marrow transplantation may be prolonged, continuously intense, exacerbated by mouth care and swallowing, or worse during waking hours. The patient

may be unable to eat or swallow. Mucositis may affect the entire GI tract, including the rectum. Morphine administered as a continuous infusion or delivered by PCA device may be required until mucositis is resolved (Hickman et al., 2014).

Other treatment-related pain includes (1) abdominal pain after allogeneic bone marrow transplantation, which may be associated with acute graft-versus-host disease; (2) abdominal pain associated with typhlitis (infection of the cecum), which occurs when the patient is immunocompromised; (3) phantom sensations and phantom limb pain after an amputation; (4) peripheral neuropathy after administration of vincristine; and (5) medullary bone pain, which may be associated with administration of granulocyte colony-stimulating factor.

Survivors of childhood cancer describe vivid memories of their experience with repeated painful procedures during treatment. These procedures include needle puncture for IM chemotherapy (L-asparaginase), IV lines, port access, blood draws, lumbar puncture, bone marrow aspiration and biopsy, removal of central venous catheters, and other invasive diagnostic procedures. Fear and anxiety related to these procedures may be minimized with parent and child preparation. The preparation starts with obtaining information from the parent about the child's coping styles, explaining the procedure, and enlisting their support, followed by an age-appropriate explanation to the child. Cognitive behavioural therapy (guided imagery, relaxation, music therapy, hypnosis), conscious sedation, and general anaesthesia have been effective in decreasing pain and distress during the procedure. Topical analgesics (cold sprays, EMLA, amethocaine gels), as discussed previously, are effective in providing analgesia before needle procedures.

Lumbar puncture for administration of chemotherapy (e.g., cytarabine, methotrexate) and collection of cerebrospinal fluid may lead to a leak at the puncture site and low intracranial pressure. Some children may experience postdural puncture headache, which may be treated by administering nonopioid analgesics and placing the patient in the supine position for 1 hour after the procedure. The pain related to bone marrow aspiration is due to the insertion of a large needle into the posterior iliac space and the unpleasant sensation experienced at the time of marrow aspiration.

If the patient is neutropenic (absolute neutrophil count $<500/mm^3$), the antipyretic action of acetaminophen may mask a fever. In patients with thrombocytopenia (platelet count $<50 \times 10^9/L$), who may be at risk for bleeding, NSAIDs are contraindicated. Morphine is the most widely used opioid for moderate to severe pain and may be administered via the oral (including sustained-release formulations, such as MS Contin), IV, subcutaneous, epidural, and intrathecal routes.

The most common clinical syndrome of neuropathic pain is painful peripheral neuropathy caused by chemotherapeutic agents, particularly vincristine and cisplatin, and rarely cytarabine (Hickman et al., 2014). After withdrawal of the chemotherapy, the neuropathy may resolve over weeks to months, or it may persist even after withdrawal. Neuropathic pain is associated with at least one of the following: (1) pain that is described as electric or shocklike, stabbing, or burning; (2) signs of neurological involvement (paralysis, neuralgia, pain hypersensitivity) other than those associated with the progression of the tumour; and (3) the location of the solid organ cancer consistent with neurological damage that could give rise to neuropathic pain. An epidural or subarachnoid infusion may be initiated if the patient experiences dose-limiting adverse effects of opioids or if pain is resistant to opioids. Tricyclic antidepressants (amitriptyline, desipramine) and anticonvulsants (gabapentin, carbamazepine) have demonstrated effectiveness in neuropathic cancer pain.

Pain and Sedation in End-of-Life Care

Many patients at the end of life require doses of opioids that make them sedated but arousable as their disease progresses (cancer, human immunodeficiency virus, cystic fibrosis, neurodegenerative disease). Patients achieve comfort with a combination of opioids and adjuvant analgesics in most situations. Parents need reassurance that the opioids are treating pain but not causing the child's death and that the child's advancing disease is the cause of death.

A small group of patients have intolerable adverse effects or inadequate analgesia despite extremely aggressive use of medications to relieve pain and adverse effects. Continuous sedation may be a means of relieving suffering when there is no feasible or acceptable means of providing analgesia that preserves alertness. A continuing high-dose infusion of opioids along with sedation is prescribed to reduce the possibility that a child might experience unrelieved pain but be too sedated to report it. Sedation in these situations is widely regarded as providing comfort, not euthanasia. Clinicians and ethicists have a range of views regarding assisted suicide and euthanasia, but they all agree that no child or parent should choose death because of inadequate efforts to relieve pain and suffering.

KEY POINTS

- Behavioural assessments are used to measure pain in infants, preverbal children, children with cognitive impairments who do not have the language skills to communicate that they are in pain, and children who for any reason have limited ability to communicate.
- Physiological measures, although less specific to pain than behavioural measures, contribute to the overall assessment of pain.
- Pain assessment and pain care are best managed as a partnership between the child, family, and the interprofessional team.
- Knowledge about pain assessment and the number and array of pain measures available for use in infants and young children have increased dramatically; these add a layer of complexity to the assessment of pain in children.
- Important components of assessment include the onset of pain; pain duration or pattern; effectiveness, or otherwise, of the current treatment; factors that aggravate or relieve the pain; other symptoms and complications concurrently felt; and interference with the child's mood, function, and interactions with family.
- A multimodal 3 P's approach to pain management using physical, psychological, and pharmacological modalities is considered an effective way to approaching a pain management care plan.
- Nonopioids, including acetaminophen and NSAIDs, are suitable for mild to moderate pain; opioids are needed for moderate to severe pain.
- Several medications—coanalgesics or adjuvant analgesics—may be used alone or with opioids to control pain symptoms and opioid adverse effects.
- A significant advance in the administration of IV, epidural, or subcutaneous analgesics is the use of PCA device.
- For procedural pain in infants, breastfeeding or skin-to-skin care, if feasible and possible, or sucrose or glucose effectively reduce pain during commonly performed minor painful procedures.
- For procedural pain in children, topical anaesthetic creams, applied as directed before needle-related painful procedures, along with age- and developmentally appropriate distraction, and a position of comfort may reduce pain and distress associated with needle-related procedures.

- Anticipation and early management of commonly occurring adverse effects of pharmacological agents is crucial to effective pain management.
- Children who receive opioids for more than 5 days require careful weaning of the medication.
- Nurses play a key role in the management of postoperative pain, burn pain, cancer pain, and pain at the end of life.

Promoting Optimum Health During Childhood

Cheryl Sams, Mollie Lavigne, and Lisa Keenan-Lindsay
With contributions from *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Demonstrate an understanding of nutrition recommendations throughout childhood.
2. Provide education to families and children regarding obesity prevention through childhood.
3. Communicate to parents the importance of preventative dental care throughout childhood.
4. Provide anticipatory guidance to parents for their child's sleep and physical activity.
5. Develop a sex education teaching plan for children of different ages.
6. Provide anticipatory guidance to parents regarding safety promotion and injury prevention based on childhood developmental achievements.
7. Identify the different forms of child maltreatment and the characteristics or circumstances that may predispose children to maltreatment.
8. Outline immunization requirements during infancy, early childhood, and adolescence.
9. Understand the implications of vaccine hesitancy on vaccine rates and communicable diseases.
10. List general contraindications, precautions, and administration routes for immunizations.
11. Explain the clinical manifestations and therapeutic management of childhood communicable diseases.

The pediatric nurse has an important role in helping children and their families achieve optimum health through the promotion of healthy living. *Health promotion* is defined as the process of enabling people to increase their control over and improve their health (Public Health Agency of Canada [PHAC], 2017). It is a proactive approach to keeping populations well through betterment of their overall health status, ensuring, for example, access to adequate nutrition and clean water and that people live in safe communities. Health promotion includes disease and injury prevention as well as school and workplace safety. Child health is a key focus of Canada's health prevention initiatives, as the health of children has a significant impact on lifelong individual health and the health of communities. Aspects of providing health care to children includes prevention of child maltreatment, health policy that supports child and adolescent rights, immunizations, school health, active living, obesity prevention, as well as early intervention programs for children at developmental risk. This chapter focuses on the role of the nurse in health promotion across the child's lifespan.

As stated throughout this text, there are many factors that have an impact on health, including individual genetic patterns and lifestyle choices as well as social and economic determinants. Determinants of health, the wide-ranging personal, social, economic and environmental factors that affect individual and population health (Box 1.1), play a key role. In addition, experiences of discrimination, racism, and historical trauma are also important social determinants of health for certain groups, such as Indigenous people, LGBTQ2 persons, new immigrants, and Black Canadians (Canadian Public Health Association, 2018).

NUTRITION

Nutrition is an essential component for healthy growth and **development**, and its promotion begins at birth. Young children tend to establish eating habits during the early years of life. The nurse can be instrumental in guiding parents in the selection of nutritious foods. During childhood, eating preferences and attitudes related to food habits are established by family influences and **culture**. During **adolescence**, parental influence diminishes as the adolescent makes food choices related to peer acceptability and sociability. Many current food choices during childhood are leading to an increased prevalence of chronic illnesses in childhood, such as diabetes, hypertension, and heart or renal disease. These diseases are occurring in higher numbers of children than ever before.

Nutrition Across the Lifespan

Infants. Infant health practices, including nutrition, can have a far-reaching, long-term impact on the child's life. Growth and development can be negatively affected, as can the risk for acquiring certain chronic health conditions. Nurses must be proactive in supporting parents in providing appropriate infant nutrition and teaching about nutritional habits, which provide the child with an optimal opportunity to grow and develop into a healthy child and adult. This section is concerned primarily with infant nutrition during the months when growth needs and developmental milestones ready the child for the introduction of solid foods.

Ideally, discussion of optimal nutrition should begin prenatally with the pregnant patient. The nurse can provide education regarding maternal intake of adequate nutrition, which involves eating a balanced diet and adequate amounts of protein, vitamins, and minerals, all of which have an impact on the growing fetus (see Chapter 12 for more information on prenatal nutrition). The nurse should also provide information regarding the importance of breastfeeding so parents can make an informed choice about feeding methods well in advance of the birth date. For instance, the incidence of childhood obesity may be significantly decreased when infants are exclusively breastfed (Moss & Yeaton, 2014; Registered Nurses Association of Ontario [RNAO], 2018).

The first 6 months. As noted earlier in this text, exclusive breastfeeding is recommended for the first 6 months and up to 2 years or longer with appropriate complementary feeding (Health Canada, Canadian Paediatric Society [CPS], Dietitians of Canada, & Breastfeeding Committee for Canada, 2015a). Human milk is the most desirable complete diet for the infant during the first 6 months, providing nutrition and immunological protection that support growth and development for infants and toddlers (Critch & CPS, Nutrition and Gastroenterology Committee, 2013/2018; Health Canada et al., 2015a). See Chapter 27 for more information on breastfeeding.

The healthy term infant receiving breast milk usually requires no vitamin and mineral supplements, with a few exceptions. It is recommended that all breast milk–fed infants receive a daily supplement of 400 International Units (IU) (10 mcg) of vitamin D, beginning in the first few days of life, to prevent rickets and vitamin D deficiency. Concentrated vitamin D drops are available with the entire 400 IU dose in one drop; this can be placed on the nipple (breast or bottle). Non-breast milk–fed infants who are taking less than 1 L per day of vitamin D–fortified formula should also receive a daily vitamin D supplement of 400 IU. The Dietary Reference Intake (DRI) guidelines for vitamin D have been set assuming minimal sun exposure for all, which means that additional recommendations are not required for subpopulations such as those at high northern latitudes, those with darker skin pigmentation, or those with heavy clothing that inhibits sun exposure (Health Canada, 2020). Table 35.1 lists the recommended daily allowances for calcium and vitamin D for all child age groups.

TABLE 35.1 The Daily Recommended Dietary Allowance for Vitamin D and Calcium

Age Group	Recommended Dietary Allowance (RDA) per Day	Tolerable Upper Intake Level (UL) per Day
DRIs for Calcium		
Infants 0–6 months	200 mg	1 000 mg
Infants 7–12 months	260 mg	1 500 mg
Children 1–3 years	700 mg	2 500 mg
Children 4–8 years	1000 mg	2 500 mg
Children 9–18 years	1300 mg	3 000 mg
DRIs for Vitamin D		
Infants 0–6 months	400 IU (10 mcg)	1 000 IU (25 mcg)
Infants 7–12 months	400 IU (10 mcg)	1 500 IU (38 mcg)
Children 1–3 years	600 IU (15 mcg)	2 500 IU (63 mcg)
Children 4–8 years	600 IU (15 mcg)	3 000 IU (75 mcg)
Children and adults 9–70 years	600 IU (15 mcg)	4 000 IU (100 mcg)

DRIs, Dietary Reference Intakes.

! NURSING ALERT

Accidental overdose of liquid vitamin D in infants due to packaging errors has been reported; the syringe for liquid administration may not be labelled clearly for 400 IU. Nurses should teach parents how to read the dosage accurately.

Up until the age of 6 months, term infants should have adequate maternal stores of iron in their bodies. Beyond 6 months of age, these stores of iron will be depleted, and breast milk alone can no longer meet all of the nutritional requirements for the rapidly growing infant. To prevent iron deficiency, at 6 months, iron-rich foods should be introduced to the diet (Health Canada, CPS, Dietitians of Canada, & Breastfeeding Committee for Canada, 2015b).

Whether breastfed or bottle-fed, infants do not require additional fluids during the first 6 months of life. Excessive intake of water in infants may result in water intoxication and hyponatremia.

An alternative to breastfeeding is commercial iron-fortified formula, although this is not equivalent to breast milk. It supplies the nutrients needed by the infant for the first 6 months. Unmodified whole cow's milk, low-fat cow's milk, skim milk, other animal milks, and imitation milks are not acceptable as a major source of nutrition for infants because of infants' limited ability to digest these foods, the increased risk of contamination, and the lack of nutritional components in animal milk that are needed for appropriate growth. Pasteurized whole cow's milk is deficient in iron, zinc, and vitamin C and has a high renal solute load, which makes it undesirable for infants less than 12 months of age.

! NURSING ALERT

Neither infant formula nor breast milk should be warmed in a microwave oven because this may cause infant oral burns as a result of uneven heating in the container. The bottle or container may remain cool while hot spots develop in the formula. To thaw breast milk, it should be placed in a container under a lukewarm water bath (less than 40.5°C) or placed in the refrigerator overnight. Warming expressed breast milk in a microwave oven also decreases the availability of anti-infective properties and vitamin C and causes a separation of the milk layers that affect fat content (Lawrence & Lawrence, 2016).

! NURSING ALERT

Dietary fat should not be restricted in infancy unless such restriction is under medical supervision. Feeding the infant skim or low-fat milk is unacceptable because the essential fatty acids are inadequate and the solute concentration of protein and electrolytes, such as sodium, is too high.

The amount of formula per feeding and the number of feedings per day vary among infants. Infants should be fed on demand. They

usually determine their own feeding schedule, but some infants may need a more planned schedule based on average feeding patterns to ensure their receiving sufficient nutrients. In general, the number of feedings per day decreases from six at 1 month of age to four or five at 6 months.

When preparing infant formula, bottled water for mixing powdered or concentrated formula is a relatively safe alternative to tap water. Tap water has a high content of contaminants such as lead. Bottled water, however, should not be assumed to be sterile unless specifically stated on the container. Fluoridated bottled water is not necessary for mixing powdered formula unless the local water source is low in fluoride, in which case fluoride supplementation is recommended after age 6 months (see Dental Health section later in this chapter). If powdered formula is being used, parents should be instructed in its safe preparation (see Chapter 27, Family-Centred Care box: Formula Preparation and Feeding). Powdered formula has a greater risk of contamination by microorganisms than concentrated formula and is only recommended to be used for infants who are healthy and full term. For low-birth-weight and immunocompromised infants, liquid formula is recommended for the first 2 months (Health Canada et al., 2015a).

Because there are potential serious health risks associated with infants' intake of homemade noncommercial formulas their use is not recommended (Health Canada, 2014). Health risks include severe malnutrition and potentially fatal illness from receiving inadequate nutrients and from contamination by harmful bacteria.

Parents should be cautioned to not feed their infant juices and nonnutritive drinks such as fruit-flavoured drinks or carbonated beverages (soft drinks). Such drinks do not replace the nutrients in milk (formula) and their use may also lead to growth or health issues; they are not recommended for children under 2 years of age.

The addition of solid foods before 6 months of age is also not recommended (Health Canada et al., 2015a). During the first months of an infant's life, solid foods are not compatible with the ability of the gastrointestinal tract and the infant's nutritional needs. Developmentally, infants are not ready for solid food. The extrusion (protrusion) reflex is strong and causes food to be pushed out of the mouth. Early introduction of solid foods is a type of forced feeding that may lead to excessive weight gain and iron-deficiency anemia.

The second 6 months. During the second half of the infant's first year, human milk or formula continues to be the primary source of nutrition. Physiologically and developmentally, the infant at 6 months of age is in a transition period. By this time, the gastrointestinal tract has matured sufficiently to handle more complex nutrients. Tooth eruption is beginning and facilitates biting and chewing. Swallowing is more coordinated to allow the infant to accept solids easily. Head control is well developed, which permits infants to sit with support and purposely turn the head away to communicate disinterest in food. Voluntary grasping and improved eye–hand coordination gradually allow infants to pick up finger foods and feed themselves. Their increasing sense of independence is evident in their desire to hold a cup or bottle and try to "help" during feeding.

Selection of solid foods. Complementary feeding, along with continued breastfeeding, is recommended beginning at age 6 months. If breastfeeding is discontinued, a commercial iron-fortified formula should be substituted. Follow-up or transition formulas specially marketed for older infants offer no special advantages over other infant formulas. Iron-rich meat, meat alternatives, and iron-fortified cereal are appropriate first foods. These should be offered a few times each day to help prevent iron deficiency (Critch & CPS, Nutrition and Gastroenterology Committee, 2014/2020; Health Canada et al., 2015b). Commercially prepared ready-to-serve dry cereals for infants include rice, barley, oatmeal, and high-protein cereals. Cereals such as cream of farina should not be used because infant commercial cereals are a better source of iron. Infant cereal (iron-fortified) should be mixed with breast milk or formula until whole milk is given. The addition of solid foods to the exclusively breastfed infant's diet does not significantly increase overall caloric intake or weight gain. Infants should be offered breast milk or formula first for the first 6 to 12 months before the solids are given, as milk is still considered the main source of nutrients for the infant.

At the age of 6 months the following foods can start to be introduced:

- Puréed, minced, diced or cooked meat, fish, or chicken, tofu, mashed beans, peas or lentils, or eggs
- Iron-fortified infant cereal, small pieces of dry toast, unsalted crackers, whole-grain bread, rice, and pasta
- Puréed, mashed, lumpy or pieces of soft cooked vegetables—yellow, green, or orange
- Puréed, mashed, or lumpy soft fruit
- Dairy foods such as yogurt (3.25% or higher), cottage cheese, or grated hard cheese

Parents should wait until the infant is 9 to 12 months old before introducing whole cow's milk (3.25%). After 12 months of age, the infant should not take more than 720 mL of milk products per day. Too much milk can lead to iron-deficiency anemia (Unger et al., 2019).

The introduction of solid foods into the infant's diet at this age is primarily for taste and chewing experience, not for growth. The majority of the infant's caloric needs continues to be derived from the primary milk source (breast milk or formula); therefore, solids should not be perceived as a substitute for milk until the child is older than 12 months. Portion sizes may vary according to the infant's taste. Food with a lumpy texture should be offered no later than 9 months, with a gradual progression to varied textures by 1 year of age (Health Canada et al., 2015b).

Parents should be cautioned to avoid reliance on foods and supplements marketed as iron- or vitamin-fortified as primary sources of minerals. Instead, they should be encouraged to offer the child a variety of fruits, vegetables, whole grains, meats, and those known to naturally be rich in iron.

Infants and toddlers should not be given low-calorie foods unless a strict, medically prescribed diet is required. The infant's growth during this phase is crucial to future development, and curtailing dietary fat should be done with great caution.

The Canadian Paediatric Society (CPS) has stated that delaying the introduction of certain "trigger" foods for allergies is shown to have no protective effect on allergic sensitization or disease development. Rather, they recommend not delaying any specified solid food beyond 6 months of age (Abrams et al., 2019/2020). When feeding an infant food that is a potential allergen, only one new food per day should be given; 2 days should pass before introducing another allergenic food (Health Canada et al., 2015b). To decrease the chance of allergies developing in infants who are at high risk for allergies (with a personal history of atopy such as eczema or a first-degree relative with atopy), peanuts and eggs should be introduced before 6 months of age, but only if the infant is developmentally ready and is older than 4 months (Abrams et al., 2019/2020).

! NURSING ALERT

Infants under 12 months of age should not be given honey or corn syrup as these may contain the bacterium *Clostridium botulinum*, a source of foodborne botulism. Botulism is a serious illness caused by the bacterium's toxin, which affects the nervous system and can cause paralysis. The most common source of the toxin is improperly sterilized home-canned foods. The disease has a wide variation in severity, from constipation to progressive sequential loss of neurological function and respiratory failure.

Introduction of solid foods. Because feeding is a learning process, as well as a means of nutrition, new foods should be given alone, not mixed with others, to allow the child to learn new tastes and textures. Food should not be mixed in the bottle and fed through a nipple with a large hole. This can cause poor chewing of food later in life because of lack of experience.

A current trend in Canada is baby-led weaning or giving the infant only finger foods that they are able to grasp and self-feed upon the introduction of solids. Baby-led weaning allows infants to self-regulate the amount and type of food they consume. Proponents of baby-led weaning feel this autonomy may lead to a healthier relationship with food long term and that children may be less picky in their food choices. Disadvantages of baby-led weaning include the possibility of not getting enough iron and calories and an increased risk for choking, depending on the type of food that is introduced (Dietitians of Canada, 2020b).

Providing foods from a spoon, such as iron-fortified baby cereals, mashed beans or lentils, or minced meats, may increase iron intake. When the spoon is first introduced, infants will often push it away and appear dissatisfied. Patience and skill are required to overcome this initial response. As infants become accustomed to the spoon, they more eagerly accept the food and eventually will open the mouth in anticipation (or keep it closed in dislike).

There is not enough evidence to recommended one approach for starting solid foods over another. Regardless of the method of introducing food, infants should be seated appropriately for all meals and snacks and supervised by a parent or caregiver. Known choking hazards such as popcorn, grapes, hot dogs, and nuts should be avoided or prepared in a way that limits the risk of choking (such as slicing grapes lengthwise).

Infants know when they are hungry and when they are full. Parents need to be able to identify signs of hunger and satiety in their infant to avoid under- or overfeeding. Hungry infants may open their mouth for food and protest if the food is taken away. Infants who are full may close their mouth, turn their head away, or push food away (Health Canada et al., 2015b). Parents also need to be taught to interpret their infant's signals of discomfort and to learn to intervene in ways other than through feeding. Crying, fussiness, and sucking do not necessarily indicate hunger. Rocking, stroking, holding, and offering a toy may be more appropriate than automatically responding with food.

Finally, parents need to be taught that while, initially, feeding can be a messy experience for infants, the child's learning to feed themselves finger foods is a part of learning and mastery.

Weaning. Weaning may mean the complete cessation of breast or bottle feeding or refer to the process of introducing complementary foods while a child continues to breastfeed (Grueger & CPS, Community Paediatrics Committee, 2013/2018). Weaning may be mother-led (planned) or infant-led (gradual). Whenever possible, nurses should advise a gradual transition that supports both parents and infant. Many infants can go directly from the breast to a cup, as most infants are developmentally ready to use a cup at 6 to 9 months of age.

In an infant under 6 months, no extra oral fluids are required other than breast milk or formula, which provides enough hydration. At 6 months to 12 months, the only fluids that are recommended are sips of water so that the infant will drink adequate breast milk or formula and eat adequate solid food. Fluids should be offered in an open cup rather than using bottles. After 12 months, the child can have water liberally. Fruit juice is not recommended before age 24 months because it can lead to other health issues such as poor nutrition, obesity, and tooth decay (Government of Canada, 2019a).

Children Over 1 Year of Age. It is now recognized that lifetime eating habits may be established in early childhood and conditions such as obesity and cardiovascular disease can be decreased by encouraging healthy eating habits in all children and their families. *Canada's Food Guide* is the foundation of healthy eating that offers meal planning tips and recipes for all Canadians over the age of 2 years, to help them achieve positive health outcomes (see Appendix A). The *Food Guide* also focuses on enjoying food and incorporating cultural and food traditions as part of health eating. Traditional foods or country foods are "foods that are available locally from natural resources that have cultural significance to Indigenous Peoples in Canada" (Government of Canada, 2019a). *Traditional food* is the preferred term for First Nations and Metis peoples and *country food* is the preferred term for Inuit people.

The *Food Guide* also places emphasis on sitting down and eating meals together as a family as much as possible and to take time at the table not to rush meals. The focus should be on spending time together and not on what is being eaten (or not eaten). Family-style meals are also encouraged in which food is placed on the table in serving dishes so that children can serve themselves on the basis of their hunger cues and food preferences. As soon as children are able to be involved in meal planning and cooking, they should be encouraged to actively participate, as this will help them learn about healthy food choices (Government of Canada, 2019a).

Younger children have smaller appetites, which can sometimes make mealtimes challenging. Parents should be encouraged to:

- Offer a variety of healthy foods
- Offer small meals and snacks at regular times throughout the day
- Let the child decide how much food they want to eat. It is normal for children to eat more at some meals and less at others, depending on things like:
  - Activity level
  - Growth spurts
  - Emotions like excitement or sadness

If food is used as a reward or sign of approval, a child may overeat for non-nutritive reasons. If food is forced and mealtime is consistently unpleasant, the usual pleasure associated with eating may not develop. Mealtimes should be enjoyable rather than times for discipline or family arguments. Young children may be unable to sit through a long meal and may become restless. This is particularly common when children are brought to the table just after active play. Calling them in from play 15 minutes before mealtime allows them ample opportunity to get ready for eating while settling down their active minds and bodies.

Excessive consumption of fruit juices has been associated with adverse health effects such as dental caries and gastrointestinal symptoms. A child's intake of high sugar content or acidic carbonated beverages contributes to the development of dental caries, and consumption of large amounts of non-nutritive calories may displace or preclude intake of nutrients necessary for growth (Government of Canada, 2019a).

Toddler. During the period from 12 to 18 months of age, the growth rate slows, decreasing the child's need for calories, protein, and fluid. However, the protein (13 g per day) and energy requirements are still relatively high, to meet the demands for muscle tissue growth and a high activity level. Toddlers usually require three meals and two snacks per day; however, the portions consumed are generally much smaller than those of older children.

At approximately 18 months of age, most toddlers manifest this decreased nutritional need with a decrease in appetite, a phenomenon known as *physiological anorexia*. They become picky, fussy eaters with strong taste preferences. They may eat large amounts one day and almost nothing the next. They become increasingly aware of the non-nutritive function of food (i.e., the pleasure of eating, the social aspect of mealtime, and the control of refusing food).

Toddlers are influenced by factors other than taste when choosing food. If a family member refuses to eat something, toddlers are likely to imitate that response. If the plate is overfilled, they are likely to push it

away, overwhelmed by its size. If food does not appear or smell appetizing, they will probably not agree to try it. In essence, mealtime is more closely associated with psychological components than with nutritional components.

The **ritualism** of this age also influences certain principles in feeding practices. Toddlers like to have the same dish, cup, or spoon every time they eat. They may reject a favourite food simply because it is served in a different dish. If one food touches another, they often refuse to eat it.

Some toddlers may have mastered using a cup; most cannot adeptly use a spoon until 18 months of age or later and generally prefer using their fingers. All beverages should be offered in a regular cup instead of a bottle or sippy cup (Critch & CPS, Nutrition and Gastroenterology Committee, 2014/2020).

The method of serving food also takes on more importance during this period. Toddlers need to have a sense of control and achievement in their abilities. In general, what is eaten is much more significant than how much is consumed. In some cases a toddler may insist on one food, such as mashed potatoes for lunch and dinner. Small amounts of meat and vegetables supply greater food value than a large consumption of bread or potato. This period of picky eating can be trying for parents and children alike.

Mastication skills continue to mature, putting children at continued risk for choking. Large round foods (hot dogs, grapes, carrots, popcorn, whole nuts, fruit gel snacks) should be avoided. Active play while eating should be discouraged, to prevent choking. Appetite and food preferences are sporadic. If exposed to the same food every day, a young toddler does not learn how to manage the complex sensory information needed to eat new, more difficult foods (vegetables with a different texture versus puréed, slippery fruits). To help prevent "food jags," it is recommended that parents present food in various physical forms. The child may need to progress to eating new foods in a stepwise fashion: visually tolerating the food, interacting with the food, smelling the food, touching the food, tasting it, and then eating the food.

Because eating habits are established in early life and affect not only the child's future eating habits but also the child's health as an adolescent and adult, it is recommended that toddlers not be forced to eat foods they are reluctant to eat. Evidence indicates that toddlers are able to regulate their hunger and satiety needs internally and that forcing foods during this period may exacerbate or lead to future eating issues. Frequent nutritious planned snacks may provide adequate caloric intake at this age. Grazing—nibbling and snacking throughout the day—is not recommended as children will often eat less at mealtimes.

Milk intake for a toddler is the chief source of calcium and phosphorus. Children should be offered 500 mL of milk per day and no more than approximately 750 mL per day as this amount results in a deficiency of dietary iron and other **nutrients** (Critch & CPS, Nutrition and Gastroenterology Committee, 2014/2020; Unger et al., 2019). After 2 years of age, children can be given a lower-fat milk to reduce daily total fat to less than 30% of calories, saturated fatty acids to less than 10% of calories, and cholesterol to less than 300 mg. Fat restriction of trans fatty acids and of saturated fats is important in the protection of toddlers' cardiovascular health. However, for the first 2 years, homogenized (3.25% milk fat) milk provides essential nutrients required for energy and brain development. Other measures to reduce dietary fat include eating lean meats and fat-modified foods (such as low-fat cheese) and cooking with low-fat products. Because less fat in children's diet can also mean fewer calories and nutrients, caregivers must know what kinds of food to choose. Parents are encouraged to provide an iron-rich diet that includes heme and nonheme iron sources (red meats, poultry, fish, green leafy vegetables, dried fruit, beans).

Research carried out by the U.S. Institute of Medicine on vitamin D and calcium levels has led to new joint recommendations of increased calcium and vitamin D intakes (Health Canada, 2020); the recommendation for adequate intake of calcium for a child 1 to 3 years of age is in Table 35.1. Whole milk, cheese, yogurt, legumes (beans), and vegetables (broccoli, collard greens, kale) are good sources of calcium. Popular calcium-fortified foods include waffles, cereals and cereal bars, orange juice, and some white breads. Adequate vitamin D intake is essential to prevent rickets (see Table 35.1). Children living in the north and children who have a high body mass index (BMI) and are overweight or obese have lower levels of vitamin D and may require higher supplements of vitamin D (Godel & CPS, First Nations, Inuit and Métis Health Committee, 2007/2017). Sources of vitamin D include fish, fish oils, and egg yolks; Fortified cereals, dairy products, and meat are also good sources of zinc and vitamin E.

Preschool. Nutritional requirements for preschoolers are fairly similar to those for toddlers. The required number of calories per unit of body weight continues to decrease slightly. Fluid requirements may also decrease slightly to approximately 100 mL/kg per day but depend on the activity level, climatic conditions, and state of health. Protein requirements increase with age; the recommended intake for preschoolers is 13 to 19 g per day.

It is important that all diets contain adequate nutrients such as calcium (see Table 35.1). If healthy food choices are made following *Canada's Food Guide* then daily requirements for nutrients should be met. Low-fat milk may be substituted so that the quantity of milk may remain the same while limiting fat intake overall.

When children reach 4 years of age, they may enter another period of finicky eating, which is generally characteristic of the more rebellious behaviour of children in this age group. By age 5 years, children are more agreeable to trying new foods, especially if they are encouraged by an adult who allows them to help with food preparation or experiment with a new taste or different dish (Figure 35.1). Mealtimes can become battlegrounds if parents expect perfect table manners. Usually the 5-year-old child is ready for the "social" side of eating, but the 3- or 4-year-old child still has difficulty sitting quietly through a long family meal.

The Dietitians of Canada (2020a) suggests the following tips:

- Eat together at regular times often as possible without distractions such as electronics.
- Let preschoolers eat with their fingers and do not expect good table manners.
- Offer three meals and three snacks and do not let the child graze or eat throughout the day.

Fig. 35.1 Preschool-age children enjoy helping adults and are more likely to try new foods if they can assist in the preparation.

- Remove food calmly if it has not been eaten within 15 minutes.
- Always serve one food that the child will eat.
- Serve foods in different ways, such as adding grated carrots to a muffin or soup.

School age. School-aged children need increased amounts of food to adequately meet the energy requirements of the body. Children develop a taste for a variety of foods at this age. Unfortunately, the easy availability of fast-food restaurants, the influence of mass media, and the temptation of "junk food" can make it easy for children to fill up on empty calories. Foods that do not promote growth, such as sugars, starches, and excess fats, are not recommended. Children should not be offered more than 250 to 375 mL of juice per day and water should be offered as the drink of choice when thirsty.

Parents are unable to monitor what their children eat when they are away from home. A parent may pack a lunch for school but is unaware of how much is eaten or thrown away. Some schools are seeking to provide healthy, nutritious meals at school, in the cafeteria. This effort includes the implementation of school policies related to vending machines, corporate sponsorships, and school and sports events. Some schools have initiated "breakfast clubs" available for all children in order to decrease the stigma for those children with food insecurity (see Chapter 30, Food Insecurity for more information). Such programs are associated with greater student engagement in the classroom.

The community health nurse can take an active role in nutrition education by working with teachers to plan and implement classes on nutrition and by working with parents and children to give nutritional guidance. Important aspects of nutrition education include the relationship of nutrition to activity, fitness, and health; elements of a wholesome diet; and how food products are grown, processed, and prepared.

Adolescent. The rapid and extensive increase in height, weight, muscle mass, and sexual maturity during adolescence is accompanied by increased nutritional requirements. Because nutritional needs are closely related to the increase in body mass, the peak requirements occur in the years of maximum growth, during which the body mass almost doubles. The caloric and protein requirements during this time are higher than at almost any other time of life. As a result of this increased anabolic need, the adolescent is highly sensitive to caloric restrictions.

Dietary intervention should promote the regular consumption of breakfast and a balanced intake of a variety of foods. There is a substantial increase in the need for the minerals calcium, iron, and zinc during periods of rapid growth: calcium for skeletal growth, iron for expansion of muscle mass and blood volume, and zinc for the generation of both skeletal and bone tissue. Girls with heavy or frequent menses may be especially susceptible to iron deficiency resulting from blood loss. Calcium intake from food sources is essential during adolescence to assist in building bone mass; the calcium deposited during these years determines the risk for osteoporosis as an older adult (Table 35.1).

Vegetarian Diets

Vegetarian diets or plant-based diets have become increasingly prevalent for many reasons: people are concerned about hypertension, cholesterol, obesity, cardiovascular disease, and cancer of the stomach, intestine, and colon; the influence of the animal rights movement; and for cultural or religious reasons. Well-planned vegetarian diets are adequate for all stages of the life cycle and promote normal growth. Children and adolescents on vegetarian diets have the potential for lifelong healthy diets and have been shown to have lower intakes of cholesterol, saturated fat, and total fat and higher intakes of fruits, fibre, and vegetables than nonvegetarians (Dietitians of Canada, 2020c).

The major types of vegetarianism are as follows:

Lacto-ovo vegetarians, who exclude meat from their diet but consume dairy products and rarely fish

Lactovegetarians, who exclude meat and eggs but drink milk

Pure vegetarians (vegans), who eliminate any food of animal origin, including milk, cheese, and eggs

Macrobiotics, who are even more restrictive than pure vegetarians, allowing only a few types of fruits, vegetables, and legumes

Semivegetarians, who consume a lacto-ovo vegetarian diet with some fish and poultry (This is an increasingly popular form of vegetarianism and poses little or no nutritional risk to children unless dietary fat and cholesterol intake is severely restricted.)

Many individuals who are concerned about their health subscribe to vegetarian diets that may not be typified by these categories. During nutritional assessment it is necessary to clearly list exactly what the diet includes and excludes.

Achieving a nutritionally adequate vegetarian diet is not difficult (except with the strictest diets), but it does require careful planning and knowledge of nutrient sources. *Canada's Food Guide* (see Appendix A) can be adapted to meet the nutrient needs of vegetarians. The introduction of solids for vegetarian infants may occur using the same guidelines as for other children (see Selection of Solid Foods earlier in the chapter). Breast milk from vegetarian mothers can be deficient in vitamin B_{12}; supplementation of both mother and child is advisable. If human milk or commercial infant formula is not given, fortified soy formula is recommended only for infants who have galactosemia or who cannot consume dairy-based products for cultural or religious reasons.

To ensure sufficient protein in the diet, **incomplete protein foods** (those that do not have all the **essential amino acids**) must be eaten at the same meal with other foods that supply the missing amino acids. (**Complete protein foods** have all the essential amino acids.) The three basic combinations of foods consumed by vegetarians that generally provide the appropriate amounts of essential amino acids are as follows:

1. Grains (cereal, rice, pasta) and legumes (beans, peas, lentils, peanuts)
2. Grains and milk products (milk, cheese, yogurt)
3. Seeds (sesame, sunflower) and legumes

The major deficiencies that may occur in the stricter vegan diets are inadequate protein for growth; inadequate calories for energy and growth; poor digestibility of many of the bulky natural, unprocessed foods, especially for infants; and deficiencies of vitamin B_6, niacin, riboflavin, vitamin D, iron, calcium, and zinc. Strict vegan diets also require supplements of vitamin B_{12} and vitamin D for children aged 2 to 12 years. Vitamin D is essential if a child drinks less than 500 mL of vitamin D–fortified milk daily. Children in this category should receive 400 IU of vitamin D daily. Many of these deficiencies can be avoided in children who are not consuming 100% of the Recommended Dietary Allowance (RDA) of vitamins and minerals by taking a multivitamin–mineral supplement (Amit & CPS, Community Paediatrics Committee, 2010/2018).

Children on strict vegetarian and macrobiotic diets should be evaluated for iron-deficiency anemia and rickets; this may occur as a result of consuming plant foods such as unrefined cereals, which impair the absorption of iron, calcium, and zinc. Other factors that affect iron absorption are listed in Box 46.1.

OBESITY

The incidence of obesity has nearly tripled over the last 25 years, with up to 26% of all Canadian and 41% of Indigenous young people aged 2 to 17 years being overweight or obese (Lipnowski et al., 2012/2017).

Physical inactivity is associated with increased risk for being obese, independent of age, sex, and ethnicity, including for the Indigenous population (Katzmarzyk, 2012). Other risk factors for obesity that all Canadian children face include increased sedentary time, non-exercise activity thermogenesis, as well as reduced frequency, intensity, amounts, and types of physical activity (Lipnowski et al., 2012/2017). Indigenous young people also face significant food insecurity in addition to limited access to fresh fruit and vegetables due to high cost, remote geography, and perishable foods of poor quality. Among the Inuit population, those who eat country food in their diet, such as Artic char and caribou, tend to be less obese than the rest of the Inuit population (Batal & Descelles, 2019).

Childhood obesity has major negative health outcomes, including metabolic syndrome with hypertension, high blood sugar, excess body fat around the waist, abnormal cholesterol or triglyceride levels, obstructive sleep apnea, and nonalcoholic steatohepatitis. Childhood obesity can also lead to poor self-esteem, social isolation, and feelings of depression and rejection as well as a decreased health-related quality of life (Lipnowski et al., 2012/2017). Childhood obesity is an important predictor of adult obesity, so preventing overweight and obesity in childhood is essential.

! NURSING ALERT

Over the past several decades, obesity has increased among young children. Efforts to provide a healthy diet and to encourage physical activity should begin early to help children achieve optimum health (Lipnowski et al., 2012/2017).

Overweight is defined as a BMI greater than 25, and *obesity* as a BMI greater than 30. BMI measurements provide the most accurate method for screening children and adolescents for obesity. The World Health Organization (WHO) growth charts have been adapted for use in Canada. These charts include ideal BMI standards according to age and gender (see Additional Resources). Children and adolescents with a BMI between the eighty-fifth and ninety-seventh percentile are considered overweight, those between the ninety-fifth and 99.9th percentile are considered obese, and those above the 99.9th percentile are categorized as severely obese.

Etiology and Pathophysiology

Obesity results from a caloric intake that consistently exceeds caloric requirements and expenditure and may involve a variety of interrelated influences, including metabolic, hypothalamic, hereditary, social, cultural, and psychological factors (Figure 35.2). Because the etiology of obesity is multifactorial, treatment requires multilevel interventions.

A balance between energy intake and energy expenditure is a critical factor in regulating body weight. Factors that raise energy intake or decrease energy expenditure by even small amounts can have a long-term impact on the development of overweight and obesity. In addition to unhealthy eating habits, a sedentary lifestyle contributes to cardiovascular disease and obesity. Therefore, the Canadian Society for Exercise Physiology [CSEP] (2021) recommends that children have several hours of both structured and unstructured light physical activity every day as well as at least 60 minutes per day of moderate to vigorous physical activity involving a variety of aerobic activities. See Table 35.2 for 24-hour activity recommendations.

There is little doubt that physical activity has decreased in elementary and secondary schools in Canada, and most of children's physical activity must occur within the family or outside of school. Children from families with low physical activity levels may adopt these patterns of their parents and other adults. Parental obesity and low levels of physical activity are correlated with decreased physical activity in children. The CPS asserts

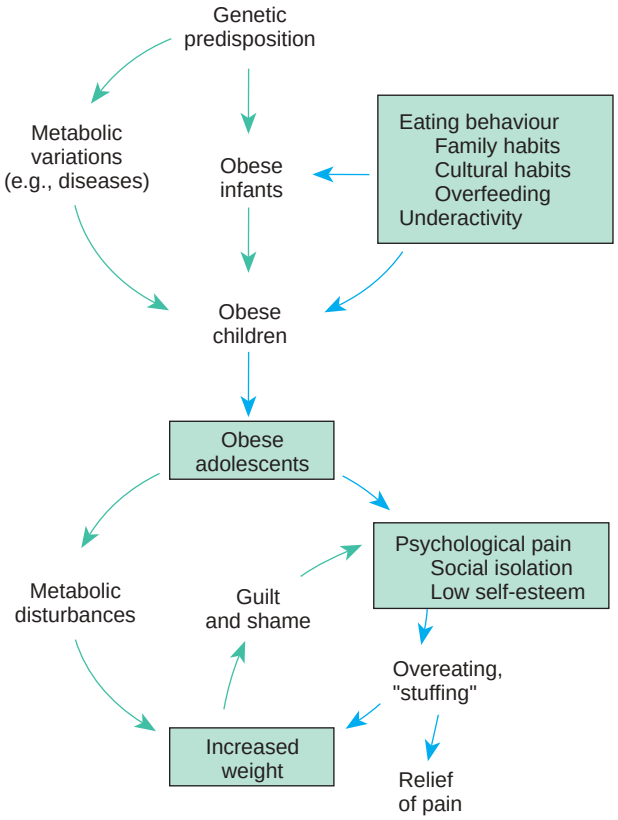

Fig. 35.2 Complex relationships in obesity.

that media time, especially advertisements of food products, has a direct correlation with the increased incidence of childhood obesity in Canada (Lipnowski et al., 2012/2017). Lack of green space, extreme climates, heavy traffic, and local crime can discourage physical activity. The type and level of adolescents' physical activity may also be influenced by sociocultural factors. A study of two Canadian provinces reported sex-based differences of youth, with girls achieving less physical activity during the week (Comtes et al., 2013). The difference was not seen on the weekend or with younger children.

The growing attraction and availability of many sedentary activities, including television, video games, social media, digital devices, and the Internet, have also greatly influenced the amount of time that children spend participating in sedentary behaviours. Studies have shown the association between screen time and obesity among children. The CPS (2017b) recommends limiting routine or regular screen time to less than 1 hour per day for children aged 2 to 5 years and to ensure that sedentary screen time is not a routine part of child care for children younger than 5 years.

Genetic influence is an epidemiological consideration in children's weight. Genetic mutations, such as *FTO* (fat mass and obesity) and *INSIG2* (insulin-induced gene 2), are rare but can predispose individuals to becoming overweight or obese (Gahagan, 2020). Studies have also indicated that a combination of genetic and environmental factors can predispose a person to obesity. Parental BMI is a more potent predictor of obesity than genetics, which suggests that behaviours and environment play a greater role in obesity (Wang et al., 2017). The increasing rates of obesity within genetically stable populations suggest that environmental and some perinatal factors and possible intrauterine factors contribute to the risk of childhood obesity. These factors include high preconceptual weight, increased gestational weight gain, high birthweight of the infant, maternal smoking, and intrauterine growth restriction with early infant catch-up growth. In addition,

TABLE 35.2 High and Low Activity Levels of the 24-Hour Movement Guidelines

Age Group	High Activity Level	Low Activity Level—Sedentary
Infants (less than 1 year)	Being physically active several times in a variety of ways, particularly through interactive floor-based play—more is better. For those not yet mobile, this includes at least 30 minutes of tummy time spread throughout the day while awake.	Not being restrained for more than 1 hour at a time (e.g., in a stroller or highchair). Screen time is not recommended. When sedentary, engaging in pursuits such as reading and storytelling with a caregiver is encouraged.
Toddlers (1–2 years)	At least 180 minutes spent in a variety of physical activities at any intensity, including energetic play, spread throughout the day—more is better	Not being restrained for more than 1 hour at a time (e.g., in a stroller or highchair) or sitting for extended periods. For those younger than 2 years, sedentary screen time is not recommended. For those aged 2 years, sedentary screen time should be no more than 1 hour—less is better. When sedentary, engaging in pursuits such as reading and storytelling with a caregiver is encouraged.
Preschoolers (3–4 years)	At least 180 minutes spent in a variety of physical activities spread throughout the day, of which at least 60 minutes is energetic play—more is better	Not being restrained for more than 1 hour at a time (e.g., in a stroller or car seat) or sitting for extended periods. Sedentary screen time should be no more than 1 hour—less is better. When sedentary, engaging in pursuits such as reading and storytelling with a caregiver is encouraged
Children and adolescents (5–17 years)	Moderate to vigorous physical activity Accumulation of at least 60 minutes per day of moderate to vigorous physical activity involving a variety of aerobic activities Vigorous physical activities, and muscle- and bone-strengthening activities should each be incorporated at least 3 days per week.	Light physical activity and sedentary activity Several hours of a variety of structured and unstructured light physical activities No more than 2 hours per day of recreational screen time Limited sitting for extended periods

children who were breastfed have decreased rates of obesity (Gahagan, 2020; RNAO, 2018).

Fewer than 5% of the cases of childhood obesity can be attributed to an underlying disease. Such diseases include hypothyroidism, adrenal hypercorticoidism, hyperinsulinism, and dysfunction of the central nervous system as a result of tumour, injury, infection, or vascular accident. Obesity is a frequent complication of muscular dystrophy, paraplegia, Down syndrome, spina bifida, and other chronic illnesses that limit mobility.

There is also little evidence to support a relationship between obesity and "low metabolism." Small differences may exist in regulation of dietary intake or metabolic rate between obese and nonobese children that could lead to an energy imbalance and inappropriate weight gain, but these small differences are difficult to accurately quantify. Obese children tend to be less active than lean children, but it is uncertain whether inactivity creates the obesity or obesity is responsible for the inactivity. The tendency toward obesity is manifested whenever environmental conditions are favourable toward excessive caloric intake, such as an abundance of food, limited access to low-fat foods, reduced or minimum physical activity, and snacking combined with excessive screen time.

Family and cultural eating patterns, as well as psychological factors, play important roles in the development of obesity; some families and cultures consider fat to be an indication of good health. It is common for obese children to have families that emphasize large meals, admonish children for leaving food on their plates, or use food as a reward or punishment. Parents may have an exaggerated concept of the amount of food children require and expect them to eat more than they need.

A report by the Standing Senate Committee on Social Affairs, Science and Technology (2016) has drawn attention to the links between childhood obesity and the key determinants of overall health (Table 35.3). In particular, family income, education, social support, geographic location, cultural norms and values, biological and genetic factors, accessibility of services for health, and gender are important determinants of body weight among Canadian children and adolescents. Lower socioeconomic groups have a greater prevalence of obesity than that of higher-income groups, especially for girls. This difference between groups is often apparent before children are 6 years of age. Food sources that are found in lower-income neighbourhoods tend to be fast-food outlets and convenience stores. It may also be difficult for these families to find transportation to shop elsewhere, which could also lead to fewer food choices in their neighbourhood.

Psychological factors such as using food as a positive reinforcement for desired behaviours can also affect risk for obesity. If this practice becomes a habit the child may continue to use food as a reward, a comfort, and a means of dealing with depression or hostility (Fig. 35.2). Many individuals eat when they are not hungry or in response to boredom, loneliness, sadness, depression, or tiredness. Difficulty determining feelings of satiety can lead to issues with weight and may compound the factor of eating in response to emotional rather than physical hunger cues.

Frequency of family meals has consistently been shown to be a protective factor for obesity (Flattum et al., 2015, Government of Canada, 2019a). Family meals tend to provide access to a variety of nutrient-rich foods, particularly fruits and vegetables. This is also a time when parents can model healthy behaviours. Parental modelling of overeating, decreased physical activity, and food availability in the home are predictors of excess weight gain during childhood and adolescence (Government of Canada, 2019a).

Diagnostic Evaluation

A careful history should be obtained and a physical examination performed to differentiate simple obesity from increased fat due to organic causes. A family history of obesity, diabetes, coronary heart disease, and

TABLE 35.3 Determinants of Health That Influence Food Intake and Physical Activity in Childhood and Adolescence

Income	Family income determines access to quality food. In isolated and northern communities, food costs are higher and fresh fruits and vegetables are very difficult to obtain. Family income shapes access to physical activity facilities and organized sports.
Education	Increased education increases resources (i.e., literacy and numeracy) available for decision making related to food and activity choices.
Social environment	Strong communities can strengthen localized food systems. Lack of control over personal lives and communities limits opportunities to promote health (e.g., in many Indigenous communities).
Physical environment/ geographic location	Children and youth living in economically advantaged neighbourhoods have a far lower risk of becoming obese than those in disadvantaged neighbourhoods. Parental perceptions of public safety influence child and adolescent physical activity. The cost of food varies widely according to community location, with prices far higher in isolated and northern communities. Access to low-fat, nutritious foods varies by location.
Values and norms	Values and norms vary widely and affect food and physical activity patterns among children and adolescents.
Biological/genetic factors	Indigenous and South Asian populations have a genetic susceptibility to type 2 diabetes.
Accessibility of services for health	Availability and accessibility of quality health promotion and health intervention services vary.
Culture	Availability of television, computers and tablets, and video games varies. Family eating patterns vary by culture. Peer group activities and eating patterns vary by culture.
Gender	Adolescent boys, on average, are more active than adolescent girls.

A whole-of-society approach for a healthier Canada.* https://sencanada.ca/content/sen/committee/421/SOCI/Reports/2016-02-25_Revised_report_Obesity_in_Canada_e.pdf.

dyslipidemia should be obtained for all children who are overweight or at risk for being overweight. Specific information from the patient and family about the effects of obesity on daily functioning—for example, difficulties with nighttime breathing and sleep, daytime sleepiness, joint pain, inability to keep up with family activities and peers at school—is helpful. The physical examination should focus on identifying comorbid conditions and identifiable causes of obesity. A psychosocial history is also helpful in understanding the impact of obesity on the child's life.

It is useful to estimate the degree of obesity to determine the component of body weight that can be modified. All of the following methods have been used to assess obesity: BMI, body weight, weight–height ratios, weight–age ratios, hydrostatic (underwater) weight, skin fold measurements, bioelectrical analysis, computed tomography (CT), magnetic resonance imaging (MRI), and neutron activation. Each of these methods has advantages and disadvantages. Hydrostatic, or underwater weighing provides the most accurate measurement of lean body weight.

Throughout the growth cycle from infancy to adolescence, the Canadian growth charts should be used and BMI measured and monitored for every child (Dietitians of Canada, 2014), as the presence of obesity may not be obvious from appearance alone. Regular assessment of height and weight and computation of the BMI facilitate early recognition. BMI is currently considered the best method to assess weight in children and adolescents. The calculation is based on the individual's height and weight. In adults, BMI definitions are fixed measures without regard to sex and age. The BMI in children and adolescents varies to accommodate age- and gender-specific changes in growth. The formula for BMI calculation is as follows:

$$\text{Weight in kilograms} \div [\text{Height in metres}]^2$$

BMI measures in children and adolescents are plotted on growth charts that enable heath care providers to determine the patient's BMI-for-age.

The initial assessment of obese children and adolescents should include screening to evaluate for comorbidities. The history is an important guide to determine the workup. The physical examination should focus on identifying **comorbid** conditions and identifiable causes of obesity. Some areas to focus on include (1) skin for stretch markings and discolorations (e.g., acanthosis nigricans), (2) joints for swelling and evidence of pain, and (3) airway for evidence of obstruction and enlarged tonsils. Basic laboratory studies include a fasting lipid panel; fasting insulin level; fasting glucose hepatic enzymes, including γ-glutamyl transferase; and, in some institutions, hemoglobin A_{1c}. Other studies, such as a sleep study, metabolic studies, and radiographic evaluations, may be added on the basis of the history and physical examination.

Therapeutic Management and Nursing Care

The best approach to the management of obesity is a preventive one. Early recognition and control measures are essential before the child or adolescent reaches an obese state. Health care providers must educate families about the medical complications of obesity, and families should be encouraged to be involved in the treatment plan.

Currently, the only treatments recommended for children are diet, exercise, behaviour modification, and, in some situations, pharmacological agents, such as orlistat. The treatment of obesity is difficult and requires a holistic treatment plan that treats the whole person physically, socially, and emotionally. Many approaches do not achieve long-term success. The average individual loses only about 5 to 10% of their weight with available therapies. Losing this amount of weight can have a significant positive effect on many comorbidities, but unfortunately, the lost weight is frequently regained in 1 or 2 years.

Diet modification is an essential part of weight-reduction programs. Nutrition counselling is directed toward improving the nutritional quality of the diet rather than dietary restriction. Educating youth about the limits and risks of fad diets is important. Educating children and families about *Canada's Food Guide* may help to

improve dietary intake. Many programs recommend using a food diary as a helpful tool to increase awareness of food choices and eating behaviours. The goal is to encourage the individual to make healthier choices in food selection and discourage eating food by habit or to appease boredom.

For children with severe obesity, strict diets have been used, such as the protein-sparing modified fast, a hypocaloric diet, or a ketogenic diet that is designed to provide enough protein to minimize loss of lean body mass during weight loss. Such diets need to be closely monitored and should be used only with an interprofessional team that includes a physician, dietitian, and behavioural therapist. Generally, the diet consists of 1.5 to 2.5 g of protein per kilogram. The intake of carbohydrates is low enough to induce ketosis. The benefits of the diet are relatively rapid weight loss and anorexia induced by ketosis. Potential complications include protein losses, hypokalemia, hypoglycemia, inadequate calcium intake, orthostatic hypotension, and increased risk for osteoporosis. Potassium and calcium supplements and adequate calorie-free beverages can minimize these complications. It is difficult to sustain such diets over a long period of time, and the long-term outcomes of using these diets have not been established.

Researchers continue searching for medications that will successfully treat obesity. Orlistat, a lipase inhibitor, has been used for adolescents 12 to 18 years of age who have a BMI more than 2 units above the ninety-fifth percentile for age and sex; however, adverse effects of the medication include fatty or oily stools and possible malabsorption of fat-soluble vitamins. Some experts do not recommend its use for children younger than 17 years. Liraglutide (Saxenda) is a medication that works by increasing insulin release from the pancreas and decreases excessive glucagon release in individuals with type 2 diabetes and obesity. It is given as an injection once a day (Wharton et al., 2017). Weight-loss medications can harm unborn fetuses, so birth control needs to be used if the person taking the medication is sexually active (Wharton et al., 2017). There are currently no medications approved for use in overweight or obese children younger than the age of 12 years.

Behaviour-modification approaches to weight loss are based on the observation that individuals with obesity have abnormal eating practices that can be altered. Attention is focused not on food but on the social and behavioral aspects surrounding food consumption. Combining behaviour modification with pharmacological therapy in children 12 years of age and older have produced mixed results in regard to total weight loss maintained over a significant period of time. Programs including family-based behaviour modification, dietary modification, and exercise have been shown to be successful in reducing obesity in some children (Wilfley et al., 2017).

Surgical techniques (bariatric surgery) that bypass portions of the intestine or occlude a segment of the stomach to produce a marked diet restriction and weight loss are hazardous and cause many metabolic complications, including severe water and electrolyte depletion, persistent diarrhea, vitamin deficiency, internal herniation, and fatty infiltration and degeneration of the liver. Bariatric surgery may be the only practical alternative for increasing numbers of severely overweight adolescents who have failed organized attempts to lose or maintain weight loss through conventional nonoperative approaches and who have serious life-threatening conditions. Until recently, there were few studies in adolescents that suggested surgical weight loss improved the early mortality of patients with severe obesity. In 2007, Toronto's Hospital for Sick Children began offering bariatric surgery to patients who (a) are between the ages of 12 and 17 years, (b) have a BMI greater than the ninety-fifth percentile for their age and gender, and (c) have at least one coexisting chronic condition. Results from this program have shown that gastric banding surgery in adolescents can be safe and effective if combined with lifestyle changes and interdisciplinary support (Akinkuotu et al., 2019). Physicians must define clear, realistic, and restrictive guidelines to apply with younger patients when surgery is considered. Candidates for surgery should be referred to centres that offer an interdisciplinary team experienced in the management of childhood and adolescent obesity.

Nurses play a key role in the helping children adhere to and maintain the phases of many weight-reduction programs. Nurses assess, manage, and evaluate the progress of the child. Nurses also play an important role in recognizing potential weight concerns and assisting parents and children in preventing obesity. Nursing care of the adolescent who is overweight is outlined in the Nursing Process box available on the Evolve site.

Before initiating a treatment plan, it is important to establish that the child and family are ready for change. Lack of readiness may result in failure, frustration, and a reluctance to address the issue in the future. The nurse should explore with the child the reasons behind the desire to lose weight, since motivation to lose weight is the key to success. Children need to take personal responsibility for their dietary habits and physical activity. Children who are forced by their parents to seek help are seldom motivated, can become rebellious, and are usually unwilling to control their dietary intake.

Nutritional Counselling. The most successful diets are those that use ordinary foods in controlled portions rather than diets that require the avoidance of specific foods. The emphasis of counselling should be on health outcomes, not weight. Studies have shown that focusing on weight can be detrimental to treatment and may promote eating disorders (Wilfley et al., 2017).

The nurse can teach children and parents how to incorporate favourite foods into their diet and to select satisfying substitutes. To maintain a healthy diet, it is necessary to encourage the consumption of high-nutrient foods such as fruits, vegetables, whole grains, and low-fat dairy protein products. Calories and fat need to be kept to a healthy level without being significantly restricted. To be successful, a dietary program should be nutritionally sound with sufficient satiety value, produce the desired weight loss, and be accompanied by nutrition education and continued support. Children and adolescents should not initiate a weight-reduction diet without health assessment and counselling.

Preventing an increase in body fat during growth is a realistic approach. This is often accomplished by adjusting four aspects of eating:

1. Reducing the quantity eaten, by purchasing, preparing, and serving smaller portions
2. Altering the quality consumed, by substituting low-calorie, low-fat foods for high-calorie foods (especially for snacks)
3. Eating regular meals and snacks, particularly breakfast
4. Altering situations by severing associations between eating and other stimuli, such as eating while watching television

Behavioural Therapy. Altering eating behaviour, including reducing inappropriate eating habits, is essential to weight reduction, especially in maintaining long-term weight control. Most behavioural modification programs include the following concepts:

- A description of the behaviour to be controlled, such as eating habits
- Attempts to modify and control the stimuli that govern eating
- Development of eating techniques designed to control the speed of eating
- Positive reinforcement for these modifications through a suitable reward system

Group Involvement. Commercial groups (e.g., Weight Watchers) or diet workshops composed primarily of adults may be helpful to some children; however, a group of other dieting children is often more effective. These groups are concerned not only with weight loss but also with the development of a positive self-image and encouragement of physical activity. Nutrition education, planning, and improvement of social skills are essential components of these groups. Improvement is determined by positive changes in all aspects of behaviour.

Family Involvement. The nurse needs to educate parents in the purposes of the therapeutic measures and their role in supporting such measures. The family needs nutrition education and counselling regarding the reinforcement plan, alterations in the food environment, and ways to maintain helpful attitudes. They can support their child in efforts to change eating behaviours, food intake, and physical activity.

Research indicates that family meals may also play a role in decreasing obesity and high-risk behaviours among children by promoting healthy eating habits.

Physical Activity. Regular physical activity is incorporated into all weight-reduction programs. Any form of increased physical activity is beneficial, provided that the activities are age appropriate and enjoyable. In recommendations for physical activity, the current health status and developmental level of the child or adolescent need to be considered. The best choice for exercise is any form that is enjoyable and likely to be sustained. Aerobic and endurance exercises help oxidize body fats. Light exercise such as walking may provide an opportunity for the family to increase time together and increase caloric expenditure. Walking for 30 minutes each day and decreasing caloric intake by 500 calories per day may significantly reduce the risk of chronic disease. Weight training can increase basal metabolic rate and replace fat mass with muscle mass. However, weight training is not generally recommended for prepubertal children until they have reached physical and skeletal maturity.

COMPLEMENTARY AND ALTERNATIVE MEDICINE

The term *complementary and alternative medicine* (CAM) is often used to describe medical therapies, practices, and products that are not typically seen as a part of conventional Western medicine, or that are not taught widely in medical schools or commonly available in North American hospitals (Esmail, 2017). The term is often used interchangeably with *traditional medicine* in some countries (WHO, 2019b). CAM can include herbs, homeopathic medicines, acupuncture, energy healing, yoga, special diets, and biofeedback techniques.

The rate of CAM use is approximately 20 to 40% in healthy children and more than 50% in children with chronic, recurrent, or intractable health conditions (Greig et al., 2016). The rates could be higher in certain subgroups, such as street-involved youth and adolescents. Health care providers need to be aware of, inquire directly about, and promote open discussion regarding CAM use. Possible interactions with prescription medications make it especially important to inquire routinely about CAM use (Greig et al., 2016). As with conventional therapies, the safe use of CAM products in adults does not ensure the same result in children and adolescents. The CPS has outlined their concerns about the use of CAMs, especially regarding homeopathic and herbal remedies. These concerns include the lack of research and safety data, particularly in relation to use in the pediatric age group, lack of standardized products, and potential drug interactions (Spigelblatt & CPS, 2005/2018).

One type of CAM is the use of high doses of vitamins, which places some children at risk for health issues. Some parents may routinely give their children megavitamin therapy; however, more research needs to be done to determine a realistic number of children using multivitamin preparations. There is concern among health care providers that terms often used to market supplements such as megavitamins may mislead parents regarding the actual benefits (or harm) of such therapies. It is important to ensure the safety and efficacy of supplements in children, who may experience inadvertent harm.

The use of various herbal therapies, or intake of herbs, is also becoming more popular. Many of these supplements have been a part of medicine for centuries and are beneficial in some cases.

Little research has been performed in children on many over-the-counter herbal medicines, yet some herbs are known to cause harm in children (Gardiner & Neri, 2020). Herbs that can produce adverse effects in children include ephedra, comfrey, and pennyroyal; some herbs may not be harmful taken alone but may counteract or potentiate prescription medications when taken concurrently. Parents should be fully informed of the use of herbs to ensure that there is more benefit than potential harm in the ingredient being used. Health care providers also need to be knowledgeable about the benefits or potential harm from herbs so that they can appropriately counsel parents and address their concerns.

DENTAL HEALTH

Developmental Aspects of Dental Health

Good dental hygiene begins with good maternal dental health and with counselling during early infancy regarding dietary intake for the promotion of optimal oral hygiene (Rowan-Legg & CPS, Community Paediatrics Committee, 2013/2018). Mouth cleaning can commence right after birth: parents should be taught to clean the infant's gums with a piece of gauze or cloth so that children become accustomed to cleaning of the mouth. Once the primary teeth erupt, the teeth and gums are initially cleaned by wiping with a damp cloth; tooth brushing is too harsh for the tender gingiva. The caregiver can stabilize the infant by cradling the child with one arm and using the free hand to cleanse the teeth. It is generally recommended that a small, soft-bristled toothbrush be used as more teeth erupt and the infant adjusts to the routine of cleaning. Water is preferred to toothpaste, which the infant will swallow (and if the toothpaste is fluoridated, the infant will ingest excessive amounts of fluoride). See Chapter 36, Teething for further discussion of teething and eruption of primary teeth.

The Canadian Dental Association (CDA, 2021) recommends that all children have their first visit to a dentist 6 months after eruption of the first tooth or by 1 year of age. Initial visits to the dentist should be nontraumatizing. Because young children may react negatively to new and potentially frightening experiences, the initial visit can centre on meeting the dentist, seeing the equipment, and sitting in the chair. If the child can cooperate, the dentist may just look at the teeth but reserve a more thorough examination for another visit. *Modelling*, in which the child observes procedures performed on the parent or a sibling, may also be effective.

By the beginning of the preschool period, the eruption of the deciduous (primary) teeth is complete. Dental care is essential to preserve these temporary teeth and to teach good dental habits. Professional care and prophylaxis, especially fluoride supplements (if needed), should be continued. Routine dental care should be well established during preschool years, and assessment by a dentist is recommended at 6- to 12-month intervals depending on the family history, the child's dental development, and the presence or absence of dental caries.

The first permanent (secondary) teeth erupt at about 6 years of age, beginning with the 6-year molar, which erupts posterior to the deciduous molars. Other permanent teeth appear in approximately the same

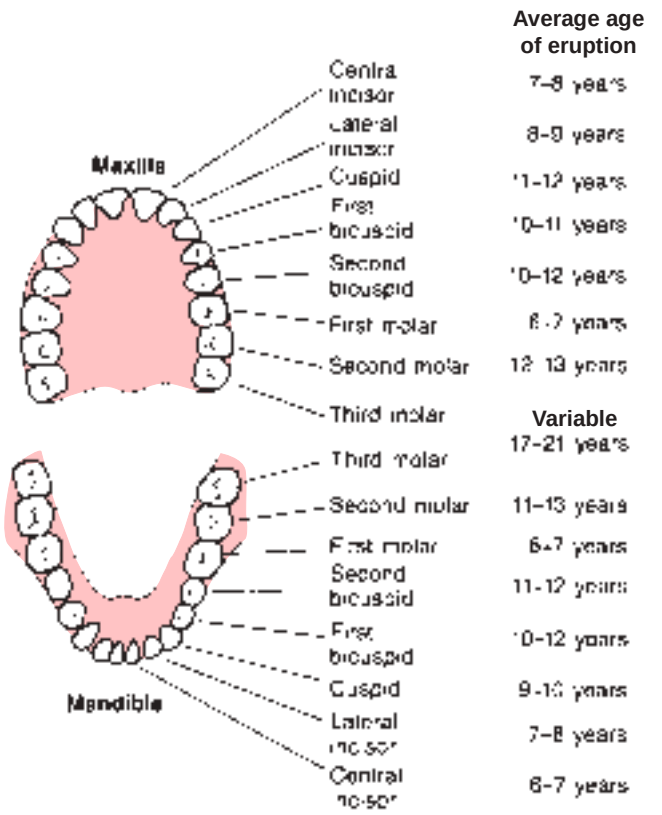

Fig. 35.3 Sequence of eruption of secondary teeth. (Data from American Dental Association [2014]. *Eruption charts*. https://www.mouthhealthy.org/en/az-topics/e/eruption-charts).

order as eruption of the primary teeth and follow shedding of the deciduous teeth (Figure 35.3). With the appearance of the second permanent (12-year) molar, most permanent teeth are present. Permanent dentition is more advanced in girls than in boys.

Because the permanent teeth erupt during the school-age years, dental hygiene and regular attention to dental caries are important parts of health supervision during this period. Correct brushing techniques should be taught or reinforced, and the role that fermentable carbohydrates play in production of dental caries should be emphasized. It is important to be alert to possible malocclusion that may result from irregular eruption of permanent teeth and that may impair function.

Additional factors that may influence oral health during adolescence include the use of tobacco (particularly chewing tobacco), pregnancy, eating disorders, increased risk for traumatic dental injury and periodontal disease, and increased awareness of appearance. Corrective orthodontic appliances (braces) are a fact of life for many teens, particularly during the early adolescent years. These may be a source of embarrassment and concern; however, in some cases these may be considered trendy, depending on the individual's and peers' attitudes toward their cosmetic effects. Reassurance regarding the temporary nature of the annoyance and anticipation of an improved appearance can help make the inconvenience tolerable. It is also important to reinforce the orthodontist's directions regarding use and care of the appliances and to emphasize careful attention to oral hygiene during this time.

The CDA (2006/2019) warns about the risks of using oral jewellery, piercings, and tattoos. The complications are connected to (a) the jewellery (aspiration, allergy, or chronic injury to adjacent teeth or mucosa, including tooth fracture and gum recession, which can lead to tooth loss) and (b) the piercing procedure (local bleeding, swelling, nerve damage, toxic shock, permanent drooling, impaired sense of taste, or distant infections of the liver, heart, or brain).

Oral Health

Oral health is an essential element of overall health. While dental care is not covered under the Canadian Medicare program, individual provinces and territories have variable plans to cover dental care for families with low incomes. Indigenous people have federal government coverage for standard dental care, although some procedures require extra funding (Indigenous Services Canada, 2020). The CPS has called for improvement in government-sponsored dental programs as there are still dental treatment gaps (Rowan-Legg & CPS, Community Paediatrics Committee, 2013/2018).

Early childhood caries (ECC) is defined as the occurrence of one or more decayed, missing (due to caries), or filled tooth surfaces in any primary tooth. Dental **caries** is the single most common chronic disease of childhood (Rowan-Legg & CPS, Community Paediatrics Committee, 2013/2018). Canadian children continue to have a high level of dental disease, which disproportionately affects lower socioeconomic groups, particularly Indigenous children, children with special needs, and new immigrant populations, who may have lower incomes. This increased level of disease is mainly due to the lack of access to appropriate dental care.

Dental pain can have a negative impact on children, including lost sleep, poor growth, behavioural concerns, and poor learning. Poor dental health also affects development of communication, socialization, and self-esteem (Rowan-Legg & CPS, Community Paediatrics Committee, 2013/2018). The WHO has linked oral disease with the four leading chronic diseases: cardiovascular disease, cancer, chronic respiratory disease, and diabetes (WHO, 2020a). The number one condition treated through day surgery in Canadian children is preventable early childhood dental caries (Zwicker et al., 2016).

Since dental caries is a preventable disease, nurses play an essential role in the promotion of early tooth care. Nurses can instruct children and their parents in dental hygiene, before the first tooth eruption, encourage them to drink fluoridated water, and promote early dental preventive care.

Use of Fluoride. In Canada, public water systems have fluoride added to the drinking water; this is proven to be the number one preventative measure against dental caries. The Government of Canada's guideline for fluoride in drinking water indicates a maximum acceptable concentration of 1.5 mg/L (Health Canada, 2017). All health care providers should know the level of fluoridation in their regional drinking water; this information is available from their local public health agency. Fluoride supplements, in the form of chewable tablets, lozenges, or drops, are not recommended for the majority of Canadians. However, health providers may wish to prescribe fluoride supplements to high-risk patients in nonfluoridated communities where individuals are not able to obtain fluoride in any other form. Young children's total daily fluoride intake from all sources should not exceed 0.05 to 0.07 mg fluoride per kg body weight, to minimize the risk of dental fluorosis (CDA, 2005; Godel & CPS, Nutrition and Gastroenterology Committee, 2002/2019).

Increased fluoride ingestion, such as when children swallow fluoridated toothpaste, leads to enamel protein retention, hypomineralization of the enamel and dentin, and disturbance of crystal formation. The effects caused by this change range from barely discernible white, fibrelike lines or spots to grey-brown stains or pitted areas. Parents should be cautioned against regular use of fluoridated water or beverages such as bottled water containing fluoride if the community water supply already has an adequate amount of fluoride.

Children under 3 years of age do not require fluoridated toothpaste or supplemental fluoride unless the following conditions prevail (Godel & CPS, Nutrition and Gastroenterology Committee, 2002/2019):

- The concentration of fluoride in drinking water is less than 0.3 ppm
- The child does not brush their teeth (or have them brushed by a parent or guardian) at least twice a day
- If, in the judgment of a dentist or other health provider, the child is susceptible to high caries activity (family history, caries trends and patterns in communities or geographic areas)

Children aged 3 to 6 years should only use a pea-sized amount of fluoridated toothpaste.

Removal of Plaque. Oral hygiene measures should be implemented to remove *plaque*, or soft bacterial deposits that adhere to the teeth and cause dental caries (decay or cavities) and periodontal (gum) disease. Poor oral hygiene and poor dietary habits are associated with the development of caries in children.

The most effective methods for plaque removal are brushing and flossing. Several brushing techniques exist, although there is no universal agreement on the best method. One that is suitable for cleaning the primary teeth is the scrub method. The tips of the bristles are placed firmly at a 45-degree angle against the teeth and gums and moved back and forth in a vibratory motion. The ends of the bristles should be wiggling but not moving forcefully back and forth, as this can damage the gums and enamel. All the surfaces of the teeth should be cleaned in this manner except the lingual (inner) surfaces of the anterior teeth. To clean these surfaces, the toothbrush is placed vertical to the teeth and moved up and down. Only a few teeth are brushed at one time, using six to eight strokes for each section. A systematic approach should be used so that all surfaces are thoroughly cleaned (Figure 35.4). For children under 6 years of age, the most effective cleaning is done by parents. For effective cleaning, a small toothbrush with soft, rounded, multitufted nylon bristles that are short and uniform in length is recommended. Toothbrushes should be replaced as soon as the bristles are frayed or bent.

After the teeth have been cleaned, flossing with dental floss is done to remove plaque and debris from between the teeth and below the gum margin, where brushing is ineffective. Since young children do not have the dexterity to manipulate the floss, parents should be taught the procedure to use in children.

Fig. 35.4 Young children can participate in tooth brushing, but parents need to brush all the child's teeth thoroughly. (Oksana Kuzmina/Shutterstock.com.)

Ideally, the teeth should be cleaned after each meal and especially before bedtime, and the child should be given nothing to eat or drink after the night brushing, except water. Children who brush their teeth frequently and become accustomed to the feel of a clean mouth at an early age usually maintain the habit throughout life. When brushing is impractical, the "swish-and-swallow" method of cleaning the mouth can be taught: with a mouthful of water, the child rinses the mouth and swallows, repeating the procedure three or four times.

Dietary Factors. Nutrition is critical to developing good teeth because carious development depends primarily on fermentable sugars, especially sucrose and other carbohydrates. Refined table sugar, honey, molasses, corn syrup, fruit juices, and dried fruits such as raisins are highly cariogenic. Complex carbohydrates such as breads, potatoes, and pasta also contribute to caries because they lower the plaque pH.

Ideally, highly cariogenic foods, especially those containing complex sugars, should be eliminated from the child's diet. However, since this is impractical, some suggestions can be helpful.

First, *the frequency with which sugar is consumed is more important than the total amount eaten*. Therefore, when sweets are eaten, they are less damaging if consumed immediately after a meal rather than as a snack between meals. When sweets are served as the dessert, the teeth should be cleaned afterward, decreasing the amount of time the sugar is in the mouth.

Second, *the form of sugar* (sucrose) is important. The more cariogenic foods are those that are sticky or hard, since they remain in the mouth longer. Consequently, sucking on lollipops is more cariogenic than eating a chocolate bar. Sometimes the source of the sugar is "hidden," as in numerous prescription and nonprescription medications and in many popular cereals, including the "all-natural" variety. Reading food labels is essential in identifying and eliminating sources of sucrose.

Some snacks do not contribute to tooth decay. Aged cheeses such as cheddar may alter the pH and slow bacterial growth. Sugarless gum chewed after eating may actually protect against cavities by stimulating saliva that neutralizes acid.

ECC (historically called *nursing caries* or *baby bottle tooth decay*) occurs when the child is routinely given a bottle of milk or juice at naptime or bedtime or uses the bottle as a pacifier while awake. Frequent nocturnal breastfeeding for prolonged periods also leads to extensive destruction of the teeth. The practice of coating pacifiers in honey or corn syrup can also contribute to the development of caries and may be a potential source of botulism poisoning in infants. As the sweet liquid pools in the mouth, the teeth are bathed for several hours in this cariogenic environment. Prolonged bottle-feeding well into toddler years may contribute to significant ECC. The maxillary (upper) incisors and molars are affected most, since the mandibular (lower) incisors are protected by the lower lip, tongue, and saliva (Figure 35.5). Severely decayed teeth may require the application of stainless steel bands to preserve the spacing until the permanent teeth erupt.

ECC is now considered to be an infectious disease of childhood. There is evidence that *Streptococcus mutans* is a highly cariogenic bacteria (Rowan-Legg & CPS, Nutrition and Gastroenterology Committee, 2013/2018). One of the early origins of *S. mutans* is the mother's saliva; infants of mothers with high counts of the bacteria have a greater incidence of ECC. Therefore, it is important to discuss oral hygiene with pregnant women because of its impact on their children's tooth development.

Prevention of nursing caries involves eliminating the bedtime bottle completely, feeding the last bottle before bedtime, substituting a bottle

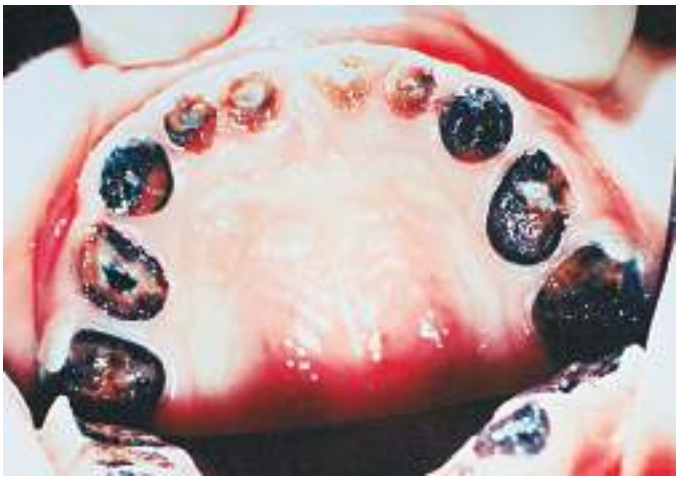

Fig. 35.5 Nursing caries. Note extensive carious involvement of maxillary primary incisors. (Courtesy Bruce Carter, DDS, Texas Children's Hospital.)

of water for milk, not using the bottle as a pacifier, and never coating pacifiers in sweet substances. Juice is not recommended for children under 2 years of age and if given should always be offered in a cup to avoid prolonging the bottle-feeding habit. Children should be encouraged to drink from a cup by their first birthday and weaned from a bottle as early as possible.

Other Dental Conditions

Periodontal disease, an inflammatory and degenerative condition involving the gums and tissues supporting the teeth, often begins in childhood and accounts for a significant amount of tooth loss in adulthood. The more common periodontal issues are *gingivitis* (simple inflammation of the gums) and *periodontitis* (inflammation of the gums and loss of connective tissue and bone in the supporting structures of the teeth). Gingivitis, the most prevalent periodontal disease, is a reversible inflammatory disease that can begin in early childhood and is most often associated with the buildup of plaque on the teeth. Changes take place in the plaque bacteria, in both the type and number of organisms, causing them to release destructive exotoxins, enzymes, and other noxious agents. These substances produce an inflammatory reaction in the gingival tissues, causing the gums to become red, edematous, tender, and subject to bleeding at the slightest irritation. Management is directed toward prevention by conscientious brushing and flossing, including the use of fluoride. The child should see the dentist at any signs of inflammation or irritation.

Malocclusion occurs when teeth of the upper and lower dental arches do not approximate in the proper relationships. As a result, the physiological function of chewing is less effective and the cosmetic effect is displeasing. Teeth that are uneven, crowded, or overlapping are unable to meet their counterparts in the opposite jaw in the appropriate relationships and may be predisposed to disease in later years.

Orthodontic treatment is most successful when it is started in the late school-age or early teenage years, after the last primary teeth have been shed and before growth ceases. However, referral should be made as soon as malocclusion is evident, since some deformities can be corrected at an earlier age or require treatment in stages over the years. Families with few financial resources may not be able to afford orthodontic treatments.

Dental injury may occur in childhood and includes fractures of varying degrees of severity, chipping, dislocation, or avulsion. All tooth injuries should be treated as a **dental emergency** requiring prompt treatment by a competent dentist to prevent permanent displacement or loss. Delayed examination and diagnosis of tooth damage can result in infection or pulp involvement. Because the loss can affect the remaining teeth, replacement of the lost tooth is needed to maintain normal alignment and position of the other teeth.

A permanent tooth that is avulsed (exarticulated, or "knocked out") should be replanted by the child, parent, or nurse and stabilized as soon as possible so that the blood supply to the tooth can be re-established and the tooth kept alive (see Emergency box: Avulsed Permanent Tooth). A tooth that is replanted promptly has a good survival rate. Avulsed primary teeth are usually not reimplanted.

EMERGENCY

Avulsed Permanent Tooth

Recover the tooth.
Hold tooth by the crown; avoid touching root area.
If the tooth is dirty, rinse it gently under running water or saline; be certain to insert a stopper in the sink or basin (to avoid losing tooth).

To Reimplant Tooth

Insert tooth into the socket; be certain that the lip side (or convex surface) is facing front.
Have child maintain tooth in place by slowly biting down on a piece of gauze.
Transport child to dentist immediately.
Avoid sudden stops or sharp turns to prevent dislodging the tooth.

If Reluctant to Reimplant Tooth

Place avulsed tooth in a suitable medium for transport:
- Cold milk
- Saliva—under the child's or parent's tongue

If child is holding tooth in the mouth, avoid sudden stops to prevent swallowing of tooth.
DO NOT FORGET TO TAKE THE TOOTH.

As with all injuries to the mouth, an avulsed tooth causes a large amount of bleeding, which is frightening to children and their families. Therefore, the nurse or anyone faced with dental trauma should be prepared to provide support and reassurance during the dental trauma.

SLEEP, REST, AND ACTIVITY INTEGRATION

In order for children to grow and develop, they need to integrate high levels of physical activity, low levels of sedentary activity, and sufficient sleep each day. The Canadian 24-hour movement guidelines were developed by the CSEP for every age group to help balance all of these important needs (see Table 35.2).

All growing children need regular exercise as well as opportunities for satisfying experiences consistent with individual likes and dislikes. Children need ample space to run, jump, skip, and climb, in addition to safe indoor and outdoor facilities and equipment. Most children have abundant energy and need little encouragement to engage in physical activity. Children with disabling conditions or those who hesitate to become involved in active play (such as children with obesity) require special assessment so that activities are identified that appeal to them and are compatible with their limitations while also meeting their developmental needs.

Activity and exercise are essential to children's physical development, by:

- Developing muscle strength to decrease risk of injury, lift objects, and have flexible joints
- Increasing cardiovascular and lung capacity

- Keeping bones strong
- Decreasing body fat
- Burning calories for weight control and decreasing the risk of type 2 diabetes through aerobic activity and strength training
- Boosting energy levels

Activity and exercise also increase children's psychological well-being by enhancing their self-esteem, decreasing feelings of depression and anxiety, increasing self-confidence and skills, and enhancing feelings of happiness.

Sedentary rest is important for resting the body and having fun with stimulating mental challenges such as puzzles. However, as noted earlier, Canadian children often spend too much of their day involved in sedentary activities such as playing video games, watching television, or using digital devices, which has led to increased rates of obesity and type 2 diabetes.

Sleep, a protective function in all organisms, allows for repair and recovery of tissues after activity. As in most aspects of development, there is wide variation among individual children in the amount and distribution of sleep at various ages. As children mature, the total time they spend in sleep and the amount of time they spend in deep sleep change. Newborns sleep much of the time. As infants grow older, the total sleep time gradually decreases, they remain awake for longer periods, and they sleep longer at night. The average sleep patterns for different age groups are in Box 35.1. See Nursing Skills on Evolve: Fostering Healthy Sleep Patterns in Children.

Infant

There are no established guidelines for infant sleep between ages 0 to 4 months because of the significant normal variability and insufficient evidence that certain sleep patterns would improve health outcomes for this group (Paruthi et al., 2016). The Canadian 24-hour movement guidelines is an integration of physical activity, sedentary behaviour, and sleep that includes the infant age group (see Table 35.2).

Parental concerns regarding sleep are common during infancy. It has been reported that between 15 and 35% of parents report difficulties with their infant's sleep during the first 6 months of life (Hiscock et al., 2014). Sometimes these concerns are as basic as parents' questioning whether the infant needs additional sleep. In this case, it is best to investigate the reason for their concern, stressing each child's individual needs. Infants who are active during wakeful periods and growing normally are sleeping a sufficient amount of time.

Sleep difficulties in early infancy have been positively correlated with higher maternal depression scores and poorer general and mental health in both mothers and fathers (Della Vedova, 2014). Therefore, nurses should discuss infant sleep issues with the mother and family in addition to other developmental aspects of newborn care before and after the baby is born.

BOX 35.1 Sleep Needs

Every child is different. Some sleep a lot and others much less. This chart is a general guide to the amount of sleep that children of different ages require over a 24-hour period, including nighttime sleep and daytime naps.

- Infants (4 to 12 months old) need 12 to 16 hours.
- Toddlers (1 to 2 years old) need 11 to 14 hours.
- Children (3 to 5 years old) need 10 to 13 hours.
- Children (6 to 12 years old) need 9 to 12 hours.
- Adolescents (13 to 18 years old) need 8 to 10 hours.

Adapted from Canadian Paediatric Society. (2017). *Healthy sleep for your baby and child.* https://www.caringforkids.cps.ca/handouts/healthy_sleep_for_your_baby_and_child.

Some researchers indicate that the best way to prevent sleep issues is to encourage parents to establish healthy sleep habits in their infant that fit with normal circadian rhythms (Whittingham & Douglas, 2014). They suggest providing parents with education on the biology of sleep, to expose the infant to normal circadian cues of daylight and noise in order to prevent oversleeping during the day and help consolidate sleep at nights. For example, the infant would be exposed to natural light early in the day, and both caregiver and infant would have appropriately timed exercise and relaxation. Parents can also be encouraged to identify and remove barriers to overall health functioning, such as difficulties with eating and frequent crying (colic), and to learn the cues for sleepiness in their infant so they can adapt to those cues instead of developing rigid, preset schedules. A recommended safe sleep environment is where the infant is near the caregivers but not in the same bed, although parents may make other decisions related to sleep location. The role of the nurse includes supporting parents' decisions related to sleep and providing safety guidelines (see Chapter 26: Prevention of Sudden Infant Death Syndrome (SIDS).

The best way to prevent infant sleep challenges is to encourage parents to establish bedtime rituals that do not foster problematic patterns. One of the most constructive routines is placing infants awake in their own crib. Children who learn to fall asleep on their own at bedtime have longer sustained sleep periods than those who fall asleep with a parent present. When infants are accustomed to falling asleep somewhere else, such as in their parent's arms, and then being transferred to their crib, they awaken in unfamiliar surroundings and are unable to fall asleep until the routine is repeated. In addition, the bed should be used for sleeping only—not as a play area. Playthings should not be hung over the bed or placed in it, so the child associates the bed with sleep and not with activity. It is much easier to prevent a sleep issue with appropriate teaching by the nurse and actions by parents during the early months of the infant's life than when the child is older.

One intervention considered to be an atraumatic approach to night crying, known as *graduated extinction* or *controlled crying*, is to let the child cry for progressively longer times between brief parental interventions that consist only of reassurance—not rocking, holding, or using a bottle or pacifier. For example, the parents may check on the child every few minutes during the first night and progressively extend this interval by a few minutes on successive nights until the infant can self-soothe. Research has shown that this intervention appears to improve sleep in the child and may also improve depression symptoms in the mother (Gradisar et al., 2016; Korownyk & Lindblad, 2018). The key message is that with gentle sleep training there was no difference in outcomes in children at age 5 years related to behaviour and relationships (Korownyk & Lindblad, 2018).

Toddler

Total sleep decreases only slightly during the second year and averages about 12 hours a day. Most toddlers take one nap a day, and by the end of the second or third year, many relinquish this habit. Children reach an adult pattern of sleep by approximately 3 years of age (see Box 35.1).

This age group enjoys exploring, examining, and manipulating their environment. They are using gross motor skills to perform high activity actions. They like to move by crawling, cruising, and walking to different toys or furniture and scribbling on paper. As well, they like to stack toys, throw balls, learn to climb stairs, and seat themselves on furniture. They enjoy the outdoors and playing in sandboxes and moving pull toys. For sedentary activities, this group enjoys a caregiver reading a book or storytelling to them.

Difficulties with sleep are common among toddlers, especially going to bed and falling asleep, and are probably related to fears and awareness of separation. Toddlers are more prone to having bedtime

Fig. 35.6 Transitional objects such as a fuzzy stuffed animal are sources of security to a toddler.

resistance (refusal to go to bed) and frequent night waking; during later toddlerhood this group of children may become more resistant about going to bed and express fears about monsters. Fears can be provoked by a child's daily stressors, such as pressure to gain toilet independence, a residential move, sibling birth, experiences of loss, or separation from parents. Bedtime rituals (e.g., same hour of sleep, snack, and quiet activity) are helpful, and transitional objects, such as a favourite stuffed animal or blanket, can help ease the child's insecurity at bedtime (Figure 35.6). Children may need a light snack before bedtime; a heavy meal immediately before bedtime may interfere with sleep. Other suggestions to help small children sleep better include keeping the television out of the child's room, making the hour before bedtime a quiet time of reading stories, and avoiding stimulating activities, such as computer games and roughhousing (Owens, 2020). Toddlers no longer sleeping in a crib may come out of their rooms after being put to bed. If they continue to get out of bed to prolong their bedtime they may need their doorways gated.

Parents of children who delay going to bed can be counselled regarding the importance of a consistent bedtime ritual and that this type of behaviour is normal in young children. Parents should ignore attention-seeking behaviour and not take children into the parents' bed or allow children to stay up past a reasonable hour. Other measures that may be helpful include keeping a light on in the room or leaving a drink of water by the bed. Parental consistency is paramount to all treatment approaches. Helping children slow down *before* bedtime also reduces the resistance to going to bed. One strategy is to establish limited rituals that signal readiness for bed, such as a bath or a story. Parents can reinforce the pattern by stating, "After this story it's bedtime," and consistently carrying out the routine.

As with infants, a safe sleeping environment is important at the toddler stage. Many factors affect sleeping arrangements, including parental and cultural values and socioeconomic factors. For example, much of Canada's Indigenous population faces overcrowding due to poverty and lack of available housing. In Manitoba, 40% of Indigenous families live in this situation. Many of these children and adults sleep on mattresses on the floor in living rooms, which can significantly disrupt sleep (Webster, 2015).

All of these factors need to be taken into consideration when health care providers offer guidance on the physical and emotional security of sleeping environments. Health care providers also need to adapt their guidance to the individual situation. See Table 35.2 for high and low activity guidelines for toddlers.

Preschooler

While sleep patterns vary widely, the average preschooler sleeps about 12 hours a night and may still take daytime naps. The *Day Nurseries Act* mandates a sleep/rest time, and most day care centres enforce this. The child who is sleeping 1 to 2 hours at day care may not be ready to sleep at the usual bedtime. Waking during the night is common and may be related to social rather than developmental or physiological factors.

Motor activity levels continue to be high and allow preschoolers to explore their environment, begin learning physical games and sports, and interact with others. Sedentary activities, such as watching television and playing video or computer games, are appealing and can become an unhealthy substitute for active play. Physical activity improves motor skills, body composition, and aspects of metabolic health and social development in children younger than 5 years of age (Lipnowski et al., 2012/2017). See Table 35.2 for activity and Box 35.1 for sleep recommendations for preschoolers.

Preschoolers' increased gross motor abilities and coordination allow them to engage in many physical activities, if only at a novice level. Whether young children should begin formalized training in an activity at this early age is controversial. Training programs must consider the child's physical and psychological immaturity; their readiness to participate in organized sports should be determined individually. The decision to participate should be based on the child's, not the parent's, motivation and enjoyment. The preschooler learns best with egocentric activities and with auditory and visual cues. Activities that should be focused on include running, throwing, catching, and tumbling. Activities need to be fun, encourage exploration and experimentation, and avoid competition in a variety of environments.

Preschool years are a prime time for sleep disturbances. Such disturbances are typically related to increasing autonomy, negative sleep associations, nighttime fears, inconsistent bedtime routines, and lack of limit setting. Sleep disturbances may also be caused by nightmares and sleep terrors. Consequences of inadequate sleep include daytime tiredness, irritability, hyperactivity, difficulty concentrating, impaired learning ability, poor control of emotions and impulses, and strain on family relationships. Interventions vary greatly; for example, *nightmares* (frightening dreams that are followed by full arousal) and *sleep terrors* (partial arousal from deep, nondreaming sleep) require different approaches. See Toddlers section above regarding setting bedtime routines.

School-Age

The amount of sleep and rest required during middle childhood is highly individualized, although the average school-age child requires approximately 9 to 12 hours of sleep from 5 to 10 years of age (Owens, 2020). The amount of sleep depends on the child's age, activity level, and state of health. The growth rate slows in the school-age years, and less energy is expended in growth than during preceding years.

Although fewer bedtime issues occur during these years, occasional difficulties are still associated with the bedtime ritual. Usually children 6 or 7 years old exhibit few issues with bedtime, and encouraging quiet activity before bedtime, such as colouring or reading, facilitates the task

of going to bed. However, most children in middle childhood must be reminded frequently to go to bed; 8- to 11-year-old children can be particularly resistant. Often these children are unaware that they are tired; if they are allowed to remain up later than usual, they are fatigued the following day. Sometimes, bedtime resistance can be resolved by allowing a later bedtime as the child gets older. Twelve-year-old children usually offer no resistance at bedtime; some even retire early to read a book or listen to music. Children who live in the far north might need to have their bedroom windows covered with something to block the light—for example, aluminum foil—during the summer because it can still be bright outside late into the night.

Because of the improved capabilities and adaptability of the school-age child, these children have greater speed and exert more effort in motor activities. Larger, stronger muscles enable longer and increasingly strenuous play without exhaustion. While school-age children acquire the coordination, timing, and concentration that are needed to participate in adult-type activities, they may lack the strength, stamina, and control of the adolescent and adult. Parents, teachers, and coaches must remember that, although children this age are large and appear strong, they may not be ready for strenuous competitive athletics.

Appropriate activities during the school-age years include running, jumping rope, swimming, roller skating, ice skating, dancing, and bicycle riding. Positive reinforcement achieved by experiencing increasingly smooth, rhythmic, and efficient use of the body conditions the child toward regular physical activity. Exercise is essential for muscle development and tone, refinement of balance and coordination, increased strength and endurance, and stimulation of body functions and metabolic processes.

Adolescent

Adolescents vary in their need for sleep and rest. Rapid physical growth, the tendency toward overexertion, and the overall increased activity of this age contribute to fatigue in adolescents. During growth spurts the need for sleep is increased. As children develop through adolescence, their need for sleep does not decline, but their opportunity for sleep may be affected by early morning school scheduling, extracurricular activities, homework, employment, and social time with peers; all of these factors can make it difficult to get sufficient sleep. The time spent in deep, restful sleep increases from 50% in infancy to 80% in the older child.

There may be a shift in the circadian rhythm and increase in melatonin in adolescence, which results in this group falling asleep later at night and finding it hard to wake up early in the morning. The CPS (2018) recommends 9 to 10 hours of sleep during the adolescent years. Sleep deprivation can affect physical and mental health and has been associated with higher rates of overweight and obesity, depression, somatic issues (e.g., headaches and stomachaches), fatigue, and difficulties with concentration. In addition, sleepiness affects reaction time and can contribute to car accidents or other accidents. Health teaching and health promotion should include information to promote sufficient sleep. To establish healthy sleep patterns, adolescents can do the following (CPS, 2018; Owens, 2020):

- Have a relaxing bedtime routine with a light snack, in a cool, dark room.
- Go to bed and wake up at approximately the same time every night.
- Use bed for sleeping only.
- Avoid watching television, doing homework, or using a computer before going to bed.
- Open curtains and let light into the room in the morning.
- Avoid napping during the day and after dinner; this can make it difficult to fall asleep. If a nap is needed it should be less than 30 minutes.

Fig. 35.7 Adolescents should be encouraged to participate in activities that contribute to lifelong physical fitness. (Jupiterimages/Stockbyte/Thinkstock.)

- Exercise daily but avoid heavy exercise activities in the evening.
- Build in some time for fun activities.
- Avoid drinking caffeine after the middle of the afternoon.
- On weekends, no matter how late going to bed, try to get up within 2 to 4 hours of usual rising time.
- Write a to-do list to help decrease worries.

Although today's youth are said to be less fit than children 20 years ago, adolescents probably spend more time and energy practising and participating in sports activities than members of any other age group. School-based, health-oriented physical education may provide both immediate effects of the activity and sustained effects through encouragement of lifelong activity patterns (Figure 35.7). Canadian provinces and territories vary in the mandates for physical activity in schools. For example, in British Columbia, students are required to have an average of 150 minutes per week built into their curriculum, but this may not be the same in all provinces (Landolfi, 2018). However, the percentage of students taking at least one physical education class per week drops significantly in higher secondary grades. The amount of time spent being sedentary also increases with age. To improve health outcomes adolescents should engage in 60 minutes or more of moderate to vigorous physical activity daily (Canadian Society for Exercise Physiology, 2021).

Sports, games, and even dancing provide exercise for growing muscles, interactions with peers, and a socially acceptable means of enjoying stimulation and conflict. In addition, competitive activities help teenagers conduct their own self-appraisal and develop self-respect and concern for others. Because physical fitness appears to be a major influence on one's lifelong health status, all adolescents should be encouraged to participate in activities that contribute to lifelong physical fitness. However, adolescents should not be encouraged to engage in physical activities that are beyond their physical or emotional capacity.

SEXUAL HEALTH

No matter where nurses practise, they can provide information on human sexuality to parents and children. To discuss the topic adequately, nurses must have an understanding of the physiological aspects of sexuality, knowledge of the cultural and societal values, and an awareness of their own attitudes, feelings, and **biases** about sexuality.

When presenting sexual information to children, nurses should treat sex as a normal part of growth and development. They should answer questions honestly, matter-of-factly, and to the same extent

as questions about other topics. Answers should be at the child's level of understanding.

Children need help differentiating sex and sexuality. Exercises on clarifying values, identifying role models, engaging in problem-solving skills, and practising responsibility are important in preparing children for early adolescence and puberty. In addition, children need explanations of sexual information provided via the media, their peers, or jokes. Information concerning pregnancy, contraceptives, and sexually transmitted infections (STIs), including human immunodeficiency virus (HIV) and human papillomavirus (HPV), should be presented in simple, accurate terms.

During interactions with parents, nurses should be open and available for questions and discussion. They can set an example by the language they use in discussing body parts and their function. Parents may need help understanding normal behaviours and viewing sexual curiosity in their children as a part of the developmental process. Assessment of the parents' level of knowledge and understanding of sexuality can provide cues to their need for supplemental information that will prepare them for the increasingly complex explanations they will need to provide as their children grow older.

It is not unusual for young children to engage in games of sexual curiosity and exploration. At about 3 years of age, children are aware of anatomical differences between sexes and are concerned with how the other "works." This is not really "sexual" curiosity because many children are still unaware of the reproductive function of genitalia. Their curiosity is for the eliminative function of anatomy. Little boys wonder how girls can urinate without a penis, so they watch girls go to the bathroom. Because they cannot see anything but the stream of urine coming out, they want to observe further.

One question that parents often have is how to handle such sexual curiosity. A positive approach is to neither condone nor condemn it but to express that if children have questions, they should ask the parents. Parents should also encourage their child to engage in some other activity. In this way, children can be helped to understand that there are ways to satisfy their sexual curiosity other than through investigative games. This in no way condemns the act but stresses alternative methods to seek solutions and answers. Allowing children unrestricted permissiveness only intensifies their anxiety and concern, since exploring and searching usually yield little evidence to satisfy their curiosity.

Another concern for some parents is *masturbation*, or self-stimulation of the genitalia. This occurs at any age for a variety of reasons and, if not excessive, is normal and healthy. It is most common at 4 years of age and during adolescence. For preschoolers, it is a part of sexual curiosity and exploration. If parents are concerned about their children masturbating, the nurse needs to investigate circumstances associated with the activity because it may be an expression of anxiety, boredom, or unresolved conflicts. Children who openly and publicly masturbate are inviting a reaction, such as **discipline**, punishment, or criticism. They may be overwhelmed by their sexual feelings and are asking others to help channel them into more constructive outlets. Masturbation, like other forms of sex play, is a private act, and parents should emphasize this to children when teaching them socially acceptable behaviour. Any adverse emotional consequences or guilt feelings depend on how the behaviour is managed by the parents, whether it is discovered, or whether children view their actions as wrong in the eyes of significant persons, particularly the parents.

Sex Education

Young children are often searching for explanations and reasons that are logical and reasonable to them. The word "why" is common, especially from the preschooler. It is only natural that as they learn about "me" they will also want to know "why me" and "how me." Questions such as "Where do babies come from?" are as casual as "What makes it rain?" or "Who is that?" It is the way in which questions about origins of human life are answered that conditions children, even the youngest, to separate these questions from others about their world.

Two rules govern answering sensitive questions about topics such as sex. The first is to *find out what children know and think*. By investigating the theories that children have produced as a reasonable explanation, parents can give correct information and help children understand why their explanation is inaccurate. Another reason for ascertaining what the child thinks before offering any information is that the "unasked for" answer may be given. For example, 4-year-old Kristen asked her father, "Where did I come from?" Both parents quickly took this inquiry as a clue for offering sex education. After the explanation Kristen exclaimed, "I don't know about all that! All I know is that Charlotte came from Winnipeg, and I want to know where I was born."

The second rule for giving information is to *be honest*. It is true that young children will forget or misunderstand much of the correct information, but the correct information can be restated until the child absorbs and comprehends the facts. Even though correct anatomical words may be hard to pronounce or even more difficult to remember, they become the foundational content for explaining other concepts at a later time.

Honesty does not imply imparting to children every fact of life or allowing excessive permissiveness in sexual curiosity. When children ask one question, they are looking for one answer. When they are ready, they will ask about the other "unfinished" parts of the story. Sooner or later they will wonder "how the sperm meets the egg" and "how the baby gets out," but during this period it is best to wait until they ask.

There are many variable cultural influences on sex education. Some cultures encourage open discussion and other cultures are more reticent. For example, for Indigenous people "Two-Spirit" refers to a person who identifies as having both a masculine and a feminine spirit, and this term is used by some Indigenous people to describe their sexual, gender, and/or spiritual identity. Before colonization, Two-Spirit people were included and respected as valued community members, often holding revered roles such as healers, matchmakers, and counsellors, among many others. As part of the colonization process, Two-Spirit people were killed or went into hiding. The role of Two-Spirit people in Indigenous communities is now being reclaimed, and it is becoming increasingly recognized that homophobia and transphobia are in direct contradiction with most traditional Indigenous values (Trans Care BC, 2020).

Many excellent books on sex education are available for children at public libraries. The Action Canada for Sexual Health and Rights website contains information on how to talk about sex with various age groups (see Additional Resources at the end of the chapter). Parents should read a children's book on sex education themselves *before* giving or reading it to a child.

Middle childhood is an ideal time for formal sex education, and many authorities believe that the topic is best presented from a lifespan approach. Information about sexual maturation and the process of reproduction minimizes the child's uncertainty, embarrassment, and feelings of isolation that often accompany puberty.

Preadolescents need precise and concrete information that will allow them to answer questions such as "What if I start my period in the middle of class?" or "How can I keep people from telling I have an erection?" It is important to tell children what they want to know and what they can expect to happen as they become mature sexually.

An important component of ongoing sex education is effective communication with parents. If parents either repress the child's sexual curiosity or avoid dealing with it, the sexual information that the child

receives may be acquired almost entirely from peers. When peers are the primary source of sexual information, it is often transmitted and exchanged in secret conversation and contains a large amount of misinformation.

SAFETY PROMOTION AND INJURY PREVENTION

Injuries are the most common cause of death and disability among children in Canada (Pike et al., 2015). Unintentional injuries are the leading cause of death for Canadian children ages 1 to 17 (O'Brien Institute for Public Health, 2018). Injuries also account for a number of hospitalizations among children. In 2013–14, 17 500 hospitalizations of children and youth were for injuries (O'Brien Institute for Public Health, 2018).

The major causes of injury-related deaths in children aged 0 to 14 years are 90% preventable (Yanchar et al., 2012/2020). Canada does not have a national injury prevention strategy for children and youth, which could help reduce childhood injuries (Yanchar et al., 2012/2020). The pattern of deaths caused by unintentional injuries, especially from motor vehicles, drowning, and burns, is remarkably consistent in most Western societies. Fortunately, prevention strategies such as the use of car restraints, bicycle helmets, and smoke and carbon monoxide detectors have resulted in a significant decrease in fatalities among children. The unintentional injury mortality rate in Canadian children ages 0 to 14 years has decreased from 4.33 per 100 000 to 3.75 per 100 000 between 2004 and 2010 (Parachute, 2015). Drowning, suffocation, and burns are also leading causes of death throughout childhood (Figure 35.8). During infancy, more males succumb to death from aspiration or suffocation than do females (Figure 35.9).

Injury prevention is particularly important in Indigenous communities in Canada, as the leading cause of death for all Indigenous people aged 1 to 44 years is injuries. In this group, 26% of all deaths are caused by injuries, compared with 6% for the rest of the Canadian population (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2012/2020). The majority of hospital admissions for most age groups in this population are for falls. School-age Indigenous children commonly fall from playground equipment, fences, and trees (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2012/2020). Indigenous communities are far more likely to lack access to necessary resources needed to prevent injuries, disproportionally live in poverty, live in substandard housing, and have less access to health care, all due to inadequate government funding. All of these factors can increase the risk and impact of injury. Thus injury surveillance, research, capacity-building, knowledge dissemination, as well as for injury prevention programs that focus on Indigenous populations are urgently needed. Effective injury prevention would involve interprofessional, collaborative, and sustainable approaches based on best practices while being culturally and linguistically specific and sensitive (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2012/2020).

Fig. 35.8 **A:** Drowning is one of the leading causes of death among children. Children left unattended are unsafe even in shallow water. **B:** Burns are among the top three leading causes of death from injury in children ages 1 to 14 years.

Fig. 35.9 Suffocation is the leading cause of death from injury in infants.

Injury Prevention Throughout Childhood

The type of injury and the circumstances surrounding it are often closely related to normal growth and developmental behaviour. As children develop, their innate curiosity compels them to investigate activities and to mimic the behaviour of others. While it is essential to acquire competency in this trait as an adult, it predisposes children to numerous hazards.

Infants. Injuries are a major cause of death during infancy, especially for children 6 to 12 months old. One third of all injuries occur in the home. Constant awareness and supervision are essential as the child gains increased locomotor and manipulative skills, coupled with an insatiable curiosity about the environment. Table 35.4 lists common types of injuries and associated objects that predispose infants to such injuries. Suggestions for promoting safety in the home environment are given for specific types of injuries. The acronym *SAFE PAD,* shown in Table 35.4, may be used to identify common types of injuries among infants and older children.

Toddlers and Preschoolers. Toddlers delight in the repetitive use of gross motor skills, and with increasing age these skills are refined. This age group is also very curious about how things work, and exploration of previously unknown or unseen objects and places is common.

TABLE 35.4 Common Infant Injuries, Associated Risk Factors, and Safety Promotion

SAFE PAD	Risk Factors	Suggested Safety Interventions
S—Suffocation, sleep position	Latex balloons	Avoid using latex balloons except with close adult supervision.
	Plastic bags	Tie unused plastic bags in a knot and dispose of in a safe container.
	Bed surface (noninfant) such as sofa or adult bed	Avoid placing infants to sleep on sofas, soft bedding, or adult bed.
	Pillows	Avoid use of pillows for sleep.
	Soft cushions and blankets	Clear bedding of soft cushions and blankets.
	Prone sleeping	Place infant to sleep on their back at all times.
A—Asphyxia, animal bites	Food items: cylindrical items such as hot dogs, hard candy, nuts	Cut hot dogs lengthwise; avoid giving hard candy to infants and toddlers. Infants should completely chew up each food item in mouth; do not feed more until item is swallowed.
	Toys: small toys such as Legos	As a general rule of thumb, if the toy fits into a toilet paper cardboard roll, it can be swallowed by a small child.
	Small objects: batteries, buttons, beads, dried beans, syringe caps, safety pins	Keep out of reach of infants, who are naturally inquisitive.
	Pacifiers	Pacifiers should be one piece.
	Baby (talc) powder	Avoid shaking powder over infant; if used, place on adult's hand and then place on infant's skin.
	Domestic dogs, cats	Supervise child around domestic animals; teach not to approach a dog that is eating, has puppies, or is not feeling well. Animals that are "tame" can be unpredictable. Small children are the right size for most domesticated animals to come face to face. Closely supervise child around visiting pets.
F—Falls	Stairs	Infants like to climb; place childproof gate at top and bottom of stairs.
	Diaper changing table	Infants do not have depth perception and cannot perceive a dangerous height from one that is safe. Never leave infants unattended on a flat surface, even if not rolling over.
	Crib, bed-crib sides can fall when infant leans on them	Drop-side infant cribs are illegal in Canada.
	Infant carriers	Never leave infant unattended in a carrier on top of a surface such as a shopping cart, clothes dryer, washer, or kitchen cabinet; place carrier on the floor.
	Car seat restraints	Secure infant in car seat restraint and never leave unattended if unrestrained.
	Highchair	Restrain infant in highchair; avoid using highchair except for feeding and only if adult supervision is adequate; even restrained infants can squirm out of some restraints and fall.
	Infant walkers	Use only stationary walkers. There is no evidence that walkers help infants "walk" any sooner. Wheeled walkers can easily be propelled off stairs and other platforms such as porches or decks, causing significant injury and are illegal in Canada.
	Windows, screens	Avoid placing furniture next to a window. Infants learn to climb and can fall out of open windows, even with screens.
	Television, stereos, sound systems	These must be secured to the stand; infants can pull the stand over, causing the TV or sound system to land on their heads, causing significant injury.
E—Electrical burns or burns	Electrical outlets	Place safety cap over electrical outlets; infants may be burned by placing conductive object into outlet.
	Hot hair styling appliances (curlers, flat irons)	Keep out of reach of infant and keep turned off when not in use.
	Water	Infants may turn on the tap or faucet in a bathtub and burn themselves. Lower water heater temperature to a safe level of 49°C (120°F). Before placing infant in tub, check temperature of water and completely turn off faucet so the child cannot alter temperature of water. NEVER leave an infant unattended in a tub or sink of water.
	Fireplace	Place a childproof screen in front of the fireplace.
	Stove, hot liquids	Keep top front burners off and keep pot handles turned toward back to avoid infant pulling hot pot onto themselves and causing burn injuries.
	Cigarettes	Avoid smoking in the same room as an infant.

Continued

TABLE 35.4 Common Infant Injuries, Associated Risk Factors, and Safety Promotion—cont'd

SAFE PAD	Risk Factors	Suggested Safety Interventions
P—Poisoning, ingestions	Medication, ointments, cream, lotions	Medications left in purses or handbags or on a table top can often be ingested by the curious infant. Keep poison control centre number readily available.
	Plants: household plants may be a source of accidental poisoning	Keep plants out of a child's reach.
	Cleaning solutions	Store in locked cabinet or in top cabinet where there are no drawers or shelves for infant to climb on. Avoid storing cleaning and caustic solutions in containers such as a pop bottle or jar—infants and toddlers cannot differentiate a pop from a caustic drain cleaner.
	Inhalation or oral or nasal ingestion of poisonous or harmful chemicals such as methamphetamine, gasoline, turpentine	Keep gasoline and turpentine stored in a locked cabinet or closet out of child's reach. Avoid storing in containers that are also used to keep drinks or food.
A—Automobile safety	Car or truck and hot weather	An automobile-related hazard for infants is overheating (hyperthermia) and subsequent death when left in a vehicle in hot weather (>26.4°C [80°F]). Infants dissipate heat poorly, and an increase in body temperature may cause death in a few hours. Caution parents against leaving infants in a vehicle alone for *any reason*.
	Air bags	Avoid placing infant in a car restraint behind an air bag. Place the infant in the back seat in a proper car seat restraint; if the front seat must be used the air bag must be deactivated.
	Car seat restraint	See discussion in this chapter.
D—Drowning	Bath tub	NEVER leave an infant unattended in a tub or sink of water.
	Swimming pools, bird baths, decorative ponds of water, splash pads	Place a fence around pools with a gate lock that is out of the child's reach. Supervise infants in water at ALL times; an infant may drown in as little as 5 cm of water. Swimming lessons are encouraged but are not foolproof for drowning if the infant or child hits their head on a hard object and becomes unconscious while falling into the water.
	Buckets of water	Keep buckets empty of water and elevated out of child's reach.

Toddlers also have not fully developed or do not understand the cause-and-effect principles that older children have and often are unable to gauge danger. Poorly developed depth perception may also contribute to falls and tumbles, as does the general bodily structure of toddlers. Specific categories of injuries and appropriate prevention are best understood by associating them with the major developmental achievements of young children (Table 35.5). Television tip-overs are a source of head trauma in toddlers and preschool age group. As with infants, play objects for toddlers must be chosen with an awareness of danger from small parts. A toy should not be able to fit into a toilet paper roll, otherwise it could be a choking hazard. Large, sturdy toys without sharp edges or removable parts are safest.

School-Age. Because school-age children have developed more refined muscular coordination and control and can apply their cognitive capacities to their behaviour, the number of injuries in middle childhood is less than that in early childhood. Most injuries occur in or near the home or school. Table 35.5 lists characteristics of school-age children that make them prone to injury and provides suggestions for injury prevention. In Canada, the leading cause of death for children under 14 years of age is child pedestrian accidents. On average, annually more than 30 child pedestrians under age 14 are killed and 2 400 are injured, with most accidents happening between the hours of 1500 and 1800, when children are walking home from school and drivers are going home from work (Parachute, 2020c). Hand-held devices such as cell phones put children at a higher risk of pedestrian injury. This equipment along with ear plugs are distractors and lessen traffic sounds and can result in pedestrian injury. Most pedestrian injuries occur at midblock, at intersections, in driveways, and in parking lots.

Physically active school-age children are also highly susceptible to cuts and abrasions; the incidence of childhood fractures, strains, and sprains is high. Trampoline injuries occur most frequently in children ages 5 through 14 years and account for numerous fractures, sprains, and head injuries. It is recommended that trampolines not be used in the home environment, in routine physical education classes, or on outdoor playgrounds for children of any age (CPS, 2017a).

Adolescents. The normal developmental need for independence and freedom in the adolescent can increase their risk for injuries. They often feel they are invincible and that nothing will happen to them. Motor vehicles continue to be the leading cause of injury-related deaths for this age group, as adolescents lack driving experience. Nurses can play an important role in education regarding injury prevention and can also advocate for legislation to decrease the rate of injury in this population. See Table 35.5 for prevention of adolescent injury.

Motor Vehicle Safety

Automobile injuries are the leading cause of accidental death in children in Canada who are between the ages of 1 and 9 years (Yanchar et al., 2012/2020). Many of the deaths are caused by injuries within the car when restraints either have not been used or have been used improperly. Severe injuries in and deaths of children have occurred from air bags deploying on impact in the front passenger seat; therefore, the back seat must be used for all children. When used correctly, child

TABLE 35.5 Injury Prevention from Early Childhood to Adolescence

Developmental Abilities Related to Risk of Injury	Injury Prevention
Toddlers and Preschoolers	
Motor Vehicles	
Walks, runs, and climbs	Use federally approved car restraint.
Able to open doors and gates	Supervise child while playing outside.
Can ride tricycle and other toy vehicles	Do not allow child to play on the curb or behind a parked car.
Can throw ball and other objects	Do not permit child to play in a pile of leaves, snow, or large cardboard container in trafficked area.
	Supervise tricycle riding.
	Lock fences and doors if not directly supervising children.
	Teach child to obey pedestrian safety rules: • Obey traffic regulations; cross only at crosswalks and only when traffic signal indicates it is safe. • Stand back a step from the curb until it is time to cross. • Look left, right, and left again and check for turning cars before crossing the street. • Use sidewalks; when there is no sidewalk, walk on the left, facing traffic. • Wear light colours at night and attach fluorescent material to clothing.
Submersion Injuries	
Has great curiosity	Supervise closely when near any source of water regardless of depth, including buckets.
Helpless in water; unaware of its danger—may consider "play" in any body of water the same as in the bath; depth of water has no significance	Keep bathroom doors closed and lid down on toilet (or install latch).
	Have fence around swimming pool and lock gate.
	Teach swimming and water safety (this is, however, not a substitute for safety).
Burns	
Able to reach heights by climbing, stretching, and standing on toes	Turn pot handles toward back of stove.
Pulls objects	Place electrical appliances out of reach.
Explores any holes or opening	Keep child out of reach of hot items and matches or lighters.
Unaware of potential sources of heat or fire	Do not let tablecloth hang within child's reach.
Plays with mechanical objects	Do not let electric cord from iron, curling iron, or other appliance hang within child's reach.
	Cover electrical outlets with protective plastic caps.
	Stress danger of open flames; teach what "hot" means.
	Always check bathwater temperature; adjust water heater temperature to 49°C or lower; do not allow children to play with faucets.
	Apply a sunscreen when child is exposed to sunlight.
Accidental Poisoning	
Cannot read labels	Place all potentially toxic agents out of reach or in a locked cabinet.
	Caution against eating nonedible items, such as plants.
	Store medications with childproof caps and safely out of reach.
	Do not treat medications like candy.
	Teach child not to play in trash containers.
	Never remove labels from containers of toxic substances.
	Do not store toxic liquids in containers not specifically intended for their storage (e.g., an empty pop bottle that the child may drink from, unaware of difference in contents).
	Know the number of the nearest poison control centre.
Falls	
Able to open doors and some windows	Use window guardrail; fasten securely.
Goes up and down stairs	Place gates at top and bottom of stairs.
Depth perception unrefined	Keep doors locked or use child-proof doorknob covers at the entry to stairs, high porch, or other elevated area, including laundry chute.
Climbs on higher surfaces	Remove unsecured or scatter rugs.
	Apply nonskid decals in the bathtub or shower.
	Ensure crib mattress is at lowest level to ensure safety and railings are fixed.
	Place carpeting under the crib and in the bathroom.
	Keep large toys out of the crib or playpen (child can use these as "stairs" to climb out), then move the child to a youth bed when they are able to climb out of the crib.
	Dress in safe clothing (soles that do not "catch" on the floor, tied shoelaces, pant legs that do not touch the floor).
	Keep child restrained in vehicles; never leave the child unattended in a shopping cart.
	Supervise child at playgrounds; select play areas with a soft ground cover and safe equipment.

Continued

TABLE 35.5 Injury Prevention from Early Childhood to Adolescence—cont'd

Developmental Abilities Related to Risk of Injury	Injury Prevention
Choking and Suffocation	
May swallow hard or nonedible pieces of food	Avoid feeding large, round chunks of meat, such as whole hot dogs (slice lengthwise into short pieces). Avoid feeding fruit with pits, fish with bones, dried beans, hard candy, chewing gum, nuts, popcorn, grapes, marshmallows. Choose large, sturdy toys without sharp edges or small removable parts. Select safe toy boxes or chests without heavy, hinged lids. Keep blind cords out of child's reach. Remove drawstrings from clothing.
Bodily Damage	
Still clumsy in many skills Easily distracted from tasks Unaware of potential danger from strangers or other people	Avoid giving the child sharp or pointed objects, such as knives, scissors, or toothpicks, especially when walking or running. Do not allow lollipops or similar objects in the child's mouth when walking or running. Store all dangerous tools, garden equipment, and firearms in a locked cabinet. Be alert to danger of supervised animals and household pets. Teach the child their name, address, and phone number and to ask for help from appropriate people (cashier, security guard, police) if lost; have identification on child (sewn in clothes, inside shoe). Teach stranger safety: • Avoid personalized clothing in public places. • Never go with a stranger. • Tell parents if anyone makes the child feel uncomfortable in any way. • Always listen to the child's concerns regarding others' behaviour. • Teach the child to say "no" when confronted with uncomfortable situations.
School-Age Child	
Motor Vehicle Accidents	
Is increasingly involved in activities away from home Is excited by speed and motion Is easily distracted by environment Can be reasoned with	Educate child regarding proper use of seat belts while a passenger in a vehicle. Children should ride in the back seat of a car until age 12. Maintain discipline while a passenger in a vehicle (e.g., keep arms inside, do not lean against doors, do not interfere with driver). Remind parents and children that no one should ride in the bed of a pickup truck. Emphasize safe pedestrian behaviour. Insist on child wearing safety apparel (e.g., helmet) when applicable, such as when riding a bicycle, motorcycle, moped, or all-terrain vehicle (see Family-Centred Care box: Bicycle Safety).
Drowning	
Is apt to overdo May work hard to perfect a skill Has cautious, but not fearful, gross motor actions Likes swimming	Teach child to swim. Teach basic rules of water safety. Select safe and supervised places to swim. Check sufficient water depth for diving. Swim with a companion. Use an approved flotation device. Learn cardiopulmonary resuscitation. Teach winter ice safety, for example, when ice skating, playing pond hockey, and snowmobiling
Burns	
Has increasing independence Is adventurous Enjoys trying new things	Make certain the home has smoke and carbon monoxide detectors. Instruct child in behaviour in areas involving contact with potential burn hazards (e.g., gasoline, matches, bonfires or barbecues, lighter fluid, firecrackers, cigarette lighters, cooking utensils, chemistry sets). Instruct child to avoid climbing or flying a kite around high-tension or electrical wires. Teach child what to do in the event of a fire (e.g., fire drills at home and school). Teach child safe cooking (use low heat; avoid any frying; be careful of steam burns, scalds, or exploding foods, especially from microwaving).
Accidental Poisoning	
Adheres to group rules May be easily influenced by peers Has strong allegiance to friends	Educate child regarding hazards of taking nonprescription drugs and chemicals, including aspirin and alcohol. Teach child to say "no" if offered illegal or dangerous drugs or alcohol. Keep potentially dangerous products in properly labelled receptacles, preferably out of reach.

Continued

TABLE 35.5 Injury Prevention from Early Childhood to Adolescence—cont'd

Developmental Abilities Related to Risk of Injury	Injury Prevention
Bodily Injury	
Has increased physical skills Needs strenuous physical activity Is interested in acquiring new skills and perfecting attained skills Is daring and adventurous, especially with peers Frequently plays in hazardous places Confidence often exceeds physical capacity Desires group loyalty and has strong need for friends' approval Attempts hazardous feats Accompanies friends to potentially hazardous facilities Is likely to overdo things Growth in height exceeds muscular growth and coordination	See Toddler and Preschooler section above. Help provide facilities for supervised activities. Encourage playing in safe places. Keep firearms safely locked up except under adult supervision. Teach proper care of, use of, and respect for devices with potential danger (e.g., power tools, firecrackers). Stress eye, ear, or mouth protection when using potentially hazardous objects or devices or when engaging in potentially hazardous sports. Teach safety regarding use of corrective devices (glasses); if the child wears contact lenses, monitor duration of wear to prevent corneal damage. Stress careful selection, use, and maintenance of sports and recreation equipment, such as skateboards and in-line skates (see Family-Centred Care box: Skateboard, In-Line Skate, and Scooter Safety). Emphasize proper conditioning, safe practices, and use of safety equipment for sports or recreational activities.
Adolescent	
Pedestrian and Motor Vehicle Passenger	
Need for independence and freedom Testing for independence Age permitted to drive a motor vehicle (varies) Inclination for risk-taking behaviours Feeling of indestructability Need for discharging energy, often at expense of logical thinking and other control mechanisms Strong need for peer approval Desire to attempt hazardous feats Peak incidence for practice and participation in sports Access to more complex tools, objects, and locations Can assume responsibility for own actions	**Pedestrian** Emphasize and encourage safe pedestrian behaviours • At night, walk with a friend. • If someone is following you, go to the nearest place with people. • Do not walk in secluded areas; take well-travelled walkways. **Motor or Non-Motor Vehicles** *Passenger* • Promote appropriate behaviour while riding motor vehicle. *Driver* • Provide competent driver education, discourage cell phone usage, text messaging while driving, maintain vehicle in proper condition (e.g., brakes, tires). • Reinforce not to drink alcohol and then drive or get into a vehicle driven by someone who has been drinking alcohol. • Teach and promote safety apparel such as helmet and long trousers when driving a motorbike. • Reinforce the dangers of using drugs, including alcohol, and cannabis when operating a motor vehicle. Reinforce the pedestrian risks when using cellular phones and listening to music with earphones when walking. Teach and encourage general safety measures in all activities.
Falls	Teach and encourage general safety measures in all activities.
Drowning	See School-Age Child section above.
Burns	Reinforce proper behaviour in areas involving contact with burn hazards (gasoline, electric wines, and fires). Advise regarding excessive exposure to natural or artificial sunlight (ultraviolet light). Encourage use of sunscreen. Discourage use of tanning beds
Poisoning	Educate in hazards of drug use, including alcohol, cannabis.
Other Sources of Physical Harm	See School-Age Child section above. Be alert for signs of depression and potential suicide.

See also Government of Canada (Public Health Agency of Canada). (2011). *The chief public health officer's report on the state of public health in Canada 2009. Growing up well—Priorities for a healthy future.* http://www.phac-aspc.gc.ca/cphorsphc-respcacsp/2009/fr-rc/pdf/cphorsphc-respcacsp-eng.pdf.

car seats reduce the risk of fatal injury by 71% and the risk of serious injury by 67% (van Schaik & CPS, Injury Prevention Committee, 2008/2013). Transport Canada advocates that the back seat is the safest place for children under the age of 13 years. Children should use specially designed car restraints (e.g., car seats, booster seats) until they are 145 cm in height or are at least 8 to 12 years old (depending on jurisdiction where they live), and they should not sit in the front seat until they are at least 13 years of age. Once a child has outgrown a car seat a booster seat should be used as they provide 60% more protection than seat belts alone (CPS, 2016).

Individual provinces and territories set the legislation regarding the use of car seats and booster seats. The CPS has called on all governments to implement booster seat legislation across Canada as not all provinces and territories have enacted booster seat legislation (van Schaik & CPS, Injury Prevention Committee, 2008/2013).

Many unfortunate outcomes of motor vehicle–related accidents can be prevented with increased public education and clinician advocacy (Yanchar et al., 2012/2020). Parents and caregivers need to know how to properly install and use child restraint systems and that there is no safe alternative. Misuse rates range from 44 to 81% for car seats and 30 to 50% for booster seats (Yanchar et al., 2012/2020). Car seat clinics are available in some communities to teach parents about which seat is the most appropriate one to use, how to install the car seat in a vehicle, and how to position a child in the car seat (Transport Canada, 2018). While there is no national network of car seat clinics, sessions are held across Canada by a variety of organizations, and local police or fire departments may have information about child car seat clinics in a particular geographic area (Transport Canada, 2018).

! NURSING ALERT

Infants and children must be in a car seat or booster seat until age 8 years. It is important that every car seat and booster seat meet Transport Canada regulations and not be purchased from other countries such as the United States because the regulations vary between the two countries. All children's car seats and booster seats sold in Canada must have a Transport Canada sticker on them and will have an expiration or useful-life date on them. People should not use children's car seats and booster seats past their expiration or useful-life date or that have previously been in a car accident (Transport Canada, 2019).

Nurses have a responsibility to educate parents and caregivers about the importance of using car restraints for children and the proper use of car restraints. Five types of restraints are available: (1) infant-only devices, (2) convertible models for both infants and toddlers, (3) booster seats, (4) safety belts, and (5) devices for children with special needs. See Nursing Skills on Evolve: Car Seat Safety.

Infant restraints are designed either as an infant-only model or as a convertible infant-toddler model (Figure 35.10). Either restraint is a semi-reclined seat that faces the rear of the car. A rear-facing car seat provides the best protection for the disproportionately heavy head and weak neck of a young child. This position minimizes the stress on the neck by spreading the forces of a frontal crash over the entire back, neck, and head; the spine is supported by the back of the car seat. It is recommended that children ride in rear-facing car safety seats until they outgrow the height and weight limit of the car seat. The earliest a child should move to a forward-facing car seat is when they are able to walk on their own and weigh at least 10 kg, but toddlers up to 24 months of age are safer riding in convertible seats in the rear-facing position (Transport Canada, 2019).

The restraint is anchored to the vehicle with the vehicle's seat belt, and the restraint has a harness system for securing the infant. Some harness systems require a clip to keep the shoulder straps correctly

Fig. 35.10 A rear-facing infant car restraint that is approved by Transport Canada and placed in the back seat provides the best protection. (Courtesy Brian and Mayannyn Sallee.)

positioned. Vehicles (manufactured after 1999) have tether straps that attach to anchors in the car seat to better secure the seat and minimize forward movement of the forward-facing convertible seats in the event of an accident. Starting in 2003, the Universal Anchorage System (UAS) (also known as LATCH [Lower Anchors and Tethers for Children]) universal child safety seat system was implemented as a requirement for all new automobiles and child safety seats (Figure 35.11). The UAS can be used but only if it has a removable base. This system provides car seat anchors between the front cushion and backrest so that the seat belt does not have to be used. The seat belt can be used if the UAS lower anchorage bars cannot be used, if the infant car seat is without its base, or if there are no lower anchorage bars in the vehicle.

! NURSING ALERT

Infants should ride in a rear-facing car seat from birth to a weight of 10 kg, until they are at least 1 year of age, and until they are able to walk independently. If the child weighs 10 kg but is not 1 year old, the rear-facing position is still recommended.

The next stage in child restraints is the forward-facing infant/child seats. Children who have outgrown the rear-facing height or weight limit for their car safety seat should use a forward-facing car safety seat with a harness up to the maximum height or weight recommended by the manufacturer (Figure 35.12). Convertible safety seats should be used until the child weighs at least 13.6 kg or more regardless of age and as long as the child fits properly into the seat (van Schaik & CPS, Injury Prevention Committee, 2008/2013). Some models are a combination of forward-facing infant/child seats that will convert to a child booster seat when the child reaches the appropriate booster weight and height.

Convertible restraints have different types of harness systems: a five-point harness that consists of a strap over each shoulder, one on each side of the pelvis, and one between the legs (all five come together at a common buckle), and a padded shield that uses shoulder straps attached to a shield that is held in place by a crotch strap.

Built-in seats are available in some cars and vans. They may be used for children who are at least 1 year of age and weigh at least 10 kg. Built-in seats eliminate difficulties with installation. However, weight and height limits vary. Owners must verify with vehicle manufacturers the details about built-in seats to ensure that the seats will adequately protect their child.

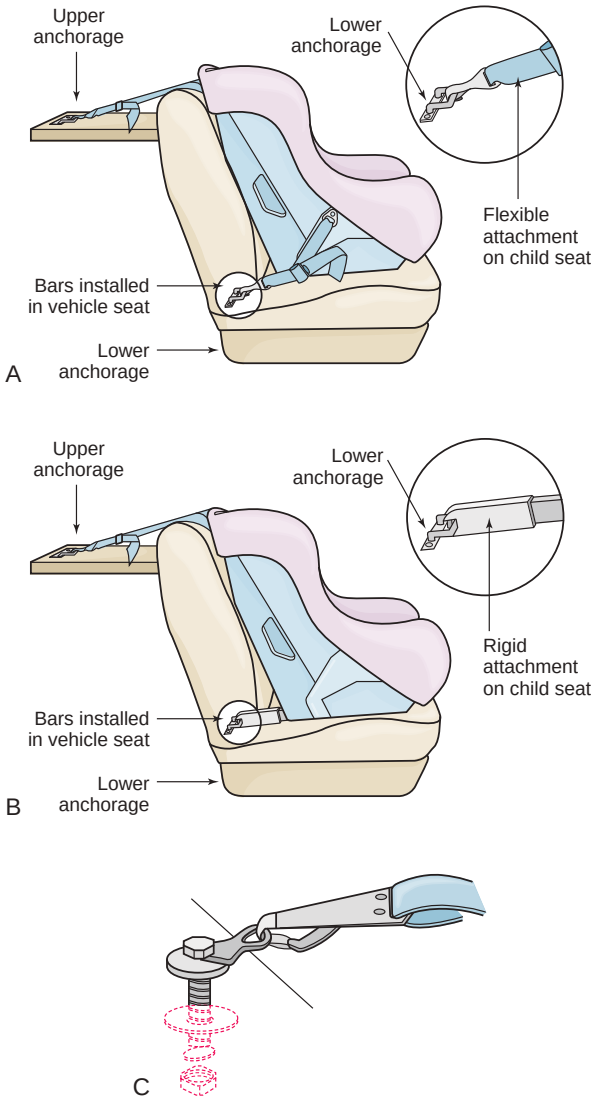

Fig. 35.11 Universal anchorage system (UAS). **A:** Flexible two-point attachment with top tether. **B:** Rigid two-point attachment with top tether. **C:** Top tether. (Courtesy U.S. Department of Transportation, National Highway Traffic Safety Administration.)

For restraints to be effective, they must be used properly. With all car seats, it is important not to add extra blankets, head cushions, or padding between the child and the restraint straps that did not come as original equipment because these "add-ons" create spaces of air between the child and the restraint and decrease support for the back, head, and neck. Children in car seats should wear lightweight outfits and not heavy coats or snowsuits because during an impact, the padding will compress, leaving the harness straps loose. For infants, a small blanket or towel rolled tightly can be placed on either side of the head to minimize movement and keep the infant's hips against the back of the seat. Padding between the infant's legs and crotch can be added to prevent slouching. Other examples of misuse include misrouting the vehicle seat belt through the restraint; failing to use the vehicle seat belt to secure the restraint; failing to use the restraint's harness system; and incorrectly positioning the child, especially by facing infants and toddlers forward instead of toward the rear.

! NURSING ALERT

Rear-facing infant safety seats must not be placed in the front seats of cars equipped with an air bag on the passenger side. If an infant safety seat is placed in the passenger seat with an air bag, the child could be seriously injured if the air bag is released, since rear-facing infant seats extend closer to the dashboard.

The third stage in child car restraints is booster car seats. Booster seats are not restraint systems like the convertible devices because they depend on the vehicle belts to hold the child and booster seat in place. These seats should be used for children who have surpassed the weight or height limits of their forward-facing car seat and weigh at least 18 kg.

A booster seat should be used until the child is able to sit against the back of the seat with feet hanging down and legs bent at the knees (approximately 145 cm in height) and weigh at least 36 kg. Some booster models accommodate children up to 45 kg. It is necessary to always check the label for the lower and upper weight and height limits because they vary depending on the manufacturer. The belt-positioning booster model raises a child higher in the seat, moving the shoulder part of the belt off the neck and the lap portion of the belt off the abdomen onto the pelvis. Children who outgrow the convertible restraint may still be able to ride safely in a booster seat until the midpoint of the head is higher than the vehicle seat back. Cars with free-sliding latch plates on the lap or shoulder belt require the use of a metal locking clip to keep

Fig. 35.12 **A:** Convertible car safety seat in forward-facing position. **B:** Use of locking clip. (*A*, Sokolova Maryna/Shutterstock.com.)

the belt in a tight-holding position. The locking clip is threaded onto the belt above the latch plate (see Figure 35.12, *B*). If parents have newer cars with automatic lap and shoulder belts, they need to have additional lap belts installed to properly secure the restraint.

Shoulder-only automatic belts are designed to protect adults. If children use manual shoulder belts they should sit in the rear seat, as deployed air bags, which face the front seats, can be lethal to young children. The safest area of the car for all children until the age of 12 years is the back seat. If children do ride in the front seat, the seat should be pushed as far back as possible to prevent serious harm or critical injury from the air bags. Many of the newer-model vehicles have side impact air bags for collision protection; these air bags are reported to be safe as long as the child is in a proper restraint system.

Children with special needs may require a restraint system that secures them appropriately in the event of a crash. Examples of such devices include car bed restraints for infants who cannot tolerate a semi-reclining position and specially adapted moulded-plastic chairs for children who have spica casts. The E-Z-On vest is a special safety harness for larger children with poor trunk control.

Nurses are in an excellent position to advise parents in using car restraints and safety seats correctly (see Family-Centred Care box: Using Car Safety Seats). For additional information about child safety restraints see Additional Resources at the end of this chapter.

FAMILY-CENTRED CARE

Using Car Safety Seats

- Read the manufacturer's directions and follow them exactly.
- Anchor the safety seat securely to the car's seat and apply harness snugly to the child.
- Adjust the harness straps so they are at or just below the child's shoulders. Some child car seats allow adjustment of the harness height by moving the headrest up or down. You may find this easier to do before you install the child car seat in the vehicle.
- As the child grows, check the fit and readjust the harness.
- Do not start the car until everyone is properly restrained.
- Always use the restraint, even for short trips.
- If the child begins to climb out or undo the harness, firmly say, "No." It may be necessary to stop the car to reinforce the expected behaviour. Use rewards, such as stars or stickers, to encourage appropriate behaviour.
- Encourage the child to help attach buckles, straps, and shields, but always double-check fastenings.
- Decrease boredom on long trips. Keep soft toys in the car for quiet play, talk to the child, point out objects, and teach the child about them. Stop periodically. If the child wishes to sleep, make certain the child stays in the restraint.
- Insist that others who transport children also follow these safety rules.

Injuries to children may also occur during sudden stops when objects are left unrestrained. On sudden impact, a loose toy or package can become a projectile missile. Therefore, all items should be secured or stored in the trunk.

Overheating (hyperthermia) of young children and their subsequent death can occur when they are left in a vehicle in hot weather (more than 26°C). Small children dissipate heat poorly, and an increase in body temperature can cause death in a few hours. In Canada, approximately one child per year dies from being trapped in an overheated vehicle (Ho et al., 2020). According to the Canada Safety Council (n.d.) the air temperature in a previously air-conditioned small car can exceed 50°C within 20 minutes on a day with temperatures of 35°C and up to 65.5°C within 40 minutes. Parents should be cautioned against leaving children in a vehicle alone *for any reason*. Parents should be encouraged to create reminders that a child is in the backseat, by placing an important object such as cell phone in the backseat, placing a sign on the rearview mirror, placing a stuffed animal or reminder object on the front seat, or installing a vehicle device created for this purpose (Ho et al., 2020). Busy parents may forget that the child is in the back when preoccupied with other thoughts.

Pedestrian Safety

Children over 3 years of age are often involved in pedestrian traffic injuries. They are able to use their gross motor skills of walking, running, and climbing and their fine motor skills of opening doors and fence gates, which results in increased likelihood of being in hazardous areas unsupervised. Unaware of danger and unable to approximate the speed of cars, they can be hit by moving vehicles. Running after a ball, riding a tricycle, and playing behind a parked car are common activities that may result in a vehicular tragedy.

A significant number of vehicle-related injuries in children occur when they are backed over by a car. A precaution for children when they are riding tricycles in driveways is attaching a pole with a bright flag that is high enough to be visible through the back window of an automobile. Another safeguard is the use of a device in the automobile that beeps when the vehicle is driven in reverse, to alert children to the oncoming car, van, tractor, or truck. Many vehicles now come equipped with rearview motion cameras so the driver can see the driveway clearly while backing out.

Prevention of vehicular injuries involves protecting and educating children and adults about the dangers of moving or parked vehicles. Although preschool children are too young to be trusted to always obey, parents should emphasize looking for moving vehicles before crossing the street, recognizing the stop and go colours of traffic lights, and following traffic officers' signals. Physical barriers that limit children from playing near vehicles can help prevent these injuries. Most important, what is preached must be practised. Children learn through imitation, and consistency reinforces learning.

All-Terrain Vehicles

All-terrain vehicles (ATVs), popular with older children, are unstable, difficult to handle, and responsible for an increasing number of childhood injuries. In some Canadian jurisdictions, children are not allowed to operate ATVs if they are under 16 years of age. The CPS advocates a Canada-wide ban on ATV operation by those under 16 years of age (Yanchar & CPS, Injury Prevention Committee, 2012/2020). As the use of ATVs grows in Canada, the number of associated injuries has risen accordingly. From 1995 to 2010, there was a 150% overall increase in the rate of serious injuries and an 85.7% increase in the rate of fatalities related to ATVs and dirt bikes in Canada (Ontario Agency for Health Protection and Promotion, 2019). Children under the age of 16 have been identified as being at a disproportionately high risk for injury with the use of these vehicles (Ontario Agency for Health

Fig. 35.13 The right-size bike is important; the child should be able to sit on the bike and place the balls of both feet on the ground. The foot should comfortably reach and manipulate the pedal in the down position. Wearing a protective helmet should be mandatory. The helmet should be positioned so it sits low on the forehead and parallel to the ground when the head is held upright. It should not rock back and forth or shift from side to side. The strap should fasten securely under the chin.

Protection and Promotion, 2019). Snowmobiles are also a source of serious injury to a child; the CPS recommends that youth under 16 years not operate a snowmobile (Stanwick & CPS, Injury Prevention Committee, 2004/2013).

Bicycles and Skateboards

Bicycle injuries are another significant cause of childhood injury and death. Most bicycling deaths are from head injuries. Helmet use reduces the risk of head injury by 85%, which means that four out of five head injuries could be prevented by the use of helmets (Johnston & Rivara, 2020). British Columbia, New Brunswick, Newfoundland and Labrador, Nova Scotia, and Prince Edward Island all require cyclists of all ages to wear a bike helmet. Alberta, Manitoba, and Ontario require helmets for persons 18 years and under (Parachute, 2019a). It is also important that children ride bicycles that are the correct size for their bodies (Figure 35.13). Community-wide bicycle helmet use campaigns and mandatory-use laws have resulted in significant increases in helmet use. Still, issues such as stylishness, comfort, and social acceptability remain important factors in whether children will actually wear a helmet.

Nurses can educate children and their families about pedestrian and bicycle safety. In particular, community nurses can promote helmet wearing and encourage peer leaders to act as role models. When parents wear helmets, their children are more likely to wear them.

Other serious injuries include those involving accidents on skateboards, roller skates, in-line skates, scooters, and other sports equipment. Skateboarders need to use a specific helmet for that sport.

The most effective means of injury prevention is education of the child and family about the hazards of risk taking and the improper use of equipment. Use of safety helmets, protective eye and mouth shields, and protective padding is strongly recommended for children engaging in active sports, even though they may not be required equipment. The Family-Centred Care boxes Bicycle Safety, and Skateboard, In-Line Skate, and Scooter Safety provide guidelines for promoting safety in these sports.

FAMILY-CENTRED CARE

Bicycle Safety

- Always wear a properly fitted bicycle helmet that is certified, e.g., by the Canadian Standards Association (CSA); look for the CSA approval sticker on the inside liner of the helmet and to find out if helmet use is legally mandated (legislation varies across provinces)
- Replace a helmet every 5 years or sooner if the manufacturer recommends it. Never use a damaged or outgrown helmet. Bike helmets can be used for in-line skating and scooter riding, but skateboarding has its own specific helmet (Parachute, 2019a).
- Ride bicycles with traffic and away from parked cars.
- Ride single file.
- Walk bicycles through busy intersections only at crosswalks.
- Give hand signals well in advance of turning or stopping.
- Keep as close to the curb as practical.
- Watch for drain grates, potholes, soft shoulders, loose dirt, or gravel.
- Keep both hands on the handlebars, except with signalling.
- Never ride double on a bicycle.
- Do not carry packages that interfere with vision or control; do not drag objects behind the bike.
- Watch for and yield to pedestrians.
- Watch for cars backing up or pulling out of driveways; be especially careful at intersections.
- Look left, right, then left, before turning into traffic or road.
- Never hitch a ride on a truck or other vehicle.
- Learn rules of the road and respect traffic officers.
- Obey all local bylaws.
- Wear shoes that fit securely while riding.
- Wear light colours at night and attach fluorescent material to clothing and the bicycle.
- Equip the bicycle with proper lights and reflectors.
- Be certain the bicycle is the correct size for rider (see Figure 35.13).
- Have the bicycle inspected to ensure good mechanical condition.
- Children riding as passengers must wear appropriate-size helmets and sit in specially designed protective seats.

Modified from American Academy of Pediatrics, Committee on Injury and Poison Prevention. (2008). Bicycle helmets. *Pediatrics, 122*(2), 450; Public Health Agency of Canada. (2014). Bicycle injuries and injury prevention. *Chronic Diseases and Injuries in Canada, 34*(2–3), 71–73. http://www.phac-aspc.gc.ca/publicat/hpcdp-pspmc/34-2-3/assets/pdf/CDIC_MCC_Vol34_2-3-eng.pdf.

FAMILY-CENTRED CARE

Skateboard, In-Line Skate, and Scooter Safety

- Children younger than 5 years of age should not use skateboards or in-line skates because they are not developmentally prepared to protect themselves from injury. Children ages 6 to 10 years should use these only with adult supervision.
- Children younger than 8 years should ride scooters only with close adult supervision.
- Children who ride skateboards, use in-line skates, or ride scooters should wear helmets and other protective equipment, especially on the knees, wrists, and elbows, to prevent injury. Ask a trusted skateboard shop for information on which helmet is best. A skateboard helmet should not be used for biking unless the label says that it is safe to do so.
- Skateboards, in-line skates, and scooters should never be used near traffic or in streets. Their use should be prohibited at night and in the rain. Activities that bring skateboards together (e.g., "catching a ride") are especially dangerous. Skateboarding should only be done in supervised skateboarding parks.
- Some types of use, such as riding homemade ramps on hard surfaces, may be particularly hazardous.
- Using music earphones is not recommended, so that traffic noise can be heard.
- Closed-toe shoes that are slip-resistant should be worn to lower the risk of injury to feet.
- Balance and coordination must be achieved before attempting to skateboard. If balance is lost while skateboarding, the child should be encouraged to crouch down on the skateboard to reduce the height of the fall and try to land on the fleshy parts of the body.
- People on skateboards must not be towed by bicycles or motor vehicles.

Data from American Academy of Pediatrics, Committee on Injury and Poison Prevention. (2006). Skateboard injuries. *Pediatrics, 109*(3), 542–543; Parachute. (2019). *Summer sports and recreation skateboarding.* https://parachute.ca/en/injury-topic/summer-sports/skateboarding/.

Aspiration and Suffocation

Threats to breathing are the fourth major cause of hospitalization and fatalities among Canadian children. These threats include strangulation, suffocation, choking, aspiration, entrapment, and traumatic asphyxia. The incidence peaks at 9 to 11 months of age, with the majority of choking and suffocation deaths occurring in the first year of life. Most hospitalizations for threats to breathing occur among children aged 3 years or under, with an elevated risk continuing until 6 years of age (Cyr & CPS, Injury Prevention Committee, 2012/2020). For survivors there can be long-term consequences with brain damage due to oxygen deprivation.

Foreign-body aspiration is most common during the second year of life. Coins, paper clips, pins, bells, button (round) batteries, toy magnets, pull-tabs on cans, thumbtacks, nails, screws, jewellery (especially pierced earrings), and all types of pins are common household objects that can cause significant harm if swallowed or aspirated. Small items such as coloured beads, green peas, pellets, or beans are often placed into the nose by toddlers and may present a danger if aspirated into the airway. Because of the danger of aspiration, parents should be taught emergency procedures for choking.

Usually by 1 year of age children chew well, but they may have difficulty with large pieces of food, such as meat and whole hot dogs, and with hard foods, such as nuts. Young children cannot discard pits from fruit or bones from fish. It takes practice to learn how to chew gum without swallowing it. Common foods causing choking include nuts, raw carrots, and popcorn kernels.

Suffocation is less frequent. Nonetheless, old refrigerators, ovens, and other large appliances are a threat as children can climb inside these appliances and, if they close the door behind them, can be trapped inside. Removing all doors before discarding or storing old appliances can prevent such tragic deaths. Young children may also suffocate when unsafe toy box lids accidentally close on their head or neck.

Drowning

In 2017, there were 290 drowning fatalities across Canada. Of those, 14% were children between age 1 and 4 (Government of Canada, 2019b). Once young children develop skills of locomotion, they are able to reach potentially dangerous areas, such as bathtubs, toilets, buckets, swimming pools, hot tubs, and lakes. Their intense drive for exploration and investigation, combined with an unawareness of the danger of water and their helplessness in water, makes drowning a viable threat. It is also one category of injuries that results in death within minutes, diminishing the chance for rescue and survival. Children under 5 years of age have a small lung capacity; their lungs can fill fast with water and they can drown in 2.5 cm of water.

Close adult supervision of children when they are near any source of water is essential; teaching swimming and water safety can be helpful but cannot be regarded as sufficient protection. To ensure safety around water, all young children need to be kept within arm's length with proper adult supervision at all times. In addition, approved lifejackets and personal flotation devices that are properly fitted must be used, and adults need to ensure a safe place for children to swim. Nurses play an important role in educating parents about water safety and advocating for all children to learn how to swim.

Burns

Children under the age of 5 account for 83% of all scald burn injuries requiring hospital admission (Parachute, 2020a). Because of their thinner skin, children are more vulnerable to burns than adults. Consequently, significant burns can cause permanent scarring with contracting of underlying tissues due to rapid growth and can lead to emotional scarring and physical disabilities (see Chapter 52 for information on how to care for a child with a burn). See Family-Centred Care: Child Safety Home Checklist later in this chapter for suggestions on how to make a home safe from threat of childhood burns.

Young children's ability to climb, stretch, and reach objects above their heads makes any hot surface a potential source of danger and increases the risk of scald burns. As a precaution, pot handles should be turned toward the back of the stove. Ideally, the knobs for controlling the range burners should be out of reach, not on the front panel where nimble fingers can turn them on and accidentally touch the hot burner. The outside of doors of ovens may become hot and, if touched, could cause a burn. It is also important to keep appliance cords out of reach, to use baby gates, and to keep toddlers seated in the kitchen.

Scald burns are also often caused by exposure to high-temperature tap water. Children come in contact with hot tap water by turning on the hot-water faucet, falling into a bathtub of hot water, or through parental deliberate abuse. Youngsters must always be supervised when they are near tap water, and bath temperatures need to be checked. Limiting household water temperatures to 49°C or medium is recommended. At 49°C it takes 10 minutes of exposure to the water to cause a full-thickness burn. Conversely, water temperatures of 55°C, a common setting of most water heaters, can cause third-degree burns to children within 5 seconds. Nurses can help prevent such burns by advising parents of this common household danger and recommending that they readjust the water heater to a safe temperature. Scalding can also occur when a curious child tries to sip a parent's coffee or tea and spills

the boiling liquid down the chin and chest. Use of lidded travelling cups can help prevent this type of injury.

Other sources of heat, such as radiators, fireplaces, accessible furnaces, kerosene heaters, or wood-burning stoves, should have a guard placed in front of them. Portable electrical heaters must be placed in a high area, well out of reach of climbing young children. Hair curling irons and hot curlers may easily burn the hands of curious toddlers when left within easy reach. Hot objects such as candles, incense, cigarettes, pots of tea or coffee, or irons must be placed away from children. The flame of a candle and the smoke of a cigarette can invite investigation.

Flame burns represent one of the most fatal types of burns and commonly occur when children play with matches and accidentally set themselves (and the home) on fire. In Canada, approximately 40 children aged 14 years and under die from fire or other burns annually. Another 770 children are hospitalized for serious injuries related to fire exposure (Parachute, 2020a). To prevent flame burns, matches and lighters must be stored safely away from children, and parents need to teach children the dangers of playing with such objects.

Electrical burns also represent an immediate danger to children. Young toddlers may explore outlets and wires by mouthing them, and since water is an excellent conductor, the chance for a severe circumoral electrical burn is great. Electrical outlets should have protective guards plugged into them when not in use (Figure 35.14) or be made inaccessible by having furniture placed in front of them, when feasible.

Sunburns are a year-round concern in certain regions. Children spend a large amount of time outdoors. Their increased mobility makes it difficult to prevent sun exposure. Sunburn can be prevented by applying a sunscreen with a sun protection factor (SPF) of 30 or greater, dressing the child in protective clothing (wide-brimmed hat, sunglasses with 100% UV protection, and loose cotton clothing), and avoiding sun exposure between 1000 and 1400 hours (see Chapter 52 for more information on burns).

Fig. 35.14 Safety demonstration board. Clockwise from lower left: Two types of cabinet latches, a shock guard for an electrical outlet in use, and two types of outlet covers (the one with the white cover has passive devices that automatically cover the outlet when a plug is removed).

Accidental Poisoning

Poisoning is a significant cause of injuries in children. According to the Public Health Agency of Canada (PHAC), approximately 3 children under the age of 14 die every year as a result of poisoning and an additional 900 children are hospitalized with serious injuries (Parachute, 2019b). The Canadian Association of Poison Control Centres reports that their centres receive thousands of calls regarding unintentional poisonings every year.

Many medications, household cleaners, personal care products, and plants can be poisonous if swallowed, if they come in contact with the skin or eyes, or if inhaled. Children manage to find access to many cupboards, so a locked cabinet is the only safe place for these items (Figure 35.15).

Although in many instances poisoning does not result in death, it may cause significant morbidity, such as esophageal stricture from lye ingestion. Newer forms of medications, such as transdermal patches, cannabinoid products, cough-suppressant lozenges, as well as laundry detergent pods have created additional dangers, since they are not packaged with safety caps and may appear similar to edible items such as candy. Unintentional medication ingestion causes 64% of the poisonings in children 14 years and younger. Ingestion of iron pills is of special concern as it is the leading cause of death (Parachute, 2019b). See Family-Centred Care: Child Safety Home Checklist later in this chapter for ways to prevent poisoning accidents.

Carbon monoxide is a leading cause of fatal poisoning among people of all ages in Canada. This toxic gas is colourless and has no odour. Defective appliances, clothes dryers, furnaces, and exhaust fumes from cars in home garages are sources of carbon monoxide poisoning. Carbon monoxide detectors are mandatory in any new building and should be installed on every level and near sleeping areas in homes. The alarms should be tested monthly and should be replaced every 5 to 7 years. Fuel-burning appliances should be checked once a year for carbon monoxide leakage (Parachute, 2019b).

Emergency and preventive measures for accidental poisoning are discussed in Chapter 46.

Fig. 35.15 Children are most likely to ingest substances that are on their level, such as cleaning agents stored under sinks, rat poison, plants, or diaper pail deodorants.

! NURSING ALERT

Parents should have ready access to the telephone number on their telephone for the local poison control centre. These telephone numbers are in the telephone book under emergency numbers for each individual provincial or territorial poison control centre. They are also available on the Canadian Association of Poison Control Centres website (http://www.capcc.ca). Parents should be prepared to act on the centre's advice.

Falls

While most falls in children do not cause serious injury, they are the leading cause of hospital admissions from injury in children aged 0 to 9 years. Nearly 4 000 children from birth to 9 years of age were admitted to a hospital as a result of a fall in 2018–19 (Parachute, 2020b). Playground injuries are common and can be serious; the Canadian Institute for Health Information (2016) reported that 1 841 children in Canada (in 2014 to 2015) under the age of 18 required hospitalization as a result of a playground injury. Falls were the leading cause of children's injury hospitalizations (44% of all admissions) and 7% of these injuries occurred on playgrounds. These injuries can include fractured bones and brain and spinal injuries. In children under 5 years of age, head and face injuries are most common (Fuselli et al., 2012/2014).

Children need to be taught safety at play areas, such as no horseplay on high slides or jungle gyms, to sit on swings, and to stay away from moving swings. Passive prevention of injury includes placement of grass, sand, or wood chips under play equipment, which lessens injuries. Swing seats should be made of plastic, canvas, or rubber and have smooth or rounded edges. Slides should not exceed an incline of 30 degrees and should have evenly spaced rungs for climbing and protective "tunnels." See Additional Resources at the end of the chapter for more information on playground safety.

The climbing and running of the typical younger child combined with their lack of awareness of danger make these children vulnerable to falls. See Family-Centred Care: Child Safety Home Checklist for measures that can be taken to decrease the risk of a child falling.

Cribs and beds are other sources of falls. To avoid injury, crib mattresses should be kept at the lowest position, and toys or bumper pads that may be used as steps to climb out should be removed. Ideally, the floor under the crib should be carpeted or have a throw rug. Once children reach a height of 90 cm or they can climb out on their own (whichever comes first) they should use a bed (Government of Canada, 2018a). If a bunk bed is selected, parents should be aware of possible dangers such as falls from the top bed and the ladder, and head entrapment between the mattress and guardrail or between the supporting mattress slats. See Additional Resources for the Government of Canada website on crib regulations.

Children can fall from highchairs, shopping carts, carriages, car seats, and strollers if not properly restrained or if the balance changes when the object is weighted down with heavy items. Therefore, proper restraint and adequate supervision are essential. Children, especially older infants who are mobile, should not be placed in an infant seat on top of a shopping cart because the infant seat may fall off the cart; the safest place for an infant seat is inside the bed of the cart.

Firearms

Currently, most deaths involving firearms are suicides. The relatively low rates of death from injuries involving firearms can be attributed to Canada's gun laws. A valid firearms licence is required in order to own, borrow, or store a firearm, and many firearms are prohibited or restricted (notably automatic guns and handguns). Potential gun owners also must pass the Canadian Firearms Safety course (Royal Canadian Mounted Police, 2021).

Youth access to firearms is generally through family members and acquaintances. Gun availability in the home is strongly correlated to unintentional death and injury in children and youth (Austin et al., 2018). When guns are in the home, adults must take preventive action to be certain that the guns are never loaded, that they are locked up in a safe place, and that ammunition is stored and locked up separately in a location where only appropriate adults have access to it.

Nonpowder Firearms. Guns that do not use powder (e.g., air guns and airsoft guns), while viewed as toys by many, account for almost as many injuries as powder guns. The regulations regarding use of nonpowder guns are relaxed; they can be purchased legally by adolescents and are labelled as suitable for children as young as 8 years of age. In Canada, some provinces, such as Ontario, restrict the sale of air guns to persons under the age of 18 years. Many cities have bylaws against discharging air guns within city limits. Paintball guns have also increased in popularity, and safety equipment with their use, such as helmets and goggles, is recommended (Austin et al., 2018).

Nurses are in a good position to advocate for laws regulating the sale of these potentially dangerous "toys." Air guns can cause deaths secondary to brain trauma, or penetration of the neck, chest wall, or abdomen and serious eye damage (Austin et al., 2018).

Sports Injuries

Because the degree of physical maturity, size, coordination, and endurance varies greatly among school-age children and adolescents, sports competition can result in predictable and unnecessary injuries for those not fit for or suited to particular sports. The matching of a child with individual sports should be done relative to physical maturity, height, weight, and physical fitness and skills, particularly in a sport involving rigorous body contact. Age is a less important consideration.

Every sport has some potential for injury, whether one participates in serious competition or for pure enjoyment. Overuse injuries are common and result in more time missed from the activity than do fractures. The increase in strength and vigour in adolescence may tempt adolescents to overextend themselves. The range of injuries sustained in sports or recreational activities can involve any part of the body and extend from relatively minor cuts, bruises, and abrasions to totally incapacitating central nervous system injuries or death. Recently, attention has focused on traumatic brain injuries resulting from concussions incurred in contact sports (see Chapter 50).

Ontario research shows that adolescents are injured at nearly twice the rate of other age groups. Males ages 12 to 19 are at the greatest risk of injury (30%), while females' risk of injury is about 23% (Forbes, 2016). Injury prevention is not a key focus of the sport and physical activity realm in Canada; evidence-informed planning for injury prevention is essential (Forbes, 2016). See Chapter 53 for more information on musculoskeletal injuries.

Role of the Nurse in Prevention of Injury

The task of injury prevention can be appreciated only when the potential environmental dangers to which children are vulnerable are considered. Injury prevention and parent education should be handled on a growth and developmental basis. Nurses must be aware of the possible causes of injury in each age group in order to carry out teaching that involves anticipatory guidance and injury prevention. For example, the guidelines for injury prevention during childhood presented in Tables 35.4 and 35.5 should be discussed before the child reaches each age group. Preventive teaching ideally can begin during pregnancy.

Two thirds of all injuries to children occur in the home, thus the importance of safety in the home cannot be overemphasized. The Family-Centred Care box: Child Safety Home Checklist contains a home safety checklist that can be presented to parents to increase their awareness of danger areas in the home and assist them in implementing safety devices and practices before their absence leads to injury in infants. In addition, displays such as a safety demonstration board can be helpful in familiarizing parents with inexpensive commercial devices that can be used in the home to prevent injuries (see Figure 35.14). To help parents appreciate the dangers to young children that are present in their home, the nurse can suggest that they get down on the floor at the child's eye level to survey the environment from a child's viewpoint, looking for any signs of danger.

Toys can also be a source of danger, thus safety must be a prime consideration when selecting toys. While most toys have age ranges written on them to designate their safety, this information must be used with knowledge of the specific child's readiness (see Additional Resources at the end of this chapter for government regulations and recalls for defective toys.)

Injury prevention during adolescence requires a multipronged approach that includes the teenager and the parents. Education about potential risk is important, as well as building a relationship with the adolescent and engaging them to help mitigate risky behaviours.

FAMILY-CENTRED CARE

Child Safety Home Checklist

Safety: Fire, Electrical, Burns

__ Guards in front of or around any heating appliance, fireplace, or furnace (including electric heaters)*
__ Electrical wires are hidden or out of reach*
__ No frayed or broken wires; no overloaded sockets
__ Plastic guards or caps over electrical outlets, furniture in front of outlets*
__ Hanging tablecloths are out of reach, away from open fires*
__ Smoke detectors are tested and operating properly
__ Kitchen matches are stored out of child's reach*
__ Large, deep ashtrays throughout house (if used)
__ Small stoves, heaters, and other hot objects (cigarettes, candles, coffee pots, slow-cookers) are placed where they cannot be tipped over or reached by children
__ Hot water heater is set at 49°C or lower
__ Pot handles are turned toward back of stove, centre of table
__ No loose clothing is worn near stove
__ No cooking or eating of hot foods or liquids with the child standing nearby or sitting in lap
__ All small appliances, such as irons, are turned off, disconnected, and placed out of reach when not in use
__ Cool, not hot, mist vaporizer is used
__ Fire extinguisher is available on each floor and checked periodically
__ Electrical fuse box and gas shutoff are accessible
__ Family escape plan in case of a fire is practised periodically; fire escape ladder is available on upper-level floors
__ Telephone number of fire or rescue squad and address of home with nearest cross street posted near phone and in cell phone contacts list

Safety: Suffocation and Aspiration

__ Small objects are stored out of reach*
__ Toys have been inspected for small removable parts or long strings*
__ Hanging crib toys and mobiles are placed out of reach
__ Plastic bags are stored away from a young child's reach, large plastic garment bags discarded after tying in knots*
__ Mattress or pillow is not covered with plastic or in manner accessible to child*
__ Crib design is according to government regulations (crib slats less than 6 cm apart) with snug-fitting mattress*
__ Crib is positioned away from other furniture or windows*
__ Portable playpen gates are up at all times while in use*
__ Accordion-style gates are not used*
__ Bathroom doors are kept closed and toilet seats down*
__ Faucets are turned off firmly*
__ Pool is fenced with locked gate
__ Proper safety equipment is at poolside
__ Electric garage door openers are stored safely and garage door adjusted to rise when door strikes object
__ Doors of oven, trunks, dishwasher, refrigerator, and front-loading clothes washer and dryer are kept closed*
__ Unused appliance, such as a refrigerator, is securely locked or doors are removed*
__ Food is served in small, noncylindrical pieces*
__ Toy chests are without lids or with lids that securely lock in open position*
__ Buckets and wading pools are kept empty when not in use*
__ Clothesline is above head level
__ Carbon monoxide monitor is installed
__ At least one member of household is trained in basic life support (cardiopulmonary resuscitation), including first aid for choking

Safety: Poisoning

__ Toxic substances, including batteries, are placed on a high shelf, preferably in locked cabinet
__ Toxic plants are hung or placed out of reach*
__ Excess quantities of cleaning fluids, paints, pesticides, medications, and other toxic substances are not stored in home
__ Used containers of poisonous substances discarded where child cannot obtain access
__ Telephone number of local poison control centre and address of home with nearest cross street are posted near phones and in cell phone contacts lists
__ Medicines are clearly labelled in childproof containers and stored out of reach, preferably in locked cupboards
__ Household cleaners, disinfectants, and insecticides are kept in their original containers, separate from food, and out of reach
__ Smoking takes place in areas away from children, with no smoking in home

Safety: Falls

__ Nonskid mats, strips, or surfaces in tubs and showers
__ Exits, halls, and passageways in rooms are kept clear of toys, furniture, boxes, or other items that could be obstructive
__ Stairs and halls are well lit, with switches at both top and bottom
__ Sturdy handrails for all steps and stairways
__ Nothing stored on stairways
__ Treads, risers, and carpeting are in good repair
__ Glass doors and walls are marked with decals
__ Safety glass is used in doors, windows, and walls
__ Windows and balcony doors are secure and locked
__ Gates are on top and bottom of staircases and elevated areas, such as porch, fire escape*
__ Guardrails are on upstairs windows with locks that limit height of window opening and access to areas such as fire escape*
__ Crib mattress is lowered as child grows*
__ Restraints are used in highchairs or other baby furniture; preferably, walkers with wheels are not used*

Continued

FAMILY-CENTRED CARE—CONT'D

__ Scatter rugs are secured in place or used with nonskid backing
__ Walks, patios, and driveways are in good repair

Safety: Bodily Injury

__ Knives, power tools, and unloaded firearms are stored safely or placed in locked cabinet
__ Garden tools are returned to storage racks after use
__ Pets are properly restrained and immunized for rabies
__ Swings, slides, and other outdoor play equipment are kept in safe condition
__ Yard is free of broken glass, nail-studded boards, and other litter
__ Cement birdbaths and large flower pots are placed where a young child cannot tip them over*

*Safety measures are specific for homes with young children. All safety measures should be implemented in homes where children reside and visit frequently, such as those of grandparents or babysitters. Information about home safety can be obtained at https://www.cdc.gov/parents/infants/safety.html, and related Government of Canada information can be found at https://www.canada.ca/en/health-canada/services/consumer-product-safety/reports-publications/consumer-education/your-child-safe/is-your-child-safe.html.

One approach to teaching prevention of injury is to relate why children in various age groups are prone to specific types of injuries. Stressing prevention is just as important as emphasizing the "why" of the injury. However, injury prevention must also be practical. Asking parents for their ideas can lead to realistic suggestions to be followed. For instance, bathroom cleaning agents, cosmetics, and personal-care items can be placed on a top shelf in the linen closet and towels or sheets can be stored on the lower shelves and floor.

If an injury has occurred, the nurse should not be too quick to admonish the parent; injuries do not always indicate neglect. It is a difficult task to watch children carefully without overprotecting or unnecessarily confining them. Allowing children to explore while maintaining consistent, age-appropriate limits is sound advice.

Parents need to remember that infants and young children cannot anticipate danger or understand when it is or is not present. Also, infants have no cognitive concept of cause and effect and therefore cannot relate meaning to experiences or potential dangers. A dead electrical wire may present no actual harm; but if the child is allowed to play with it, a poor behaviour develops and may be practised when the child encounters a live wire. Although it is always wise to explain why something is dangerous, it must be remembered that small children need to be physically removed from the situation.

It is not easy to teach safety, supervise closely, and refrain from saying "no" multiple times a day. Parents become acutely aware of this dilemma as soon as the infant learns to crawl. Preventing injuries to children is usually the first reason for limit setting and discipline, but limits are also set to prevent danger to valuable household objects. When small children are in the home, dangerous objects must be removed or guarded and valuable articles placed out of reach.

When children are taught the meaning of "no," they should also be taught what "yes" means. Children should be praised for playing with suitable toys, their efforts at behaving or listening should be reinforced, and innovative and creative recreational toys should be provided for them. Infants love to tear paper and avidly pursue books, magazines, or newspapers left on the floor. Instead of always scolding them for destroying a valued book, child-safe books (such as those constructed of fabric) can be kept available for them to play with. If they enjoy pots and pans, a cabinet can be arranged with safe utensils for them to explore.

One additional factor must be stressed concerning injury prevention and education: Children are imitators; they copy what they see and hear. *Practising safety teaches safety*. This applies to parents and their children and to nurses and their patients. Saying one thing but doing another confuses children and can lead to difficulties as the child grows older.

CHILD MALTREATMENT

Children are one of the more vulnerable populations in the context of violence. The Government of Canada defines *child maltreatment* as the harm, or risk of harm, that a child or youth may experience while in the care of a person they trust or depend on, including a parent, sibling, other relative, teacher, caregiver, or guardian. Harm may occur through direct actions by the person (acts of commission) or through the person's neglect to provide a component of care necessary for healthy child growth and development (acts of omission). There are five types of child maltreatment: physical abuse, sexual abuse, neglect, emotional harm, and exposure to family violence (PHAC, 2012). It is one of the most significant social concerns affecting children around the world. In Canada, family violence rates have been generally declining. Between 2009 and 2017, the rate of family violence against children and youth decreased by 7%. The rate of non-family violence among children and youth decreased by 30% (Conroy, 2018). However, in 2017, there were 59 236 child and youth victims (aged 17 years and younger) of police-reported violence in Canada; 56% of victims in this age group were female. Of these child and youth victims 33% had been subjected to violence by a casual acquaintance and 18% by a stranger. Of all the child and youth victims of violence, 30% were victimized by a family member such as a parent, sibling, or other family member (Conroy, 2018).

Indigenous children have been identified as a key at-risk group. These children are severely overrepresented in foster care, at a rate of 52% of children in care, despite making up only 7% of the population of all children in Canada (McKay, 2018). Overrepresentation was most marked for investigations of neglect and exposure to intimate partner violence (Fallon et al., 2015; McKay, 2018). Some of the reasons for Indigenous children being taken into care are the impacts of the residential school system and the imposition of federal, provincial, and territorial systems of laws and child welfare systems. In addition, children often return home without adequate family supports in place (McKay, 2018). In order to decrease the rates of child apprehensions among Indigenous children, programs must be developed that ensure that children both in and transitioning out of care have consistent opportunities to build meaningful, loving relationships with healthy, supportive Elders, knowledge holders, and role models within their communities (McKay, 2018). Improved access to food, water, housing, clothing, transportation, and health services may also be beneficial (McKay, 2018).

Legal steps to address child maltreatment in Canada include mandatory reporting laws, creation of child abuse registries, changes to the Criminal Code and the *Canada Evidence Act*, extended time limits for filing charges in child sexual abuse cases, and establishment of child protection agencies run by Indigenous peoples (PHAC, 2012).

NURSING ALERT

Nurses have a mandatory legal and professional ethical responsibility to report suspected cases of child maltreatment to Child Welfare Services. Every new abuse incident must be reported.

Factors Predisposing to Child Maltreatment

The causes of child abuse are multifaceted. Child maltreatment occurs across all socioeconomic, religious, cultural, racial, and ethnic groups. Three risk factors are commonly identified in child abuse: parental characteristics, characteristics of the child, and environmental characteristics. However, no single factor or group of factors is predictive of abuse. Rather, the interaction of these factors is thought to increase the risk of abuse occurring in a particular family.

Parental Characteristics. Certain identified characteristics occur more frequently in parents who abuse their children and are therefore considered risk factors. In the context of family violence, 79% of abusers are male; this rate holds irrespective of the victim's age or sex (Sinha, 2015a). In one study, one-quarter (25%) of violence committed against children and adolescents was committed by a family member, including a parent, sibling, extended family member, or spouse, while more than half (54%) of violent crimes involved other individuals known to the victim. Researchers identified that the most frequent characteristics within families of violence were the following: 1) previous victims of domestic violence (46%), few social supports (39%), mental health issues (27%), alcohol use (21%), and drug or solvent use (17%) (PHAC, 2010).

Abusive families are often more socially isolated and have fewer supportive relationships. These parents are often from low-income circumstances, with lower levels of education. Parents with substance use disorder pose a greater risk for abuse and neglect because of a variety of factors. The additional stressors of substance use along with the demands of normal care of children create situations in which abuse and neglect can occur because these parents have impaired judgement and may react with violence while under the influence of drugs or alcohol. With little or no available support system and concurrent stressors imposed by the child or environment, these parents are vulnerable to additional crises of any nature and may strike out at the child as a method of releasing their increasing frustration and anxiety.

Other characteristics identified in abusive parents include low self-esteem and little knowledge of appropriate parenting skills. Parenting skills are learned behaviours, and parents who grew up with poor parental role models may have difficulty parenting their own children. Often, child abusers were abused or observed some type of abuse in their childhood home. For Indigenous families, the role model that many parents had was a caregiver in residential school who subjected children to many types of abuse.

Characteristics of the Child. The onus for child abuse is always on the abuser; however, children who are abused do have some common characteristics. Children from birth to 3 years of age are at highest risk for being abused (Sinha, 2015b). Infants and small children require constant attention and must have all of their needs met by others. This can result in parental or caretaker fatigue with resultant striking out at the child with physical force, shaking the child, or ignoring the child's needs. Overall, girls consistently experience higher rates of family violence for nearly every type of violent offence. However, this risk is most marked for sexually based offences (Sinha, 2015b).

The physical and emotional demands placed on the parents or caretaker of an unwanted, cognitively delayed, hyperactive, or physically disabled child may overwhelm them, resulting in abuse. Children with disabilities may not understand that abusive behaviours are not appropriate; thus, they may not tell others or defend themselves. Preterm infants may be at risk for maltreatment because of failure of parent–child bonding during early infancy, increased physical needs, or irritability. One child in the family may be singled out in an abusive family. Removing that child from the home often places the other siblings at risk for abuse. Therefore, no child is safe if left in the abusive environment unless the parents can be helped to learn new parenting skills, meet the children's needs, and release their frustration through alternatives other than attacking their children.

Environmental Characteristics. The environment is a significant part of the potentially abusive situation. A typical abusive environment is one of chronic stress, including difficulties related to divorce, relationship issues, poverty, unemployment, inadequate housing, frequent relocation, and substance use issues. Increased exposure between children and parents, such as that which occurs in crowded living conditions, also increases the likelihood of abuse.

Although most reporting of abuse has been from populations of lower socioeconomic status, as stated previously, child maltreatment is not a phenomenon of any one societal group. Stresses imposed by poverty predispose low-income families to abusive situations, and abuse in these groups is more apt to be reported. However, concealed crises may also be present in upper-income families. Families who have substitute caregivers such as day care providers and babysitters may also be at risk for child maltreatment, especially if the family has not fully evaluated the caregiver. Nurses need to be aware of all these factors in order to identify the less obvious examples of child abuse and neglect.

Child Neglect

Child neglect is the most common form of maltreatment. *Neglect* is generally defined as the failure of a parent or other person legally responsible for the child's welfare to provide for the child's basic needs and an adequate level of care. Neglect takes many forms and can be classified broadly as physical or emotional maltreatment. *Physical neglect* involves the deprivation of necessities, such as food, clothing, shelter, supervision, medical care, and education. *Emotional neglect* generally refers to failure to meet the child's needs for affection, attention, and emotional nurturance. Neglect may also include lack of intervention for or fostering of maladaptive behaviour, such as delinquency or substance use.

Important factors contributing to child neglect are lack of knowledge of children's needs, lack of resources, and caretaker substance use. For example, neglectful parents often demonstrate poor parenting skills. They may be unaware that an infant needs to be fed on demand, may not know what to feed the child, and may have insufficient funds to buy food. Another serious lack of knowledge is failure to recognize emotional nurturing as an essential need of children. (See also Chapter 36, Growth Failure [Failure to Thrive].)

Emotional Abuse

Emotional abuse, an even more difficult aspect of maltreatment to define, refers to the deliberate attempt to destroy or significantly impair a child's self-esteem or competence. Emotional abuse may take the following forms: rejecting, isolating, terrorizing, ignoring, corrupting, verbally assaulting, or overpressuring the child.

Physical Abuse

The deliberate infliction of physical injury on a child, usually by the child's caregiver, is termed *physical abuse. Nonaccidental trauma* is the term used to describe the injury resulting from the abuse. Minor physical injury is responsible for more reported cases of maltreatment than major physical injury, but major physical abuse causes more deaths. Despite the importance of the issue, a universally accepted definition of what constitutes minor and major physical abuse does not exist. Reported statistics only partially represent the actual incidence

of child maltreatment, since many cases likely go unreported. **Abusive head trauma (AHT)** is a serious form of physical abuse caused by violent shaking of infants and young children. Other commonly used terms include *shaken baby syndrome, inflicted head injury,* or *neuro-inflicted brain injury*. This is discussed in more detail in Chapter 50, Traumatic Head Injury due to Child Maltreatment.

! NURSING ALERT

It is important to stress to parents and caregivers the danger of shaking infants. Education must include coping mechanisms for caring for infants with inconsolable crying.

Sexual Abuse

Sexual abuse is one of the most devastating types of child maltreatment. No universal definition for sexual abuse exists. Definitions cover a range of acts, including involvement of children in sexual acts they do not understand, to which they cannot give consent, or that violate social taboos. Sexual abuse and exploitation in Canada involves using a child for sexual purposes. Estimates of sexual abuse indicate that it has increased significantly during the past decade. According to research, 1 in 10 Canadians reported being sexually victimized before they turned 18, and in the majority of sexual abuse cases, the offender was known to the child (Canadian Centre for Child Protection, 2018). It is difficult to estimate the number of children in Canada who are sexually abused, as assaults are underreported and there is no nationwide reporting system. The number of estimated sexual assaults and exploitations, however, is very concerning.

Some of the apparent increase in reporting can be attributed to increased awareness. These trends in sexual assault do not include child-specific sexual offences, such as luring a child over the Internet and invitation to sexual touching, which have generally increased in recent years (Sinha, 2015b).

Sexual abuse includes the following types of sexual maltreatment (Sinha, 2015b):

- *Incest*—Any physical sexual activity between family members; blood relationship is not required (abusers can include stepparents, unrelated siblings, grandparents, uncles, and aunts)
- *Molestation*—Vague term that includes "indecent liberties" such as touching, fondling, kissing, single or mutual masturbation, or oral–genital contact
- *Exhibitionism*—Indecent exposure, usually exposure of the genitalia by an adult man to children or women
- *Child pornography*—Arranging and photographing, in any media, sexual acts involving children, alone or with adults or animals, regardless of consent by the child's legal guardian; also may denote distribution of such material in any form with or without profit
- *Child prostitution*—Involving children in sex acts for profit and usually with changing partners
- *Pedophilia*—Literally means "love of child" and does not denote a type of sexual activity but rather the preference of an adult for prepubertal children as a means of achieving sexual excitement

To protect children from sexual abuse, the Criminal Code has been changed to create new criminal offences relating to child sexual assault, and to amend provisions on child sex tourism to make it easier to prosecute offenders. Bill C-15 aims to protect children from sexual exploitation by criminalizing actions such as luring children via the Internet to meet them somewhere in person; transmitting, making available, or exporting child pornography; or accessing child pornography on the Internet. Sentencing provisions have also been strengthened.

Human trafficking often involves some form of coerced sexual activity and thus sexual abuse that may also often involve physical and mental abuse. Many victims of human trafficking are females under the age of 18 years who are forced to perform sexual acts for the monetary profit of the perpetrators. One form of sex trafficking called "sex tourism" involves adult men travelling to developing nations to have sex with young children. Nurses may encounter victims of sex trafficking and subsequent sexual and physical abuse who are seeking medical care in outpatient and emergent health care settings for many different health conditions (STIs, bruises, wound infections, post-traumatic stress disorder [PTSD], suicidal ideation, and addiction). However, nurses may not be aware of the victim's plight unless they delve further into the person's history and background (Peternelj-Taylor, 2016). See Chapter 5, Human Trafficking for further information.

Characteristics of Sexual Abusers and Victims. Anyone, including siblings and mothers, can be sexual abusers, but a typical abuser is a man whom the victim knows. While offenders come from all levels of society, a higher risk for child abuse has been noted among families with incomes below the poverty level (Breyer & MacPhee, 2015). In addition, parents with a high school education are more likely than parents with a college education to be abusers (Breyer & MacPhee, 2015). Many offenders hold full-time jobs and are active in community affairs, and they may not have prior criminal records. Offenders often are employed in or volunteer for positions that will bring them into contact with young girls and boys, such as teachers or coaches. Offenders may commit many assaults before being caught.

As noted earlier, child and youth victims of violence most often know the abuser. About one quarter (26%) of those accused of violence against children and youth were family members, including a parent, stepparent, foster parent, sibling, grandparent, or extended family member, while another 53% were either acquaintances or friends of the child or youth (Sinha, 2015b). The abusers who were family members were equally likely to be a biological father or stepfather and less apt to be a biological mother or foster or adoptive parent (Sinha, 2015b).

Incestuous relationships between father or stepfather and daughter are often prolonged, and the victims are usually reluctant to report the situation because of fear of retaliation and fear that they will not be believed. Typically, incestuous relationships begin later than other forms of child abuse. The eldest daughter is usually abused, but in her absence another sister may be substituted. Sibling incest may also occur. Sexual abuse by relatives with a strong emotional bond with the victim can be the most devastating to the child.

Boys are also victims of both intrafamilial and extrafamilial abuse. Male victims are much less likely to report abuse, and they may suffer much greater emotional harm from incestuous relationships. Boys are likely to be subjected to anal penetration and oral–genital contact. They often have subtle physical findings and are abused by a father, stepfather, or mother's boyfriend.

Children who have a disability or a limiting health condition are at higher risk for sexual assault. In one study, these children were twice as likely to report being physically abused (Kaufman & CPS, 2011/2018).

Significant risk factors for child sexual abuse include parenting difficulties, parental unavailability, lack of emotional closeness and flexibility, social isolation, emotional deprivation, and communication difficulties.

Initiation and Perpetuation of Sexual Abuse. The cycle of sexual abuse often starts insidiously unless it involves an isolated attack, such as rape. Often offenders spend time with the victims to gain their trust before initiating any sexual contact. Most victims are then pressured into being an accessory to the sexual activity through various means and may be unaware that sexual activity is part of the offer (Box 35.2). Children may not reveal the truth for fear that their parents would not believe them if told, especially if the offender is a trusted

BOX 35.2 Methods Used to Pressure Children Into Sexual Activity

- The child is offered gifts or privileges.
- The adult misrepresents moral standards by telling the child that it is "okay to do."
- Isolated and emotionally and socially impoverished children are enticed by adults who meet their needs for warmth and human contact. The offender asks the child for help in finding a favourite pet or object with which the child can easily identify.
- The offender pressures the victim into secrecy regarding the activity by describing it as a "secret between us" that other people may take away if they find out.
- The offender plays on the child's fears, including fear of punishment by the offender, fear of repercussions if the child tells, and fear of abandonment or rejection by the family.

member of the family. Some fear that they will be blamed for the situation, and many young children with limited vocabulary have difficulty describing the activity when they do have the courage or opportunity to reveal the abuse.

Incest most frequently occurs between fathers and daughters but may be between grandfather and granddaughter or brother and sister. Sibling incest can be just as damaging as father–daughter abuse. Victims may take years to disclose this abuse. However, not all incestuous relationships follow a pattern of silence. Reports of father–daughter incest during child custody conflicts have become more common and have raised serious concerns regarding the possibility of false accusation. Rather than tolerating or denying the child's sexual abuse, the other parent (usually the mother) is typically the chief accuser.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy (MSBP), also known as *medical child abuse* or *factitious disorder by proxy*, is a rare but serious form of child abuse in which caregivers deliberately exaggerate or fabricate histories and symptoms or induce symptoms. It is a form of child maltreatment that may include physical, emotional, and psychological abuse for the gratification of the caretaker. In most cases the perpetrator is the biological mother, with some degree of health care knowledge and training. Health care providers can become easily misled and unknowingly enable the perpetrator. Because of the history of symptoms provided by the caretaker, the child endures painful and unnecessary medical testing and procedures. Common symptoms are seizures, nausea and vomiting, diarrhea, and altered mental status; these symptoms are usually witnessed only by the perpetrator.

Considerations when determining whether a child is a victim of MSBP include the following:

- Is the child's condition consistent with the reported history?
- Does the diagnostic evidence support the reported history?
- Has anyone other than the caretaker witnessed the symptoms?
- Is treatment being provided primarily because of the caretaker's demands?

The resolution of symptoms after separation from the perpetrator confirms the diagnosis.

Nursing and Interprofessional Care

Identification and Assessment of Child Abuse. A critical responsibility of health care providers is identifying abusive situations as early as possible. Nurses who increase their knowledge of the different types of abuse and neglect and underlying causes enhance their ability to identify maltreatment and neglect and to intervene on children's behalf and prevent them from suffering more harm. The characteristics that may predispose members of some families to commit abuse can serve as a framework for assessing vulnerability, but these are never predictive of actual abuse. A careful, detailed history and interview combined with a thorough physical examination are the diagnostic tools needed to identify maltreatment. Nurses have a special role in identifying abuse, because they may be the first person to see the child and parent and are the consistent caregivers if the child is hospitalized (see Guidelines box: Talking With Children Who Reveal Maltreatment).

GUIDELINES

Talking With Children Who Reveal Maltreatment

- Provide a private time and place to talk.
- Do not promise not to tell; tell them that you are required by law to report the abuse.
- Do not express shock or criticize their family.
- Use their vocabulary to discuss body parts.
- Avoid using any leading statements that can distort their report.
- Reassure them that they have done the right thing by telling you.
- Tell them that the abuse is not their fault, that they are not bad or to blame.
- Determine their immediate need for safety.
- Let the child know what will happen when you report the incident.

During the interview with the child and family, the nurse must be careful to avoid biasing the child's retelling of the events. Some experts suggest that health care providers limit the interview to the child's physical and mental health concerns and leave topics of the family's social, legal, or other issues to the police or Child Protection Services. If this is not possible, an effort should be made to coordinate the interview process so that all pertinent health care providers can be present.

Recognition of abuse or neglect requires a familiarity with both the physical and behavioural signs that suggest maltreatment (Box 35.3). No one indicator can be used to diagnose maltreatment. It is a pattern

BOX 35.3 Warning Signs of Child Maltreatment

- Physical evidence of abuse or neglect, including previous injuries
- Conflicting stories about the "accident" or injury from the parents or others
- Cause of injury blamed on sibling or other party
- An injury inconsistent with the history, such as a concussion and broken arm from falling off a bed
- History inconsistent with child's developmental level, such as a 6-month-old turning on the hot water
- A health concern other than the one associated with signs of abuse (e.g., a chief health concern of a cold when there is evidence of first- and second-degree burns)
- Inappropriate response of caregiver, such as an exaggerated or absent emotional response, refusal to sign for additional tests or to agree to necessary treatment, excessive delay in seeking treatment, or absence of parents for questioning
- Inappropriate response of child, such as little or no response to pain, fear of being touched, excessive or lack of separation anxiety, indiscriminate friendliness to strangers
- Child's report of physical or sexual abuse
- Previous reports of abuse in the family
- Repeated visits to emergency facilities with injuries
- Parent or caregiver report of being gone and finding the child unresponsive, indicating absence during the supposed event that resulted in harm

or combination of indicators that should arouse suspicion and further investigation. Some situations may be misinterpreted as abuse, such as bleeding disorders, osteogenesis imperfecta, sudden infant death syndrome, and cultural practices such as cupping or coin rubbing that may mimic physical abuse. Unintentional injuries, such as burns from metal buckles on car seats, bruising from seat belts, or spiral fractures from a twist and fall injury, may also be wrongly diagnosed as abuse. Normal variants, such as dermal melanocytosis and congenital anomalies of genitalia, can also be mistaken for abuse.

Caregiver–child interaction. The initial contact with the family is used to assess the interaction between the caregiver and the child. Observations of the caregivers should include emotional support for the child, attentiveness to the child's needs, and concern for their injury. Although caregivers and children may vary in responses to a stressful event, an unusual caregiver–child relationship should be noted and factored into the overall evaluation of the child.

Certain behavioural responses of the parents to their child and to the interviewer should alert the nurse to the possibility of maltreatment. Abusive parents may have difficulty showing concern toward their child. They may be unable or unwilling to comfort the child. Abusers may blame the child for the injuries or belittle them for being "clumsy" or "stupid." When interacting with health care providers the parent may become hostile or uncooperative. During the child's hospitalization they may not participate in the child's care and may show little concern for the child's progress, eventual discharge, or need for follow-up care.

Abused children's responses to their parents or the injury may also support the suspicion of abuse. Although no one pattern is typical, extremes of behaviour may be observed. Children may be unresponsive to the parent or excessively clinging and intolerant of separation. They may be overly attached to the abusive parent, possibly in the hope of preventing any upset that may precipitate anger and another attack. During care of the injury, children may be passive and accepting of the discomfort or uncooperative and fearful of any physical contact. They may avoid eye contact. Some children maintain a wary watchfulness of all strangers; some shy away from strangers as if frightened; others are unusually affectionate and outgoing.

History and Interview

Child physical abuse. It is often difficult to distinguish child maltreatment from accidental injuries. Caregivers whose history of events may be deceptive or incomplete and children who are nonverbal may make the assessment more complex. A purposeful, skilled history and appropriate interview questions will help the nurse to ensure the right course of action. Knowledge of the mechanism of injury and child development is essential. Cases of abuse are often detected by inconsistencies in child or caregiver history of events compared with physical findings. Children who are verbal can often give a history of the injury. Separating the child from the caregiver may provide a more reliable history. It is important to ask nonleading, open-ended questions. The history should include a narrative of the injury from both the caregiver and child (if verbal). Date, time, and location where the injury took place, along with who was present at the time of the injury, are essential questions. Family history for bleeding or bone disorders is important. Box 35.4 outlines areas of the history that are of concern for potential abuse.

BOX 35.4 Clinical Manifestations of Potential Child Maltreatment

Physical Neglect

Suggestive Physical Findings

Failure to thrive (growth failure)
Signs of malnutrition, such as thin extremities, abdominal distension, lack of subcutaneous fat
Poor personal hygiene
Unclean or inappropriate dress
Evidence of poor health care, such as delayed immunization, untreated infections, frequent colds
Frequent injuries from lack of supervision

Suggestive Behaviours

Dull and inactive affect; excessively passive or sleepy
Self-stimulatory behaviours, such as finger sucking or rocking
Begging for or stealing food
Absenteeism from school
Child's substance use
Vandalism or shoplifting

Emotional Abuse and Neglect

Suggestive Physical Findings

Failure to thrive
Eating or feeding disorder
Enuresis
Sleep disorder

Suggestive Behaviours

Self-stimulatory behaviours, such as biting, rocking, sucking
During infancy, lack of social smile, and anxiety toward strangers
Withdrawal from environment and people
Unusual fearfulness
Antisocial behaviour, such as destructiveness, stealing, or cruelty toward animals or people
Extremes of behaviour, such as being overcompliant and passive, or aggressive and demanding
Lags in emotional and intellectual development, especially language
Suicide attempts or attempts to harm self

Physical Abuse

Suggestive Physical Findings

Bruises and welts
- On face, lips, mouth, back, buttocks, thighs, or areas of torso
- Regular patterns descriptive of object used, such as belt buckle, hand, wire hanger, chain, wooden spoon; squeeze or pinch marks
- May be present in various stages of healing

Burns
- On soles of feet, palms of hands, back, or buttocks
- Patterns descriptive of object used, such as round cigar or cigarette burns; sharply demarcated areas from immersion in scalding water; rope burns on wrists or ankles from being bound; burns in the shape of an iron, radiator, or electric stove burner
- Absence of "splash" marks and presence of symmetrical burns
- Stun gun injury: lesions circular, fairly uniform (up to 0.5 cm) and paired about 5 cm apart

Fractures and dislocations
- Skull, nose, or facial structures
- Injury denoting type of abuse, such as spiral fracture or dislocation from twisting of an extremity or whiplash from shaking the child
- Multiple new or old fractures in various stages of healing

Continued

BOX 35.4 Clinical Manifestations of Potential Child Maltreatment—cont'd

Lacerations and abrasions
- On backs of arms, legs, torso, face, or external genitalia
- Unusual symptoms, such as abdominal swelling, pain, and vomiting from punching
- Descriptive marks such as from human bites or pulling out of hair

Chemical
- Unexplained repeated poisoning, especially drug overdose
- Unexplained sudden illness, such as hypoglycemia from insulin administration

Suggestive Behaviours

Wary of physical contact with adults
Apparent fear of parents or of going home
Lying very still while surveying environment
Inappropriate reaction to injury, such as failure to cry from pain
Lack of reaction to frightening events
Apprehension when hearing other children cry
Indiscriminate friendliness and displays of affection
Superficial relationships
Acting-out behaviour, such as aggression, to seek attention
Withdrawal behaviour

Sexual Abuse

Suggestive Physical Findings

Bruises, bleeding, lacerations, or irritation of external genitalia, anus, mouth, or throat
Torn, stained, or bloody underclothing
Pain on urination or pain, swelling, and itching of genital area
Penile discharge
Sexually transmitted infection, nonspecific vaginitis, or venereal warts
Difficulty in walking or sitting
Unusual odour in the genital area
Recurrent urinary tract infections
Presence of sperm
Pregnancy in young adolescent

Suggestive Behaviours

Sudden emergence of sexually related issues, including excessive or public masturbation, age-inappropriate sexual play, promiscuity, or overtly seductive behaviour
Withdrawn behaviour, excessive daydreaming
Preoccupation with fantasies, especially in play
Poor relationships with peers
Sudden changes, such as anxiety, weight loss or gain, clinging behaviour
In incestuous relationships, excessive anger at mother for not protecting daughter
Regressive behaviour, such as bed-wetting or thumb-sucking
Sudden onset of phobias or fears, particularly fears of the dark, men, strangers, or particular settings or situations (e.g., undue fear of leaving the house or staying at the day care centre or the babysitter's house)
Running away from home
Substance use, particularly of alcohol or mood-elevating drugs
Profound and rapid personality changes, especially extreme depression, hostility, and aggression (often accompanied by social withdrawal)
Rapidly declining school performance
Suicidal attempts or ideation

Neglect and emotional abuse. Each child may manifest different responses to neglect depending on the situation and the child's developmental age. The goal of the interview is to determine whether the child is in a safe environment and whether the caregiver has the skills and resources to care for the child. It is often difficult to determine whether the circumstances constitute poor parenting skills or true neglect. Warning signals of behaviours to look for are found in Box 35.3.

Sexual abuse. An essential component to identifying sexual abuse is the interview. Several dynamics may impede the child's revelation of sexual abuse. Child sexual abuse is often perpetrated by someone known to the child, including family members. In some cases, the children may have been sworn to secrecy. They may have been told that no one will believe them or their family would be harmed if they tell someone about the abuse. Small children may imitate behaviours they have had perpetrated on themselves or have seen others do. Normal, age-related sexual curiosity and self-stimulating behaviours are distinguished. Typically children do not act out specific details of the sexual act or perform intrusive acts on others unless they have sexual knowledge beyond their normal, age-related development (Dubowitz & Lane, 2020).

Children's reports of sexual abuse may vary from contradictory stories to unwavering versions of the experience. Stories that sound contradictory may reflect the child's experiences in several instances of abuse. In addition, children who repeatedly tell identical facts may have been prompted to do so.

Increasing evidence suggests that the types of interrogation that children are exposed to after reports of sexual abuse shape their thinking. To avoid biasing the interaction, nurses must be skillful interviewers when questioning children who may be victims of abuse. Medical records should include verbatim statements made by the child and the interviewer that reflect appropriate nonleading questions and statements. The child may not be emotionally ready to discuss the abuse. Establishing rapport with the child is essential to gain their trust. Interviews should not be rushed. Engaging the child in play activities while encouraging conversation may help the child discuss the abuse. It may take several interviews or psychological counselling for the child to be forthcoming about the abuse. Information regarding the last sexual contact is important because it determines the need for a forensic evaluation. Children who have been sexually abused within the past 72 to 96 hours should be considered for forensic testing.

Unfortunately, there is no typical profile of the victim, and there must be a high index of suspicion to identify these children. Physical signs vary and may include any of those listed for sexual abuse. The victim may exhibit various behavioural manifestations, none of which is diagnostic. When abused children exhibit these behaviours, the signs

may be incorrectly attributed to the normal stresses of childhood, especially in older school-age children or adolescents. Even signs considered most predictive of sexual abuse, such as certain genital findings, sexually inappropriate behaviour for age, enactment of adult sexual activity, and intense focus on sexual activity (e.g., masturbation), do not always indicate that sexual abuse has occurred. Conversely, abused children may not demonstrate more knowledge of sexual activity than nonabused children. However, one difference in the abused children's explanation of sexual activity may be unusual affective responses. For example, abused children may have an increased incidence of conduct disorders, aggressive behaviour, and poor academic performance (Dubowitz & Lane, 2020).

! NURSING ALERT

When children report potentially sexually abusive experiences, their reports need to be taken seriously but also with caution, to avoid alarming the child or falsely accusing someone.

Physical Assessment

Child physical abuse. The goal of the physical assessment for child physical maltreatment is identification of all injuries. A systems approach ensures that the whole body is evaluated. In instances of severe abuse and injuries, the assessment should begin with a rapid assessment of airway, breathing, circulation (ABC) and of neurological systems. A systematic head-to-toe examination follows. Attention to areas often overlooked, such as the scalp, behind the ears, and the lingual frenulum, is essential. The child's exterior genitalia and posterior surface should be completely examined.

The location and a detailed description of all injuries should be recorded. Colour, size, and location of all bruising need to be noted. Burn documentation should include location, pattern, demarcation lines, and presence of eschar or blisters. Diagrams of the injuries using a body diagram form are helpful. If available, photographs of the injuries using a measurement tool should be obtained.

Not all forms of physical abuse have obvious signs. Intra-abdominal organ injury from blunt trauma to the abdomen can occur without signs of external abdominal bruising. Nurses should consider intra-abdominal injury in infants and children who have any other signs of abuse.

! NURSING ALERT

Incompatibility between the history and the injury is probably the most important criterion on which to base the decision to report suspected abuse.

Neglect and emotional abuse. Neglect from deprivation of necessities is easier to identify than emotional neglect or abuse because physical signs are usually evident. Assessment of the child's height, weight, nutritional status, hygiene, and age-appropriate interactions is important for the overall picture of potential neglect. Emotional maltreatment may be readily suspected, but it is difficult to substantiate. Physical signs are often nonspecific, and nurses must rely on behavioural indicators, which range from depression to acting-out behaviour, to help identify a possibly abusive situation. Any persistent and unexplained change in the child's behaviour is an important clue to possible emotional abuse.

Sexual abuse. Identifying instances of sexual abuse is particularly difficult because often, few if any obvious physical indications of the activity exist. Physical signs vary and may include any of those listed in Box 35.4 for sexual abuse. The goal of the physical examination is to document genital findings. In most cases the genital examination is normal, which does not mean that sexual abuse did not occur. Fondling or genital-to-genital contact without penetration may leave no physical findings. Forensic evidence obtained directly from a prepubertal victim's body diminishes greatly after 24 hours, with the best chance for evidence collection coming from bed linens or the child's underwear.

The female genital examination should include a description of the vulva, hymen, and surrounding tissue. Abnormal findings of concern are injuries to the posterior vulva or the lower half of the hymenal ring, or abrasions, bruising, or bleeding of the genital or anal tissue. It is often helpful to use a magnifying instrument (colposcope) to detect subtle injuries. There are many variants of normal findings for female genital anatomy, so it is recommended that the examination be done by a practitioner experienced in these types of cases. Contrary to popular myth, the size of the hymenal opening is not predictive of the likelihood of sexual abuse. For male victims, presence of swelling, abrasions, or bruising of the genital tissue is of concern for abuse. The anal area should be examined for symmetry, tone, fissures, or scars.

Genital tissue heals quickly and most often without scars. Therefore, unless seen within a few days of injury, the genital tissue may appear normal. In addition, the vaginal and anal mucosa is elastic; therefore, penetration without disruption of tissue is possible. This defies another myth that there is always evidence of female virginity. Collection of specimens should be considered for determining the presence of STIs, which may have been contracted during the sexual contact.

Protecting the Child From Further Abuse. Initially, identification of instances of suspected abuse or neglect is essential. The nurse may come in contact with abused children in an emergency department, practitioner's office, home, day care centre, or school.

! NURSING ALERT

The priority is to ensure that the child is not at risk for further injury. This may be involve removing the child from the abusive situation or putting into place supports to decrease stress within families to decrease the risk of further abuse.

All provinces and territories have laws of mandatory reporting of child maltreatment. Suspected child abuse is reported to the local Child Welfare Agency. After a referral has been made, a caseworker is assigned to investigate the report. Based on the findings, the child is left in the home or removed temporarily. The approach is to try to keep the family together if it is safe for the child.

A court proceeding may be necessary before the child can be placed outside the home or when parental rights are to be terminated. When the courts are involved, they usually require firsthand testimony by the referring parties. Nurses may be subpoenaed to appear in court, or their notes may be introduced as evidence in court hearings. Accurate and factual documentation is essential. Behaviours need to be described, not interpreted, and recorded daily to establish a progress record (see Guidelines box: Recording Assessment Data in Suspected Abuse). Conversations among the nurse, child, and parent should be recorded verbatim as much as possible.

GUIDELINES

Recording Assessment Data in Suspected Abuse

History of Injury

- Date, time, and place of occurrence
- Sequence of events with recorded times
- Presence of witnesses, especially person caring for child at time of incident
- Time lapse between occurrence of injury and initiation of treatment
- Interview with child, when appropriate, including verbal quotations and information from drawing or other play activities, such as using a doll to represent the body to demonstrate what happened, which decreases anxiety
- Interview with parent, witnesses, or other significant persons, including verbal quotations
- Description of parent–child interactions (verbal interactions, eye contact, touching, parental concern)
- Name, age, and condition of other children in home (if possible)

Physical Examination

- Nursing physical examination to be done with permission from the child or parent(s)
- Location, size, shape, and colour of bruises; approximate location, size, and shape on drawing of body outline
- Distinguishing characteristics, such as a bruise in the shape of a hand, or a round burn (possibly caused by cigarette)
- Symmetry or asymmetry of injury; presence of other injuries
- Ophthalmic exam for intraocular bleeds
- Degree of pain; any bone tenderness
- Evidence of past injuries; general state of health and hygiene
- Digital photographs with date and time stamp should be taken if there is evidence on the child's body for physical abuse, sexual abuse, or neglect (there may no specialized team outside of urban centres that can do the photography)
- Developmental level of child; perform screening test (see Developmental Assessment, Chapter 33)

Supporting the Child. Children suspected of being abused may be hospitalized for medical management of their injuries and to allow further assessment of their safety needs. The needs of these children are the same as those of any hospitalized child. The child should be treated as a child with the usual physical needs, developmental tasks, and play interests—not as a victim of abuse. The goal of the nurse–child relationship is to provide a role model for the parents in helping them relate positively and constructively to their child and to foster a therapeutic environment for the child in their reprieve from the abusing situation.

Supporting the Family. The nurse also needs to encourage the child's relationship with the parents. The nurse does not become a substitute parent, but rather acts as a role model for parents in helping them to relate positively and constructively to their child. When parental ignorance of child-rearing practices have played a part in the maltreatment, the nurse can educate the parent about children's physical and emotional needs. Because of the parents' own child-rearing, they may not be aware of nonviolent methods of discipline, such as time-out. They may also need help in dealing with their frustration so that they do not vent anger on the child. Because these parents may be sensitive to criticism or perceptions of domination, teaching is best implemented through demonstration and example rather than through lecturing. Any competent parenting abilities they demonstrate should be praised to promote their sense of parental adequacy.

Family members should be advised to encourage the child to resume normal activities and to observe the child for signs of distress. Children express their feelings primarily through behaviour. Parents should be alert for changes in behaviour that indicate distress resulting from the incident, such as remaining in the house, refusing to go to school, changing sleeping patterns, and having more frequent dreams and nightmares. Children should be encouraged to talk about these feelings and nightmares, because the more they talk about the experience, the more they are able to gain control over it.

Referral to appropriate social service agencies is also essential. Some abusive parents live in poverty, and the daily stresses imposed by their circumstances are overwhelming. Resources for financial aid, improved housing, and child care should be sought. Self-help groups can also provide important services. Groups such as Parents Anonymous (a group for parents who have abused or fear that they may abuse their child, but only in terms of physical abuse, not sexual abuse) and Parents United International, Inc. (a group devoted to helping sexually abused families) are accepting and nonjudgemental (see Additional Resources at the end of this chapter).

Planning for Discharge. Discharge planning should begin as soon as the legal disposition for placement has been decided, which may be to return to the parents, temporary foster home placement, or permanent termination of parental rights. The latter is the most drastic solution but is necessary in situations of life-threatening abuse. Whenever children are sent to a foster home they must be allowed an opportunity to express their feelings. No matter how severe the abuse, they usually mourn the loss of their parents. They need help in understanding why they must not return home and that this new home is in no way a punishment. Whenever possible, foster parents should be encouraged to visit the child in the hospital, and the nurse should take an active role in helping these new parents understand the child and the child's health care needs. Studies have shown that the health care needs of children in foster care can go unmet (Beal et al., 2018).

Preventing Abuse. Prevention of child maltreatment has been an extremely difficult goal. Programs aimed at identifying potential abusers and instituting supportive intervention before the occurrence of an abusive act have met with variable success. However, nurses have played an important role in such programs. For example, nurses in prenatal clinics can prepare expectant families for adjustment to parenthood. Postpartum nurses can foster the attachment process by encouraging parents to hold and look at their newborn and by teaching coping mechanisms for prolonged crying. Nurses in neonatal intensive care units can minimize the effects of separation by encouraging parents to visit and can help parents become comfortable caring for their child. Nurses in ambulatory settings can teach parents appropriate methods of bathing, feeding, toileting, and disciplining their child and of preventing injuries, while stressing the normal needs and developmental characteristics of children. Nurses must be sensitive to parental needs for attention, reassurance, and reinforcement and should refer parents to community services and self-help groups as needed.

Unlike preventive efforts for neglect and physical abuse, which are aimed at the potential offender, prevention of child sexual abuse centres on education of children to protect themselves. Materials are available for parents that describe sexual abuse and its prevention (see Additional Resources at the end of the chapter). Supporting parental qualities of respect, affection, empathy, and ability to set boundaries and providing high-quality child care and education represent the true preventive approach to sexual abuse. Helpful games such as "What if the babysitter wants to wrestle and hug but tells you to keep it a secret?" can be used to explore dangerous situations in advance and help children learn the importance of saying "no." They need reassurance that no matter what the other person says or does, the parents want to know about it and will

not punish them. Even if children participate in the activity before telling the parents, they must be reassured that it was not their fault.

It is equally important to teach children safety in terms of potential risk situations. Several suggestions for parents regarding protecting and educating children against possible molestation are presented in the Family-Centred Care box: Preventing or Dealing With Sexual Abuse of Children. The nurse is frequently in a position to discuss the topic of abuse with parents and to provide guidelines.

FAMILY-CENTRED CARE

Preventing or Dealing With Sexual Abuse of Children

Sexual assault of children is much more common than most people realize. It may be preventable if children have good preparation. To provide protection and preparation, the following measures can be taken:

- Pay careful attention to who is around children. (Unwanted touch may come from someone liked and trusted.)
- Back up a child's right to say "no."
- Encourage communication by taking seriously what children say.
- Take a second look at signals of potential danger.
- Refuse to leave children in the company of those not trusted.
- Include information about sexual assault when teaching about safety.
- Provide specific definitions and examples of sexual assault.
- Remind children that even "nice" people sometimes do mean things.
- Urge children to tell about anybody who causes them to be uncomfortable.
- Prepare children to deal with bribes, threats, and possible physical force.
- Eliminate secrets between children and parents.
- Teach children how to say "no," ask for help, and control who touches them and how.
- Model self-protective and limit-setting behaviour for children.

Should it ever become necessary to help a child recover from a sexual assault:

- Listen carefully to understand children.
- Support the child for telling through praise, belief, sympathy, and lack of blame.
- Know local resources and choose help carefully.
- Provide opportunities to talk about the assault.
- Provide opportunities for the entire family to go through a recovery process.

Sexual assault affects everyone. To help deal with this social issue:

- Provide care and support to those who have been victimized.
- Recognize that offenders do not change without intervention.
- Organize neighbourhood programs to support each other's efforts to protect children.
- Encourage schools to provide information about sexual assault as an issue of health and safety.
- Organize community groups to support educational treatment and law enforcement programs.

IMMUNIZATIONS

One of the most dramatic advances in pediatrics has been the decline of infectious diseases during the twentieth century because of the widespread use of immunization for preventable diseases. This trend has continued into the twenty-first century with the development of newer vaccines. Although many of the immunizations can be given to individuals of any age, the recommended primary schedule begins during infancy and, with the exception of boosters, is completed during early childhood. Therefore, health promotion includes a discussion of immunizations for diphtheria, tetanus, and acellular pertussis (DTaP); poliovirus; measles, mumps, and rubella (MMR); *Haemophilus influenzae* type b (Hib); hepatitis A virus (HAV); hepatitis B virus (HBV); pneumococcal conjugate vaccine (PCV); influenza; meningococcal; and varicella-zoster virus (VZV; chickenpox).

In Canada most vaccines are included in publicly funded immunizations programs. PHAC has a nationally notifiable diseases list that contains communicable diseases that have been identified by the federal government and all provinces and territories as priorities for monitoring and control efforts. The public can access the website and discover the trends in these communicable diseases since 1924 (PHAC, 2021).

Vaccine Hesitancy

Canada does not rank well in comparison with other developed countries in attaining optimal levels of vaccines among children and adolescents (MacDonald et al., 2018/2020; UNICEF, 2013). In recent years, childhood vaccines have been widely criticized, and fear related to vaccine components has prompted vaccine hesitancy in some people. Many of the diseases for which children are vaccinated are rarely seen on a large-scale basis, leading some parents to believe that such vaccines are no longer necessary in the twenty-first century. A variety of misinformation is available, especially on the Internet, suggesting that parents avoid childhood vaccines altogether. Unfounded fears and lack of knowledge of contraindications can needlessly prevent a child from having protection from life-threatening diseases. Issues that have surfaced regarding vaccines include the misconception that administering combination vaccines may overload the child's immune system; the combined vaccines have undergone rigorous study in relation to adverse effects and immunogenicity rates following administration. Others may express concern that vaccines are not a part of the individual's natural immunity and that administering too many vaccines may decrease the child's immunity to such diseases. Another concern of parents is the number of vaccines or "shots" given to infants at any given time and the pain and discomfort this may cause (MacDonald et al., 2018/2020).

It is the nurse's responsibility to provide parents with accurate information about vaccine safety, benefits, and risks so that they can make informed decisions regarding vaccinations for their children. The advantage of widespread media via television and the Internet is that information is readily available at any given moment; the disadvantage is that some of this information may be incorrect, incomplete, or misleading and may influence parents to make decisions that may have deleterious consequences for their children's health. To help parents make informed decisions about immunizations for their children, parents may be directed to resources such as the CPS's *A Parent's Guide to Immunization Information on the Internet*. Nurses should address parents' concerns about childhood vaccines and avoid judgemental attitudes regarding the parents' decision to not vaccinate their children.

Schedule for Immunizations

In Canada, recommendations for immunization are from the National Advisory Committee on Immunization, under the authority of the Minister of Health and the PHAC (see Additional Resources at the end of this chapter). The recommendations for which age the vaccines are administered are made on the basis of earliest age an infant can develop antibodies to the disease. These recommendations are interpreted differently among the provinces and territories, so children may receive vaccines at different ages across the country (Figure 35.16). For some time, the CPS has been lobbying for a harmonized countrywide schedule, which is the standard in other industrialized countries. The current system is very confusing, with some vaccines given at different ages (e.g., Hepatitis B) (MacDonald et al., 2011/2018). Many countries also have different immunization recommendations, so it is important that nurses obtain immunization information from the family when their children are being immunized.

Canada's Provincial and Territorial Routine (and Catch-up) Vaccination Schedule for Infants and Children

This table summarizes the current routine vaccination schedule for infants and children in all provinces and territories across Canada. Changes to this schedule are updated regularly in collaboration with the Canadian Nursing Coalition for Immunization (CNCI) and the Canadian Immunization Committee (CIC) schedules for each province or territory can be found here. Additional information is available on Canada.ca/vaccines (last update: January 2020).

VACCINES		Provincial & Territorial Vaccination Schedules												
Abbreviations	Description	BC	AB	SK	MB	ON	QC[6]	NB	NS	PE	NL	YT	NT	NU
DTaP-IPV-Hib	Diphtheria, Tetanus, acellular Pertussis, Inactivated Polio Virus, *Haemophilus Influenzae* type B vaccine	Age: 18 mos	Age: 18 mos	Age: 2,4,6,18 mos	Age: 2,4,6,18 mos	Age: 2,4,6,18 mos	Age: 12 mos[4]	Age: 2,4,6,18 mos	Age: 2,4,6,18 mos	Age: 18 mos	Age: 2,4,6,18 mos	Age: 18 mos	Age: 2,4,6,18 mos	Age: 2,4,6,18 mos
DTaP-HB-IPV-Hib	Diphtheria, Tetanus, acellular Pertussis, Hepatitis B, Inactivated Polio Virus, *Haemophilus Influenzae* type B vaccine	Age: 2,4,6 mos	Age: 2,4,6 mos				Age: 2,4 mos[4]			Age: 2,4,6 mos		Age: 2,4,6 mos		
Tdap-IPV	Tetanus, diphtheria (reduced toxoid), acellular pertussis (reduced toxoid), Inactivated Polio Virus vaccine	Age: 4-6 yrs	Age: 4 yrs	Age: 4-6 yrs	Age: 4-6 yrs	Age: 4-6 yrs	Age: 4-6 yrs	Age: 4 yrs	Age: 4-6 yrs	Age: 4-5 yrs	Age: 4-6 yrs[7]	Age: 4-6 yrs	Age: 4-6 yrs[7]	Age: 4-6 yrs
Tdap	Tetanus, diphtheria (reduced toxoid), acellular pertussis (reduced toxoid) vaccine	Grade 9	Grade 9	Grade 8	Grade 8,9	Age: 14-16 yrs		Grade 7	Grade 7	Grade 9	Grade 9	Grade 9	Grade 7	Grade 6
Td	Tetanus, diphtheria (reduced toxoid),						3rd year of high school							
BCG	Bacille Calmette-Guérin (BCG) Vaccine													Age : At birth
HAHB	Hepatitis A vaccine, Hepatitis B vaccine						Age: 18 mos[4] 4th year of primary school							
HB	Hepatitis B vaccine	HB is provided in a 3-dose combination vaccine (DTaP-HB-IPV-Hib) in infancy	(2-dose) Grade 6	(2-dose) Grade 6	(2-dose), Grade 6	(2-dose) Grade 7	HB is provided in a combination vaccine (DTaP-HB-IPV-Hib) in infancy and HAHB in adolescents[5]	Age: At birth,2,6 mos	(2-doses) Grade 7	HB is provided in a 3-dose combination vaccine (DTaP-HB-IPV-Hib) in infancy	(2-dose) Grade 6	HB is provided in a 3-dose combination vaccine (DTaP-HB-IPV-Hib) in infancy	Age: At birth,1,6 mos	Age: At birth,1,9 mos
MMR	Measles, Mumps, Rubella vaccine	Age: 12 mos				Age: 12 mos						Age: 12 mos		
Var	Varicella vaccine	Age: 12 mos		(2nd dose) Grade: 6		Age: 15 mos	Age: 4-6 yrs[4]	(2nd dose) Grade 9				Age: 12 mos		Grade 6
MMR-V	Measles, Mumps, Rubella, Varicella vaccine	2nd dose Age: 4-6 yrs	Age: 12 mos, 4yrs	Age: 12,18 mos	Age: 12 mos, 4-6yrs	2nd dose Age: 4-6 yrs	Age: 12,18 mos[4]	Age: 12,18 mos	Age: 12 mos, 18 mos-6 yrs	Age: 12,18 mos	Age: 12,18 mos	(2nd dose) Age: 4-6 years	Age: 12,36 mos	Age: 12, 18mos
Men-C-C	Meningococcal conjugate (Strain C) vaccine	Age: 2,12 mos	Age: 4,12 mos	Age: 12 mos	Age: 12 mos	Age: 12 mos	Age: 18 mos[4] 3rd year of high school[4]	Age: 12 mos	Age: 12 mos	Age: 12 mos	Age: 12 mos	Age: 2,12 mos	Age: 2,12 mos	Age: 12 mos
Men-C-ACYW-135	Meningococcal conjugate (Strains A, C, Y, W135) vaccine	Grade 9	Grade 9	Grade 6	Grade 6	Grade 7		Grade 9	Grade 7	Grade 9	Grade 4	Grade 9	Grade 12[1]	Grade 9
Pneu-P-23	Pneumococcal polysaccharide (23-valent) vaccine													Age: 2-3 yrs
Pneu-C-13	Pneumococcal conjugate (13-valent) vaccine	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 12 mos	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 2,4,12 mos	Age: 2,4,6,12 mos	Age: 2,4,12 mos	Age: 2,4,6,18 mos	Age: 2,4,6,15 mos
Pneu-C-10	Pneumococcal conjugate (10-valent) vaccine						Age: 2,4,mos							
Rota	Rotavirus vaccine	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4, 6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos	Age: 2,4,6 mos
HPV	Human Papillomavirus vaccine	(2-dose) Grade: 6	(2-dose) Grade 6	(2-dose) Grade 6	(2-dose) Grade 6)	(2-dose) Grade 7 (2 or 3 -dose) Grades 8, to 12[2] Grade 10[3]	(2-dose) 4th year of primary school	(2-dose) Grade 7	(2-dose) Grade 7	(2-dose) Grade 6	(2-dose) Grade 6	(2-dose) Grade 6	(9-14 yrs: 2-dose 15 yrs +: 3-dose) Grade 4-6	(2-dose) Grade 6

Public Health Agency of Canada / Agence de la santé publique du Canada

Canada

Fig. 35.16 Canada's provincial and territorial routine (and catch-up) vaccination routine schedule programs for infants and children. (Source: Public Health Agency of Canada [2019].)

Nurses also need to keep informed of the latest advances and changes in immunization policies and guidelines.

Children who began primary immunization at the recommended age but then fail to receive all of the doses do not need to begin the series again but instead should receive only the missed doses (Government of Canada, 2021c). For situations in which there is doubt that the child will return for immunization according to the optimum schedule, HBV vaccine (HepB), DTaP, IPV (poliovirus vaccine), MMR, varicella, and Hib vaccines can be administered simultaneously at separate injection sites.

Strategies that may ensure parents follow immunization guidelines include giving parents vaccine information at the time of the newborn's discharge, mailing reminder cards, making immunization services readily available, removing barriers to vaccination (such as long waiting times, transportation to appointments, and appointment-only systems), and taking every opportunity to immunize children when they enter a health care facility (such as emergency departments, clinics, private offices, and hospitals). It is important to consider all the reasons a person may not be keeping up with an immunization schedule and not to label them as negligent as there can be multiple factors involved in this issue.

Recommendations for Routine Immunizations

Because of constant changes in the pharmaceutical industry, trade names of some single and combination vaccines in this section may differ from those currently available. The reader is encouraged to access the *Canadian Immunization Guide* (see Additional Resources), which is updated periodically.

Hepatitis B Virus (HBV). Hepatitis B is a significant pediatric disease because HBV infections that occur during childhood and adolescence can lead to fatal consequences from cirrhosis or liver cancer during adulthood. Up to 90% of infants infected perinatally and 25 to 50% of children infected before age 5 years become HBV carriers. In addition, the incidence of HBV infection increases rapidly during adolescence (Government of Canada, 2021a). HBV is a highly infectious disease that can be transmitted by blood and infected body fluids and can be prevented by vaccination. While Canada is a region of low endemicity, certain vulnerable populations, including Indigenous people, men who have sex with men, street youth, and people who are or have been incarcerated, are disproportionately affected. The low prevalence is mainly attributable to Canada's universal HBV immunization programs. See Chapter 46 for more information on hepatitis.

Since the early 1990s, all provinces and territories have had either a universal school-based hepatitis B vaccination program aimed at children aged 9 to 13 years or an infant vaccination program (Government of Canada, 2021a) (see Figure 35.16). In jurisdictions where the first dose is not given at birth, HepB vaccine is recommended for infants born to mothers with acute or chronic hepatitis B infection, as well as infants who are household contacts of individuals with acute hepatitis B or chronic carriers of hepatitis B. HepB vaccine can be considered for infants born to mothers with hepatitis C infection (Lemyre et al., 2018) (see Chapter 26, Immunizations). Parental consent must be obtained before administering the medication. If the mother's status is unknown, testing should be done at the time of birth. If maternal HBV status is not available within 12 hours after birth, serious consideration should be given to administering HepB vaccine and hepatitis B immunoglobulin (HBIG) while the results are pending, taking into account the mother's risk factors and erring on the side of providing vaccine and HBIG if there is any suspicion that the mother could be infected (Government of Canada, 2021a).

The vaccine is given intramuscularly in the vastus lateralis in newborns (see Figure 26.4) or in the deltoid for older infants and children. Regardless of age, the dorsogluteal site should never be used for intramuscular injections because it has been associated with low antibody **seroconversion** rates, indicating a reduced immune response. The vaccine can be safely administered simultaneously at a separate site with DTaP, MMR, and Hib vaccines.

Hepatitis A Virus (HAV). Hepatitis A has been recognized as a significant child health concern, particularly in communities with unusually high infection rates. HAV is spread by the fecal–oral route and from person-to-person contact, by ingestion of contaminated food or water, and rarely by blood transfusion. The illness has an abrupt onset, with fever, malaise, anorexia, nausea, abdominal discomfort, dark urine, and jaundice being the most common clinical signs of infection. In children younger than 6 years of age, who represent approximately one third of all cases of hepatitis A, the disease may be asymptomatic, and jaundice is rarely evident.

In Canada, universal HepA vaccination is not recommended. Individuals at risk, such as those living in communities where hepatitis A is endemic or those travelling to countries where HAV is endemic, should be immunized (Government of Canada, 2021a). If HepA vaccine is given, it is given in a two-dose series with the second dose administered no sooner than 6 months after the first dose. The combination HepA/HepB vaccine is recommended for individuals at increased risk for hepatitis A and/or B infection. Quebec is the only province and territory that recommends the combination vaccine at 18 months and catch-up in the fourth year of primary school (Government of Quebec, 2021).

Diphtheria. While diphtheria is still endemic in some countries, in the last 20 years less than five cases per year have been reported in Canada, with the majority of these occurring in children less than 14 years of age (Government of Canada, 2021a). Diphtheria can result in significant morbidity with death occurring in 5 to 10% of cases (Government of Canada, 2021a). Respiratory manifestations include respiratory nasopharyngitis or obstructive laryngotracheitis with upper airway obstruction. Diphtheria can also cause infections on the skin that show up as rashes or ulcers (Government of Canada, 2018b).

Diphtheria vaccine is commonly administered (1) in combination with tetanus and acellular pertussis vaccines (DTaP) or DTaP and Hib vaccines for children younger than 7 years of age; (2) in combination with a conjugate Hib vaccine; (3) in a combined vaccine with tetanus (Td) for children younger than 7 years of age who have some contraindication to receiving pertussis vaccine; or (4) as a single antigen when combined antigen preparations are not indicated. All children get four doses of the combined vaccine. See Figure 35.16 for the schedule of doses. Although the diphtheria vaccine does not produce absolute immunity, protective antitoxin persists for 10 years or more when given according to the recommended schedule, and boosters are given every 10 years for life (Government of Canada, 2021a).

Tetanus. Tetanus (also known as "lockjaw") is an infection spread by a bacterium and is totally preventable through vaccination. The bacterium is present in dirt, soil, and dust but can also be found in the intestinal tracts of humans and animals, especially herbivorous animals. The organisms are not invasive but enter the body by way of wounds, particularly a puncture wound, burn, or an unnoticed break in the skin (such as a thorn or needle prick, bee sting, or scratch). Tetanus affects the nerves that control muscles; they become stiff and painful and also make swallowing and breathing difficult. Additional symptoms include

headache, seizures, fever, diaphoresis, high blood pressure, and tachycardia. Without proper intervention, tetanus can be fatal.

Tetanus is a rare disease in Canada because of tetanus immunizations. Only eight deaths due to tetanus have been reported since 1990 (Government of Canada, 2021a).

Two forms of tetanus vaccine—tetanus toxoid and tetanus immune globulin (TIG) (human)—are available. Tetanus toxoid is used for routine primary immunization, usually in one of the combinations listed for diphtheria, and provides protective antitoxin levels for approximately 10 years. For wound management, **passive immunity** is available with TIG. This is recommended for children who have immune deficiency, in addition to the vaccine.

Pertussis. Pertussis (whooping cough) is a highly contagious infection of the respiratory tract caused by the bacterium *Bordetella pertussis* that is preventable by vaccination (see Chapter 45 for further discussion). Pertussis is a cyclical disease in Canada with peaks in activity occurring every 2 to 5 years (Government of Canada, 2018b). Outbreaks have been reported in a number of Canadian provinces (Halperin, 2014). The outbreaks have been mainly in children under 14 years of age, although rates are higher in children under 1 year of age who may not have effective immunity. Some of these outbreaks have resulted in deaths. Under-immunization, particularly among communities that refuse childhood immunization, may have contributed to the increase in pertussis rates (Government of Canada, 2021a; Halperin, 2014). In 2019, there were outbreaks in Alberta with 42 confirmed cases (Rieger & Canadian Broadcasting Corporation, 2019).

Pertussis vaccine is recommended for all children 6 weeks through 6 years of age (up to the seventh birthday) who have no neurological contraindications to its use. Concerns over outbreaks of the disease in the past decade have prompted discussion about vaccinating infants and adults. Many cases of pertussis have been seen in children less than 6 months or persons over 7 years of age, both groups falling in the category for which there was inadequate vaccine protection from pertussis infection (Government of Canada, 2021a).

Pertussis vaccine is only available as an acellular preparation in combined form with other agents such as diphtheria (D) and tetanus (T) toxoids with or without inactivated polio vaccine (IPV) and Hib conjugate vaccine (Hib) (see Figure 35.16). The acellular pertussis vaccine contains one or more immunogens derived from the *B. pertussis* organism.

Adolescents 11 to 16 years of age should receive a single tetanus–diphtheria–acellular pertussis (Tdap) vaccine if they have received the recommended childhood series of diphtheria–tetanus–acellular pertussis (DTaP) immunizations. This vaccine is now necessary because of the increased incidence of pertussis seen in adolescents and adults who were previously immunized with the DTaP series. Adolescents who have received tetanus-diphtheria (Td) but not Tdap vaccine should also receive a single dose of the Tdap vaccine, provided 5 years have elapsed between the Td and Tdap vaccination (Government of Canada, 2021a). In order to prevent newborns under 2 months from getting pertussis, it is recommended that pregnant patients receive one dose of Tdap, ideally between 27 and 32 weeks of gestation, regardless of their immunization history (Government of Canada, 2015).

Health care and child care workers who may be susceptible to pertussis as a result of waning immunity and who have potential exposure to children or adults with pertussis should receive a single dose of Tdap if this vaccine was not previously administered in adulthood, even if the person is not due for a tetanus and diphtheria booster, and take the necessary protective precautions against droplet contamination (wear procedural or surgical masks and practise hand hygiene). The diagnosis of pertussis may be missed or delayed in unvaccinated infants, who often are seen with respiratory distress and apnea without the typical cough.

Polio. Poliomyelitis is a disease that may cause irreversible paralysis in 1 out of 200 polio infections. Among those paralyzed, 5 to 10% die when their breathing muscles become immobilized. It is a highly infectious disease that is spread from person to person, principally through the fecal–oral route (Government of Canada, 2018b). The Global Polio Eradication Initiative (GPEI) has eliminated wild-type 2 poliovirus from global circulation (Government of Canada, 2018b). Canada was certified polio-free in 1994. Polio is still endemic in Nigeria, Afghanistan, and Pakistan. Cases due to wild poliovirus have decreased by over 99% since 1988, from an estimated 350 000 cases then to 33 reported cases in 2018 worldwide (WHO, 2019a).

An all-inactivated polio virus (IPV) schedule for routine childhood polio vaccination is now recommended; oral poliovirus (OPV) is no longer used in Canada. For routine immunization beginning in infancy, four doses of IPV are recommended, in combination with other routinely administered vaccines (DTaP and Hib) at 2 months, 4 months, 18 months, and 4 to 6 years of age (preschool booster) (see Figure 35.16). The fourth dose is not needed if the third dose is given on or after the fourth birthday. It is acceptable to give an additional dose of IPV at 6 months of age for convenience of administration in combination with DTaP and Hib (Government of Canada, 2021a).

The change from the exclusive use of OPV to the exclusive use of IPV is related to the rare risk of vaccine-associated polio paralysis (VAPP) from OPV. The exclusive use of the IPV vaccine eliminates the risk for VAPP but is associated with an increased number of injections.

It is important for all health care providers to remain vigilant about polio vaccinations. One infected child puts children in all countries at risk and could result in as many as 200 000 new cases every year, and within 10 years, all over the world. Afghanistan, Nigeria, and Pakistan remain the only three countries with individuals with active polio infections (WHO, 2019a). Adults and children can still get infected with polio if travelling to a country that has polio infections. Travellers should check with their health care provider to see if they need a booster at least 6 weeks ahead of entering the country.

Measles. Measles is a highly contagious, serious respiratory viral disease characterized by fever, cough, coryza, conjunctivitis, and generalized maculopapular erythematous rash. Measles infection can result in serious complications such as blindness, encephalitis, or severe respiratory infections such as pneumonia and is preventable by vaccination. The World Health Organization (WHO, 2020b) reported that there is an increase in the number of measles outbreaks worldwide and that in 2019 an estimated 207 500 people, died from measles. Even with implementation of routine immunization, measles continues to circulate globally due to suboptimal vaccination coverage and population immunity gaps. Any community with less than 95% population immunity is at risk for an outbreak (WHO, 2020b).

In 2019, 113 cases of measles were reported among several Canadian provinces (Government of Canada, 2020). Several factors contributed to this outbreak: increased travel of Canadians importing the disease, an increased incidence of measles in countries with a high population exchange with Canada (France, the Netherlands, the Philippines), and suboptimal immunization coverage in small pockets across Canada (Government of Canada, 2020). Parents who have infants under 1 year of age who have not been immunized need to be encouraged to be vigilant about exposure of their child to

nonimmunized children and watch for the signs and symptoms of measles, if exposed.

For routine immunization of all children, two doses of measles vaccine should be given. Infants should receive a first dose combined with MMR vaccine on or shortly after their first birthday; the second dose should be given after 15 months of age but before school entry. The MMR vaccine is an attenuated live virus vaccine. Children with immune deficiencies should not receive the MMR vaccine because of a lack of evidence of its safety in this population. See Figure 35.16 for the catch-up schedule for children who have missed this immunization.

Vaccine may be recommended for children less than 12 months of age during outbreaks or before international travel to an area where measles is common. MMR vaccine may be given as early as 6 months of age. Under these circumstances, or if vaccine was inappropriately given before the child's first birthday, two doses of MMR should still be given after the first birthday.

Individuals born before 1970 are thought to be immune from exposure to natural measles virus. Because of the continuing occurrence of measles in older children and young adults, potentially susceptible adolescents and young adults should be identified and immunized if two doses of measles vaccine have not been administered previously or the person had a confirmed case of the illness (Government of Canada, 2021a).

Mumps. Mumps is an acute infectious disease caused by the mumps virus that is preventable by vaccination. Mumps virus vaccine is recommended for children 12 to 15 months of age and is typically given in combination with measles and rubella. It should not be administered to infants younger than 12 months of age because persisting maternal antibodies can interfere with the immune response.

Because of recent outbreaks of the disease, especially in children 10 to 19 years of age, mumps immunization is recommended for all individuals born after 1957 who may be susceptible to mumps (i.e., those who have no history of having had the disease or vaccine and who have no laboratory evidence of immunity).

Large Canadian outbreaks have been rare in recent years, but from 2007 to 2010, large mumps outbreaks were reported in several Canadian provinces. In several of the outbreaks, the most mumps cases occurred in individuals aged 20 to 29 years, many of whom had received only one dose of a mumps-containing vaccine. Other outbreaks occurred in communities that had low vaccination rates. These outbreaks tended to be in a younger age group and similar to outbreaks that were seen in the pre-vaccine era. In January 2017 to February 2018, there was an outbreak of 143 cases in Toronto among mostly young adults who had frequently visited the downtown bars and restaurants. Almost 30% were fully vaccinated with two doses of mumps-containing vaccine, which showed that even two doses may not provide complete protection (Dubey et al., 2018).

Rubella. Rubella is a relatively mild infection in children, but in a pregnant patient the actual infection presents serious risks to the developing fetus. Therefore, the aim of rubella immunization is actually protection of the unborn child rather than the recipient of the immunization.

One dose of rubella-containing vaccine (MMR) is recommended routinely for all children on or as soon as practical after their first birthday. The second dose, given for measles protection, should be given after 15 months of age and before school entry. Increased emphasis should also be placed on vaccinating all unimmunized prepubertal children and susceptible adolescents and adult persons in the childbearing age group. Because the live attenuated virus may cross the placenta and theoretically present a risk to the developing fetus, rubella vaccine is currently not given to any pregnant patient. Postpubertal females without evidence of rubella immunity should be immunized unless they are pregnant; they should be counselled not to become pregnant for 28 days after receiving the rubella-containing vaccine (Government of Canada, 2021a).

Varicella. Varicella (chickenpox) is caused by the varicella-zoster virus (VZV) and is preventable by vaccination. In Canada, children receive two doses of vaccine. Administration of the cell-free live-attenuated varicella vaccine (Varivax) is recommended for any susceptible child (one who lacks proof of varicella vaccination or has a reliable history of varicella infection). Children 13 years of age or older who are susceptible should receive two doses of univalent vaccine only, which is to be administered at least 4 weeks apart.

Varicella vaccine may be administered simultaneously with MMR. Two doses of varicella-containing vaccine can be used, either univalent varicella or combination MMRV vaccine. If they are not administered simultaneously, the interval between administration of varicella vaccine and MMR should be at least 1 month. Varicella vaccine may also be given simultaneously with DTaP, IPV, HBV, or Hib (Government of Canada, 2021a).

Pneumococcal Infections. Streptococcal pneumococci are responsible for a number of bacterial infections called *invasive pneumococcal disease* (IPD) in children under 2 years of age, which may cause serious morbidity and mortality. Among these are generalized infections such as septicemia and meningitis or localized infections such as otitis media, sinusitis, and pneumonia. These illnesses are particularly problematic in children who attend day care facilities (the incidence among children in day care centres is two to three times higher than in children not attending out-of-home day care) and in those who are immunocompromised.

There are two major types of vaccine to prevent IPD: conjugate pneumococcal vaccines and pneumococcal polysaccharide vaccines. The pneumococcal conjugate vaccine (Prevnar) is approved for use in Canada for children from 6 weeks to 9 years of age and is composed of the purified polysaccharides of the capsular antigens of seven *Streptococcus pneumoniae* serotypes, individually conjugated to CRM197 (cross-reacting material 197), a purified nontoxic variant of diphtheria **toxin**. The pneumococcal conjugate (13-valent) vaccine is recommended for routine immunization of infants up to 12 months. The polysaccharide vaccine is recommended for those over the age of 2 years who are at high risk of IPD and for all healthy adults. The vaccine can prevent 24 of the 92 recognized serotypes of *S. pneumoniae*, invasive disease. Resistance to some of the serotypes is developing, so prevention is very important (Government of Canada, 2021a).

The recommended optimal schedule for infants is three to four doses of the conjugate vaccine administered between 2 and 18 months of age, depending on the province or territory schedule (see Figure 35.16). Infants of very low birth weight (less than 1 500 g) should be given their first dose according to their chronological age and not their calculated gestational age.

Conjugate pneumococcal vaccine is recommended for routine administration to all children 23 months of age or younger. It is also recommended for children 24 to 59 months of age at higher risk of IPD: those who attend child care centres; those who have sickle cell disease and other sickle cell hemoglobinopathies or who have other types of functional or anatomical asplenia, HIV infection, immunocompromising conditions (e.g., primary immunodeficiencies; malignancies; conditions resulting from immunosuppressive therapy, solid organ transplantation, or the use of long-term systemic corticosteroids;

nephrotic syndrome), or chronic medical conditions (e.g., chronic cardiac and pulmonary disease such as bronchopulmonary dysplasia, diabetes mellitus, chronic renal disease, or cerebrospinal fluid leak); and children with cochlear implants or those receiving cochlear implants (Government of Canada, 2021a).

The polysaccharide vaccine (PPV) should be given to all individuals older than 5 years of age who have not received the vaccine previously and who are at higher risk of IPD (Government of Canada, 2021a).

***Haemophilus influenzae* Type B (Hib).** Hib conjugate vaccines protect against a number of serious infections caused by *H. influenza* type b, especially bacterial meningitis, epiglottitis, bacterial pneumonia, septic arthritis, and sepsis (Hib is not associated with the viruses that cause influenza, or "flu"). Hib vaccines that are currently available in Canada are conjugate vaccines that connect Hib to a nontoxic form of another organism, such as meningococcal protein or diphtheria protein. While there is no **antibody** response to these nontoxic proteins, they significantly improve the antibody response to Hib, especially in infants. The use of combination vaccines provides equivalent immunogenicity and decreases the number of injections an infant receives; however, it is important that they be given to the appropriate-age child (Government of Canada, 2021a).

All Canadian provinces and territories include Hib conjugate vaccine in their immunization program for children (see Figure 35.16). Hib vaccine is not routinely recommended for children 5 years and older. However, children with sickle cell disease, leukemia, or HIV infection or children who have had a splenectomy may benefit from one dose of the Hib vaccine (Government of Canada, 2021a). When possible, the Hib conjugate vaccine used at the first vaccination should be used for all subsequent vaccinations in the primary series.

Influenza. Influenza vaccine may be administered to any healthy individual for whom contraindications are not present. The influenza vaccine is recommended annually for children starting at 6 months to 18 years of age. Influenza vaccine (inactivated influenza vaccine [IIV]) may be given to healthy children 6 months of age and older. The vaccine is administered in early fall before the flu season begins and is repeated yearly for ongoing protection (Government of Canada, 2021a).

There are two quadrivalent flu vaccines available with strains of influenza A and B. One is inactivated intramuscular influenza vaccine (IIV) and is recommended for all children 6 months and older. The intramuscular vaccine is administered as two separate doses 4 weeks apart in first-time recipients younger than 9 years of age. The dose is 0.25 mL for children 6 to 35 months of age and 0.5 mL for children 3 years of age and older. The vaccine may be given simultaneously with other vaccines but in a separate syringe and at a separate site. The other vaccine is an intranasal, live attenuated influenza vaccine (LAIV). For non-immunocompromised, children 2 years of age or older, either IIV or LAIV may be used. Either IIV or LAIV can be given to individuals with egg allergy but should have the vaccine in a setting where anaphylaxis can be managed (Moore & CPS, Infectious Diseases and Immunization Committee, 2021). The vaccine is administered yearly because different strains of influenza are used each year in the manufacture of the vaccine.

Meningococcal Infections. Invasive meningococcal disease (IMD) is an acute and serious communicable disease caused by the bacterium *Neisseria meningitides*. This bacterium results in meningitis or septicemia as well as a characteristic nonblanching petechial or purpuric rash (Government of Canada, 2018b). Meningococcal infections are also responsible for significant morbidities, including limb or digit amputation, skin scarring, hearing loss, and neurological disabilities.

The National Advisory Committee on Immunization (NACI) recommends routine immunization against meningococcal disease and the Committee to Advise on Tropical Medicine and Travel (CATMAT) recommends immunization before travel to high-risk meningococcal destinations (Government of Canada, 2021a).

Infants younger than 1 year of age are particularly susceptible, yet the highest fatalities occur in adolescents (approximately 20%). There is also evidence that the risk for meningococcal infections is high in college freshmen living in dormitories. An average of 298 cases of meningococcal disease have been reported annually. Disease occurs year-round, but with seasonal variation, with most cases occurring in the winter months (Government of Canada, 2018b).

Meningococcal C conjugate vaccines are recommended for routine immunization of infants (see Figure 35.16). There are routine programs for serogroup C vaccine at 12 months of age, with some provinces and territories routinely providing additional earlier doses. Adolescents routinely receive a booster dose of serogroup C vaccine or of a quadrivalent (serogroups A, C, W and Y) vaccine. Infants born prematurely should receive the vaccine at the same chronological age as term infants (Robinson & CPS, Infectious Diseases and Immunization Committee, 2018).

Tuberculosis. Active, infectious tuberculosis (TB) disease is caused by a bacterium spread through the air from person to person. The TB infection is most infectious and is transmitted by an individual who has active TB disease of the lungs or airways via coughing, sneezing, singing, playing a wind instrument, or sometimes even just talking.

Bacille Calmette-Guérin (BCG) is the collective term applied to a family of live, attenuated vaccines derived from *Mycobacterium bovis*. Presently, the use of BCG is being systematically withdrawn in Canada. BCG vaccination may be considered in exceptional circumstances, such as for infants in high-risk communities (e.g., Indigenous communities in the north), for persons at high risk of repeated exposure, for certain long-term travellers to high-prevalence countries, and in infants born to mothers with infectious TB disease (Government of Canada, 2021a) (see section on tuberculosis in Chapter 45).

COVID-19. COVID-19 is caused by infection with the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) virus strain. Symptoms can range from symptoms of the common cold to shortness of breath or difficulty breathing, a temperature equal to or over 38°C, chills, fatigue or weakness, muscle or body aches, new loss of smell or taste, headache, and gastrointestinal symptoms (abdominal pain, diarrhea, vomiting). Children tend to have abdominal symptoms and skin changes or rashes (Government of Canada, 2021). Symptoms may take up to 14 days to appear after exposure to COVID-19.

Prevention of COVID-19 involves physical distancing (2 metres), wearing a mask, hand hygiene, and vaccination. There are several vaccines available for COVID-19 although as of the publication of this text, the vaccine is waiting for approval for use in children under 12 years of age. Children aged 12 to 17 are strongly recommended to get the vaccine. Some vaccines are one dose although the majority are two dose vaccines which are given 4 weeks apart.

Human Papillomavirus Virus (HPV). HPV is the most common sexually transmitted infection, with an overall prevalence of HPV infection in Canada between 11 and 29%. Peak prevalence is among adolescents and young adults (younger than 25 years of age). There

are over 100 types of HPV, each one having a number to identify it. HPV are viruses that can infect many parts of the body. Some types of HPV are sexually transmitted and can cause warts or other consequences such as cancer. A quadrivalent HPV vaccine has been approved and is recommended for female and male children and adolescents to prevent HPV-related cervical, penile, and anal cancer (see Chapter 7).

The HPV vaccines currently available are CERVARIX® (HPV2), GARDASIL® (HPV4), and GARDASIL® 9 (HPV9). HPV2 vaccines protect against anogenital cancers. HPV4 and HPV9 vaccines also protect against genital warts. The vaccines do not protect against all types of HPV. Even when someone is vaccinated, it is still possible to become infected with one of the types of HPV that the vaccine does not protect against. Therefore, it is important that vaccinated patients continue to have regular Pap tests as recommended by provincial guidelines. The vaccine is administered intramuscularly in two separate doses; the first dose in the series may be given at 11 to 12 years of age (minimum age 9 years), the second dose is administered 2 months after the first (Government of Canada, 2021a). The vaccine is covered by all provincial and territorial health plans for all females and some provinces cover the cost for males.

Rotavirus. Rotavirus is one of the leading causes of severe diarrhea in infants and young children. Two rotavirus vaccines, RotaTeq and Rotarix, are available in Canada and recommended for all infants starting at 6 weeks and before 15 weeks of age. RotaTeq is licensed for administration to infants 6 to 12 weeks of age, with two additional doses administered at 4- to 10-week intervals but not after 32 weeks of age. Rotarix (1 mL) may be administered beginning at 6 weeks of age, with a second dose at least 4 weeks after the first dose but before 24 weeks of age. Both vaccines are administered orally. There is a small increased risk of intussusception (bowel blockage) especially in the first week after receiving the vaccine. Parents should return to the health care provider if the child is not well.

Administration of Immunizations

Administration of immunizations requires additional education and certification (see Additional Resources). The principal precautions in administering immunizations include proper storage of the vaccine to protect its potency and the institution of recommended procedures for injection. The nurse must be familiar with the manufacturer's directions for storage and reconstitution of the vaccine. For example, if the vaccine is to be refrigerated, it should be stored on a centre shelf and not in the door, where frequent temperature increases from opening the refrigerator can alter the vaccine's potency. For protection against light, the vial can be wrapped in aluminum foil. Periodic checks should be scheduled to ensure that no vaccine is used after its expiration date.

The DTaP vaccines contain the adjuvant *alum* to retain the antigen at the injection site and to prolong the stimulatory effect. Because subcutaneous or intracutaneous injection of the adjuvant can cause local irritation, inflammation, or abscess formation, excellent intramuscular injection technique must be used (see Atraumatic Care box; Immunizations). To decrease pain in infants, the DTaP-Hib vaccine should be given before the PCV vaccine.

The total series requires several injections, and every attempt is made to rotate the sites and administer the injections as painlessly as possible. When two or more injections are given at separate sites, the order of injections is arbitrary. Because allergic reactions can occur after injection of vaccines, appropriate precautions need to be taken (see Chapter 47, Anaphylaxis).

ATRAUMATIC CARE

Immunizations

Needle length and gauge size are important factors and must be considered for each individual child; fewer reactions to immunizations are observed when the vaccine is given deep into the muscle rather than into subcutaneous tissue. Deep intramuscular tissue has a better blood supply and fewer pain receptors than adipose tissue, thus providing an optimum site for immunizations with fewer adverse effects.

To minimize local reactions from vaccines the following techniques are recommended:

- The recommended needle length for newborn to 2 months is 16 mm (5/8 inch) in order to deposit the antigen deep into the muscle mass.
- Toddlers and older children require a needle length of 16 to 25 mm for deltoid, or 25 to 32 mm for vastus lateralis.
- Adolescents require a needle length of 25 to 38 mm in deltoid or vastus lateralis.
- Inject into the vastus lateralis or ventrogluteal muscle; the deltoid may be used in children 18 months of age or older. Do not withdraw the plunger in the syringe after injecting the needle into the muscle.

Use one or more of the following techniques to minimize pain:

- Apply a topical anaesthetic such as EMLA (lidocaine-prilocaine) or Maxilene to the injection site and cover with an occlusive dressing for at least 1 hour.
- Apply the topical anaesthetic LMX4 (4% lidocaine) to the injection site 30 minutes before the injection; there is no evidence that an occlusive dressing is required except to prevent ingestion or accidental application to the eyes in infants.
- Apply a vapocoolant spray (e.g., ethyl chloride or FluoriMethane) directly to the skin or to a cotton ball, which is placed on the skin for 15 seconds immediately before the injection.
- There is evidence that a concentrated oral sucrose solution (20 to 30%) (MacDougall et al., 2019), along with non-nutritive sucking (pacifier) and breastfeeding (Harrison et al., 2016) decrease the pain related to minor invasive procedures in newborns and infants. At least one of these methods should be used for all newborns to decrease the pain of immunizations.
- NOTE: Changing the needle on the syringe after drawing up the vaccine and before injecting it has not been shown to make a difference with local reactions.

Another important nursing responsibility is accurate documentation. Each child should have an immunization record for parents to keep, especially for families who move often. Although immunization rates have increased significantly, health care providers should use every opportunity to encourage complete immunization of all children. Blank immunization records may be downloaded as an app or from websites, including Immunize Canada (see Additional Resources at the end of the chapter), which has vaccine information and records.

The following information is documented on the medical record: day, month, and year of administration; manufacturer and lot number of vaccine; expiration date of vaccine; and the name, work address, and title of the person administering the vaccine. Additional data to record are the site and route of administration and evidence that the parent or legal guardian gave informed consent before the immunization was administered.

Practitioners are required to fully inform families of the risks and benefits of the vaccines. Any adverse reactions after the administration of any vaccine should be reported to the Canadian Adverse Events Following Immunization Surveillance System (CAEFISS) (see Additional Resources).

Reactions

Vaccines used for routine immunizations are among the safest and most reliable medications available. However, minor adverse effects

do occur after many of the immunizations, and, rarely, a serious reaction may result from the vaccine (Government of Canada, 2021d).

With inactivated antigens, such as DTaP, adverse effects are most likely to occur within a few hours or days of administration and are usually limited to local tenderness, **erythema**, and swelling at the injection site; low-grade fever; and behavioural changes (e.g., drowsiness, fretfulness, eating less, and prolonged or unusual cry). Local reactions tend to be less severe when the deltoid (except in small infants) rather than the vastus lateralis site is used and when a needle of sufficient length to deposit the vaccine in the muscle is used (see Atraumatic Care box: Immunizations). Rarely, more severe reactions may occur, especially with pertussis. Reactions to DTaP tend to be more severe if they occurred with a previous immunization; fever, swelling, irritability, and pain are more common after the fourth DTaP vaccination in the series. Acetaminophen may help reduce this discomfort and should be given in an age-appropriate dose and time interval.

Hib vaccine is one of the safest vaccines available but may be associated with low-grade fever and mild local reactions at the site of injection, which resolve rapidly. Fever (temperature higher than 38.5°C) may rarely occur.

A number of inactive components are incorporated in vaccines to enhance their effectiveness and safety. Some of these components include preservatives, stabilizers, adjuvants, antibiotics, and purified culture medium proteins to enhance effectiveness. A child may react to the preservative in the vaccine rather than the vaccine component; an example of this is the HepB vaccine, which is prepared from yeast cultures. Yeast hypersensitivity would preclude one from receiving that particular vaccine. Trace amounts of neomycin are used to decrease bacterial growth within certain vaccine preparations, and persons with documented anaphylactic reactions to neomycin should avoid those vaccines. Most vaccine preparations now contain vial stoppers with a synthetic rubber to prevent latex allergy reactions; however, health care personnel administering vaccines should make sure that the package insert specifies there is no latex in the stopper. In the event that an individual has had a severe reaction to a vaccine and subsequent immunizations are required, an allergist should be consulted to determine the best course of action.

Some vaccines contain a preservative, *thimerosal*, which contains ethyl mercury. Concerns regarding possible mercury poisoning in the 1990s prompted many to put off vaccination of infants and small children for fear of childhood developmental conditions such as autism. A number of manufacturers have since stopped producing vaccines containing thimerosal. No local hypersensitivity reactions to thimerosal have been recorded, and studies on thimerosal and the potential link to autism or any other pervasive developmental disorder failed to establish a causal relationship between the two.

Unlike the inactivated antigens, live attenuated virus vaccines such as MMR multiply for days or weeks, and unfavourable reactions and vaccine-associated disorders can occur for 30 to 60 days. These reactions are usually mild, although reactions to rubella tend to be more troublesome in older children and adults than in infants.

Contraindications

Nurses need to be aware of the reasons for withholding immunizations—both for the child's safety in terms of avoiding reactions and for the child's maximum benefit from receiving the vaccine.

A *contraindication* is considered a condition in an individual that increases the risk for a serious adverse reaction (e.g., not administering a live virus vaccine to a severely compromised child). A *precaution* is a condition in a recipient that might increase the risk for a serious adverse reaction or that might compromise the ability of the vaccine to produce immunity. For contraindications and precautions to the usual childhood vaccines, see Table 35.6.

COMMUNICABLE DISEASES

The incidence of childhood communicable diseases has declined significantly since the advent of immunizations. Serious complications resulting from such infections have been further reduced with the use of antibiotics and antitoxins. However, infectious diseases do occur, and nurses must be familiar with the particular infectious agent to recognize the disease and to institute appropriate preventive and supportive interventions.

Nursing Care

The more common communicable diseases of childhood, their therapeutic management, and specific nursing care are described in Table 35.7.

TABLE 35.6 Contraindications and Precautions to Vaccinations*

True Contraindications	Precautions†	Not Contraindications (Vaccines May Be Administered)
General for All Vaccines (DTaP, IPV, MMR, Hib, HepB, Varicella, PCV, HepA, Influenza, Meningococcal)		
Anaphylactic reaction to vaccine is contraindication to further doses of that vaccine or to use of vaccines containing that substance Moderate or severe illnesses with or without fever		Mild to moderate local reaction (soreness, redness, swelling) after a dose of injectable antigen Mild acute illness with or without low-grade fever Current antimicrobial therapy Convalescent phase of illnesses Prematurity (same dosage and indications as for normal, full-term infants) Recent exposure to infectious disease History of penicillin or other nonspecific allergies or family history of such allergies
Diphtheria, Tetanus, and Pertussis or Acellular Pertussis Vaccine (DTP or DTaP)		
Encephalopathy within 7 days of administration of previous dose of DTaP	Fever of ≥40.5°C within 48 hr after vaccination with prior dose of DTaP Collapse or shock-like state (hypotonic-hyporesponsive episode) within 48 hr of receiving prior dose of DTaP Seizures within 3 days of receiving prior dose of DTaP‡ Persistent, inconsolable crying lasting ≥3 hr within 48 hr of receiving prior dose of DTaP	Temperature of <40.5°C after previous dose of DTaP Family history of seizures‡ Family history of sudden infant death syndrome Family history of adverse event after DTaP administration

Continued

TABLE 35.6 Contraindications and Precautions to Vaccinations—cont'd

True Contraindications	Precautions	Not Contraindications (Vaccines May Be Administered)
Diphtheria, Tetanus (Td)		
Severe allergic reaction after a previous dose or to a vaccine component	GBS ≤6 wk after previous dose of tetanus toxoid–containing vaccine Moderate or severe acute illness with or without fever	Same as DTaP or DTP
Inactivated Poliovirus Vaccine (IPV)		
Anaphylactic reaction to neomycin or streptomycin	Pregnancy	Breastfeeding Diarrhea
Measles, Mumps, Rubella Vaccine (MMR)		
Pregnancy Known altered immunodeficiency (hematological and solid tumours, congenital immunodeficiency, long-term immunosuppressive therapy)	Recent immune globulin administration Immune globulin products and MMR should not be given simultaneously; if unavoidable, give at different sites and revaccinate or test for seroconversion in 3 mo; if immune globulin is given first, MMR should not be given for at least 3–6 mo, depending on dose; if MMR is given first, immune globulin should not be given for 2 wk. Thrombocytopenia or thrombocytopenic purpura	Tuberculosis or positive tuberculin skin test Simultaneous tuberculosis skin testing[§] Breastfeeding Pregnancy of mother of recipient Immunodeficient family member or household contact Infection with HIV Nonanaphylactic reactions to eggs or neomycin Consider MMR for mildly symptomatic HIV-infected children. In HIV-infected individuals, measles antibody titre is known to decline more rapidly over time than in those who are not HIV infected. A dose of immune globulin should be considered in HIV-infected individuals with severe immunosuppression after a known exposure to confirmed measles, even with documented previous MMR immunization. (Government of Canada, 2021a).
***Haemophilus influenzae* Type b Vaccine (Hib)**		
None identified		History of Hib disease
Hepatitis B Virus Vaccine (HepB)		
Anaphylactic reaction to common baker's yeast	Preterm birth	Pregnancy[‖]
Pneumococcal Vaccine (PCV)		
Severe allergic reaction after a previous dose or to a vaccine component	Moderate or severe acute illness with or without fever A child who has received pneumococcal polysaccharide vaccine (PPV) previously should wait at least 2 mo before receiving PCV.	Minor illnesses with or without fever Mild upper respiratory tract infection Allergic rhinitis
Varicella Vaccine		
Severe allergic reaction after a previous dose or to a vaccine component (e.g., neomycin or gelatin) Infection with HIV Known altered immunodeficiency (hematological and solid tumours, congenital immunodeficiency, and long-term immunosuppressive therapy) Pregnancy Children receiving corticosteroids	Recent immune globulin administration (see MMR, above) (Government of Canada, 2021a) Family history of immunodeficiency	Breastfeeding
Rotavirus Vaccine		
Severe allergic reaction after a previous dose or to a vaccine component Infants born to HIV-positive mother Known or suspected weakened immune system caused by radiation; medications; or conditions such as leukemia, blood disorders, cancer	Altered immunocompetence Moderate to severe acute gastroenteritis Moderate to severe febrile illness Chronic gastrointestinal diseases Intussusception	Pregnancy Previous history of rotavirus infection; history of intussusception; temperature ≥38°C; close contact with immunocompromised person(s); blood transfusion or immune globulins within previous 42 days

TABLE 35.6 Contraindications and Precautions to Vaccinations—cont'd

True Contraindications	Precautions	Not Contraindications (Vaccines May Be Administered)
Influenza Vaccine (Inactivated/Live-Attenuated)[¶]		
Severe allergic reaction after a previous dose or to a vaccine component Egg hypersensitivity: children can have the flu vaccine LAIV should not be administered to persons taking salicylates, with known or suspected immunodeficiency, with a history of GBS, or with a reactive airway disease or other chronic disorder considered high risk for severe influenza.	GBS within 6 wk after previous influenza immunization	Pregnancy
Meningococcal Vaccine		
MCV4—Allergy to vaccine components, including diphtheria toxoid, and possible reaction to latex stopper; history of GBS		Pregnancy
MPSV4—Allergy to vaccine components		Pregnancy
Tetanus (Booster Toxoid), Reduced Diphtheria Toxoid, Acellular Pertussis Adsorbed (Tdap)		
Serious reaction to any vaccine component History of encephalopathy (e.g., coma, prolonged seizures) within 7 days of administration of a pertussis vaccine that is not attributable to another identifiable cause	GBS ≤6 wk after previous dose of a tetanus toxoid vaccine Progressive neurological disorder, uncontrolled epilepsy, or progressive encephalopathy until the condition has stabilized	Temperature ≥40.5°C within 48 hr after DTP/DTaP immunization not attributable to another cause Collapse or shocklike state within 48 hr after DTP/DTaP immunization Persistent crying lasting ≥3 hr, occurring within 48 hr after DTP/DTaP immunization Seizures with or without fever, occurring within 3 days after DTaP/DTP immunization History of entire limb swelling reaction after pediatric DTaP/DTP or dT immunization that was not an Arthus hypersensitivity reaction Stable neurological disorder, including well-controlled seizures, history of seizure disorder, and CP Brachial neuritis Latex allergy other than anaphylactic allergies (e.g., history of contact to latex gloves) Immunosuppression, including persons with HIV Antibiotic use Intercurrent minor illness
Human Papillomavirus Vaccine		
Pregnancy Hypersensitivity to yeast or any vaccine component		Immunosuppressed person Minor acute illness Lactation

CP, Cerebral palsy; *GBS,* Guillain-Barré syndrome; *HIV,* human immunodeficiency virus; *LAIV,* live-attenuated influenza vaccine.
[*]This information is based on the recommendations of the Advisory Committee on Immunization Practices (ACIP) and those of the Committee on Infectious Diseases (Red Book Committee) of the American Academy of Pediatrics. Sometimes these recommendations vary from those contained in manufacturer's package inserts. For more detailed information, consult published recommendations of the ACIP and American Academy of Pediatrics and manufacturer's package inserts.
[†]Events or conditions listed as precautions, although not contraindications, should be carefully reviewed. Benefits and risks of administering a specific vaccine to an individual under the circumstances should be considered. If risks are believed to outweigh benefits, vaccination should be withheld; if benefits are believed to outweigh risks (e.g., during an outbreak or foreign travel), vaccination should be administered. Whether and when to administer DTaP to children with proven or suspected underlying neurological disorders should be decided on an individual basis. It is prudent on theoretical grounds to avoid vaccinating pregnant women.
[‡]Acetaminophen given before administering DTaP and thereafter every 4 hours for 24 hours should be considered for children with a personal history of seizures or family history of seizures in siblings or parents.
[§]Measles vaccination may temporarily suppress tuberculin reactivity. If testing cannot be done the day of MMR vaccination, the test should be postponed for 4 to 6 wk.
[‖]Birth weight <2 000 g and unknown or hepatitis B surface antigen–positive mother is not a contraindication for vaccination.

TABLE 35.7 Communicable Diseases of Childhood

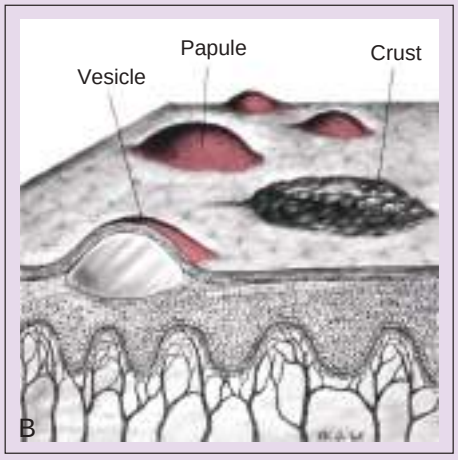

Fig. 35.17 Chickenpox (varicella). **A:** Progression of disease. **B:** Simultaneous stages of lesions. **C:** Clinical view. (*C,* From Habif, T. P. [2010]. *Clinical dermatology: A color guide to diagnosis and therapy* [5th ed.]. Mosby.)

Disease

Chickenpox (Varicella) (Figure 35.17)

Agent—Varicella-zoster virus (VZV)

Source—Primary secretions of respiratory tract of infected persons; to a lesser degree, skin lesions (scabs not infectious)

Transmission—Direct contact, droplet (airborne) spread, and contaminated objects

Incubation period—2–3 wk, usually 14–16 days

Period of communicability—Probably 1–2 days before eruption of lesions (prodromal period) until all lesions have crusted

Diphtheria

Agent—*Corynebacterium diphtheriae*

Source—Discharges from mucous membranes of nose and nasopharynx, skin, and other lesions of infected person

Transmission—Direct contact with infected person, a carrier, or contaminated articles

Incubation period—Usually 2–5 days, possibly longer

Period of communicability—Variable; until virulent bacilli are no longer present (identified by three negative cultures); usually 2 wk but as long as 4 wk

Erythema Infectiosum (Fifth Disease) (Figure 35.18)

Agent—Human parvovirus B19

Source—Infected persons, mainly school-age children

Transmission—Respiratory secretions, blood, blood products

Incubation period—4–14 days; may be as long as 21 days

Period of communicability—Uncertain but before onset of symptoms in children with aplastic crisis

Fig. 35.18 Erythema infectiosum ("Slapped face" appearance). (From Habif, T. P. [2010]. *Clinical dermatology: A color guide to diagnosis and therapy* [5th ed]. Mosby.)

Clinical Manifestations	Therapeutic Management and Complications	Nursing Care
Prodromal stage—Slight fever, malaise, and anorexia for first 24 hr; rash highly pruritic; begins as macule, rapidly progresses to papule and then vesicle (surrounded by erythematous base, becomes umbilicated and cloudy, breaks easily and forms crusts); all three stages (papule, vesicle, crust) present in varying degrees at one time **Distribution**—Centripetal, spreading to face and proximal extremities but sparse on distal limbs and less on areas not exposed to heat (i.e., from clothing or sun) **Constitutional signs and symptoms**—Elevated temperature from lymphadenopathy, irritability from pruritus Breakthrough varicella seen in previously vaccinated; primarily maculopapular, with 50 lesions or fewer that often appear to be insect bites; heals faster than varicella and fever lasts fewer days; one-third less contagious to other people	**Specific**—Antiviral agent acyclovir (Zovirax); varicella-zoster immune globulin (VariZIG) or immune globulin intravenous (IGIV) after exposure in high-risk children **Supportive**—Diphenhydramine hydrochloride or antihistamines to relieve itching; skin care to prevent secondary bacterial infection **Complications**—Secondary bacterial infections (abscesses, cellulitis, necrotizing fasciitis, pneumonia, sepsis) Encephalitis Varicella pneumonia (rare in normal children) Hemorrhagic varicella (tiny hemorrhages in vesicles and numerous petechiae in skin) Chronic or transient thrombocytopenia	Maintain routine, airborne, and contact precautions if hospitalized, until all lesions are crusted; for immunized child with mild breakthrough varicella, isolate until no new lesions are seen. Keep child in home away from susceptible individuals until vesicles have dried (usually 5–7 days after onset of disease), and isolate high-risk children from infected children. Administer skin care; give bath and change clothes and linens daily; administer topical calamine lotion; keep child's fingernails short and clean; apply mittens if child scratches. The goal is to prevent secondary infection and make the child comfortable. Administer antipyretics and antihistamine for pruritus. Keep child cool (may decrease number of lesions). Minimize pruritus; keep child distracted; use oatmeal or baking soda baths to minimize pruritus. Remove loose crusts that rub and irritate skin. Teach child to apply pressure to pruritic area rather than scratching it. Avoid use of Aspirin (possible association with Reye syndrome). Administer acetaminophen for fever.
Vary according to anatomical location of pseudomembrane **Nasal**—Resembles common cold, serosanguineous mucopurulent nasal discharge without constitutional symptoms; may be frank epistaxis **Tonsillar/pharyngeal**—Malaise; anorexia; sore throat; low-grade fever; pulse increased above that expected for temperature within 24 hr; smooth, adherent, white or grey membrane; lymphadenitis possibly pronounced ("bull's neck"); in severe cases, toxemia, septic shock, and death within 6–10 days **Laryngeal**—Fever, hoarseness, cough, with or without previous signs listed; potential airway obstruction, apprehensive, dyspneic retractions, cyanosis	Equine antitoxin (usually intravenously); preceded by skin or conjunctival test to rule out sensitivity to horse serum Antibiotics (penicillin G procaine or erythromycin) in addition to equine antitoxin Tracheostomy for airway obstruction Treatment of infected contacts and carriers **Complications**—Toxic cardiomyopathy (second to third week) Toxic neuropathy	Follow routine and droplet precautions until two cultures are negative for *C. diphtheriae*; contact precautions with cutaneous manifestations. Administer antibiotics in a timely manner. Participate in sensitivity testing; have epinephrine available. Observe respiration for signs of obstruction. Administer humidified oxygen as prescribed.
Rash appearing in three stages: **I**—Erythema on face, chiefly on cheeks, "slapped face" appearance; disappears by 1–4 days (see Figure 35.18) **II**—About 1 day after rash appears on face, maculopapular red spots appear, symmetrically distributed on upper and lower extremities; rash progresses from proximal to distal surfaces and may last a week or more. **III**—Rash is subsiding but reappears if skin is irritated or traumatized (sun, heat, cold, friction). In children with aplastic crisis, rash is usually absent and prodromal illness includes fever, myalgia, lethargy, nausea, vomiting, and abdominal pain. Child with sickle cell disease may have concurrent vaso-occlusive crisis.	**Symptomatic and supportive**—Antipyretics, analgesics, anti-inflammatory medications Possible blood transfusion for transient aplastic anemia **Complications**—Self-limited arthritis and arthralgia (arthritis may become chronic); more common in adult women May result in serious complications (anemia, hydrops) or fetal death if mother is infected during pregnancy (primarily second trimester) Aplastic crisis in children with hemolytic disease or immunodeficiency Myocarditis (rare)	Isolation of child is not necessary, except hospitalized child (immunosuppressed or with aplastic crises) suspected of parvovirus infection is placed on routine and droplet precautions. Pregnant persons need not be excluded from workplace where parvovirus infection is present; they should not care for patients with aplastic crises; explain low risk of fetal death to those in contact with affected children; assist with routine fetal ultrasound for detection of fetal hydrops. Newborn with intrauterine hydrops does not need to be isolated.

TABLE 35.7 Communicable Diseases of Childhood—cont'd

Disease

Exanthem Subitum (Roseola Infantum; Sixth Disease) (Figure 35.19)

Agent—Human herpesvirus type 6 (HHV-6; rarely HHV-7)

Source—Possibly acquired from saliva of healthy adult; entry via nasal, buccal, or conjunctival mucosa

Transmission—Year round; no reported contact with infected individual in most cases (virtually limited to children under age 3 yr but peak age is between 6 and 15 mo)

Incubation period—Usually 5–15 days

Period of communicability—Unknown

Fig. 35.19 Roseola infantum. (From Habif, T. P. [2010]. *Clinical dermatology: A color guide to diagnosis and therapy* [5th ed]. Mosby.)

Measles (Rubeola) (Figure 35.20)

Agent—Virus

Source—Respiratory tract secretions, blood, and urine of infected person

Transmission—Usually by direct contact with droplets of infected person; primarily in winter

Incubation period—8–12 days

Period of communicability—From 4 days before to 4 days after rash appears but mainly during prodromal (catarrhal) stage

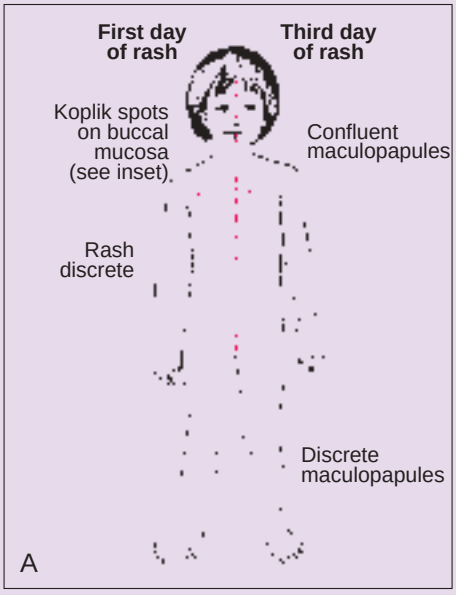

Fig. 35.20 Measles (rubeola). **A:** Progression of disease. **B:** Exanthem first appears at hairline and spreads from head to toe over 3 days. **C:** Measles ultimately involves palms and soles. (*B* and *C*, from Zitelli, B. J., & Davis, H. W. [2012]. *Atlas of pediatric physical diagnosis* [6th ed.]. Mosby; courtesy Michael Sherlock, M.D., Lurville, MD.)

Clinical Manifestations	Therapeutic Management and Complications	Nursing Care
Persistent high fever for 3–4 days in child who appears well Precipitous drop in fever to normal with appearance of rash **Rash**—Discrete rose-pink macules or maculopapules appearing first on trunk, then spreading to neck, face, and extremities; nonpruritic, fades on pressure, lasts 1–2 days **Associated signs and symptoms**—Cervical/postauricular lymphadenopathy, inflamed pharynx, cough, coryza	Nonspecific Antipyretics to control fever **Complications**—Recurrent febrile seizures (possibly from latent infection of central nervous system that is reactivated by fever) Encephalitis, myocarditis, hepatitis, acute cerebellitis (all rare)	Teach parents measures for lowering temperature (antipyretic medications); ensure adequate parental understanding of specific antipyretic dosage to prevent accidental overdose. If child is prone to seizures, discuss appropriate precautions and possibility of recurrent febrile seizures. Ensure adequate oral fluid intake.
Prodromal (catarrhal) stage—Fever and malaise, followed in 24 hr by coryza, cough, conjunctivitis, Koplik's spots (small, irregular red spots with a minute, bluish white centre first seen on buccal mucosa opposite molars 2 days before rash); symptoms gradually increasing in severity until second day after rash appears, when they begin to subside (see Figure 35.20, *A*) **Rash**—Appears 3–4 days after onset of prodromal stage; begins as erythematous maculopapular eruption on face and gradually spreads downward; more severe in earlier sites (appears confluent) and less intense in later sites (appears discrete); after 3–4 days assumes brownish appearance, and fine desquamation occurs over area of extensive involvement (Figure 35.20, B and C) **Constitutional signs and symptoms**—Anorexia, abdominal pain, malaise, generalized lymphadenopathy	Vitamin A supplementation for children with acute illness **Supportive**—Bedrest during febrile period; antipyretics Antibiotics to prevent secondary bacterial infection in high-risk children **Complications**—Otitis media Pneumonia (bacterial) Obstructive laryngitis and laryngotracheitis Encephalitis (rare but has high mortality)	Isolate until fourth day of rash; if hospitalized, institute droplet precautions. Encourage rest during prodromal stage; provide quiet activity. **Fever**—Instruct parents to administer antipyretics; avoid chilling; if child is prone to seizures, institute appropriate precautions. **Eye care**—Dim lights if photophobia present; clean eyelids with warm saline solution to remove secretions or crusts; keep child from rubbing eyes. **Coryza, cough**—Use cool-mist vaporizer; protect skin around nares with layer of petrolatum; encourage fluids and soft, bland foods. **Skin care**—Keep skin clean.

Continued

TABLE 35.7 Communicable Diseases of Childhood—cont'd

Disease
Mumps **Agent**—Paramyxovirus **Source**—Saliva of infected persons **Transmission**—Direct contact with other droplet spread from an infected person **Incubation period**—16–18 days **Period of communicability**—Most communicable immediately before and after swelling begins
Pertussis (Whooping Cough) **Agent**—*Bordetella pertussis* **Source**—Discharge from respiratory tract of infected person **Transmission**—Direct contact or droplet spread from infected person; indirect contact with freshly contaminated articles **Incubation period**—7–10 days, range 5–21 days **Period of communicability**—Greatest during catarrhal stage and the first 2 weeks after cough onset
Rubella (German Measles) (Figure 35.21) **Agent**—Rubella virus **Source**—Primarily nasopharyngeal secretions of person with apparent or inapparent infection; virus also present in blood, stool, and urine **Incubation period**—14–21 days **Period of communicability**—2–3 days before to about 7 days after appearance of rash

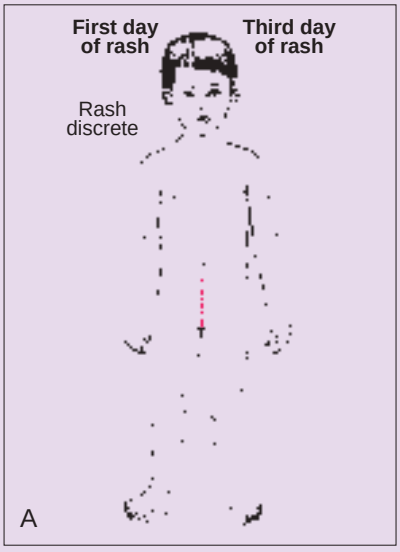

Fig. 35.21 Rubella (German measles). **A:** Progression of rash. **B:** Clinical view. (*B*, from Zitelli, B. J., & Davis, H. W. [2012]. *Atlas of pediatric physical diagnosis* [6th ed.]. Mosby; courtesy Michael Sherlock, M.D., Lurville, MD.)

Clinical Manifestations	Therapeutic Management and Complications	Nursing Care
Prodromal stage—Fever, headache, malaise, and anorexia for 24 hr, followed by "earache" that is aggravated by chewing **Parotitis**—Parotid gland(s) (either unilateral or bilateral) enlarges and reaches maximum size in 1–3 days; accompanied by pain and tenderness; or exocrine glands (submandibular) may also be swollen	**Symptomatic and supportive**—Analgesics for pain and antipyretics for fever Intravenous fluid may be necessary for child refusing to drink or child vomiting because of meningoencephalitis **Complications**—Sensorineural deafness Postinfectious encephalitis Myocarditis Arthritis Hepatitis Orchitis Oophoritis Pancreatitis Sterility (extremely rare in adult males) Meningitis Thyroiditis (rare)	Isolate during period of communicability; institute droplet and contact precautions during hospitalization. Encourage rest and decreased activity during prodromal phase until swelling subsides. Give analgesics for pain; if child is unable to swallow pills or tablets medication, use elixir form. Encourage fluids and soft, bland foods; avoid foods requiring chewing. Apply hot or cold compresses to neck or groin, whichever are more comforting.
Catarrhal stage—Begins with symptoms of upper respiratory tract infection, such as coryza, sneezing, lacrimation, cough, and low-grade fever; symptoms continue for 1–2 wk, when dry, hacking cough becomes more severe. **Paroxysmal stage**—Cough most often occurs at night and consists of short, rapid coughs followed by sudden inspiration associated with a high-pitched crowing sound or "whoop"; during paroxysms, cheeks become flushed or cyanotic, eyes bulge, and tongue protrudes; paroxysm may continue until thick mucous plug is dislodged; vomiting frequently follows attack; stage generally lasts 4–6 wk, followed by convalescent stage. Infants under 6 mo of age may not have characteristic whoop cough, but have difficulty maintaining adequate oxygenation with amount of secretions, frequent vomiting of mucus and formula or breast milk.	Antimicrobial therapy (e.g., erythromycin, clarithromycin, azithromycin) **Supportive treatment**—Hospitalization sometimes required for infants, children who are dehydrated, or those who have complications Supplemental oxygen Adequate fluid intake Intensive care and mechanical ventilation may be necessary for infant <6 mo **Complications**—Pneumonia (usual cause of death) Atelectasis Otitis media Seizures Hemorrhage (scleral, conjunctival, epistaxis; pulmonary hemorrhage in newborn) Weight loss and dehydration Hernias (umbilical and inguinal) Prolapsed rectum	Isolate during catarrhal stage; if hospitalized, institute droplet and routine precautions. Obtain nasopharyngeal culture for diagnosis. Encourage oral fluids; offer small amount of fluids frequently. Ensure adequate oxygenation during paroxysms; position infant on side to decrease chance of aspiration with vomiting. Provide high humidity (humidifier); suction as needed to prevent choking on secretions. Observe for signs of airway obstruction (infants), such as increased restlessness, apprehension, retractions, cyanosis. Encourage household contacts to complete antibiotic therapy. Encourage adolescents to obtain pertussis booster (Tdap). Health care workers should use routine precautions when exposed to children with persistent cough and high suspicion of pertussis.
Constitutional signs and symptoms—Occasionally low-grade fever, headache, malaise, and lymphadenopathy **Prodromal stage**—Absent in children, present in adults and adolescents; consists of low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, cough, and lymphadenopathy; lasts 1–5 days, subsides 1 day after appearance of rash **Rash**—First appears on face and rapidly spreads downward to neck, arms, trunk, and legs; by end of first day, body is covered with discrete, pinkish red maculopapular exanthema; disappears in same order as it began and is usually gone by third day	No treatment necessary other than antipyretics for low-grade fever and analgesics for discomfort **Complications**—Rare (arthritis, encephalitis, or purpura); most benign of all childhood communicable diseases but can be serious for some children; greatest danger is teratogenic effect on fetus; miscarriage and fetal death may occur.	Reassure parents of benign nature of illness in affected child. Use comfort measures as necessary. Avoid contact with pregnant persons and unimmunized or immunocompromised children. Monitor rubella titre in pregnant adolescent. Use routine precautions for hospitalized child; droplet precautions for 7 days after onset of rash. Contact isolation is needed for infant with suspected or confirmed congenital rubella or until two cultures are negative for rubella.

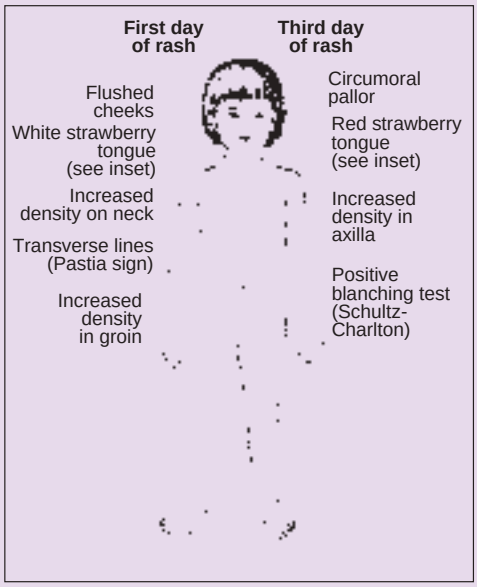
Continued

TABLE 35.7 Communicable Diseases of Childhood—cont'd

Disease

Scarlet Fever (Figure 35.22)

Agent—Group A β-hemolytic streptococci (GAS)



Source—Usually from nasopharyngeal secretions of infected persons and carriers

Transmission—Direct contact with infected person or droplet spread; indirectly by contact with contaminated articles or ingestion of contaminated milk or other food

Incubation period—2–5 days, with range of 1–7 days

Period of communicability—During incubation period and clinical illness, approximately 10 days; during first 2 wk of carrier phase, although may persist for months

Severe cases now rare

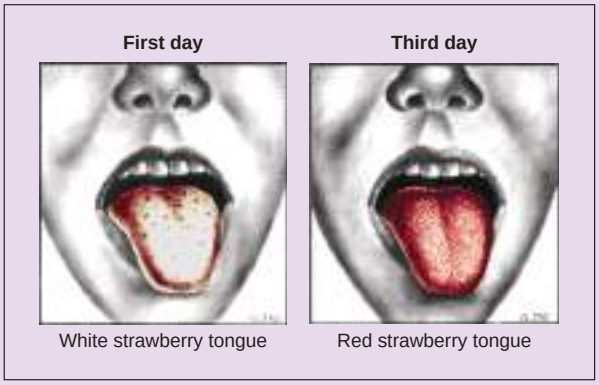


Fig. 35.22 Scarlet fever.

Clinical Manifestations	Therapeutic Management and Complications	Nursing Care
Prodromal stage—Abrupt high fever, pulse increased out of proportion to fever, vomiting, headache, chills, malaise, abdominal pain, halitosis Tonsils enlarged, edematous, reddened, and covered with patches of exudates; in severe cases appearance resembles membrane seen in diphtheria; pharynx edematous and beefy red; during first 1–2 days tongue is coated and papillae become red and swollen (white strawberry tongue); by fourth or fifth day white coat sloughs off, leaving prominent papillae (red strawberry tongue); palate covered with erythematous punctate lesions. **Exanthema**—Rash appears within 12 hr after prodromal signs; red pinhead-sized punctate lesions rapidly become generalized but are absent on face, which becomes flushed with striking circumoral pallor; rash is more intense in folds of joints; by end of first week desquamation begins (fine, sandpaper-like on torso; sheetlike sloughing on palms and soles), which may be complete by 3 wk or longer.	**Treatment of choice**—Full course of penicillin (or erythromycin in penicillin-sensitive children), or oral cephalosporin **Supportive measures**—Rest during febrile phase, analgesics for sore throat; antipruritics for rash if bothersome **Complications**—Peritonsillar and retropharyngeal abscess Sinusitis Otitis media Acute glomerulonephritis Acute rheumatic fever Polyarthritis (uncommon) Toxic shock syndrome Osteomyelitis	Institute routine and droplet precautions until 24 hr after initiation of treatment. Ensure compliance with oral antibiotic therapy; intramuscular benzathine penicillin G [Bicillin] may be given if difficulty in giving oral medications as prescribed. Encourage rest during febrile phase; provide quiet activity during convalescent period. Relieve discomfort of sore throat with analgesics, gargles, lozenges, and antiseptic throat sprays. Encourage oral fluids during febrile phase; avoid irritating liquids (certain citrus juices) or rough foods (chips); when child is able to eat, begin with soft diet. Advise parents to consult practitioner if fever persists after beginning therapy. Discuss procedures for preventing spread of infection—discard toothbrush; avoid sharing drinking and eating utensils. Monitor for sequelae of GAS-acute rheumatic fever and acute glomerulonephritis.

The following is a general discussion of nursing care management for communicable diseases.

Identification of the infectious agent is of primary importance to prevent exposure to susceptible individuals. Nurses in ambulatory care settings, child care centres, and schools are often the first persons to see signs of a communicable disease, such as a rash or sore throat. The nurse must operate under a high index of suspicion for common childhood diseases to identify potentially infectious cases and to recognize diseases that require medical intervention. An example is the common symptom of sore throat. Although most often a symptom of a minor viral infection, it can signal diphtheria or a streptococcal infection, such as scarlet fever. Each of these bacterial conditions requires appropriate medical treatment to prevent serious sequelae.

When a communicable disease is suspected, it is important to assess the following:

- Recent exposure to a known case
- Prodromal symptoms (symptoms that occur between early manifestations of the disease and its overt clinical syndrome) or evidence of constitutional symptoms, such as a fever or rash (see Table 35.7)
- Immunization history
- History of having the disease

Immunizations are available for many diseases, and infection usually confers lifelong immunity; therefore, the possibility of many infectious agents can be eliminated on the basis of these two criteria.

Preventing Spread. Prevention consists of two components: prevention of the disease and control of its spread to others. Primary prevention rests almost exclusively on immunization. Control measures to prevent the spread of disease should include techniques to reduce the risk of cross-transmission of infectious organisms between patients and to protect health care workers from organisms harboured by patients. If the child is hospitalized, the facility's policies for infection control should be followed (see Chapter 44, Infection Control). The most important procedure is hand hygiene. Persons directly caring for the child or handling contaminated articles must wash their hands and practise effective routine precautions in care of their patients.

The child should be instructed to practise good hand hygiene technique before eating and after toileting. For diseases spread by droplets, the child and parents should be instructed in measures to reduce airborne transmission. Children who are old enough should be taught to sneeze or cough into their sleeves and not their hands or to use a tissue and then discard it. The nurse needs to stress to the family the usual hygiene measures of not sharing eating and drinking utensils.

! NURSING ALERT

If a child is admitted to the hospital with an undiagnosed exanthema, strict additional precautions (contact, airborne, and droplet) and routine precautions are instituted until a diagnosis is confirmed. Childhood communicable diseases requiring these precautions include diphtheria, chickenpox, measles, tuberculosis, adenovirus, *Haemophilus influenzae* type b, influenza, mumps, *Mycoplasma pneumoniae*, pertussis, plague, streptococcal pharyngitis, pneumonia, and scarlet fever.

Preventing Complications. Although most children recover without difficulty, certain groups are at risk for serious, even fatal, complications from communicable diseases, especially the viral diseases chickenpox and erythema infectiosum (fifth disease) caused by human parvovirus B19.

Children with immunodeficiency—those receiving steroid or other immunosuppressive therapy, those with a generalized malignancy such as leukemia or lymphoma, or those with an immunological disorder—are at risk for viremia from replication of the varicella-zoster virus (VZV) in the blood. VZV is so named because it causes two distinct diseases: varicella (chickenpox) and zoster (herpes zoster, or shingles). Varicella occurs primarily in children younger than 15 years of age. However, it leaves the threat of herpes zoster, an intensely painful varicella that is localized to a single dermatome (body area innervated by a particular segment of the spinal cord). In children, the dermatomes most likely affected by herpes zoster are the cervical, lumbar, and thoracic dermatomes (Weinmann et al., 2013). Immunocompromised patients and healthy infants younger than 1 year of age (who also have reduced immunity) are at a higher risk for reactivation of VZV causing herpes zoster, probably as a result of a deficiency in cellular immunity. Complications of herpes zoster virus in children include secondary bacterial infection, depigmentation, and rarely postherpetic neuralgia and scarring. Fetal infection after maternal varicella, especially if infection occurs before the twentieth week of gestation, may be fatal or result in congenital varicella syndrome. Varicella infection occurring in newborns exposed to maternal varicella from a period 5 days before birth to 2 days after birth have an increased likelihood of becoming infected and should be treated with varicella-zoster immunoglobulin intravenously (Government of Canada, 2018b).

The use of varicella-zoster immune globulin (VariZIG) or intravenous immune globulin (IGIV) is recommended for children who are immunocompromised, who have no previous history of varicella, and who are likely to contract the disease and have complications as a result (Government of Canada, 2021a). The antiviral agent acyclovir (Zovirax) may be used to treat varicella infections in susceptible immunocompromised persons; it is effective in decreasing the number of lesions, shortening the duration of fever, and decreasing itching, lethargy, and anorexia. Oral acyclovir be considered for immunocompromised children who cannot receive VariZIG.

Children with hemolytic disease, such as sickle cell disease, are at risk for aplastic anemia from erythema infectiosum. Human parvovirus B19 (fifth disease) infects and lyses red blood cell (RBC) precursors, thus interrupting the production of RBCs. Thus the virus may precipitate a severe aplastic crisis in patients who need increased RBC production to maintain normal RBC volumes. Thrombocytopenia and neutropenia may also occur as a result of human parvovirus B19 infection. Fetuses have a relatively high rate of RBC production and immature immune systems; they may develop severe anemia and hydrops as a result of maternal human parvovirus infection. The spontaneous loss rate of fetuses affected with parvovirus B19 before 20 weeks' gestation is 13% and after 20 weeks' gestation is 0.5% (Crane et al., 2014).

The past decade has seen an increase in the incidence of pertussis, particularly in infants less than 6 months old and children 10 to 14 years of age. Early clinical manifestations of pertussis in infants may include gagging, coughing, emesis, and apnea; the typical whooping cough associated with the disease is absent. In older children, the disease may manifest as a common cold (see Table 35.7). Because pertussis is contagious, especially among close household members, pertussis should be identified early and treatment initiated for the child and those who have been exposed. Azithromycin (for infants under 1 month) and erythromycin, clarithromycin, or azithromycin are administered to infants and children with pertussis.

Prevention of complications from diseases such as diphtheria, pertussis, and scarlet fever requires adherence to antibiotic therapy. With oral preparations, the need to complete the entire course of therapy needs to be stressed.

There is evidence that vitamin A supplementation reduces both morbidity and mortality in individuals with measles and that all children with severe measles should be given vitamin A supplements. A

single oral dose of 200 000 IU (6 000 mcg) for children at least 1 year old (or half that dose for children 6 to 12 months of age) is recommended. The higher dose may be associated with vomiting and headache for a few hours. The dose should be repeated once the next day (National Collaborating Centre for Infectious Diseases, 2017).

! NURSING ALERT

Although the risk of vitamin A toxicity from these doses (they are 100 to 200 times the recommended dietary allowance) is relatively low, nurses should instruct parents on safe storage of the medication. Ideally, vitamin A should be dispensed in the age-appropriate unit dose, to prevent excessive administration and possible toxicity.

Providing Comfort. Many communicable diseases cause skin manifestations that are bothersome to the child. The chief discomfort from most rashes is itching, and measures such as cool baths (usually without soap) and lotions (e.g., calamine) are helpful.

! NURSING ALERT

When lotions with active ingredients such as diphenhydramine in Caladryl are used, they should be applied sparingly, especially over open lesions, where excessive absorption can lead to medication toxicity. These lotions should be used with caution in children who are simultaneously receiving an oral antihistamine. Cooling the lotion in the refrigerator beforehand often makes it more soothing on the skin than using it at room temperature.

To avoid overheating, which increases itching, children should wear lightweight, loose, nonirritating clothing and keep out of the sun. If the child persists in scratching, the nails should be kept short and smooth; mittens and clothes with long sleeves or legs may be needed. For severe itching, antipruritic medication, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), may be required, especially when the child has trouble sleeping because of itching. Loratadine, cetirizine, and fexofenadine do not cause drowsiness and may be preferred for urticaria during the day.

An elevated temperature is common, and both antipyretic medicine (acetaminophen or ibuprofen) and environmental manipulation should be implemented (see Chapter 44, Controlling Elevated Temperatures). The acetaminophen is effective in lowering the fever but does not significantly reduce the symptoms of itching, anorexia, abdominal pain, fussiness, or vomiting.

A sore throat, another frequent symptom, is managed with lozenges, saline rinses (if the child is old enough to assist), and analgesics. Because most children have a decreased appetite during an illness, bland foods and increased liquids are usually preferred. During the early stages of the disease, children voluntarily curtail their activity, and although bed rest is beneficial, it should not be imposed unless specifically indicated. During periods of irritability, quiet activity (e.g., reading, music, television, video games, puzzles, colouring) can help distract children from the discomfort.

Supporting the Child and Family. Most communicable diseases are benign but may produce considerable concern and anxiety for parents. Often the occurrence of a communicable disease is the first time the child is acutely uncomfortable. Parents need assistance to cope with manifestations of the illness, such as intense itching. The family and child need reassurance that recovery is generally rapid. However, visible signs of the dermatosis may be present for some time after the child is well enough to resume usual activities.

! NURSING ALERT

The occurrence of a communicable disease provides the opportunity to ask parents about the child's immunization status and reinforce the benefits of vaccines for children.

KEY POINTS

- Health promotion is directed toward proper nutrition, adequate sleep, proper dental care, and injury prevention.
- Breast milk provides optimum nutrition for the infant during the first 6 months; introduction of solid food occurs from the second 6 months. While not equivalent to breast milk, commercial iron-fortified infant formula is an alternative to human milk. Whole milk is not recommended until after 1 year of age.
- Nutrition is important during every developmental stage because eating habits established in these periods have lasting effects on health in subsequent years.
- Cleaning teeth regularly and appropriate dietary intake promote good dental health at every age. Regular dental examinations, fluoride supplementation, removal of plaque, and provision of a low-cariogenic diet promote optimum dental health.
- Activities involving physical movement should be encouraged; sedentary activities such as watching television or playing video games for long periods of time can contribute to development of health challenges.
- The sleep needs of children change during the lifespan, but sleep needs are individualized.
- Developmental stage and environment are important factors in the prevalence of injuries at every age and should guide injury prevention measures. Injury prevention is directed toward provision of safe sleep, play areas, and equipment and supervision of activities.
- Child maltreatment may take the form of physical abuse or neglect, emotional abuse or neglect, or sexual abuse.
- Parental, child, and environmental characteristics are criteria that may predispose children to maltreatment.
- Identification of abuse entails securing evidence of maltreatment, taking a history pertaining to the incident, and assessing parental and child behaviours.
- Recommended immunizations for children include those for HBV, HAV, diphtheria, influenza, tetanus, pertussis, polio, measles, mumps, rubella, pneumococcus, meningococcus, chicken pox, Hib, rotavirus, and HPV.
- Many communicable diseases are preventable with effective vaccinations, although some diseases still occur and some require specific nursing care, including additional isolation precautions.

The Infant and Family

Constance O'Connor
Originating US Chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the major biological, psychosocial, cognitive, and social developments that occur during the first year of life.
2. Relate parent–child attachment, separation anxiety, and stranger fear to developmental achievements during infancy.
3. Provide anticipatory guidance to parents regarding common parental concerns during infancy.
4. Provide anticipatory guidance in the care of the family with an infant who is experiencing colic.
5. Plan nursing care that can meet the physical and emotional needs of the child with growth failure as well as the needs of the family.
6. Provide anticipatory guidance for the prevention of sudden infant death syndrome.
7. Provide nursing care that aims to meet the immediate and long-term needs of the family that has lost a child from sudden infant death syndrome.

PROMOTING OPTIMUM GROWTH AND DEVELOPMENT

Biological Development

At no other time in life are physical changes and developmental achievements as dramatic as during infancy. All major body systems undergo progressive maturation, and there is concurrent development of skills that increasingly enable infants to respond to and cope with the environment. Acquisition of these fine and gross motor skills occurs in an orderly head-to-toe and centre-to-periphery (**cephalocaudal** and **proximodistal**) sequence.

Proportional Changes. Growth is very rapid during the first year, especially during the initial 6 months. Infants gain 150 to 200 grams weekly until approximately age 5 to 6 months. Birth weight is often doubled by 4 months. An average weight for a 6-month-old child is 7.0 kg. Weight gain slows during the second 6 months. By 1 year of age the infant's birth weight has tripled, for an average weight of 9.75 kg. Height increases by 2.5 cm a month during the first 6 months and then slows during the second 6 months. Increases in length occur in sudden spurts, rather than in a slow, gradual pattern. Average height is 65 cm at 6 months and 74 cm at 12 months. By age 1 year the birth length has increased by almost 50%. This increase occurs mainly in the trunk, rather than in the legs, and contributes to the infant's characteristic physique.

Head growth in infants is also rapid. During the first 6 months, head circumference increases approximately 1.5 cm a month, but the rate of increase falls to only 0.5 cm monthly during the second 6 months. The average size is 43 cm at 6 months and 46 cm at 12 months. By 1 year of age, head size has increased by almost 33%. Closure of the cranial sutures occurs, with the posterior fontanel closing by 6 to 8 weeks of age and the anterior fontanel closing by 12 to 18 months of age (the average age being 14 months).

Expanding head size reflects the growth and differentiation of the nervous system. By the end of the first year, the brain has increased in weight by about 2.5 times that of the newborn. Maturation of the brain is exhibited in the dramatic developmental achievements of infancy. Primitive reflexes are replaced by voluntary, purposeful movement, and new reflexes that influence motor development appear.

The chest assumes a more adult contour, with the lateral diameter becoming larger than the anteroposterior diameter. The chest circumference approximately equals the head circumference by the end of the first year. The heart grows less rapidly than the rest of the body. Its weight is usually doubled by 1 year of age; in comparison, body weight triples during the same period. The size of the heart is still large in relation to the chest cavity; its width is approximately 55% of the chest width.

The developmental process during the first 12 months is complex. Table 36.1 presents the physical, motor, sensory, language, and social traits as they develop throughout an infant's first year, along with average monthly age at which various skills are attained. Although all milestones are important, some represent essential integrative aspects of

TABLE 36.1 Growth and Development During Infancy

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization/Cognition
Birth–6 mo	Weight gain of 150–200 g weekly for first 6 mo Height gain of 2.5 cm monthly for first 6 mo Head circumference increases by 1.5 cm monthly for first 6 mo Primitive reflexes present and strong doll's eye reflexes and dance reflex fading Obligatory nose breathing (most infants)	Assumes flexed position with pelvis high but knees not under abdomen when prone (at birth, knees flexed under abdomen)* Can turn head from side to side when prone; lifts head momentarily from bed (see Figure 36.3, *A*)* Has marked head lag, especially when pulled from lying to sitting position (see Figure 36.2, *A*) Holds head momentarily parallel and in midline when suspended in prone position Assumes asymmetrical tonic neck reflex position when supine When held in standing position, body is limp at knees and hips In sitting position, back is uniformly rounded, absence of head control	Hands predominantly closed Grasp reflex strong Hand clenches on contact with rattle	Able to fixate on moving object in range of 45 degrees when held at a distance of 20–25 cm Visual acuity approaches 20/100† Follows light to midline Quiets when hears a voice	Cries to express displeasure Makes small, throaty sounds Makes comfort sounds during feeding	Is in sensorimotor phase—stage I, use of reflexes (birth–1 mo), and stage II, primary circular reactions (1–4 mo) Watches parent's face intently as parent talks to infant
2	Posterior fontanel closed Crawling reflex disappears	Assumes less flexed position when prone—hips flat, legs extended, arms flexed, head to side* Less head lag when pulled to sitting position (see Figure 36.2, *B*) Can maintain head in same plane as rest of body when held in ventral suspension When prone, can lift head almost 45 degrees off table When moved to sitting position, head is held up but bends forward (see Figure 36.5, *B*) Assumes asymmetrical tonic neck reflex position intermittently	Hands often open Grasp reflex fading	Binocular fixation and convergence to near objects beginning When supine, follows dangling toy from side to point beyond midline Visually searches to locate sounds Turns head to side when sound is made at level of ear	Vocalizes, distinct from crying* Crying becomes differentiated Coos Vocalizes to familiar voice	Demonstrates social smile in response to various stimuli*

Continued

TABLE 36.1 Growth and Development During Infancy—cont'd

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization/Cognition
3	Primitive reflexes fading	Able to hold head more erect when sitting, but still bobs forward Has only slight head lag when pulled to sitting position Assumes symmetrical body positioning Able to raise head and shoulders from prone position to a 45- to 90-degree angle from table; bears weight on forearms When held in standing position, able to bear slight fraction of weight on legs Looks at own hand	Actively holds rattle but will not reach for it* Grasp reflex absent Hands kept loosely open Clutches own hand; pulls at blankets and clothes	Follows object to periphery (180 degrees)* Locates sound by turning head to side and looking in same direction* Begins to have ability to coordinate stimuli from various sense organs	Squeals aloud to show pleasure* Coos, babbles, chuckles Vocalizes when smiling "Talks" a great deal when spoken to Less crying during periods of wakefulness	Displays considerable interest in surroundings Ceases crying when parent enters room Can recognize familiar faces and objects Shows awareness of strange situations
4	Drooling begins Moro, tonic neck, and rooting reflexes have disappeared* Birth weight doubles	Has almost no head lag when pulled to sitting position (see Figure 36.2, *C*)* Balances head well in sitting position (see Figure 36.5, *C*)* Back less rounded, curved only in lumbar area Able to sit erect if propped up Able to raise head and chest off surface to angle of 90 degrees (see Figure 36.3, *B*) Assumes predominant symmetrical position Rolls from back to side*	Inspects and plays with hands; pulls clothing or blanket over face in play* Tries to reach objects with hand but overshoots Grasps object with both hands Plays with rattle placed in hand, shakes it, but cannot pick it up if dropped Can carry objects to mouth	Able to accommodate to near objects Binocular vision fairly well established Can focus on a 1.25-cm block Beginning eye–hand coordination	Makes consonant sounds *n, k, g, p, b* Laughs aloud* Vocalization changes according to mood	Is in stage III, secondary circular reactions Demands attention by fussing; becomes bored if left alone Enjoys social interaction with people Anticipates feeding when sees bottle or mother if breastfeeding Shows excitement with whole body, squeals, breathes heavily Shows interest in strange stimuli Begins to show memory
5	Beginning signs of tooth eruption	No head lag when pulled to sitting position When sitting, able to hold head erect and steady Able to sit for longer periods when back is well supported Back straight When prone, assumes symmetrical positioning with arms extended Can turn over from abdomen to back* When supine, puts feet to mouth	Able to grasp objects voluntarily* Uses palmar grasp, bidextrous approach Plays with toes Takes objects directly to mouth Holds one cube while looking at a second one	Visually pursues a dropped object Is able to sustain visual inspection of an object Can localize sounds made below ear	Squeals Makes cooing vowel sounds interspersed with consonant sounds (e.g., *ah-goo*)	Smiles at mirror image Pats breast or bottles with both hands More enthusiastically playful, but may have rapid mood swings Is able to discriminate strangers from family Vocalizes displeasure when object is taken away Discovers parts of body

Continued

TABLE 36.1 Growth and Development During Infancy—cont'd

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization/Cognition
6	Growth rate may begin to decline Weight gain of 85–140 g weekly for next 6 mo Height gain of 1.25 cm monthly for next 6 mo Teething may begin with eruption of two lower central incisors* Chewing and biting occur*	When prone, can lift chest and upper abdomen off surface, bearing weight on hands (see Figure 36.3, *C*) When about to be pulled to a sitting position, lifts head Sits in highchair with back straight Rolls from back to abdomen When held in standing position, bears almost all of weight Hand regard absent	Re-secures a dropped object Drops one cube when another is given Grasps and manipulates small objects Holds bottle Grasps feet and pulls to mouth	Adjusts posture to see an object Prefers more complex visual stimuli Can localize sounds made above ear Will turn head to the side, then look up or down	Begins to imitate sounds* Babbling resembles one-syllable utterances—*ma, mu, da, di, hi** Vocalizes to toys, mirror image Takes pleasure in hearing own sounds (self-reinforcement)	Recognizes parents; begins to fear strangers Holds arms out to be picked up Has definite likes and dislikes Begins to imitate (cough, protrusion of tongue) Excites on hearing footsteps Laughs when head is hidden in a towel Briefly searches for a dropped object (object permanence beginning)* Frequent mood swings—from crying to laughing with little or no provocation
7	Eruption of upper central incisors	When supine, spontaneously lifts head off surface Sits, leaning forward on hands (see Figure 36.5, *D*)* When prone, bears weight on one hand Sits erect momentarily Bears full weight on feet (see Figure 36-6, *A*) When held in standing position, bounces actively	Transfers objects from one hand to the other (see Figure 36.5, *E*)* Has unidextrous approach and grasp Holds two cubes more than momentarily Bangs cube on table Rakes at a small object	Can fixate on very small objects* Responds to own name Localizes sound by turning head in a curving arch Beginning awareness of depth and space Has taste preferences	Produces vowel sounds and chained syllables—*baba, dada, kaka** Vocalizes four distinct vowel sounds "Talks" when others are talking	Increasing fear of strangers; shows signs of fretfulness when parent disappears* Imitates simple acts and noises Tries to attract attention by coughing or snorting Plays peekaboo Demonstrates dislike of food by keeping lips closed Exhibits oral aggressiveness in biting and mouthing Demonstrates expectation in response to repetition of stimuli
8	Begins to show regular patterns in bladder and bowel elimination Parachute reflex appears (see Figure 36.4)	Sits steadily unsupported (see Figure 36.5, *E*)* Readily bears weight on legs when supported; may stand holding onto furniture Adjusts posture to reach an object	Has beginning pincer grasp using index, fourth, and fifth fingers against lower part of thumb Releases objects at will Rings bell purposely Retains two cubes while regarding third cube Secures an object by pulling on a string Reaches persistently for toys out of reach		Makes consonant sounds *t, d, w* Listens selectively to familiar words Utterances signal emphasis and emotion Combines syllables, such as *dada*, but does not ascribe meaning to them	Increasing anxiety over loss of parent, particularly mother, and fear of strangers Responds to word "no" Dislikes dressing, diaper change
9	Eruption of upper lateral incisor may begin	Creeps on hands and knees Sits steadily on floor for prolonged time (10 min) Recovers balance when leaning forward but cannot do so when leaning sideways Pulls self to standing position and stands holding onto furniture (see Figure 36.6, *B, C*)*	Uses thumb and index fingers in crude pincer grasp (see Figure 36.1)* Preference for use of dominant hand now evident Grasps third cube Compares two cubes by bringing them together	Localizes sounds by turning head diagonally and directly toward sound Depth perception increasing	Responds to simple verbal commands Comprehends "no-no"	Parent (mother) is increasingly important for own sake Shows increasing interest in pleasing parent Begins to show fears of going to bed and being left alone Puts arms in front of face to avoid having it washed

Continued

TABLE 36.1 Growth and Development During Infancy—cont'd

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization/Cognition
10	Labyrinth-righting reflex is strongest—when infant is in prone or supine position, is able to raise head	Can change from prone to sitting position Stands while holding onto furniture, sits by falling down Recovers balance easily while sitting While standing, lifts one foot to take a step (see Figure 36.6, *D*)	Crude release of an object beginning Grasps bell by handle		Says "dada," "mama" with meaning* Comprehends "bye-bye" May say one word (e.g., "hi," "bye," "no")	Inhibits behaviour to verbal command of "no-no" or own name Imitates facial expressions; waves bye-bye Extends toy to another person but will not release it Develops object permanence* Repeats actions that attract attention and cause laughter Pulls clothes of another to attract attention Plays interactive game such as pat-a-cake Reacts to adult anger; cries when scolded Demonstrates independence in dressing, feeding, locomotive skills, and testing of parents Looks at and follows pictures in a book
11	Eruption of lower lateral incisor may begin	When sitting, pivots to reach toward back to pick up an object Cruises or walks holding onto furniture or with both hands held*	Explores objects more thoroughly (e.g., clapper inside bell) Has neat pincer grasp Drops object deliberately for it to be picked up Puts one object after another into a container (sequential play) Able to manipulate an object to remove it from tight-fitting enclosure		Imitates definite speech sounds	Experiences joy and satisfaction when a task is mastered Reacts to restrictions with frustration Rolls ball to another on request Anticipates body gestures when a familiar nursery rhyme or story is being told (e.g., holds toes and feet in response to "This little piggy went to market") Plays game up-down, "so big," or peek-a-boo Shakes head for "no"
12	Birth weight tripled* Birth length increased by 50%* Head and chest circumference equal (head circumference 46 cm) Has total of six to eight deciduous teeth Anterior fontanel almost closed Landau reflex fading Babinski reflex disappears Lumbar curve develops; lordosis evident during walking	Walks with one hand held* Cruises well May attempt to stand alone momentarily; may attempt first step alone* Can sit down from standing position without help	Releases cube in cup Attempts to build two-block tower but fails Tries to insert a pellet into a narrow-necked bottle but fails Can turn pages in a book, many at a time	Discriminates simple geometrical forms (e.g., circle) Amblyopia may develop with lack of binocularity Can follow rapidly moving object Controls and adjusts response to sound; listens for sound to recur	Says three to five words besides "dada," "mama"* Comprehends meaning of several words (comprehension always precedes verbalization) Recognizes objects by name Imitates animal sounds Understands simple verbal commands (e.g., "Give it to me," "Show me your eyes")	Shows emotions such as jealousy, affection (may give hug or kiss on request), anger, fear Enjoys familiar surroundings and explores away from parent Is fearful in strange situation; clings to parent May develop habit of "security blanket" or favourite toy Has increasing determination to practise locomotor skills Searches for an object even if it has not been hidden, but searches only where object was last seen*

*Milestones that represent essential integrative aspects of development that lay the foundation for the achievement of more advanced skills.
†Degree of visual acuity varies according to vision measurement procedure used.

development that lay the foundation for achievement of more advanced skills. These essential milestones are designated by an asterisk (*) in the table. It must be remembered that although the sequence is the same, the rate will vary among children.

It is important for individual children to have specific measurements taken so that their growth pattern can be accurately tracked. These measurements need to be done on a regular basis with a growth chart that gives a basis for comparing them with the average measurements of other children. The Dietitians of Canada, Canadian Paediatric Society (CPS), College of Family Physicians, Community Health Nurses of Canada, and Canadian Pediatric Endocrine Group have developed Canadian pediatric growth charts from the World Health Organization (WHO) 2006 Child Growth Standards and the 2007 WHO International Growth Reference charts (see Additional Resources). There are also recently updated growth charts that have been developed for specialized conditions, such as Down syndrome, where the growth pattern is different (Zemel et al., 2015). The CPS recommends using both the standard and specialized growth charts when tracking growth in children with such conditions.

Maturation of Systems. Other organ systems also change and grow during infancy. The respiratory rate slows somewhat (see Appendix C) and is relatively stable. Respiratory movements continue to be abdominal. Several factors predispose the infant to more severe and acute respiratory conditions. Because of the close proximity of the trachea to the bronchi and its branching structures, infectious agents can be rapidly transmitted from one anatomical location to another. The short, straight eustachian tube closely communicates with the ear, allowing **infection** to ascend from the pharynx to the middle ear. In addition, because the infant's immune system is unable to produce sufficient immune globulin A (IgA) in the mucosal lining, there is less protection against infection in infancy than during later childhood.

The heart rate slows (see Appendix C), and the rhythm is often sinus arrhythmia (i.e., rate increases with inspiration and decreases with expiration). Blood pressure also changes during infancy (see Appendix C). Systolic pressure rises during the first 2 months as a result of the increasing ability of the left ventricle to pump blood into the systemic circulation. Diastolic pressure decreases during the first 3 months then gradually rises to values close to those at birth. Fluctuations in blood pressure occur during varying states of activity and emotion.

Significant hematopoietic changes occur during the infant's first year (see Appendix B). Fetal hemoglobin (HgbF) is present in large quantities for the first 5 months, with adult hemoglobin steadily increasing through the first half of infancy. HgbF has a shorter lifespan than that of adult hemoglobin; thus there is an increased turnover of these cells and a gradual decrease in hemoglobin. This process results in a physiological anemia around 3 to 6 months of age. High levels of HgbF depress the production of erythropoietin, a hormone released by the kidney that stimulates red blood cell production. Hemoglobin levels decrease to a point at which tissue oxygenation needs stimulate erythropoietin, and erythropoiesis resumes, forming new red blood cells (Blackburn, 2018). Maternally derived iron stores are present for the infant's first 5 to 6 months and then gradually diminish, which also accounts for lowered hemoglobin levels toward the end of the first 6 months. The occurrence of physiological anemia is not affected by an adequate supply of iron. However, when erythropoiesis is stimulated, iron supplies are necessary for the formation of hemoglobin.

The digestive processes are immature at birth. Although term newborns have some limitations in digestive function, human milk has properties that partially compensate for decreased digestive enzymatic activity, thus enabling breastfed infants to receive optimal nutrition during the first several months of life. The salivary form of the enzyme amylase, called *ptyalin*, is present in small amounts but usually has little effect on the foodstuffs because of the small amount of time the food stays in the mouth. Gastric digestion in the stomach consists primarily of the action of hydrochloric acid and rennin, an enzyme that acts specifically on the casein in milk to cause the formation of curds (i.e., coagulated semisolid particles of milk). The curds cause the milk to be retained in the stomach long enough for digestion to occur.

Digestion also takes place in the duodenum, where pancreatic enzymes and bile begin to break down protein and fat. Secretion of the amylase, which is needed for digestion of complex carbohydrates, is deficient until about the fourth to sixth month of life. Lipase is also limited, and infants do not achieve adult levels of fat absorption until 4 to 5 months of age. Trypsin is secreted in sufficient quantities to catabolize protein into polypeptides and some amino acids.

The immaturity of the digestive processes is evident in the appearance of stools. During infancy, solid foods (e.g., peas, carrots, corn, and raisins) are passed incompletely broken down in the feces. An excess quantity of fibre easily disposes the child to loose, bulky stools. During infancy, the stomach enlarges to accommodate a greater volume of food. By the end of the first year, infants are able to tolerate three meals a day and an evening feeding by breast or bottle and may have one or two bowel movements daily. With any type of gastric irritation, however, the infant is vulnerable to diarrhea, vomiting, and dehydration (see Chapter 46).

The liver is the most immature of all the gastrointestinal organs throughout infancy. The ability to conjugate bilirubin and secrete bile is achieved after the first couple weeks of life. However, the capacities for gluconeogenesis, formation of plasma protein and ketones, storage of vitamins, and deaminization of amino acids remain relatively immature for the first year of life.

Maturation of the suckling, sucking, and swallowing reflexes and the eruption of teeth (see Teething, later in chapter) parallel the changes in the gastrointestinal tract and prepare the infant for the introduction of solid foods.

The immunological system undergoes numerous changes during the first year. Full-term newborns receive significant amounts of maternal immunoglobulin G (IgG), which for approximately 3 months confers immunity against **antigens** to which the mother was exposed. During this time, the infant begins to synthesize IgG; approximately 40% of adult levels are reached by 1 year of age. Significant amounts of IgM are produced at birth, and adult levels are reached by 9 months of age. Secretory IgA is not present at birth but is found in saliva and tears by 2 to 5 weeks.

Prebiotic oligosaccharides found in breast milk produce probiotic bacteria such as bifidobacteria and lactobacilli, which in turn stimulate synthesis and secretion of secretory IgA (sIgA). Secretory IgA is present in large amounts in colostrum; IgA confers protection to the mucous membranes of the gastrointestinal tract (Blackburn, 2018; Lawrence & Lawrence, 2016) against many bacteria, such as *Escherichia coli,* and viruses, such as rubella, poliovirus, and the enteroviruses. The development of the mucosa-associated lymphoid tissue occurs during infancy; in part, this system is believed to prevent colonization and passage of bacteria across the infant's mucosal barrier (Lawrence & Lawrence, 2016). The function and quantity of T lymphocytes, lymphokines, interferon-γ, interleukins, tumour necrosis factor-α, and complement are reduced in early infancy, thus preventing optimal response to certain bacteria and viruses. The production of IgA and immunoglobulins D and E (IgD and IgE) is much more gradual, and maximum levels are not attained until early childhood. Probiotics may have a significant role in helping the gastrointestinal tract establish a "good" bacterial colonization in the gut to prevent many illnesses, including antibiotic-induced diarrhea and possibly *Helicobacter pylori* gastritis (Thomas et al., 2010; Vitetta et al., 2014).

Evidence indicates that vernix caseosa, a white oily substance that coats the term newborn's body and is often found in abundance in the creases of the axilla and groin, has innate immunological properties that serve to protect the newborn from infection (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2018; Visscher et al., 2015). Vernix also appears to have a role in maintaining the integrity of the stratum corneum and facilitating acid mantle development. The epidermis of the full-term newborn undergoes maturation during the first month of life; the newborn's skin acts as a barrier to infection, assists in thermal regulation, and prevents transepidermal water loss in term newborns.

During infancy, *thermoregulation* becomes more efficient; the ability of the skin to contract and of muscles to shiver in response to cold increases. The peripheral capillaries respond to changes in ambient temperature to regulate heat loss. The capillaries constrict in response to cold, conserving core body temperature and decreasing potential evaporative heat loss from the skin surface. The capillaries dilate in response to heat, decreasing internal body temperature through evaporation, conduction, and convection. Shivering (**thermogenesis**) causes the muscles and muscle fibres to contract, generating metabolic heat that is distributed throughout the body. Increased adipose tissue during the first 6 months insulates the body against heat loss.

A shift in the total body fluid also occurs. At birth, 75% of the term newborn's body weight is water, and there is an excess of **extracellular fluid (ECF)**. As the percentage of body water decreases, so does the amount of ECF—from 44% at term to 20% in adulthood. The high proportion of ECF, which is composed of blood plasma, **interstitial fluid**, and lymph, predisposes the infant to a more rapid loss of total body fluid and, consequently, dehydration. The loss of 5 to 10% of the term newborn's initial birth weight in the first 5 days of life is attributed to ECF compartment contraction, enhanced renal tubular function, and rapidly increasing glomerular filtration rate (Blackburn, 2018).

The immaturity of the renal structures also predisposes the infant to dehydration. Complete maturity of the kidney occurs during the latter half of the second year, when the cuboidal epithelium of the glomeruli becomes flattened. Before this time the glomeruli's filtration capacity is reduced. Urine is voided frequently and has a low specific gravity (i.e., 1.000 to 1.010). At term, most newborns produce and excrete approximately 15 to 60 mL/kg/24 hr; an output of less than 0.5 mL/kg/hr after 48 hours of age is considered to be oliguria (Blackburn, 2018).

Auditory acuity is at adult levels during infancy. Visual acuity begins to improve, and binocular fixation is established. Binocularity, or the fixation of two ocular images into one cerebral picture (fusion), begins to develop by 6 weeks of age and should be well established by age 4 months. Depth perception (**stereopsis**) begins to develop by age 7 to 9 months but may not be fully mature until 2 to 3 years of age, thus increasing the infant's and younger toddler's risk for falling.

Fine Motor Development. Fine motor behaviour includes the use of the hands and fingers in the prehension (grasp) of an object, as discussed in Table 36.1. Grasping occurs during the first 2 to 3 months as a reflex and gradually becomes voluntary. At 1 month of age the hands are predominantly closed, and by 3 months they are mostly open. If a rattle is placed in the hand, the infant will actively hold onto it. By 5 months the infant is able to voluntarily grasp an object.

Gradually the palmar grasp (using the whole hand) is replaced with a **pincer grasp** (using the thumb and index finger). The infant uses a crude pincer grasp by 8 to 9 months of age and has progressed to a neat pincer grasp by 11 months (Figure 36.1).

By 6 months of age, infants have increased manipulative skill: they can hold a bottle, grasp their feet and pull them to their mouth, and feed themselves a cracker. By 7 months they transfer objects from one hand to the other, enjoy banging objects, and will explore the movable parts of a toy.

Fig. 36.1 Crude pincer grasp at 8 to 10 months. (Photo by Paul Vincent Kuntz.)

By 10 months of age, the pincer grasp is sufficiently established to enable infants to pick up a raisin and other finger foods. By 11 months they can put objects into a container and like to remove them. By age 1 year, infants try, but may fail, to build a tower of two blocks.

Gross Motor Development.

Head control. The full-term newborn can momentarily hold the head in midline and parallel when the body is suspended ventrally and can lift and turn the head from side to side when prone. This is not the case when the newborn is lying prone on a pillow or soft surface; newborns do not have the head control to lift their head out of the depression of the object and thus risk possible suffocation in the prone position early in infancy (see Sudden Infant Death Syndrome later in chapter and in Chapter 26). Marked head lag is evident when the infant is pulled from a lying to a sitting position. By 3 months of age, infants can hold their head well beyond the plane of the body. By 4 months infants can lift the head and front portion of the chest approximately 90 degrees above the table, bearing their weight on the forearms. Only slight head lag is evident when the infant is pulled from a lying to a sitting position, and by 4 to 6 months head control is well established (Figures. 36.2 and 36.3).

! NURSING ALERT

An infant who displays head lag at 6 months of age should have a developmental and neurological evaluation.

Rolling over. Newborns may roll over accidentally because of their rounded back. The ability to willfully turn from the abdomen to the back generally occurs at 5 months, and the ability to turn from the back to the abdomen occurs at 6 months. Infants put to sleep on their sides may easily roll over to a prone (face-down) position, thus placing them at higher risk for sudden infant death syndrome (SIDS). It is therefore important to place infants in a supine position for sleep. While the infant is awake and being observed, a prone position is acceptable to enhance achievement of milestones such as head control, crawling,

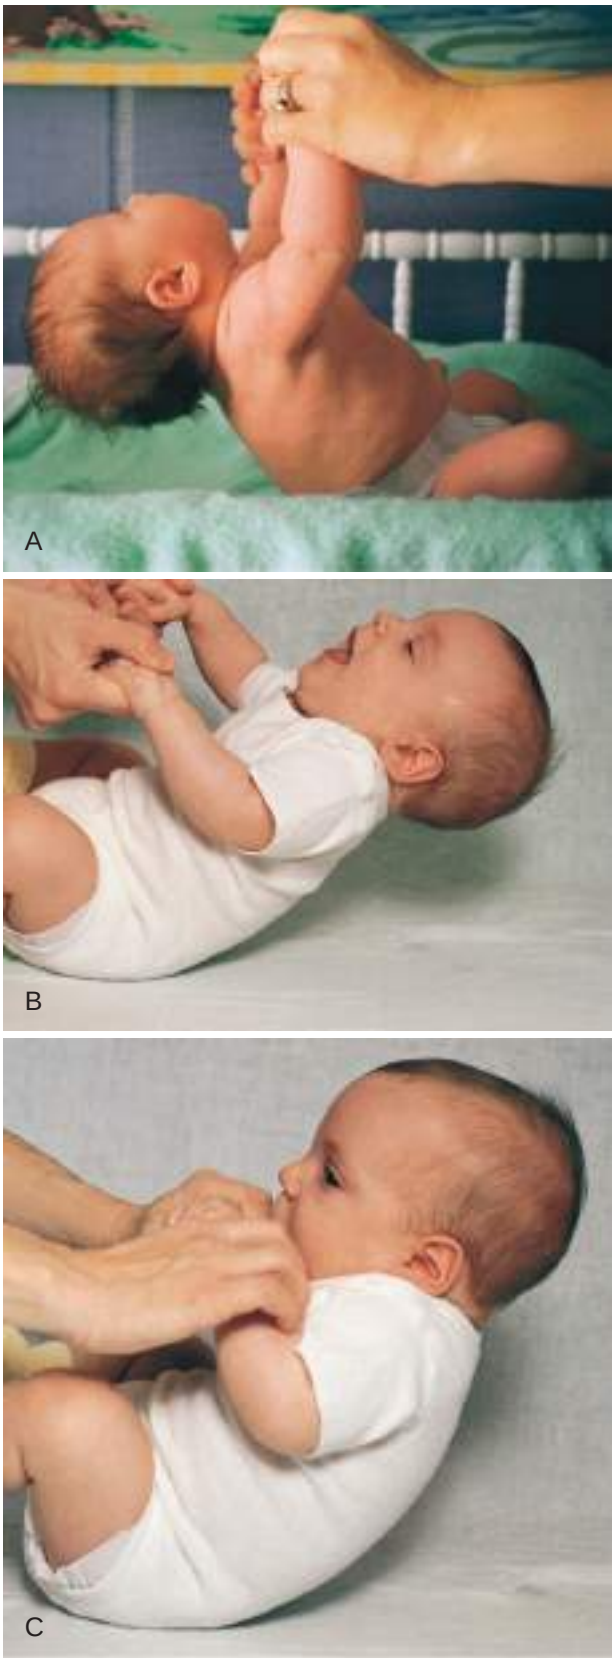

Fig. 36.2 Head control while pulled to sitting position. **A:** Complete head lag at 1 month. **B:** Partial head lag at 2 months. **C:** Almost no head lag at 4 months.

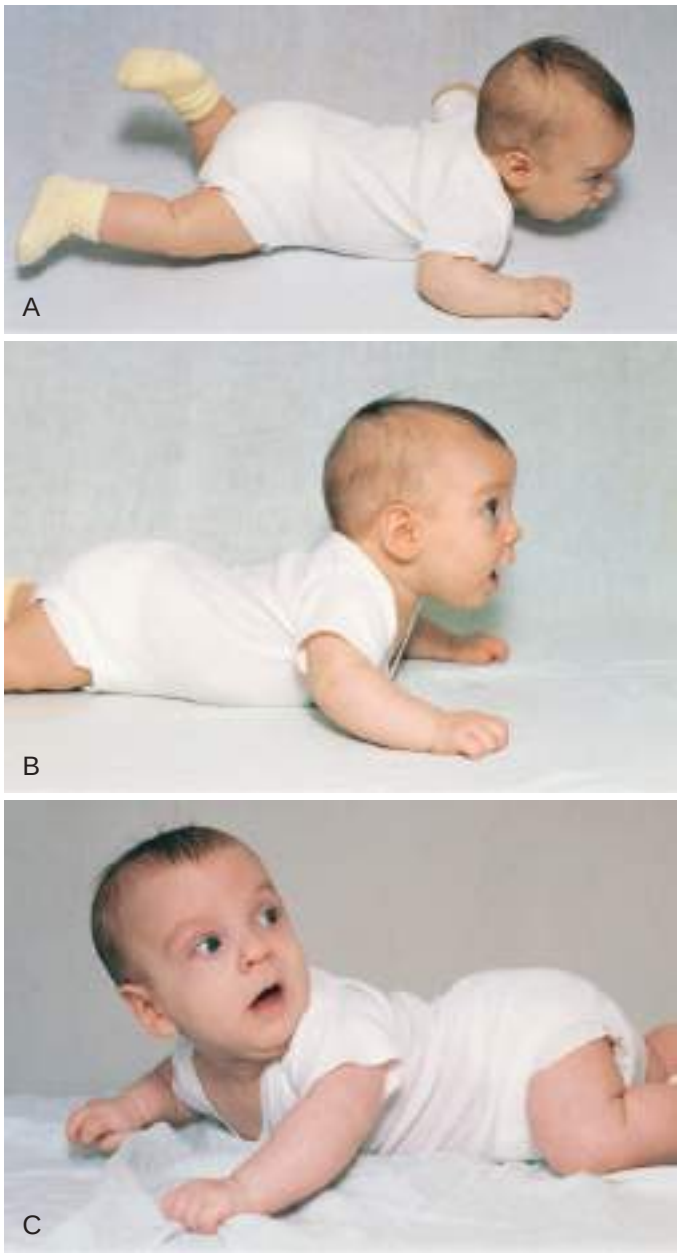

Fig. 36.3 Head control while prone. **A:** Infant momentarily lifts head at 1 month. **B:** Infant lifts head and chest 90 degrees and bears weight on forearms at 4 months. **C:** Infant lifts head, chest, and upper abdomen and can bear weight on hands at 6 months. Note how this position facilitates turning from abdomen to back.

creeping, and turning over. The parachute reflex (Figure 36.4), a protective response to falling, appears at 7 months.

Sitting. The ability to sit follows progressive head control and straightening of the back (Figure 36.5). For the first 2 to 3 months the back is uniformly rounded. The convex cervical curve forms at approximately 3 to 4 months of age, when head control is established. The convex lumbar curve appears when the child begins to sit, at about age 4 months. As the spinal column straightens, the infant can be propped in a sitting position. By age 7 months infants can sit alone, leaning forward on their hands for support. By age 8 months they

Fig. 36.4 Parachute reflex. (Photo by Paul Vincent Kuntz.)

can sit well while unsupported and begin to explore their surroundings in this position rather than in a lying position. By 10 months they can manoeuvre from a prone to a sitting position.

Locomotion. Locomotion involves acquiring the ability to bear weight, propel forward on all four extremities, stand upright with support, and, finally, walk alone (Figure 36.6). Following a cephalocaudal pattern, infants 4 to 6 months old develop increasing coordination in their arms. Initial locomotion results in infants propelling themselves backward by pushing with the arms. By 6 to 7 months of age, they are able to bear all their weight on their legs with assistance. Crawling (propelling forward with belly on floor) progresses to creeping (on hands and knees with belly off floor) by 9 months. At this time, they stand while holding onto furniture and can pull themselves to the standing position, but they are unable to manoeuvre back down except by falling. By 11 months they can usually walk while holding onto furniture or with both hands held, and by age 1 year they may be able to walk with one hand held. A number of infants attempt their first independent steps by their first birthday. Although there is considerable variation among infants for the achievement of these milestones, they provide guidelines for early intervention.

Fig. 36.5 Development of sitting. **A:** Back is completely rounded, and infant has no ability to sit upright at 1 month. **B:** At 2 months, infant exhibits more control; back is still rounded, but infant can sit up momentarily with some head control. **C:** Back is rounded only in lumbar area, and infant is able to sit erect with good head control at 4 months. **D:** Infant can sit alone, leaning on hands for support, at 7 months. **E:** Infant sits without support at 8 months. Note the transferring of objects that occurs, beginning at 7 months. (Photos by Paul Vincent Kuntz.)

Fig. 36.6 Development of locomotion. **A:** Infant bears full weight on feet by 7 months. **B:** Infant can manoeuvre from sitting to kneeling position. **C:** Infant can stand holding onto furniture at 9 months. **D:** While standing, infant takes deliberate step at 10 months. **E:** Infant crawls with abdomen on floor and pulls self forward, and then **(F)** creeps on hands and knees at 9 months. (Photos by Paul Vincent Kuntz.)

! NURSING ALERT

An infant who does not pull to a standing position by 11 to 12 months of age should be further evaluated for possible developmental **dysplasia** of the hip (see Chapter 53). Although there is considerable variation among infants for the achievement of these milestones, they provide guidelines for early intervention.

Psychosocial Development

Developing a Sense of Trust (Erikson). Erikson's (1963) phase I (birth to 1 year) is concerned with *acquiring a sense of* **trust** while *overcoming a sense of* **mistrust** (termed "trust versus mistrust") (see Chapter 32). The trust that develops is a trust of self, of others, and of the world. Infants "trust" that their feeding, comfort, stimulation, and caring needs will be met. The crucial element for the achievement of this task is the quality of both the parent–child (or caregiver–child) relationship and the care that the infant receives. The provision of food, warmth, and shelter alone is inadequate for the development of a strong sense of self. The infant and parent must jointly learn to satisfactorily meet their needs in order for mutual regulation of frustration to occur. When this synchrony fails to develop, mistrust is the eventual outcome.

Mistrust can result either from too much or too little frustration. If parents always meet their children's needs before the children signal their readiness, infants will never learn to test their ability to control the environment. If the delay is prolonged, infants experience constant

frustration and eventually mistrust others in their efforts to satisfy them. Therefore, consistency of care is essential.

The trust acquired in infancy provides the foundation for all succeeding phases. Trust gives infants a feeling of physical comfort and security, which assists them in experiencing unfamiliar situations with a minimum of fear. Erikson divided the first year of life into two oral/social stages. During the first 3 to 4 months, food intake is the most important social activity in which the infant engages. The newborn can tolerate little frustration or delay of gratification. Primary **narcissism** (total concern for oneself) is at its height. However, as bodily processes such as vision, motor movements, and vocalization become better controlled, infants use more advanced behaviours to interact with others. For example, rather than cry, infants may put their arms up to signify a desire to be held.

The next social modality involves a mode of reaching out to others through grasping. *Grasping* is initially reflexive, but even as a reflex it has a powerful social meaning for the parents. The reciprocal response to the infant's grasping is the parents' holding on and touching. There is pleasurable tactile stimulation for both the child and the parents.

Tactile stimulation is extremely important in the total process of acquiring trust. The degree of mothering skill, the quantity of food, or the length of sucking does not determine the quality of the experience. Rather, it is the overall quality of the interpersonal relationship that influences the infant's formulation of trust.

During the second stage, the more active and aggressive modality of biting occurs. Infants learn that they can hold onto what is their own and can more fully control their environment. During this stage, infants may be confronted with one of their first conflicts. If they are breastfeeding, they quickly learn that biting causes the mother to become upset and withdraw the breast. Yet biting also brings internal relief from teething discomfort and a sense of power or control.

This conflict may be solved by teaching the infant not to bite and by the mother saying "no" and withdrawing the nipple from the baby's mouth. The successful resolution of this conflict strengthens the mother–child relationship because it occurs at a time when infants are recognizing the mother as the most significant person in their life.

Cognitive Development

The theory most commonly used to explain *cognition*, or the ability to know, is that of Piaget (1952) (see Chapter 32). The period from birth to 24 months is termed the **sensorimotor phase** and is composed of six stages; however, because this discussion is concerned with ages birth to 12 months, only the first four stages are discussed here. The last two stages (tertiary circular reactions and invention of new means) occur during the toddler period of 12 to 24 months and are discussed in Chapter 37.

During the sensorimotor phase, infants progress from reflex behaviours to simple repetitive acts to imitative activity. Three crucial events take place during this phase. The first event involves *separation*, in which infants learn to separate themselves from other objects in the environment. They realize that others besides themselves control the environment and that certain readjustments must take place for mutual satisfaction to occur. This coincides with Erikson's concept of the formation of trust.

The second major accomplishment is achieving the concept of **object permanence**, or the realization that objects that leave the visual field still exist. A typical example of the development of object permanence is when infants are able to pursue objects they observe being hidden under a pillow or behind a chair (Figure 36.7). This skill develops at approximately 9 to 10 months of age, which corresponds to the time of increased locomotion skills.

The last major intellectual achievement of this period is the ability to use *symbols*, or *mental representation*. The use of symbols allows the infant to think of an object or situation without actually experiencing it. The recognition of symbols is the beginning of the understanding of time and space.

Fig. 36.7 Nine-month-old infant actively searches for object hidden behind pillow. (Photo by Paul Vincent Kuntz.)

Piaget's first stage, from birth to 1 month, is identified by the infant's *use of reflexes*. At birth, the newborn's individuality and temperament are expressed through the physiological reflexes of sucking, rooting, grasping, and crying. The repetitious nature of the reflexes is the beginning of associations between an act and a sequential response. When newborns cry because they are hungry, a nipple is put in the mouth, and they suck, feel satisfaction, and sleep. They are assimilating this experience while perceiving auditory, tactile, and visual cues. This experience of perceiving certain patterns, or "ordering," provides a foundation for the subsequent stages.

The second stage, *primary circular reactions*, marks the beginning of the replacement of reflexive behaviour with voluntary acts. During the period from 1 to 4 months, activities such as sucking or grasping become deliberate acts that elicit certain responses. The beginning of accommodation is evident. Infants incorporate and adapt their reactions to the environment and recognize the stimulus that produced a response. Previously they would cry until the nipple was brought to the mouth. Now they associate the nipple with the sound of the parent's voice. They accommodate this new piece of information and adapt by ceasing to cry when they hear the voice—before receiving the nipple. What is taking place is a realization of causality and a recognition of an orderly sequence of events. The environment is taken in with all of the senses and with whatever motor ability is present.

The *secondary circular reactions* stage is a continuation of primary circular reactions and lasts until 8 months of age. In this stage, the primary circular reactions are repeated and prolonged for the resulting response. Grasping and holding now become shaking, banging, and pulling. Shaking is performed to hear a noise, not solely for the pleasure of shaking. The quality and quantity of an act become evident. More or less shaking produces different responses. Understanding of causality, time, deliberate intention, and separateness from the environment begins to develop.

Three new processes of human behaviour occur. *Imitation* requires the differentiation of selected acts from several events. By the second half of the first year, infants can imitate sounds and simple gestures.

Play becomes evident as they take pleasure in performing an act after they have mastered it. Many of the infant's waking hours are absorbed in sensorimotor play. *Affect* (the outward manifestation of emotion and feeling) is seen as infants begin to develop a sense of permanency. During the first 6 months, infants believe that an object exists only for as long as they can visually perceive it—in other words, out of sight, out of mind. Affect in relation to external objects is evident when the object continues to be present or remembered even though it is beyond the range of perception. Object permanence is a critical component of parent–child attachment and is seen in the development of **separation anxiety** at 6 to 8 months of age.

During the fourth sensorimotor stage, *coordination of secondary schemata and their application to new situations*, infants use previous behavioural achievements primarily as the foundation for adding new intellectual skills to their expanding repertoire. This stage is largely transitional. Increasing motor skills allow for greater exploration of the environment. They begin to discover that hiding an object does not mean that it is gone but that removing an obstacle will reveal the object. This marks the beginning of intellectual reasoning. Furthermore, they can experience an event by observing it, and they begin to associate symbols with events (e.g., "bye-bye" with "Daddy or Mommy goes to work"), but the classification is purely their own. In this stage, they learn from the object itself; this is in contrast to the second stage, in which infants learn from the type of interaction between objects or individuals. Intentionality is further developed, in that infants now actively attempt to remove a barrier to the desired (or undesired) action (see Figure 36.7). If something is in their way, they attempt to climb over it or push it away. Previously, an obstacle would have caused them to give up any further attempt to achieve the desired goal.

Development of Body Image

The development of body image parallels sensorimotor development. Infants' kinesthetic and tactile experiences are the first perceptions of their body, and the mouth is the principal area of pleasurable sensations. Other parts of the body are primarily objects of pleasure—the hands and fingers to suck and the feet to play with. As physical needs are met, they feel comfort and satisfaction with their body. Messages conveyed by the caregivers reinforce these feelings. For example, when infants smile, they receive emotional satisfaction from others who smile back.

Achieving the concept of object permanence is basic to the development of self-image. By the end of the first year, infants recognize that they are distinct from their parents. At the same time, they have increasing interest in their own image, especially in the mirror (Figure 36.8). As motor skills develop, they learn that parts of the body are useful; for example, the hands bring objects to the mouth, and the legs help them move to different locations. All of these achievements transmit messages to them about themselves. Therefore, it is important to transmit positive messages to infants about their bodies.

Social Development

Infants' social development is initially influenced by their reflexive behaviour, such as the grasp, and eventually depends primarily on the interaction between them and the principal caregivers. **Attachment** to the parent is increasingly evident during the second half of the first year, and tremendous strides are made in communication and personal-social behaviour. Whereas crying and reflexive behaviour are initial ways in which newborns meet their needs, the social smile is an early step in social communication. This has a profound effect on family members and is stimulus for evoking continued responses from others. By 4 months of age, infants can laugh out loud.

Play is a major socializing activity and provides stimulation needed to learn from and interact with the environment. By age 6 months infants are personable. They can play games such as peek-a-boo when their head is hidden behind a towel, signal their desire to be picked up by extending their arms, and show displeasure when a toy is removed or their face is being washed.

Fig. 36.8 Nine-month-old infant enjoying own image in mirror.

Attachment. The importance to infants of human physical contact cannot be overemphasized. Parenting is not an instinctual ability but a learned, acquired process. The attachment of parent and child, which begins before birth, assumes even greater importance at birth and during the first year (see Chapter 23, Parental Attachment, Bonding, and Acquaintance). In the following discussion of attachment, the term *mother* is used in the broad context of the consistent caregiver with whom the child relates more than anyone else. However, in society's changing social climate and sex-role stereotypes, this person may very well be the father, partner, or a grandparent.

Studies on paternal–infant attachment demonstrate that stages similar to those in maternal attachment occur and that fathers are often more involved in child care when mothers are employed outside the home (although mothers continue to do the majority of infant care).

Additional research has shown that inexperienced, first-time fathers are as capable as experienced fathers of developing a close attachment with their infants. Fathers verbalize more positive feelings of love and affection toward their newborns when they are able to have close physical contact, such as holding their infant (Feeley et al., 2013). Research demonstrates that fathers develop feelings of attachment with their offspring and that their relationship with the infant is an important factor in the mother's emotional well-being. Breastfeeding mothers reported that the most important factor in establishing and maintaining breastfeeding in early infancy was the father's acceptance of breastfeeding and support for the mother (Feldman-Winter, 2013; Wang et al., 2018). It is important for nurses to recognize that infant–parent attachments may be present or absent in situations where caregiver roles are less well defined by those involved.

When the infant is not provided a safe haven and consistent and loving care, an *insecure attachment* develops; such infants do not feel they can trust the world in which they live. This insecure attachment may result in psychosocial difficulties as the child grows and may persist even into adulthood. Insecure attachment may also exist in homes where there is intimate partner violence or maternal perinatal mood disorder.

Attachment progresses during infancy, with the child assuming an increasingly significant role. Two components of cognitive development are required for attachment: (1) the ability to discriminate the mother or primary caregiver from other individuals, and (2) the

achievement of object permanence. Both of these processes prepare the infant for an equally important aspect of attachment: separation from the parent. Separation–individuation should occur as a harmonious, parallel process with emotional attachment.

During the formation of attachment to the parent, the infant progresses through four distinct but overlapping stages. For the first few weeks, newborns respond indiscriminately to anyone. Beginning at approximately 8 to 12 weeks of age, they cry, smile, and vocalize more to the primary caregiver than to anyone else but continue to respond to others, whether familiar or not. At approximately 6 months of age, infants show a distinct preference for the primary caregiver. They follow them more, cry when they leave, enjoy playing with them more, and feel most secure in their arms. About 1 month after showing attachment to the primary caregiver, many infants begin attaching to other members of the family, most often the other parent.

Infants acquire other developmental behaviours that influence the attachment process. These include the following:

- Differential crying, smiling, and vocalization (more to the primary caregiver than to anyone else)
- Visual–motor orientation (looking more at the primary caregiver, even if they are not close)
- Crying when the primary caregiver leaves the room
- Approaching through locomotion (crawling, creeping, or walking)
- Clinging (especially in the presence of a stranger)
- Exploring away from the primary caregiver while using them as a secure base

Severe attachment disorders involve psychological and developmental issues that stem from maladaptive or absent attachment between the infant and parent (Zeanah & Gleason, 2015). There are two different patterns of attachment disorders: the emotionally withdrawn–inhibited pattern and an indiscriminate-disinhibited pattern. These two subtypes have been classified into separate disorders: reactive attachment disorder (RAD) and disinhibited social engagement disorder (DSED) of infancy or early childhood. Infants at risk for severe attachment disorders include those who have been victims of physical or sexual abuse or neglect; infants exposed to parental alcoholism, mental illness, or substance use; and infants who have experienced the absence of a consistent primary caregiver as a result of foster care, institutionalization, parental abandonment, or parental incarceration (Zeanah & Gleason, 2015). Children with RAD may manifest behaviours such as not being cuddly with parents, failing to seek and respond to comfort when distressed, showing minimal social and emotional reciprocity, and emotional dysregulation such as unexplained fearfulness or irritability (Zeanah & Gleason, 2015). Children with DSED may exhibit behaviours such as inappropriate approaching of unfamiliar adults, lack of suspicion of strangers, and poor impulse control (Zeanah & Gleason, 2015). Without early intervention, some of these children fail to develop a conscience and develop an antisocial personality disorder that may lead to committing criminal acts. Children with autism or other pervasive developmental disorders have behaviours that are categorically different from those with RAD (Zeanah & Gleason, 2015).

Separation anxiety. Between ages 4 and 8 months, the infant progresses through the first stage of separation–individuation and begins to have some awareness of self and primary caregiver as separate beings. At the same time, the sense of object permanence is developing, and the infant is aware that the parent can be absent. Thus, separation anxiety develops and is manifested through a predictable sequence of behaviours.

During the early second half of the first year, infants usually protest when placed in their crib, and a short time later they will object when their caregiver leaves the room. Infants may not notice the caregiver's absence if they are absorbed in an activity. However, when they realize their absence, they may protest. From this point on, they become very alert to their caregiver's activities and whereabouts. By 11 to 12 months of age, they are able to anticipate the imminent departure of their caregiver by watching their behaviours, and they may begin to protest before they leave. At this point, many parents learn to postpone alerting the child to their departure until just before leaving.

Fear of strangers. As infants demonstrate attachment to one person, they correspondingly exhibit less friendliness to others. Between 6 and 8 months of age, fear of strangers and **stranger anxiety** become prominent and are related to infants' ability to discriminate between familiar and unfamiliar people. Behaviours such as clinging to the parent, crying, and turning away from the stranger are common (Figure 36.9).

Play. Play during infancy represents the various social modalities observed during cognitive development (see Chapter 32, Role of Play in Development). Infants' activity is primarily narcissistic and revolves around their own body. As discussed under Development of Body Image, body parts are primarily objects of play and pleasure.

During the first year, play becomes more sophisticated and interdependent. From birth to 3 months of age, infants' responses to the environment are global and largely undifferentiated. Play is dependent; pleasure is demonstrated by a quieting attitude (1 month), a smile (2 months), or a squeal (3 months). From 3 to 6 months, infants show more discriminate interest in stimuli and begin to play alone with a rattle or a soft stuffed toy or with someone else. There is much more interaction during play. By 4 months of age, they laugh out loud, show a preference for certain toys, and become excited when food or a favourite object is brought to them. They recognize an image in a mirror, smile at it, and vocalize to it.

By age 6 months to 1 year, play involves sensorimotor skills. Actual games such as peekaboo and pat-a-cake are played. Verbal repetition and imitation of simple gestures occur in response to demonstration. Play is much more selective, not only in terms of specific toys but also in terms of "playmates." Although play is solitary or one-sided, infants choose with whom they will interact. At 6 to 8 months of age they usually refuse to play with strangers. Parents are definite favourites, and infants know how to attract their attention. At 6 months they will extend the arms to be picked up, at 7 months cough or squeal to make their presence known, at 10 months pull at the parent's clothing, and at 12 months call them by name. This represents a tremendous advance from the newborn, who signalled biological needs by merely crying to express displeasure.

Fig. 36.9 Behaviours related to fear of strangers include clinging to the parent and turning away from the stranger. (Photo by Paul Vincent Kuntz.)

Stimulation is important for psychosocial growth. Knowledge of **developmental milestones** enables nurses to guide parents in proper play for infants. For instance, it is not sufficient to place a mobile over a crib and toys in a playpen for a child's optimum social, emotional, and intellectual development. Likewise, the television or recorded videos, for the most part, do not provide infants with appropriate sensory stimulation, do not increase language skills, and therefore should be strictly limited in children younger than 2 years of age (Canadian Paediatric Society [CPS], Digital Health Taskforce, 2017). Play must provide interpersonal contact and recreational and educational stimulation. Infants need to be *played with*, not merely *allowed to play*. Although the type of play infants engage in is called *solitary*, this is a figurative, not literal, term to denote one-sided play. The type of toys given to the child is much less important than the quality of personal interaction that occurs. Having a parent that is interactive with the infant is very important—for example, smiling often and directly at the infant helps the child learn to be responsive.

Language Development

The infant's first means of verbal communication is crying. Crying as a biological sign conveys a message of urgency and signals displeasure, such as hunger. However, crying is also a social event that affects the development of the parent–infant relationship—either by its absence, which usually has a positive effect on parents, or its presence, which may involve a negative response or persuade parents to minister to the child's physical or emotional needs.

In the first few weeks of life, crying has a reflexive quality and is mostly related to physiological needs. Newborns cry for 1 to 1.5 hours a day up to 3 weeks of age, then build up to 2 and even 4 hours a day by 6 weeks. Crying tends to decrease by 12 weeks of age. It is thought that the increase in crying for no apparent reason during the first few months may be related to the discharge of energy and the maturational changes in the central nervous system. During the end of the first year, infants cry for attention; from fear (especially stranger fear); and from frustration, usually in response to their developing but inadequate motor skills.

! NURSING ALERT

Be alert to parents' reports about maternal perinatal mood disorder and infant crying, since these concerns may indicate a stressed mother–infant relationship.

Infants vocalize as early as 5 to 6 weeks of age by making small throaty sounds. See Table 36.1 for discussion of language ability. By 8 months they can imitate sounds; add the consonants *t, d,* and *w*; and combine syllables (e.g., "dada"), but they do not ascribe meaning to the word until 10 to 11 months of age (see Family-Centred Care box: Child's Developing Language Skills).

Because language development is based on expressive skills (ability to make thoughts, ideas, and desires known to others) and receptive skills (ability to understand the words being spoken), it is important that infants are exposed to expressive speech. Infants with delays in achieving milestones should be evaluated for potential hearing loss.

FAMILY-CENTRED CARE

Child's Developing Language Skills

During the acquisition of new language skills the child temporarily may stop using other recently learned sounds or words. This is often distressing for parents, who have waited in anticipation for the words "dada" or "mama," because these sounds are commonly replaced by other vocalizations and may not be repeated for several weeks. Nurses can reassure parents that the child will again say these special words, and with increased meaning.

Temperament

The infant's temperament or behavioural style influences the type of interaction that occurs between the child and parents (see general discussion of temperament in Chapter 32). In assessments of a child's temperament, it is the parents' perception of the child and the degree of fit between their expectations and the child's actual temperament that are important. The more dissonance, or lack of harmony, between the child's temperament and the parent's ability to accept and deal with the behaviour, the more risk there is for subsequent parent–child conflicts.

Although most behavioural researchers agree that there is a strong biological component to temperament, researchers also suggest that temperament may be modified by the environment, particularly the family (Gallitto, 2015). Family interaction with the infant is perceived as a circular process in which family members affect each other and the family as a unit. With these concepts in mind, the nurse has an important role in helping the family understand the infant's temperament as it relates to family dynamics and the eventual well-being of the child and family unit.

Some researchers speculate that infant temperament may contribute to parents' depression. Depressed mothers and fathers (vs. nondepressed mothers and fathers) rate their infant's temperament as more difficult at 3 and 18 months of age (Kerstis et al., 2013). When reciprocity is lacking between the infant and the parent or when the infant's behaviour does not meet expectations, there is increased risk for discord. Thus depressed mothers need to be identified and assisted in making the transition to motherhood and in developing synchronicity with their infants. Researchers have also correlated fussy infant temperament with the introduction of early complementary feedings (at 3 months of age) (Wasser et al., 2011).

Several instruments can measure infant temperament. These instruments include the Revised Infant Temperament Questionnaire (Carey & McDevitt, 1978), the Infant Behavior Questionnaire (Gartstein & Rothbart, 2003), and the Early Infancy Temperament Questionnaire (Medoff-Cooper et al., 1993). In discussing test results to parents, it is best to avoid descriptors (such as "difficult"); instead, infants can be described in terms of characteristics (such as "intense" or "less predictable").

With knowledge of the infant's temperament, nurses are better able to (1) provide parents with background information that will help them see their child in a better perspective, (2) offer a more organized picture of their child's behaviour and possibly reveal distortions in their perceptions of the behaviour, and (3) guide parents in appropriate child-rearing techniques. Appropriate counselling based on awareness of the child's temperament can greatly enhance the quality of interactions between parents and infant.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Knowledge of the developmental sequence allows the nurse to assess normal growth and minor or abnormal deviations. It also helps parents gain realistic expectations of their child's ability and provides guidelines for suitable play and stimulation. Parents who lack knowledge of child growth and development may set inappropriate behavioural expectations for their child. Emphasizing the child's developmental rather than chronological age strengthens the parent–child relationship by fostering trust and lessening frustration. Therefore, thorough understanding and appreciation of children's growth and development are essential.

Separation and Fear of Strangers

A number of fears can appear during infancy. However, the fear that causes parents the most concern is fear related to strangers and

separation. Although erroneously interpreted by some as a sign of undesirable, antisocial behaviour, fear of strangers and separation anxiety are important components of a strong, healthy, parent–child attachment. Nevertheless, this period can present difficulties for the parent and child. Parents may experience guilt at having to leave the infant because the child violently protests having a babysitter. To accustom the infant to new people, parents can have close friends or relatives visit often. This gives the child the opportunity to become comfortable with other persons and can give parents time for themselves.

Infants also need opportunities to safely experience strangers. Usually toward the end of the first year, infants begin to venture away from the parent and demonstrate curiosity about strangers. If allowed to explore at their own rate, many infants eventually "warm up" to strangers. The best approach for the stranger (who may be the nurse) is to talk softly; meet the child at eye level (to appear smaller); maintain a safe distance from the infant; and avoid sudden, intrusive gestures, such as holding the arms out and smiling broadly.

Parents also may wonder whether they should encourage the child's clinging, dependent behaviour, especially if there is pressure from others who view this as "spoiling the baby." Parents need to be reassured that such behaviour is healthy, desirable, and necessary for the child's optimum emotional development. If parents can reassure the infant of their presence, the infant will learn to realize that they are still there even if not physically present. Talking to infants when leaving the room, allowing them to hear one's voice on the telephone, and using transitional objects (e.g., a favourite blanket or toy) reassures them of the parent's continued presence.

Alternative Child Care Arrangements

For many parents, especially working parents, locating safe and competent child care facilities for the infant has become increasingly difficult. This situation is compounded by the number of families with both parents working outside the home.

The basic types of care are in-home care, either in the parents' or caregivers' home, and centre-based care, usually in a day care centre. *In-home care* may consist of a full-time babysitter who lives in the home, a full-time babysitter who comes to the home, cooperative arrangements such as exchange babysitting, and family day care. A licensed in-home day care typically provides care and protection for up to six children for part of a day and does not include informal arrangements such as exchange babysitting or caregivers in the child's own home. The six-children rule is expected to include the day care provider's own children younger than 6 years of age living in the home. If the children are less than 1 year of age, the ratio may be smaller (i.e., 3:1).

Child centre–based care usually refers to a licensed day care facility that provides care for six or more children, for 6 or more hours a day. *Work-based group care* is another option that is becoming increasingly popular as employers recognize the benefit of providing high-quality and convenient child care to their employees. *Sick-child care* may also be available for times when the youngster is ill.

Nurses may fulfill a unique role in guiding parents in locating suitable facilities that have a well-qualified staff. Provincial licensing regulations exist in most provinces and territories to ensure that facilities meet minimum standards for such things as staff qualifications, the ratio of staff to children, the safety and cleanliness of the care environment, and behaviour management. These regulations help ensure that any potential risks to the child's well-being are kept to a minimum. Community agencies can assist parents in identifying day care centres that accept children of specific age groups and that are convenient to home and work. Their records should be available to the public and provide reports from the health, safety, and fire departments; periodic evaluations from the licensing agency; complaints filed against the centre; and qualifications of the centre's employees.

The same attention should be applied to locating competent babysitters. References from other parents are essential, and there is no substitute for observing the interaction between the individual and the child. Although very young infants need little if any preparation for the introduction of a new caregiver, older infants may benefit from a gradual placement to reduce stranger anxiety.

One of the areas that is increasingly important in selecting child care is the day care centre's health practices; however, parents often do not check the centre for health and safety features. The CPS has described factors characterizing high-quality child care centres and the developmental and behavioural outcomes of children in these centres (CPS, Public Education Advisory Committee, 2017). Children in day care centres, especially those under 3 years of age, tend to have more illnesses—especially diarrhea, otitis media, respiratory tract infections (especially if the caregiver smokes), hepatitis A, meningitis, and cytomegalovirus—than children cared for in their own home (Lang & CPS, Community Paediatrics Committee, 2009). The strongest predictor of risk of illness is the number of unrelated children in the room. Proactive infection control measures and education of staff have been effective in reducing the incidence of upper respiratory tract infections, diarrhea, and rotavirus in day care centres. Families who have children in out-of-home child care may lose several days of work per year as a result of childhood infections. Parents with infants in day care or in-home care need to discuss safe sleep positions and environments in order to prevent SIDS.

Limit-Setting and Discipline

As infants' motor skills advance and mobility increases, parents face the need to set safe limits to protect the child and establish a positive and supportive parent–child relationship (see Role of the Nurse in Injury Prevention in Chapter 35). Although there are numerous disciplinary techniques, some are more appropriate for this age than others. An effective approach used in disciplining a child is the use of "time-out." The important principle to consider is that the place for time-out needs to be commensurate with the child's abilities. For example, a playpen is better for most infants than a chair. Although parents may be concerned with instituting discipline during infancy, it is important to stress that the earlier effective disciplinary methods are employed, the easier it is to continue these approaches.

Parents must recognize the child's cognitive and behavioural limitations; adequate protection from hazards must be implemented because infants and toddlers do not understand a cause–effect relationship between dangerous objects and physical harm. Children will innately test limits and explore during the exploratory phase of growth; instead of discouraging exploration, parents should provide safe alternatives, put away dangerous household items, and provide consistent discipline and nurturing.

Effective teaching for injury prevention optimally begins in infancy, by helping parents understand the nature of their child's normal development. See Chapter 35 for a discussion of injury prevention. Parents need to be reminded that infants cry because a need is not being met, not to intentionally irritate an adult. The fussy or irritable infant may be a potential victim of abusive head trauma (or other bodily harm) since adults and caregivers may not understand the nature of the infant's crying.

Thumb-Sucking and Use of a Pacifier

Sucking is the infant's chief pleasure and may not be satisfied by breastfeeding or bottle-feeding. It is such a strong need that infants who are deprived of sucking, such as those with a cleft lip repair, will suck on their tongues. Some newborns are born with sucking blisters on their hands from in utero sucking activity.

Pacifier use, particularly that in the early days after birth and in the birth hospital, has gained considerable attention in the scientific

literature. Lawrence and Lawrence (2016), as well as other experts in breastfeeding, recommend that health care workers not introduce pacifiers to breastfed infants unless at the request of the parent. Pacifier use is not recommended as part of the WHO Baby-Friendly Hospital Initiative (Breastfeeding Committee for Canada, 2021). However, in a Cochrane review, the investigators concluded that pacifier use in full-term and healthy infants, started from birth or after lactation was established, did not significantly affect the prevalence or duration of exclusive or partial breastfeeding up to 4 months of age (Jaafar et al., 2016). (For further discussion of the relation between breastfeeding and pacifier use, see Chapter 27, Bottles and Pacifiers.)

Researchers have found that infants put to sleep with a pacifier had a reduced risk of SIDS (see Sudden Infant Death Syndrome later in this chapter). Based on SIDS research, investigators have postulated the following reasons why pacifiers help to prevent SIDS: pacifiers lower the auditory arousal threshold; they may provide a mechanical barrier to rolling over into the prone position; sucking on a pacifier keeps the tongue forward, maintaining upper airway patency; an infant who is soothed by a pacifier may not move as often during sleep, thus limiting the chance of becoming covered by blankets; pacifiers might reduce gastroesophageal reflux and subsequent apnea; and pacifier use could lead to slight carbon dioxide retention and increase the respiratory drive. The CPS (Ponti & CPS, Community Paediatrics Committee, 2003/2018) has also stated that pacifier use may decrease the risk of SIDS, but given the lack of definitive research on pacifiers the decision on their use is left to the parents. If pacifiers are used, they should not be given to the child until breastfeeding is well established and should be restricted if infants and children experience frequent or recurrent otitis media (Ponti & CPS, Community Paediatrics Committee, 2003/2018). Pacifier use should not replace actual feeding or suckling; prohibiting pacifier use will not ensure an increase in the length of breastfeeding; and there should be an emphasis on allowing the infant to control the pace, frequency, and termination of feeding rather than allowing the pacifier (or anything else) to become the focus of the interaction.

Pacifier use during painful procedures in newborns has also been shown to produce an analgesic effect when combined with a concentrated sucrose solution (Harrison et al., 2015) (see Chapter 34).

Infants' use of a pacifier has been suggested as a causative factor in the increase in episodes of acute otitis media, particularly when use is extended and more frequent (Ponti & CPS, Community Paediatrics Committee, 2003/2018).

Families need to receive instruction on the safe and appropriate use of pacifiers (CPS, 2017) and on safety considerations when purchasing one (see Figure 26.27). Parents should be cautioned against altering a pacifier, thus making it more dangerous.

To decrease dependence on non-nutritive sucking in young infants, sucking pleasure can be increased by prolonging feeding time. Also, the parent's excessive use of the pacifier to calm the child should be explored. It is not unusual for parents to place a pacifier in the infant's mouth as soon as crying begins, thus reinforcing a pattern of distress-relief. By the same token, when parents are overly concerned about the child's sucking of the fingers, thumb, or pacifier they may attempt to restrain this natural tendency. Before giving advice, the nurse should investigate the parents' feelings and base guidance on this information.

During infancy and early childhood there is no need to restrain non-nutritive sucking of the fingers. Malocclusion may occur if thumb-sucking persists past 4 to 6 years of age, or when the permanent teeth erupt. Pacifiers may be perceived by some parents as less damaging because they are discarded by 2 to 3 years of age, whereas thumb-sucking may persist well into school-age years. Both pacifier use and thumb-sucking may also have significant cultural variations. Thumb-sucking reaches its peak at age 18 to 20 months and is most prevalent when the child is hungry, tired, or feeling insecure. Persistent thumb-sucking in a listless, apathetic child always warrants investigation. It may be a sign of an emotional issue between parent and child or of boredom, isolation, and lack of stimulation.

Teething

One of the more difficult periods in the infant's (and parents') life is the eruption of the deciduous (primary) teeth, often referred to as *teething*. The age of tooth eruption varies considerably among children, but the order of tooth appearance is fairly regular and predictable (Figure 36.10). The first primary teeth to erupt are the lower central incisors, which appear at approximately 6 to 10 months of age (average 8 months). These are followed by the upper central incisors. The following is a quick guide to assessment of deciduous teeth during the first 2 years:

Age of the child in months − 6 = Number of teeth

For example: 8 months of age − 6 = 2 teeth

Teething is a physiological process; some discomfort is common as the crown of the tooth breaks through the periodontal membrane. Some children show minimum evidence of teething, such as drooling, gum rubbing, increased finger sucking, or biting on hard objects. Others are very irritable and have difficulty sleeping, ear rubbing, and decreased interest in solid foods. Generally, signs of illness such as fever, vomiting, or diarrhea are not symptoms of teething but of illness and may warrant further investigation. Parents need to be cautioned not to overdiagnose teething; the ill-appearing child or child with a temperature over 38°C should be evaluated by a health care provider.

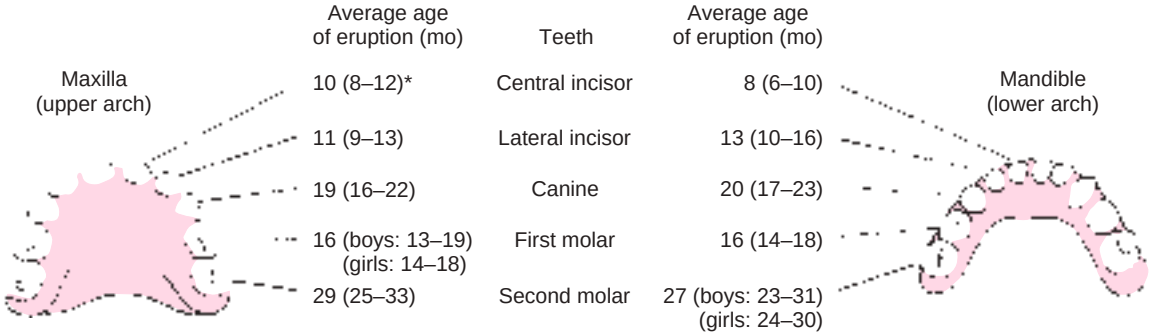

Fig. 36.10 Sequence of eruption of primary teeth. *Range represents ±1 standard deviation, or 67% of subjects studied. (From American Dental Association. [n.d.]. *Eruption charts*. Retrieved from http://www.mouthhealthy.org/en/az-topics/e/eruption-charts.)

Because teething pain is a result of **inflammation**, application of cold is soothing. Giving the child a cold teething ring helps relieve the inflammation (but liquid-filled teaching rings should not be frozen). Several nonprescription topical anaesthetic ointments are available, although parents and health practitioners should be aware of the risks of using topical anaesthetic products, as absorption rates vary in infants and the active ingredient, benzocaine, can rarely cause methemoglobinemia (a condition in which an abnormal amount of methemoglobin, a type of hemoglobin, is produced). If such products are used, parents are advised to apply them according to the product recommendations. The CPS (2021b) does not recommend the use of topical anaesthetics because of the risk of the infant swallowing it. In the event of persistent irritability that affects sleeping and feeding, systemic analgesics such as acetaminophen or ibuprofen (age-appropriate dose) can be given for no more than 3 days. However, parents should know that this is a temporary measure and should contact the health care provider if symptoms persist or if the child's condition changes.

! NURSING ALERT

The use of teething powders or procedures, such as cutting the gums or rubbing them with aspirin, is discouraged because ingestion of the powder, infection or irritation of the tissue, or aspiration of the aspirin can occur. Hard candy may cause accidental choking or aspiration and should be avoided at this age.

HEALTH PROMOTION AND ANTICIPATORY GUIDANCE FOR FAMILIES

Child-rearing is no easy task; it presents challenges to both new and "seasoned" parents. Society's changing roles and mores, combined with a highly mobile population, leave little stability for traditional role models and time-honoured methods of raising children. As a result, parents often look to health care providers for guidance. Nurses are in an advantageous position to render assistance and offer suggestions. For parents of an infant, some challenges centre on dependency, discipline, increased mobility, and safety. Major areas for parental guidance during the first year are listed in the Family-Centred Care box: Guidance During the Infant's First Year.

Chapter 35 discusses topics that are important to teach caregivers related to health promotion during infancy. Topics include nutrition, sleep and activity, dental health, immunizations, and injury prevention.

FAMILY-CENTRED CARE

Guidance During the Infant's First Year

First 6 Months

- Teach car passenger safety with use of a government-approved restraint, facing toward the rear, in the middle of the back seat—not in a front seat with an air bag.
- Understand each parent's adjustment to the newborn, especially the parent's postpartum emotional needs.
- Teach care of the infant and help parents understand the infant's individual needs and temperament and that the infant expresses wants through crying.
- Reassure parents that the infant cannot be spoiled by too much attention during the first 4 to 6 months.
- Encourage parents to establish a schedule that meets the needs of the child and themselves.
- Help parents understand the infant's need for stimulation in the environment.
- Support parents' pleasure in seeing the child's growing friendliness and social response, especially smiling.
- Plan anticipatory guidance for safety.
- Stress the need for routine childhood immunizations.
- Prepare parents for the introduction of solid foods.

Second 6 Months

- Prepare parents for the child's "stranger anxiety."
- Encourage parents to allow the child to cling to them and to avoid long separation from either parent.
- Guide parents concerning discipline because of the infant's increasing mobility.
- Encourage use of negative voice and eye contact rather than physical punishment as a means of discipline.
- Encourage showing the most attention when the infant is behaving well, rather than when the infant is crying.
- Teach injury prevention with regard to the child's advancing motor skills and curiosity.
- Encourage parents to leave the child with a suitable caregiver to allow them some free time.
- Discuss readiness for introduction of using a cup.
- Explore parents' feelings about their infant's sleep patterns.

Traumatic Head Injury due to Child Maltreatment

Traumatic head injury due to child maltreatment (THI-CM), formerly known as abusive head trauma or **shaken baby syndrome** (SBS), is a serious form of child abuse caused by violent shaking of an infant or young child. This shaking can be easily recognized by others as dangerous and is most often a result of the caregiver's frustration with an infant's crying. Shaken babies can have serious neurological injuries with significant morbidity and mortality.

It is important to understand what happens in THI-CM. Infants have a large head-to-body ratio, weak neck muscles, and a large amount of water in the brain. Violent shaking causes the brain to rotate within the skull, resulting in shearing forces that tear blood vessels and neurons. The characteristic injuries that occur are intracranial bleeding (subdural and subarachnoid hematomas) and retinal hemorrhages, but they may also include fractures of the ribs and long bones. Most often there are no external signs of injury. THI-CM is often not an isolated event; in one study, 45% of the children with inflicted traumatic brain injury caused by shaking showed some evidence of prior injury (CPS, Child and Youth Maltreatment Section, 2007/2013).

Victims of THI-CM can manifest a variety of symptoms, from generalized flulike symptoms to unresponsiveness with impending death (CPS, Child and Youth Maltreatment Section, 2007/2013). Many of the presenting symptoms, such as vomiting, irritability, poor feeding, and listlessness, are often mistaken for common infant and childhood ailments. In more severe forms, presenting symptoms may include seizures, posturing, alterations in level of consciousness, apnea, bradycardia, or death. The long-term outcomes of THI-CM include seizure disorder, visual impairments, including blindness, developmental delays, hearing loss, cerebral palsy, and mild to profound mental, cognitive, and motor impairments. See Chapter 35 for information on child maltreatment.

Nurses can take an active role in preventing THI-CM by teaching all caregivers about infant crying and techniques to safely cope with inconsolable crying, such as checking the infant for obvious signs of upset (such as hunger, need to burp, illness, discomfort from clothes or pinching, dirty diaper); calling a friend or family member to talk if frustrated; placing the baby safely in their crib on their back and leaving the child, checking every 5 to 10 minutes; and talking to a help line or health care provider for support. The Period of PURPLE Crying

program has been implemented in many provinces; see Chapter 26, Family-Centred Care box: The Period of PURPLE Crying (also see Additional Resources at the end of the chapter). This program is designed to help parents understand increased levels of crying that occur at about 2 weeks of age and continue until about 3 to 4 months of age, which is a normal developmental stage when infants cry more and turn purple. The program provides tips on how to soothe infants, such as carrying the infant over the shoulder. HealthLink BC (2019) provides tips for parents dealing with children who cry from being overstimulated or overtired. One such tip involves taking the child to a quiet, dark, and safe space, closing the door, and setting a kitchen timer for 15 to 20 minutes. If the child has not settled down after 15 to 20 minutes, parents should check to see whether there is another reason for the crying.

! NURSING ALERT

Nurses should emphasize to parents the danger of shaking an infant (shaking can cause abusive head trauma). Education must include coping mechanisms for caring for children with inconsolable crying.

SPECIAL HEALTH CONCERNS

Colic (Paroxysmal Abdominal Pain)

Colic is reported to occur in 15 to 20% of all infants (Milidou et al., 2014; Savino et al., 2015). In fewer than 5% of infants who have excessive crying, a medical cause for the crying may be identified (Akhnikh et al., 2014). The condition is defined by the rule of threes: crying and fussing for more than 3 hours per day occurring more than 3 days per week and for more than 3 weeks in a healthy infant (Johnson et al., 2015). Infants commonly develop an increase in symptoms (fussiness and crying) in the evening that is unprovoked (Johnson et al., 2015); however, in some infants, the onset of symptoms occurs at another time. Colic is more common in infants younger than 3 months of age than in older infants, and infants with difficult temperaments are more likely to be colicky.

The condition is generally described as paroxysmal abdominal pain or cramping that is manifested by loud crying and drawing the legs up to the abdomen. Despite the obvious behavioural indications of pain, the infant with colic gains weight and usually thrives. There is no evidence of a residual effect of colic on older children, except perhaps a strained parent–child relationship in some cases; in other words, infants who are colicky grow up to be healthy children and adults. Colic is self-limiting and in most cases resolves as infants mature, generally at around 12 to 16 weeks of age (Akhnikh et al., 2014).

Among the theories that have been investigated as potential causes are too-rapid feeding, overeating, swallowing excessive air, poor feeding technique (especially in positioning and burping), and emotional stress or tension between the parent and child. Although all of these may occur, there is no evidence that one factor is consistently present. Infants with symptoms of cow's milk allergy (CMA) have a high rate of colic (44%), and eliminating cow's milk products from the infant's diet can reduce the symptoms. However, there is considerable controversy about the role of allergy and colic because there does not appear to be an increased incidence of atopy in infants with colic.

The exact cause of colic is not fully understood, but some experts believe maternal smoking, inadequate parent–infant interaction, lactase deficiency, difficult infant temperament, fecal microflora, and abnormal gastrointestinal motility are potential causes of colic (Johnson et al., 2015). The consensus of most experts who study colic is that it is multifactorial in nature and no single treatment for every colicky infant will be effective in alleviating the symptoms. New information suggests that what used to be called colic is actually a normal part of an infant's development (CPS, 2021a). All infants go through a time period early in life when they cry more than at any other time, and some infants generally cry more often than others.

Therapeutic Management. Management of colic should begin with an investigation of possible organic causes, such as CMA, intussusception, or some other gastrointestinal issue. If a sensitivity to cow's milk is strongly suspected, a trial substitution of another formula, such as an extensively hydrolyzed (e.g., Nutramigen, Alimentum, Pregestimil), whey hydrolysate, or amino acid (e.g., Neocate, EleCare) formula, is warranted. Soy formulas are usually avoided because of the possibility of sensitivity to soy protein as well. An analysis of several small studies has suggested that probiotic use, specifically *Lactobacillus reuteri*, may improve colic in breastfed babies, although the benefit of probiotic use in formula-fed infants requires further study (Sung et al., 2018). Despite showing promise as a potential therapeutic option in the treatment of colic, the CPS cautions that there is insufficient evidence to support probiotics as a treatment for colic (Marchand & CPS, Nutrition and Gastroenterology Committee, 2012/2019). In a position statement, Critch and the CPS Nutrition and Gastroenterology Committee (2011/2018) concluded that dietary modifications are beneficial in some cases but not all. The CPS does not recommend making nutrition interventions in most infants with colic unless the infant has CMA symptoms. Breastfeeding mothers could try eliminating cow's milk from their diet as a trial for 3 to 5 days.

The use of medications, including sedatives, antispasmodics, antihistamines, and antiflatulents is sometimes recommended. However, in most controlled studies, none of these medications completely eliminated the symptoms of colic. Behavioural interventions have not proved effective at reducing symptoms of colic but have helped parents cope with the crying infant in a more positive manner. The use of complementary medicines for infantile colic, such as fennel extract, herbal tea, and sugar solutions, lack sufficient evidence to recommend their use (Perry et al., 2011).

Nursing Care. The initial step in managing colic is to take a thorough, detailed history of the usual daily events. Areas that should be examined include (1) the infant's diet; (2) the diet of the breastfeeding mother; (3) the time of day when crying occurs; (4) the relationship of the crying to feeding time; (5) the presence of specific family members during the crying and of habits of family members, such as smoking; (6) activity of the mother or usual caregiver before, during, and after the crying; (7) characteristics of the cry (e.g., duration, intensity); (8) measures used to relieve the crying and their effectiveness; and (9) the infant's stooling, voiding, and sleeping patterns. Of special emphasis is a careful assessment of the feeding process via demonstration by the parent.

If CMA is suspected, the breastfeeding parent should follow a milk-free diet for a minimum of 3 to 5 days in an attempt to reduce the infant's symptoms. Mothers need to be cautioned that some nondairy creamers may contain calcium caseinate, a cow's milk protein. If a milk-free diet is helpful, lactating mothers may need calcium supplements to meet their own body's requirement. Formula-fed infants may improve with the same dietary modifications as for the child with CMA (Critch & CPS, Nutrition and Gastroenterology Committee, 2011/2018). Additional approaches for managing colic are listed in the Family-Centred Care box: Caring for the Colicky Infant. Parents should be encouraged to try as many of these approaches as possible, since not all are effective for every infant.

Perhaps the most important nursing intervention (before or after an organic cause has been eliminated) is reassurance of both parents that they are not doing anything wrong and that the infant is not experiencing any physical or emotional harm. Parents, especially mothers, can

become easily frustrated with the infant's crying and perceive this as a sign that there is something horribly wrong, when this may be part of an infant's normal development. In addition, colicky infants may be at increased risk for being shaken or otherwise abused by their caregivers and experiencing THI-CM. A survey of fathers of colicky infants revealed that professional assistance was limited. The fathers described the experience of having a colicky infant as similar to falling into an abyss from which they had to climb with the assistance of family and friends, thus reinforcing the importance of support from empathetic nurses (Ellett et al., 2009). An empathetic, gentle, and reassuring attitude, in addition to suggestions for treatment, will help allay parents' anxieties, which are usually exacerbated by loss of sleep and preoccupation over the infant's welfare. Colic disappears spontaneously, usually by 3 to 4 months of age, although guarantees should never be given since it may continue for much longer. Other support persons and extended family members may be enlisted to help support the parents during this difficult time.

FAMILY-CENTRED CARE

Caring for the Colicky Infant

- Place the awake infant prone over a covered hot-water bottle, heated towel, or covered heating pad set on "low."
- Massage the infant's abdomen.
- Respond immediately to the crying.
- Change the infant's position frequently; walk with the child's face down and body across the parent's arm, with the parent's hand under the infant's abdomen, applying gentle pressure (Figure 36.11).
- Use a front carrier for transporting the infant.
- Place the infant in an electric (or wind-up) infant swing for short periods.
- Take the infant for car rides or outside for a change in environment.
- Use bottles that minimize air swallowing (curved bottle or inner collapsible bag).
- Use a commercial device in the crib that stimulates the vibration and sound of a car ride or plays soothing "noise," in utero sounds, or music.
- Provide smaller, frequent feedings; burp the infant during and after feedings using the shoulder position or sitting upright, and place the infant in an upright seat after feedings.
- Introduce a pacifier for added sucking.
- If household members smoke they should avoid smoking near the infant; smoking must be done outside the home.
- If nothing reduces the crying, place the infant in the crib and allow them to cry; periodically hold and comfort the child and put them down again.
- Maintain a brief diary of the time of day the crying starts; events going on in household; time, amount, and type of last feeding; length of crying; and characteristics of cry. Although this will not stop the crying, it may help the practitioner identify a possible cause.

Failure to Thrive (Growth Failure)

Failure to thrive (FTT), or growth failure, is a sign of inadequate growth resulting from an inability to obtain or use calories required for growth. FTT has no universal definition, although one of the more common parameters is a weight (and sometimes height) that falls below the fifth percentile for the child's age. Another definition of FTT includes a weight for age (height) *z*-value of less than −2.0 (a *z*-value is a standard deviation value that represents anthropometric data normalizing for sex and age with greater precision than growth percentile curves) (Atalay & McCord, 2012). The Canadian growth charts should be used to measure growth. A third way to define FTT is a weight curve that crosses more than 2 percentile lines on a standardized growth chart after previous

Fig. 36.11 The "colic carry" may be comforting to an infant with colic. (iStock.com/OndroM)

achievement of a stable growth pattern. Weight for length is reported to be a better indicator of acute undernutrition (Becker et al., 2015). Growth measurements alone are not used to diagnose children with FTT. Rather, the finding of a pattern of persistent deviation from established growth parameters is cause for concern. In addition to lack of consensus on the precise definition of FTT, some advocate for a change in terminology; thus terms such as *growth failure* and *pediatric undernutrition* are used in the literature for FTT. The term *FTT* will be used in the following discussion. According to Cole and Lanham (2011), approximately 5 to 10% of children in primary care have FTT, with the majority presenting before the age of 18 months.

Some experts suggest that the previously used classifications of organic FTT and nonorganic FTT are too simplistic because most cases of growth failure have mixed causes; they suggest that FTT be classified according to pathophysiology in the categories in Box 36.1.

The cause of growth failure is often multifactorial and involves a combination of infant organic disease, dysfunctional parenting behaviours, subtle neurological or behavioural issues, and disturbed parent–child interactions (Marchand & CPS, Nutrition and Gastroenterology Committee, 2012/2020). However, the primary etiology is inadequate caloric intake, regardless of the cause.

Infants who are premature and have a very low birth weight (VLBW) or extremely low birth weight (ELBW), as well as those with

BOX 36.1 Pathophysiological Causes of Failure to Thrive

Inadequate caloric intake: Incorrect formula preparation, neglect, food fads, excessive juice consumption, lack of food availability, breastfeeding difficulties, behavioural issues affecting eating, or central nervous system conditions affecting intake

Inadequate absorption: Food allergy, malabsorption, pyloric stenosis, gastrointestinal atresia, inborn errors of metabolism

Excessive caloric expenditure: Hyperthyroidism, malignancy, congenital heart disease, chronic pulmonary disease, or chronic immunodeficiency

Adapted from Cole, S. Z., & Lanham, J. S. (2011). Failure to thrive: An update. *American Family Physician, 83*(7), 829–834.

intrauterine growth restriction (IUGR), are often referred for FTT within the first 2 years of life because they typically do not grow physically at the same rate as term normal-weight infants even after discharge from the acute care facility. Catch-up growth has been shown to be much more difficult to achieve in ELBW and VLBW infants.

Other factors that can contribute to inadequate caloric intake in infancy include inadequate financial resources for food, health or child-rearing beliefs involving fad diets, inadequate nutritional knowledge, family stress, feeding resistance, and insufficient breast milk intake. In infants younger than 8 weeks, breastfeeding difficulties as a result of inadequate latch or uncoordinated sucking and swallowing may occur (Cole & Lanham, 2011).

Diagnostic Evaluation. Diagnosis is initially made from evidence of growth failure. If FTT is recent, the weight, but not the height, is below accepted standards (usually the fifth percentile); if FTT is long-standing, both weight and height are low, indicating chronic malnutrition. The use of weight velocities (according to the WHO growth charts) may be a better indicator of short-term growth failure while considering age-dependent changes in growth (Cole & Lanham, 2011) (see Additional Resources at the end of this chapter). Perhaps as important as anthropometric measurements are a complete health and dietary history (including perinatal history), physical examination for evidence of organic causes, developmental assessment, and family assessment. A dietary intake history, either a 24-hour food intake or a history of food consumed over a 3- to 5-day period, is also essential. In addition, the child's activity level, perceived food allergies, and dietary restrictions, as well as parental height, should be explored. An assessment of household organization and mealtime behaviours and rituals is important in the collection of pertinent data. It is also helpful to obtain the growth patterns of parents and siblings. An assessment of the home environment and child–parent interaction may be helpful as well. Other tests (lead toxicity, anemia, stool-reducing substances, occult blood, ova and parasites, alkaline phosphatase, and zinc levels) are selected only as indicated to rule out organic causes.

To prevent the overuse of diagnostic procedures, FTT should be considered early in the differential diagnosis. To avoid the social stigma of FTT during the early investigative phase, many health care providers use the term *growth delay* (or *failure*) until the actual cause is established.

Therapeutic Management. The primary management of FTT is aimed at reversing the cause of the growth failure. If malnutrition is severe, the initial treatment is directed at reversing the malnutrition. The goal is to provide sufficient calories to support "catch-up" growth—a rate of growth greater than the expected rate for age. In addition to adding caloric density to feedings, the child may require multivitamin supplements and dietary supplementation with high-calorie foods and drinks. Any coexisting medical conditions are treated.

In most cases of FTT, an interdisciplinary team of physician, nurse, dietitian, child life specialist, occupational therapist, pediatric feeding specialist, and social worker or mental health care provider is needed to manage the multiple issues in order to provide comprehensive care that addresses the biological, psychiatric, and socioeconomic aspects of the child's life. Efforts are made to relieve any additional stresses on the family by offering referrals to welfare agencies or supplemental food programs. In some cases, family therapy may be required; temporary placement in a foster home may relieve the family's stress, protect the child, and allow the child some stability if insurmountable obstacles are preventing appropriate family functioning. Behaviour modification aimed at mealtime rituals (or lack thereof) and family social time may be required. Hospitalization is indicated for (1) evidence (anthropometric) of severe acute malnutrition, (2) child abuse or neglect, (3) significant dehydration, (4) caretaker substance use or psychosis, (5) serious intercurrent infection, or (6) outpatient management that does not result in weight gain.

Prognosis. The prognosis for FTT is related to the cause. If the parents have simply not understood the infant's needs, teaching may remedy the child's limited caloric intake and permanently reverse the growth failure. Inadequate or infrequent feeding periods by the infant's primary caregiver, in conjunction with family disorganization, are often the cause of FTT.

Few long-term studies provide evidence on the prognosis for children with FTT; however, experts indicate that children who had FTT as infants are at risk for shorter heights and delayed development compared to that of their peers (Nangia & Tiwari, 2013). Factors related to poor prognosis are severe feeding resistance, parents' lack of awareness of and collaboration in healthy child care, limited family income, low maternal educational level, the mother being an adolescent, preterm birth, IUGR, and early age of onset of FTT. Because later cognitive and motor function are affected by malnourishment in infancy, many of these children are below normal in intellectual development, with childhood IQ scores significantly lower than those of peers without a history of malnourishment (Romano et al., 2015). In addition, there is a higher likelihood of eating and behavioral issues among children with a history of malnutrition than among their peers (Romano et al., 2015). Such findings indicate that a long-term plan and follow-up care are needed for the optimal development of these children.

Nursing Care. Nurses play a critical role as part of the interdisciplinary team in the diagnosis of FTT through their assessment of the child, parents, and family interactions. Having a primary core of nurses is beneficial in understanding the family dynamics (Figure 36.12). Knowledge of the characteristics of children with FTT and their families is essential in helping identify these children and hastening confirmation of a diagnosis (Box 36.2). Accurate assessment of initial weight and height and daily weight, as well as recording of all food intake, is essential. The nurse needs to document the child's feeding behaviour and the

Fig. 36.12 Consistent nursing contact is important in developing trust in infants with failure to thrive.

BOX 36.2 Clinical Manifestations of Growth Failure (Failure to Thrive)

Growth failure (see earlier in chapter for definitions)
Undernutrition
Developmental delays—social, motor, adaptive, language
Apathy
Withdrawn behaviour
Feeding or eating disorders, such as vomiting, feeding resistance, anorexia, pica, rumination
No fear of strangers (at age when stranger anxiety is normal)
Avoidance of eye contact
Wide-eyed gaze and continual scan of the environment ("radar gaze")
Stiff and unyielding or flaccid and unresponsive
Minimal smiling

parent–child interaction during feeding, other caregiving activities, and play.

Some parents are at increased risk for attachment issues because of (1) isolation and social crisis; (2) inadequate support systems, such as for teenage and single mothers; and (3) inadequate parenting role models as a child. Other factors that should be considered are lack of education; physical and mental health challenges such as physical and sexual abuse, depression, or medication dependence; immaturity, especially in adolescent parents; and lack of commitment to parenting, such as giving priority to entertainment or employment. Often these parents and their families are under stress and in multiple chronic emotional, social, and financial crises.

Children with FTT may use feeding as a control mechanism or an attention-seeking mechanism in a poorly organized or chaotic family situation. Parents may allow the child to dictate the norms for behaviour and feeding because of inexperience with parenting or poor parenting role models. Thus, refusing to eat or eating only sweets and snacks with non-nutritive value may be the child's norm, based on food availability and family tradition. General guidelines for the feeding process are outlined in the Guidelines box: Feeding Children With Growth Failure (Failure to Thrive).

GUIDELINES

Feeding Children With Growth Failure (Failure to Thrive)

Provide a primary core of staff to feed the child. The same nurses are able to learn the child's cues and respond consistently.

Provide a quiet, unstimulating atmosphere. A number of these children are very distractible, and their attention is diverted with minimal stimuli. Older children do well at a feeding table; bottle-fed infants and children should always be held.

Maintain a calm, even temperament throughout the meal. Negative outbursts may be commonplace in this child's habit formation. Limits on eating behaviour definitely need to be provided, but they should be stated in a firm, calm tone. If the nurse is hurried or anxious, the feeding process will not be optimized.

Talk to the child by giving directions about eating. "Take a bite, Lisa" is appropriate and directive. The more distractible the child, the more directive the nurse should be to refocus attention on feeding. Positive comments about feeding need to be actively given.

Be persistent. This is perhaps one of the most important guidelines. Parents often give up when the child begins negative feeding behaviour. Calm perseverance through 10 to 15 minutes of food refusal will eventually diminish negative behaviour. Although forced feeding is avoided, "strictly encouraged" feeding is essential.

Maintain a face-to-face posture with the child when possible. Encourage eye contact and remain with the child throughout the meal.

Introduce new foods slowly. Often these children have been exclusively bottle-fed. If acceptance of solids is difficult, begin with puréed food and, once accepted, advance to junior and regular solid foods.

Follow the child's rhythm of feeding. The child will set a rhythm when the previous conditions are met.

Develop a structured routine. Disruptions in their other activities of daily living have a great impact on feeding responses, so bathing, sleeping, dressing, and playing, as well as feeding, should be structured. The nurse should feed the child in the same way and place as often as possible. The length of the feeding should also be established (usually 30 minutes).

Four primary goals in the nutritional management of FTT are to (1) correct nutritional deficiencies and achieve ideal weight for height, (2) provide adequate calories for catch-up growth, (3) restore optimum body composition, and (4) educate the parents or primary caregivers regarding the child's nutritional requirements and appropriate feeding methods. For infants, 24 kcal/30 mL formulas may be provided to increase caloric intake; older children (1 to 6 years) may benefit from a 30 kcal/30 mL formula (Marchand & CPS, Nutrition and Gastroenterology Committee, 2012/2020). Other carbohydrate additives include fortified rice cereal and vegetable oil. Because vitamin and mineral deficiencies may be present, multivitamin supplementation, including zinc and iron, is recommended. Usually only in extreme cases of malnourishment are tube feedings or intravenous therapy required. Juice intake needs to be restricted in children with FTT until adequate weight gain has been achieved with appropriate milk sources; thereafter, no more than 120 mL/day of juice should be given.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant younger than 1 year of age that remains unexplained after a complete postmortem examination, including an investigation of the death scene and a review of the case history. Since 2002, the data have included another term, *sudden unexplained death in infants* (SUDI). SIDS and SUDI combined are the third leading cause of infant deaths (birth to 12 months) and the first leading cause of postneonatal deaths (between 1 and 12 months). The rate of SIDS in Canada is 11.3 per 100 000 live births; in 2013, 43 infants died as a result of SIDS (Canadian Institute of Child Health, 2021). Infants who are male, premature, or of low birth weight, as well as infants from socioeconomically disadvantaged and Indigenous populations, have a higher incidence of SIDS (Public Health Agency of Canada [PHAC], 2014). The PHAC has reported that the infant mortality rates due to SIDS have fallen in Canada in recent decades; this decrease is attributed to the Back to Sleep campaign, initiated in 1999. Table 36.2 summarizes the major epidemiological characteristics of SIDS.

Etiology. Numerous theories have been proposed regarding the etiology of SIDS; however, the cause remains unknown. One compelling hypothesis is that SIDS is related to a brainstem abnormality in the neurological regulation of cardiorespiratory control. This abnormal development affects the arousal and physiological responses to a

TABLE 36.2 Epidemiology of Sudden Infant Death Syndrome (SIDS)

Factors	Occurrence
Incidence	11.3 per 100 000 live births in 2013 in Canada*
Peak age	2 to 3 months and 95% occur by 6 months. Premature infants die at mean age 6 weeks later than mean age of death from SIDS for term infants
Sex	Higher percentage of males affected
Time of death	During sleep
Time of year	Increased incidence in winter
Socioeconomic	Increased occurrence in lower socioeconomic class
Birth	Higher incidence in: • Preterm infants, especially infants of extremely and very low birth weight • Multiple births† • Newborns with low Apgar scores • Infants with central nervous system disturbances and respiratory disorders such as bronchopulmonary dysplasia • Increasing birth order (subsequent siblings as opposed to firstborn child) • Infants with a recent history of illness, lower incidence in immunized infants
Sleep habits	Highest risk associated with prone position; use of soft bedding; overheating (thermal stress); co-sleeping with adult, especially on sofa or noninfant bed; higher incidence of co-sleeping with an adult smoker
	Infants co-sleeping with adult at higher risk if they are younger than 11 weeks
Feeding habits	Lower incidence in breastfed infants
Pacifier	Lower incidence in infants put to sleep with pacifier
Siblings	May have greater incidence in siblings with SIDS
Maternal	Young age; cigarette smoking, especially during pregnancy; limited prenatal care; substance use (heroin, methadone, cocaine); a few studies have shown an increased risk in infants exposed to secondhand environmental tobacco smoke

*Data from Canadian Institute of Child Health. (2019). *The health of Canada's children and youth. Section 7: Health outcomes*. https://cichprofile.ca/module/8/section/7/page/rate-of-infant-deaths-due-to-sudden-infant-death-syndrome-sids-canada-2000-to-2013/.
†Although rare, twins can die simultaneously of SIDS.
Adapted from Public Health Agency of Canada. (2018). *Joint statement on safe sleep: Preventing sudden infant deaths in Canada*. http://www.phac-aspc.gc.ca/hp-ps/dca-dea/stages-etapes/childhood-enfance_0-2/sids/pdf/jsss-ecss2011-eng.pdf.

life-threatening situation during sleep (PHAC, 2018). Abnormalities include prolonged sleep apnea, increased frequency of brief inspiratory pauses, excessive **periodic breathing**, and impaired arousal responsiveness to increased carbon dioxide or decreased oxygen. However, *sleep apnea is not the cause of SIDS*. The vast majority of infants with apnea do not die, and only a minority of SIDS victims have documented apparent life-threatening events (ALTEs) (see Brief Resolved Unexplained Events section later in this chapter). Numerous studies indicate that there is no association between SIDS and any childhood vaccine.

A genetic predisposition to SIDS has been postulated as a cause. A deficiency of the complement component C4 is associated with SIDS cases (Opdal & Rognum, 2011). In addition, polymorphisms among interleukin genes, transforming growth factor, tumour necrosis factor, and interferon gamma are closely associated with cases of SIDS (Opdal & Rognum, 2011).

Three triple-threat hypotheses have been proposed to explain the etiology of SIDS. Proposed factors include an underlying infant vulnerability factor (e.g., brain abnormality), a critical incidence in fetal development period or in early newborn life, and an environment stressor such as prone sleeping (Matthews & Moore, 2013). However, the triple-risk theories have not been fully accepted by all experts as a cause for SIDS, and further data are needed to identify a single cause or combination of causes for SIDS deaths.

Risk Factors for SIDS. Maternal smoking during pregnancy has emerged in numerous epidemiological studies as a major factor in SIDS, and tobacco smoke in the infant's environment after birth has also been shown to have a possible relationship with the incidence of SIDS (PHAC, 2014). It has been postulated that 12% of all SIDS deaths could be prevented with prenatal maternal smoking cessation.

Bed sharing refers to a child sharing a bed with an adult or older child on a noninfant bed. Bed sharing has been reported to have an increased association with SIDS; there is a high association between infant deaths, use of nonstandard beds (sofa, day bed), and bed sharing; a large percentage of infants were found dead on their backs when bed sharing, which suggests suffocation. Studies have correlated higher incidences of SIDS in the context of infant bed sharing when there is also maternal smoking, bed sharing with multiple family members, maternal overweight, soft bedding, or unintentional asphyxiation resulting from adult intoxication (overlaying) (PHAC, 2018). The term *co-sleeping* can refer to a range of sleeping practices that include both bed sharing and room sharing. Co-sleeping occurs in many cultures, and the nurse needs to ask parents about this practice to provide appropriate health teaching.

Room sharing refers to a situation in which an infant is sleeping in close proximity to another person in the same room but in a different bed. Room sharing with infants in the age range when most SIDS deaths occur has been shown to be preventive. The latest recommendation for prevention of SIDS from the PHAC (2018) is that the infant's crib or bassinette be placed in close proximity to the parent's bed and that the infant be placed in the adult bed only for breastfeeding, then placed to sleep in their own crib once the feeding session is completed.

Other studies have linked sleep position with an increased risk of SIDS. Prone sleeping may cause oropharyngeal obstruction or affect thermal balance or arousal state. Healthy full-term infants may have significantly impaired arousal from active and quiet sleep states when sleeping prone. Rebreathing of carbon dioxide by infants in the prone position is another possible cause of SIDS. Infants sleeping prone and on soft bedding may not be able to move their heads to the side, thus increasing the risk of suffocation and lethal rebreathing. There is an increased incidence of SIDS among infants placed in a side-lying position; these infants are able to turn to a prone position. Thus the side-lying position is no longer recommended for infants sleeping at home or in day care centres or hospitals (unless medically indicated); healthy infants should be placed to sleep in the supine position (on the back) (PHAC, 2018). Most preterm infants being discharged from the hospital should be placed in a supine sleeping position unless special factors predispose them to airway obstruction.

Parents need to know that certain sleep environments (prone sleeping, tobacco smoke exposure, soft bedding, noninfant bed surface, use of certain medications by the individual sharing the bed with the infant, and overheating) can increase the risk for SIDS. Soft bedding such as waterbeds, sheepskins, beanbags, pillows, or quilts should not be used for infant sleeping surfaces. Head covering by a blanket has also been found to be a risk factor for SIDS, thus supporting the recommendation to avoid use of extra bed linens or other items. Bedding items such as stuffed animals or toys should be removed from the crib while the infant is asleep. Use of crib bumper pads has not been shown to reduce infant injury and should therefore be avoided (PHAC, 2014).

Protective Factors Against SIDS. Research has indicated that breastfeeding during the first 16 weeks of life decreased the likelihood of SIDS. Some studies have found pacifier use in infants to be a protective factor against the occurrence of SIDS; the data for pacifier use in this population of infants (first year of life) are more compelling than data linking pacifier use to the development of dental complications and the inhibition of breastfeeding (PHAC, 2018; Ponti & CPS, Community Paediatrics Committee, 2003/2018).

Although the etiology of SIDS is ultimately unknown, autopsies have revealed consistent pathological findings, such as pulmonary edema and intrathoracic hemorrhages, that confirm the diagnosis of SIDS. Consequently, autopsies should be performed on all infants suspected of dying of SIDS. The findings should be shared with the parents as soon as possible after the death.

Nursing Care. Nurses have a vital role in preventing SIDS, by educating families about the risk of the prone sleeping position in infants from birth to 6 months of age, the use of appropriate bedding surfaces, the association of SIDS with maternal smoking, and the dangers of bed sharing on noninfant surfaces with adults or other children. Also, nurses have an important role in modelling behaviours for parents to foster practices that decrease the risk for SIDS, including placing infants in a supine sleeping position in the hospital. A concern of many health care providers is that infants placed on their back to sleep will aspirate emesis or mucus; studies have failed to show an increase in infant deaths, spitting up during sleep, aspiration, asphyxia, or respiratory failure as a result of supine sleep positioning (American Academy of Pediatrics, Task Force on Sudden Infant Death Syndrome, 2016).

Education can change practice. In one study, after an educational session and use of a laminated reminder card on safe sleep recommendations, neonatal intensive care unit (NICU) nurses showed a significantly increased rate of supine positioning (39% before and 83% after), providing a firm sleeping surface (5% before and 96% after), and removal of soft objects from the bed (45% before and 75% after) for their NICU patients (Gelfer et al., 2013). Role modelling safe sleep practices and providing education to parents are imperative before hospital discharge because limited opportunities exist for parents to receive information about caring for their infant (Ateah, 2013). Nurses must be proactive in further decreasing the incidence of SIDS; after-birth discharge planning, newborn discharges, follow-up home visits, well-baby clinic visits, and immunization visits provide excellent opportunities to educate parents in these matters. The Family-Centred Care box: Safe Sleep for Infants—Reducing the Incidence of Sudden Infant Death provides families ways to reduce the potential incidence of SIDS. There is no evidence that home cardiorespiratory or oxygen saturation monitoring decreases the incidence of SIDS and it is therefore not recommended for this purpose (Hauck et al., 2020).

FAMILY-CENTRED CARE

Safe Sleep for Infants—Reducing the Incidence of Sudden Infant Death

- Always place your baby to sleep on their back. Side and tummy positions are not safe.
- Ensure that the baby spends time on their tummy every day when they are awake and observed.
- Use a crib that meets current safety standards. The mattress should be firm and fit snugly in the crib. Cover the mattress with only a tight-fitting crib sheet.
- Do not put anything soft, loose, or fluffy in your baby's sleep space. This includes pillows, blankets, comforters, soft or pillow-like bumpers, stuffed animals, and other soft items.
- Use a sleep sack or other type of sleeper instead of blankets to keep your baby warm and safe. Make sure your baby doesn't get too warm during sleep.
- Place your baby's separate, safe sleep space near your bed to help you protect them and to make breastfeeding easier. This is called *room sharing*. Bed sharing is not recommended.
- Never place your baby to sleep on top of any soft surface. This includes adult beds, waterbeds, pillows, cushions, comforters, and sheepskins.
- Do not use anything to prop your baby up or keep them on their back.
- Offer your baby a nonsweetened pacifier every time you place them down to sleep. If you are breastfeeding, wait until nursing is well established before using a pacifier (usually around 1 month).
- Avoid smoking.
- Educate everyone who cares for your baby about these safe sleep rules!

Care of the Family of an Infant Lost to Sudden Infant Death Syndrome. Loss of a child from SIDS presents several crises for the parents. In addition to grief and mourning the death of their child, the parents must face a tragedy that was sudden, unexpected, and unexplained. The psychological intervention for the family must deal with these additional variables. The discussion here focuses primarily on the objectives of care for families experiencing SIDS, rather than on the process of grief and mourning, which is explored in Chapter 41.

The first persons to arrive may be the police and emergency medical service personnel. Ideally, they will handle the situation by asking few questions; giving no indication of wrongdoing, abuse, or neglect; making sensitive judgements concerning any resuscitation efforts for the child; and comforting the members of the family as much as possible. A compassionate, sensitive approach to the family during the first few minutes can help spare them some of the overwhelming guilt and anguish that commonly follow this type of death.

The medical examiner or coroner may go to the home or place of death and make the death pronouncement; until then, the sleep environment should remain as it was when the infant was initially found. If the

infant is not pronounced dead at the scene, they may be transported to the emergency department to be pronounced dead by a physician. Usually there is no attempt at resuscitation in the emergency department. While they are in the emergency department, the parents should be asked only factual questions, such as when they found the infant, how the child looked, and whom they called for help. The nurse should avoid any remarks that may suggest responsibility, such as "Didn't you hear the infant cry out?" or "Was the head buried in a blanket?" It is the investigators' responsibility to document these findings at the scene rather than have parents recount the experience in the emergency department. Parents may also express feelings of guilt about administering cardiopulmonary resuscitation (CPR) correctly or the timing of CPR in relation to finding the infant.

At this time, the physician should initiate the discussion of an autopsy, often with the nurse being present to support the family. The physician or medical examiner, depending on the circumstances, should emphasize that a diagnosis cannot be confirmed until the postmortem examination is completed. Requesting an autopsy may be difficult because of the parents' emotional state; however, an autopsy may clear up possible misconceptions regarding the death. Instructions about the autopsy and funeral arrangements may need to be repeated or put in writing. If the mother was breastfeeding, they need information about abrupt discontinuation of lactation. The nurse or physician should contact the primary care practitioner for the infant and the mother to avoid any miscommunications or telephone calls at a later date inquiring about the child's health status. Comprehensive guidelines have been published for health care providers involved in SIDS investigations to assist the family and at the same time determine that the infant's death was not the result of other factors, such as child maltreatment.

Parents experiencing perinatal death perceive health care workers' responses as having a significant impact on the parents' grieving process. A family-centred approach that involves the sociocultural context and unique needs of the family is essential for perinatal bereavement care (Flenady et al., 2014). An important aspect of compassionate care for these parents is allowing them to say goodbye to their child. These are the parents' last moments with their child, and this time should be as quiet, meaningful, peaceful, and undisturbed as possible. Encourage parents to hold their infant before leaving the emergency department. Because the parents leave the hospital without their infant, it can be helpful to accompany them to the car or arrange for someone else to take them home.

When the parents return home, they should be visited by a competent, qualified health care provider as soon after the death as possible. Printed material and websites that contain excellent information about SIDS (available from national organizations) should be provided. One such resources is Baby's Breath, listed in Additional Resources at the end of this chapter. When the unexpected death of a child occurs, it is common for one parent to blame the other for the child's death. Parents may also experience guilt over the child's death; if they had checked earlier, the child might still be alive. It is important that the health care team assist parents in working through these feelings to prevent relationship disruption in addition to the loss of the loved child.

A debriefing session may help health care workers who cared for the family and deceased infant to cope with emotions that are often engendered when a SIDS victim is brought into the acute care facility.

Positional Plagiocephaly

Since the Back to Sleep campaign began in 1999 in Canada, which advocates nonprone sleeping for infants to prevent SIDS, an increase in the incidence of positional plagiocephaly has been observed (Cummings & CPS, Community Paediatrics Committee, 2011/2018). The term *plagiocephaly* connotes an oblique or asymmetrical head; *positional plagiocephaly, deformational plagiocephaly*, or *nonsynostotic plagiocephaly* implies an acquired condition that occurs as a result of cranial **moulding** during infancy. Because the infant's sutures are not closed, the skull is pliable and, when the infant is placed on the back to sleep, the posterior occiput flattens over time (Figure 36.13, *A*); a transient typical bald spot will develop. As a result of prolonged pressure on one side of the skull, that side becomes misshapen; mild facial asymmetry may develop. The sternocleidomastoid muscle may tighten on the preferential side, and torticollis may also develop. Congenital or acquired torticollis may cause plagiocephaly; the discussion here centres only on plagiocephaly caused by the supine sleeping position.

Fig. 36.13 **A:** Plagiocephaly. **B:** Helmet used to correct plagiocephaly. (Courtesy Dr. Gerardo Cabrera-Meza, Department of Neonatology, Baylor College of Medicine.)

Diagnostic Evaluation. The diagnosis of positional plagiocephaly may be made on physical examination of the infant's head; the infant's head is viewed frontally and from above. The typical infant's head shape will resemble a parallelogram, with unilateral flattening of the occiput,

frontal and parietal bossing, a prominent cheekbone, and an anterior ear displacement. An evaluation of neck movement and range of motion is also made to determine the presence of torticollis. In most cases, skull films and further radiological studies (computed tomographic scan) are used only to rule out **craniosynostosis** or any other cranial deformity that may affect brain growth.

Therapeutic Management. Prevention of positional plagiocephaly may begin shortly after birth by placing the infant to sleep supine and alternating the infant's head position nightly, avoiding prolonged placement in car safety seats and swings, and using prone positioning or "tummy time" for approximately 30 to 60 minutes per day when the infant is awake (Cummings & CPS, Community Paediatrics Committee, 2011/2018; PHAC, 2014).

Treatment of torticollis and plagiocephaly initially involves exercises to loosen the tight muscle and changing head position from side to side during feeding, carrying, and sleep. If the plagiocephaly is not resolved within 4 to 8 weeks of physiotherapy, a customized helmet may be worn to decrease the pressure on the affected side of the skull (see Figure 36.13, *B*). The helmet is worn 23 hours a day for a prescribed period (usually 3 months). Repositioning and physiotherapy are said to be more effective when used before the infant can roll over or move their head alone (i.e., before approximately 3 to 4 months of age) (Cummings & CPS, Community Paediatrics Committee, 2011/2018).

Nursing Care. When a nurse or parent notices plagiocephaly, a consultation with the primary health care provider is recommended to evaluate the head shape and ascertain the need for early intervention.

Nurses are in a unique position in well-child care settings to encourage parents to follow guidelines for preventing plagiocephaly, to demonstrate alternating head placement for sleeping, to demonstrate sternocleidomastoid muscle exercises (as appropriate to the condition), and to encourage supervised tummy time for infants during awake periods. Most important, nurses should continue to encourage parents to place the infant in a supine sleep position despite the development of plagiocephaly. Nurses can also assist parents in the proper use of a skull-moulding helmet and reassure them of the high rate of success with the helmet's use. Parents should be encouraged to express concerns and feelings related to the health status of the child. Parents should not become so alarmed by plagiocephaly that they abandon the supine sleeping position for the infant; instead, they should consult with the practitioner for further advice.

Brief Resolved Unexplained Events

A *brief resolved unexplained event* (BRUE), formerly known as an apparent life-threatening event (ALTE), occurs in an infant younger than 1 year and typically lasts less than 30 seconds. It is described by the observer as a sudden, brief, and now-resolved episode that involved at least one of the following (Tieder, 2020):

- Cyanosis or pallor
- Absent, decreased, or irregular breathing
- Marked change in tone, either hyper- or hypotonia
- Altered level of responsiveness

It is erroneous to characterize BRUE as a near-miss SIDS incident. These events are not associated with SIDS and are rarely life-threatening (Tieder, 2020).

Diagnostic Evaluation. An essential component of the diagnostic process includes a physical examination of the infant and a detailed description of the event by the person who witnessed the event. The following questions can be asked (Tieder, 2020):

- What was the infant doing before, during, and after the event?
- Did the infant change colour?
- Did the infant experience apnea or just choking or gagging?
- Was there a concerning change in muscle tone?
- Was there an altered level of responsiveness?
- Did the event self-resolve, or was an intervention required?

Other questions that should be asked include the following: Did the infant have any other symptoms (e.g., fever, upper respiratory infection [URI] symptoms, spitting up)? Is there a history of breathing problems, prenatal or perinatal concerns, prematurity, growth or developmental concerns, or exposure to infectious diseases (e.g., pertussis, respiratory syncytial virus)? A careful feeding history may be used to determine oropharyngeal dysphagia or gastroesophageal reflux–related issues (i.e., laryngospasm). A social history, particularly by someone trained to detect nonaccidental trauma, can reveal recent trauma, prior child welfare involvement, substance use, poisoning or misuse of medications, and environmental exposures (e.g., secondhand smoke and mould) (Tieder, 2020). A BRUE is a diagnosis of exclusion and should be used only when the event is transient and remains unexplained after an appropriate medical evaluation (Tieder, 2020). Further testing should be done given concerns from the history and physical or to further characterize repeat BRUEs.

Therapeutic Management. Occasionally the infant may be admitted to the hospital, although this does not usually lead to a diagnosis of a serious underlying disorder. Sometimes, however, a longer period of observation can help characterize repeat events, should they recur, and reduce the uncertainty of a recurrent event for parents. Additional benefits of hospitalization include further assessments of feeding, breathing, sleep, and social patterns. The decision for hospital admission should incorporate the needs and preferences of the family and the ability to follow up closely with a primary care provider (Tieder, 2020). CPR education should be considered for all families. Home apnea monitoring should not be done as it has not been shown to change outcomes. Close outpatient follow-up with a primary care physician is important, to monitor for repeat events and caregiver support (Tieder, 2020).

Nursing Care. The diagnosis of a BRUE may cause great anxiety and concern in parents. The nurse needs to provide teaching and support to the family. Family members should be encouraged to take a CPR course. Instructions for infant CPR should be posted in a central location of the house and on cell phones. Parents should be encouraged to tell visitors and other family members about the location of such instructions. If a cell phone is the main house phone, it should stay in a central location for all family members to access in an emergency.

! NURSING ALERT

If the infant is apneic, gently stimulate the trunk by patting or rubbing it. Call loudly for help even if alone. If the infant is prone, turn to the back and flick the feet. If there is still no response, immediately begin CPR. After approximately 2 minutes of CPR, activate the emergency medical service—"Call 911!" and then resume CPR until emergency responders arrive or the infant starts breathing. Never vigorously shake the child. No more than 10 seconds are spent on stimulation before implementing CPR.

KEY POINTS

- Biological development of the child encompasses proportional changes; sensory changes, including binocularity, depth perception, and visual preference; maturation of biological systems; fine motor development; and gross motor development.

- Erikson's theory of psychosocial development (birth to 1 year) is concerned with acquiring a sense of trust while overcoming a sense of mistrust.
- Piaget's theory of cognitive development, as it applies to the infant, focuses on the sensorimotor phase, which includes the use of reflexes, primary circular reactions, secondary circular reactions, and coordination of secondary schemata and their application to new situations.
- Development of body image begins in infancy; by 1 year of age, infants recognize that they are distinct from their parents.
- Social development of the infant is guided by attachment, language development, personal-social behaviour, and participation in play.
- Temperament influences the type of interaction that occurs between the child and parents and siblings.
- Parents are faced with many concerns, including selecting an appropriate day care, limit setting and discipline, thumb-sucking and pacifier use, and teething.
- Treatment of colic may involve change in feeding practices, correction of a stressful environment, behaviour modification, and support of the parent.
- Growth failure, or FTT, may occur in children who have a chronic illness, or it may occur in a family environment in which healthy infant feeding practices are poorly managed or understood. FTT is often multifactorial and not always associated with a pattern of a disturbed maternal–infant relationship.
- SIDS is the third leading cause of infant death.
- Factors that place the infant at high risk for SIDS include prone sleeping position, soft bedding, sleeping in a noninfant bed with an adult or older child, low socioeconomic status, and maternal prenatal smoking.
- The primary nursing responsibilities in care associated with sudden infant death are educating the newborn's family about the risks for SIDS; modelling appropriate behaviours in the hospital, such as placing the infant in a supine sleep position; and providing emotional support of the family that has experienced a SIDS loss.
- Positional plagiocephaly can be easily prevented by allowing the awake infant to have periods of supervised tummy time and by alternating the infant's head position during sleep.
- Infants with BRUEs are carefully evaluated for clues to the underlying cause.

The Toddler and Family

Constance O'Connor
Originating US chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the major biological, psychosocial, cognitive, and social developments during the toddler years.
2. Relate separation anxiety and negativism to developmental tasks.
3. Recognize a child's readiness for toilet independence and offer parents guidelines.
4. Prepare parents of toddlers for the birth of a sibling.
5. Provide parents with guidelines for handling temper tantrums.

PROMOTING OPTIMUM GROWTH AND DEVELOPMENT

For children aged 12 to 36 months, it is a time of intense exploration of the environment as they attempt to figure out how things work and learn how to control others through their behaviour, which can include temper tantrums, negativism, and obstinacy. The term *terrible twos* has often been used to describe the toddler years, the period from 12 to 36 months of age. Although the term may be used to describe the toddler's *behaviour*, it is not meant to typify or label the child. Toddlers are very lovable, but because of their search for autonomy, they may test parents' and caregivers' patience. This can be a challenging time for parents and child as each comes to know the other better. It is also an important period for developmental achievement and intellectual growth. Neuroscientists are building a knowledge base supporting the strong relationship between a child's earliest development and environment and the long-term effects later in life on the child's physical and mental health, school performance, and behaviour (Williams et al., 2011). The Canadian Paediatric Society (CPS) has recommended specific evidence-based clinical tools to collect standardized developmental data that are used across Canada. Currently, different tools are being used in various parts of the country. The most commonly used tools include the Nipissing District Developmental Screening (NDDS), the Ages and Stages Questionnaires (ASQ), PEDS/PEDS: DM, and the Rourke Baby Record; these can all be used to assess the toddler stage of growth and development (see Additional Resources at the end of this chapter). See Chapter 33 for more information on developmental screening tools.

Biological Development

Proportional Changes. Growth slows considerably during toddlerhood. The average weight gain is 1.8 to 2.7 kg per year. The birth weight is quadrupled by 2½ years of age. The rate of increase in height also slows. The usual increment is an addition of 7.5 cm per year and occurs mainly in elongation of the legs rather than the trunk. The average height of a 2-year-old is 86.6 cm. In general, adult height is about twice the 2-year-old child's height. Accurate measurement of height and weight during the toddler years should reveal a steady growth curve that is steplike in nature rather than linear, which is characteristic of the growth spurts during the early childhood years. It is important that individual children have specific measurements taken to accurately track their growth patterns. These measurements need to be recorded on a regular basis using a growth chart that compares them with the averages of other children. The Dietitians of Canada, CPS, College of Family Physicians, and Community Health Nurses of Canada have put forward a joint recommendation to use the WHO 2006 Child Growth Standards and the 2007 WHO Growth Reference growth charts for Canadian children (Dietitians of Canada, 2019).

The rate of increase in head circumference slows somewhat by the end of infancy; head circumference is usually equal to chest circumference by 1 to 2 years of age. The usual total increase in head circumference during the second year is 2.5 cm. The anterior fontanel closes between 12 and 18 months of age.

Chest circumference continues to increase in size and exceeds head circumference during the toddler years. After the second year the chest circumference exceeds the abdominal measurement; this, in addition to the growth of the lower extremities, gives the child a taller, leaner appearance. However, the toddler still appears relatively squat and "pot-bellied" because of the less well-developed abdominal musculature and short legs. The legs remain slightly bowed or curved during the second year from the weight of the relatively large trunk.

Sensory Changes. Visual acuity of 20/40 is considered acceptable during the toddler years. Full binocular vision is well developed, and

any evidence of persistent strabismus requires professional attention as early as possible to prevent **amblyopia**. Depth perception continues to develop but, because of the child's lack of motor coordination, falls from heights are a persistent danger.

The senses of hearing, smell, taste, and touch become increasingly well developed, coordinated with each other and associated with other experiences. All of the senses are used to explore the environment. Toddlers will visually inspect an object by turning it over; they may taste it, smell it, and touch it several times before they are satisfied with their investigation. They will shake it to see if it makes noise and vigorously test its durability.

Another example of the integrated function of the senses is the toddler's development of specific taste preferences. The toddler is much less likely than an infant to try a new food because of its appearance, texture, or smell, not just its taste.

Maturation of Systems. Most of the physiological systems are relatively mature by the end of toddlerhood. The volume of the respiratory tract and growth of associated structures continue to increase during early childhood, lessening some of the factors that predisposed the child to frequent and serious infections during infancy. The internal structures of the ear and throat continue to be short and straight, and the lymphoid tissue of the tonsils and adenoids continues to be large. As a result, otitis media, tonsillitis, and upper respiratory tract infections are common. The respiratory and heart rates slow, and the blood pressure increases (see Appendix C). Respirations continue to be abdominal.

Under conditions of moderate variation in temperature, the toddler is able to maintain body temperature. The mature functioning of the renal system serves to conserve fluid under times of **stress**, decreasing the risk of dehydration.

The digestive processes are fairly complete by the beginning of toddlerhood. The acidity of the gastric contents continues to increase and has a protective function, since they are capable of destroying many types of bacteria. Stomach capacity increases to allow for the usual schedule of three meals a day.

One of the more prominent changes of the gastrointestinal system is the voluntary control of elimination. With complete myelination of the spinal cord, control of the anal and urethral sphincters is gradually achieved. The physiological ability to control the sphincters probably occurs somewhere between ages 18 and 24 months. Bladder capacity also increases considerably, and by 14 to 18 months of age the child is able to retain urine for up to 2 hours or longer.

The defence mechanisms of the skin and blood, particularly phagocytosis, are much more efficient in toddlers than in infants. The production of antibodies is well established. However, many young children demonstrate a sudden increase in colds and minor infections when they enter preschool or other group situations, such as day care, because of their exposure to pathogens.

Gross and Fine Motor Development. The major gross motor skill during the toddler years is the development of locomotion. By 12 to 13 months of age, toddlers try to walk alone using a wide stance for extra balance, and by 18 months they try to run, but they fall easily (Figure 37.1). At age 2 years, toddlers can walk up and down stairs; by age 2 ½ years they can jump using both feet, stand on one foot for a second or two, manage a few steps on tiptoe, and climb stairs with alternate footing.

Mastery of gross and fine motor skills is evident in all phases of the child's activity, such as play, dressing, language comprehension, response to discipline, social interaction, and propensity for injuries. Fine motor development is demonstrated in increasingly skillful manual dexterity. Activities occur less in isolation and more in conjunction with other physical and mental abilities to produce a purposeful result. For example, the toddler will walk to reach a new location, release a toy to pick it up or to choose a new one, and scribble to look at the image produced. The possibilities of the exploration, investigation, and manipulation of the environment—and its hazards—are endless.

Fig. 37.1 Typical toddling gait. (iStock.com/AJ Watt)

The major features of growth and development for the age groups of 15, 18, 24, and 30 months are summarized in Table 37.1.

Psychosocial Development

Toddlers are faced with the mastery of several important tasks. If the need for basic **trust** has been satisfied, they are ready to give up dependence for control, independence, and **autonomy**. Some of the specific tasks to be dealt with include the following:

- Differentiation of self from others, particularly the mother
- Toleration of separation from the parent
- Ability to withstand delayed gratification
- Control over bodily functions
- Acquisition of socially acceptable behaviour
- Verbal means of communication
- Ability to interact with others in a less egocentric manner

Mastery of these goals is only begun during late infancy and the toddler years, and tasks such as developing interpersonal relationships with others may not be completed until adolescence. However, crucial foundations for successful completion of such **developmental tasks** are established during these early formative years.

Developing a Sense of Autonomy (Erikson). According to Erikson (1963), the developmental task of toddlerhood is acquiring a sense of autonomy while overcoming a sense of doubt and shame. As infants gain trust in the predictability and reliability of their parents, environment, and interaction with others, they begin to discover that their behaviour is their own and that it has a predictable, reliable effect on others. However, although they realize their will and control over others, they are confronted with the conflict of exerting autonomy and relinquishing the much-enjoyed dependence on others. Exerting their will has definite negative consequences, whereas retaining dependent, submissive behaviour is generally rewarded with affection and approval. At the same time, continued dependency creates a sense of doubt regarding their potential capacity to control their actions. This doubt is compounded by a sense of shame for feeling this urge to revolt against others' will and a fear that they will exceed their own capacity for manipulating the environment. Skillful monitoring and balance of

TABLE 37.1 Growth and Development During Toddler Years

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization
15	Steady growth in height and weight Head circumference 48 cm Weight 11 kg Height 78.7 cm	Walks without help (usually since age 13 mo) Creeps up stairs Kneels without support Cannot walk around corners or stop suddenly without losing balance Cannot throw ball without falling Runs clumsily; falls often	Constantly casting objects to floor Builds tower of two cubes Holds two cubes in one hand Releases a pellet into a narrow-necked bottle Scribbles spontaneously Uses cup well but rotates spoon before it reaches mouth	Able to identify geometric forms; places round object into appropriate hole Binocular vision well developed Displays an intense and prolonged interest in pictures	Uses expressive jargon Says four to six words, including names "Asks" for objects by pointing Understands simple commands May use head-shaking gesture to denote "no" Uses "no" even while agreeing to the request Uses common repetitive gestures such as putting cup to mouth when empty	Tolerates some separation from parent Less likely to fear strangers Beginning to imitate parents, such as cleaning house (sweeping, dusting), folding clothes May discard bottle Kisses and hugs parents; may kiss pictures in a book
18	Picky eater from decreased growth needs Anterior fontanel closed Physiologically able to control sphincters	Assumes standing position without support Walks up stairs with one hand held Pulls and pushes toys Jumps in place with both feet Seats self on chair Throws ball overhand without falling	Builds tower of three or four cubes Release, prehension, and reach are well developed Turns pages in a book two or three at a time In drawing, makes stroke imitatively Manages spoon without rotation		Says 10 or more words Points to a common object, such as a shoe or ball, and to two or three body parts Forms word combinations Forms gesture–word combinations Forms gesture–gesture combinations	Expresses emotions; has temper tantrums Great imitator (domestic mimicry) Takes off gloves, socks, and shoes and unzips Beginning awareness of ownership ("my toy") May develop dependence on transitional objects, such as "security blanket"
24	Head circumference 49–50 cm Chest circumference exceeds head circumference Lateral diameter of chest exceeds anteroposterior diameter Usual weight gain of 1.8–2.7 kg; birth weight quadruples by age 2 ½ years Usual gain in height of 10–12.5 cm; height at age 2 is approximately 50% of eventual adult height May have achieved readiness for beginning daytime control of bowel and bladder Primary dentition of 16 teeth	Goes up and down stairs alone with two feet on each step Runs fairly well, with wide stance Picks up object without falling Kicks ball forward without overbalancing	Builds tower of six or seven cubes Aligns two or more cubes like a train Turns pages of book one at a time In drawing, imitates vertical and circular strokes Turns doorknob; unscrews lid	Accommodation well developed In geometric discrimination, able to insert square block into oblong space	Has vocabulary of approximately 300 words Uses two- or three-word phrases Uses pronouns *I, me, you* Understands directional commands Gives first name; refers to self by name Verbalizes need for toileting, food, or drink Talks incessantly	Stage of parallel play Has sustained attention span Temper tantrums decreasing Pulls people to show them something Increased independence from parent Dresses self in simple clothing Develops visual recognition and verbal self-reference ("Me big")

Continued

TABLE 37.1 Growth and Development During Toddler Years—cont'd

Age (mo)	Physical	Gross Motor	Fine Motor	Sensory	Language	Socialization
30	Birth weight quadrupled Primary dentition (20 teeth) completed May have daytime bowel and bladder control	Jumps with both feet Jumps from chair or step Stands on one foot momentarily Takes a few steps on tiptoe	Builds tower of eight cubes Adds chimney to train of cubes Good hand–finger coordination; holds crayon with fingers rather than fist Moves fingers independently In drawing, imitates vertical and horizontal strokes; makes two or more strokes for cross		Gives first and last name Refers to self by appropriate pronoun Uses plurals Names one colour	Separates more easily from parent In play, helps put things away; can carry breakable objects; pushes with good steering Begins to notice sex differences; knows own sex May attend to toilet needs without help except for wiping Emotions expand to include pride, shame, guilt, embarrassment

controls by parents allows a growing rate of realistic successes and the emergence of autonomy.

Just as the infant has the social modalities of grasping and biting, the toddler has the newly gained modality of holding on and letting go. To hold on and let go is evident with the use of the hands, mouth, eyes, and, eventually, the sphincters, when toilet learning is begun. These social modalities are expressed constantly in the child's play activities, such as casting or throwing objects; taking objects out of boxes, drawers, or cabinets; holding on tighter when someone says, "No, don't touch"; and spitting out food as taste preferences become strong.

Several characteristics, especially negativism and ritualism, are typical of toddlers in their quest for autonomy. As toddlers attempt to express their will, they often act with **negativism**, the persistent negative response to requests. The words "no" or "me do" can be the sole vocabulary. Emotions are strongly expressed, usually in rapid **mood** swings. One minute, toddlers can be engrossed in an activity, and the next minute they might be extremely frustrated because they are unable to manipulate a toy or open a door. If scolded for doing something wrong, they can have a temper tantrum and almost instantaneously pull at the parent's legs to be picked up and comforted. Understanding and coping with these swift changes in behaviour is often difficult for parents. Many parents find the negativism exasperating and, instead of dealing constructively with it, give in to it, which further threatens children in their search for learning acceptable methods of interacting with others (see Temper Tantrums section later in the chapter).

In contrast to negativism, which often disrupts the environment, *ritualism*, the need to maintain sameness and reliability, provides a sense of comfort. Toddlers can venture out with security when they know that familiar people, places, and routines still exist. One can easily understand why change, such as hospitalization, represents such a threat to these children. Without the comfortable rituals, there is little opportunity to exert autonomy. Consequently, dependency and **regression** can occur (see Regression section later in this chapter).

Erikson focused on the development of the ego, which may be thought of as reason or common sense, during this phase of psychosocial development. There is a struggle as the child deals with the impulses of the id and attempts to tolerate frustration and learn socially acceptable ways of interacting with the environment. The ego is evident as the child is able to tolerate delayed gratification.

Toddlers also have a rudimentary beginning of the *superego*, or conscience, which is the incorporation of the morals of society and the process of acculturation. With the development of the ego, children further differentiate themselves from others and expand their sense of trust within themselves. But as they begin to develop awareness of their own will and capacity to achieve, they also become aware of their ability to fail. This ever-present awareness of potential failure creates doubt and shame. Successful mastery of the task of autonomy necessitates opportunities for self-mastery while withstanding the frustration of necessary limit setting and delayed gratification. Opportunities for self-mastery are present in appropriate play activities, toilet independence, the crisis of **sibling rivalry**, and successful interactions with significant others.

Cognitive Development

Sensorimotor Phase (Piaget). The period from 12 to 24 months of age is a continuation of the final two stages of Piaget's (1952) sensorimotor phase. During this time, the cognitive processes develop rapidly and at times seem similar to those of mature thinking. However, reasoning skills are still primitive and need to be understood in order for parents and caregivers to effectively deal with the typical behaviours of a child of this age.

In the fifth stage of the sensorimotor phase (13 to 18 months of age), the child uses active experimentation to achieve previously unattainable goals. Newly acquired physical skills are increasingly important for the function they serve rather than for the acts themselves. The child incorporates the old learning of secondary circular reactions with new skills and applies the combined knowledge to new situations, with emphasis on the results of the experimentation. In this way, there is the beginning of rational **judgement** and intellectual reasoning. During this stage, there is further differentiation of one's self from objects. This is evident in the child's increasing ability to venture away from the parent and to tolerate longer periods of separation.

The child also starts to develop awareness of a causal relationship between two events. After flipping a light switch, toddlers are aware that a reciprocal response occurs. However, they are not able to transfer that knowledge to new situations. Therefore, every time they see what appears to be a light switch, they must reinvestigate its function. Such behaviour demonstrates the beginning of categorizing data into distinct classes and subclasses. Examples of this type of behaviour are

innumerable as toddlers continuously explore the same object each time it appears in a new place.

Because classification of objects is still rudimentary, the appearance of an object denotes its function. For example, if the child's toys are stored in a paper bag or large container, that toy receptacle is no different from the garbage pail or laundry basket. If allowed to turn over the toy receptacle, the child will just as quickly do the same to other similar containers because, in the child's mind, there is no difference. Expecting the child to judge which receptacles are permissible to explore and which are not is inappropriate for this age group. Instead, the forbidden object, such as the garbage pail, should be placed out of reach. This has significance in relation to protecting the toddler from injury; the toddler is not able to differentiate between what is a safe object to play with in any given situation and what is unsafe in another. For example, if the child is allowed to throw a toy ball, they do not necessarily understand why a different toy that may harm someone cannot be thrown as well.

The discovery of objects as objects leads to the awareness of their spatial relationships. Children are able to recognize different shapes and their relationship to each other. For example, they can fit slightly smaller boxes into each other (nesting) and can place a round object into a hole, even if the board with the hole is turned around, turned upside down, or reversed. Children are also aware of space and the relationship of their body to dimensions such as height. They will stretch, stand on a low stair or stool, and pull a string to reach an object.

Object permanence has also advanced. Although they still cannot find an object that has been invisibly displaced or moved from under one pillow to another without their seeing the change, toddlers are increasingly aware of the existence of objects behind closed doors, in drawers, on countertops, and under tables. Parents are usually acutely aware of this developmental achievement and find high places and locked cabinets the only places inaccessible to toddlers.

From ages 19 to 24 months, the child is in the final sensorimotor stage. During this stage, the child completes the more primitive thought processes of infancy and is prepared for the more complex mental operations that occur during the phase of preoperational thought. One of the most dramatic achievements of this stage is in the area of object permanence. Children will now actively search for an object in several potential hiding places. In addition, they can infer a cause when only experiencing the effect. They can infer that an object was hidden in any number of places even if they only saw the original hiding place.

Imitation displays deeper meaning and understanding. There is greater symbolization to imitation. The child is acutely aware of others' actions and attempts to copy them in gestures and in words. Domestic **mimicry** (imitating household activities) and gender-role behaviour become increasingly common during this stage, especially during the second year. Identification with the parent of the same gender becomes apparent by the second year and represents the child's intellectual ability to identify different models of behaviour and to imitate them appropriately (Figure 37.2).

While the concept of time is still embryonic, children have some sense of timing in terms of anticipation, memory, and a limited ability to wait. They may listen to the command, "Just a minute," and behave appropriately. However, their sense of time is exaggerated—one minute can seem like an hour. Toddlers' limited attention spans also indicate their sense of immediacy and concern for the present.

Preoperational Phase. At approximately 2 years of age, the child enters the *preconceptual phase* of cognitive development, which lasts until about age 4 years. The preconceptual phase is a subdivision of the *preoperational phase*, which spans ages 2 to 7 years. The preconceptual phase is primarily one of transition that bridges the purely

Fig. 37.2 Domestic mimicry and gender-role behaviour are common during toddlerhood. (iStock.com/SbytovaMN)

self-satisfying behaviour of infancy and the rudimentary socialized behaviour of latency. *Preoperational thought* implies that children cannot think in terms of operations—the ability to manipulate objects in relation to each other in a logical fashion. Rather, toddlers think primarily on the basis of their perception of an event. Problem solving is based on what they see or hear directly rather than on what they recall about objects and events. Several characteristics are unique to preoperational thought (Box 37.1).

Within the second year, the child increasingly uses language symbolically and is concerned with the "why" and "how" of things. For example, a pencil is "something to write with," and food is "something to eat." However, such mental symbolization is closely associated with prelogical reasoning. For instance, a needle is "something that hurts." Such painful experiences take on new significance because memory is associated with the specific event, and fears are likely to develop, such as resistance to people who wear a uniform or rooms that look like the practitioner's office. Because of the vulnerability of these early years, it is essential to prepare children for any new experience, whether it is a new babysitter or a visit to the health care provider or dentist.

Spiritual Development

Spiritual development in children is often discussed in terms of the child's developmental level because the evolution of spirituality often parallels cognitive development. The child's family and environment strongly influence the child's perception of the world around them, and this often includes spirituality. Furthermore, family values, beliefs, customs, and expressions of these will influence the child's perception of their spiritual self. Neuman (2011) proposes that Fowler's stages of faith (Fowler, 1981) be used to better understand children and spirituality; she provides an excellent overview of the stages of faith in childhood.

Toddlers learn about God or other spiritual powers through the words and the actions of those closest to them. They have only a vague idea of God or greater powers and religious teachings because of their immature cognitive processes; however, if God or the divine is spoken about with reverence, young children associate that with something special. During this period, the designation of powerful religious symbols and images is strongly influenced by the manner in which they are presented, usually in the form of rituals, games, and songs. Toddlers are said to be in the intuitive-projective phase of Fowler's faith construct (Fowler, 1981) in which thinking is largely based on fantasy and is fluid

BOX 37.1 Characteristics of Preoperational Thought

Egocentrism—Inability to envision situations from perspectives other than one's own

Example—If a person is positioned between the toddler and another child, the toddler, who is facing the person, will explain that both children can see the middle person's face. The young child is unable to realize that the other person views the middle person from a different perspective, the back.

Implication—Avoid moralizing about "why" something is wrong if it requires an understanding of someone else's feelings or opinion. Telling a child to stop hitting because hitting hurts the other person is often ineffective because, to the aggressor, it feels good to hit someone else. Instead, emphasize that hitting is not allowed.

Transductive reasoning—Reasoning from the particular to the particular

Example—Child refuses to eat a food because something previously eaten did not taste good.

Implication—Accept the child's reasoning; offer refused food at a different time.

Global organization—Reasoning that changing any one part of the whole changes the entire whole

Example—Child refuses to sleep in their room because the location of the bed is changed.

Implication—Accept the child's reasoning; use the same bed position or introduce change slowly.

Centration—Focusing on one aspect rather than considering all possible alternatives

Example—Child refuses to eat a food because of its colour, even though its taste and smell are acceptable.

Implication—Accept the child's reasoning.

Animism—Attributing lifelike qualities to inanimate objects

Example—Child scolds stairs for making the child fall down.

Implication—Join the child in the "scolding." Keep frightening objects out of view.

Irreversibility—Inability to undo or reverse the actions initiated physically

Example—When told to stop doing something, such as talking, the child is unable to think of positive activity.

Implication—State requests or instructions positively (e.g., "Be quiet.")

Magical thinking—Believing that thoughts are all-powerful and can cause events

Examples—Child wishes someone died; then if the person dies, the child feels at fault because of the "bad" thought that made the death happen.

- Calling children "bad" because they did something wrong makes children feel as if they are bad.

Implications—Clarify that thoughts do not make things happen and that the child is not responsible.

- Use "I" messages rather than "you" messages to communicate thoughts, feelings, expectations, or beliefs, without imposing blame or criticism. Emphasize that the *act* is bad, not the child.

Inability to conserve—Inability to understand the idea that a mass can be changed in size, shape, volume, or length without losing or adding to the original mass (instead, children judge what they see by the immediate perceptual clues given to them)

Example—If two lines of equal length are presented in such a way that one appears longer than the other, the child will state that one line is longer, even if the child measures both lines with a ruler or yardstick and finds that each has the same length.

Implications—Change the most obvious perceptual clue to reorient the child's view of what is seen. For example, give medicine in a small medicine cup, rather than a large cup, since the child will imagine that the large vessel contains more liquid. If the child refuses the medicine in the small cup, pour it into a large cup, because the liquid will appear to be less in a tall, wide container. Give a large, flat cookie rather than a thick, small one, or do the reverse with meat or cheese; the child will usually eat a larger size of favourite food and a smaller size of less favourite food.

in relation to reality and fantasy. God or the divine may be described as being around like air by the toddler because of the fluidity in dividing fantasy and reality (Neuman, 2011).

Toddlers begin to assimilate behaviours associated with the divine (e.g., folding hands in prayer). Routines such as saying prayers before meals or at bedtime can be important and comforting. Because toddlers tend to find solace in ritualistic behaviour and routines, they incorporate routines associated with religious practices into their behavioural patterns without understanding all of the implications of the rituals until later. Near the end of toddlerhood, when children use preoperational thought, there is some advancement of their understanding of God or other religious figures. Religious teachings, such as reward or fear of punishment (heaven or hell) and moral development (see Chapter 31), may influence their behaviour.

The relationship between spirituality, illness in childhood, and nursing has been studied in the context of suffering, terminal illness such as cancer, and end-of-life care, with an emphasis on understanding the influence of one's spirituality on health, illness, and well-being. For instance, the Canadian Virtual Hospice website provides information on how to talk to children, including toddlers, about serious illness (see Additional Resources at the end of this chapter).

Development of Body Image

As in infancy, the development of **body image** closely parallels cognitive development. During their second year, children recognize themselves in a mirror and make verbal references to themselves ("Me big"). With increasing motor ability, toddlers recognize the usefulness of body parts and gradually learn their names. They also learn that certain parts of the body have various meanings; for example, during toilet learning the genitalia become significant and cleanliness is emphasized. By 2 years of age there is recognition of gender differences and reference to self by name and then by pronoun. Gender identity is developed by age 3 years. Also by this time, the child begins to remember events with reference to their personal significance, forming an autobiographic memory that helps establish a continuous identity throughout life's events.

Once they begin preoperational thought, toddlers can use symbols to represent objects, but their thinking may lead to inaccuracies. For example, if someone who is pregnant is called "fat," they will describe all "fat" women as having babies. There is a beginning recognition of words used to describe physical appearance, such as "pretty," "handsome," or "big boy." Such expressions eventually influence how children view their own bodies.

It is evident that body integrity is poorly understood and that intrusive experiences are threatening. For example, toddlers forcefully resist procedures such as examination of the ear or mouth and taking of an axillary temperature. The procedure itself (e.g., taking vital signs) is not hurting the child, but it represents an intrusion into the child's personal space, which will elicit a strong protest. Toddlers also have unclear body boundaries and may associate nonviable parts, such as feces, with essential body parts. This can be seen in a toddler who is upset by flushing the toilet and watching the stool disappear.

Nurses can assist parents in fostering a positive body image in their child by encouraging them to avoid negative labels, such as "skinny

arms" or "chubby legs," self-perceptions that can last a lifetime. Body parts, especially those related to elimination and reproduction, should be called by their correct names. Respect for the body should be practised.

Development of Gender Identity

Just as toddlers explore their environment, they also explore their bodies and find that touching certain body parts is pleasurable. Genital fondling (masturbation) can occur and involves manual stimulation of genitalia and posturing movements (especially in young girls) such as tightening the thighs or applying mechanical pressure to the pubic or suprapubic area. Other demonstrations of pleasurable activities include rocking, swinging, and hugging people and toys. Parental reactions to toddlers' sexual behaviour influence the children's own attitudes and should be accepting rather than critical. If such acts are performed in public, parents should not condone or bring attention to the behaviour but should teach the child that it is more acceptable to perform the behaviour in private.

Children in this age group are learning vocabulary associated with anatomy, elimination, and reproduction. Certain associations between words and functions become significant and can influence future sexual attitudes. For example, if parents refer to the genitalia as dirty, especially in the context of elimination, this association between "genitalia" and "dirty" may be transferred to sexual functions. Gender-role differences become obvious to children and are evident in much of their imitative play. Between the age of 2 and 3, most children can identify themselves as a "boy" or "girl," although this may or may not match the sex they were assigned at birth (CPS, 2021). Early attitudes are formed about affectionate behaviours between adults from observing parental and other adult sexual or sensual activities (see also Chapter 35, Sex Education). The quality of relationships with parents is important to the child's capacity for sexual and emotional relationships later in life.

Social Development

A major task of the toddler period is differentiation of self from significant others, usually the mother. The differentiation process consists of two phases: *separation*, the child's emergence from a symbiotic fusion with the mother or primary caregiver; and *individuation,* those achievements that mark the child's expressions of their individual characteristics in the environment. Although the process begins during the latter half of infancy, the major achievements occur during the toddler years (see Table 37.1).

Toddlers have an increased understanding and awareness of object permanence and have some ability to withstand delayed gratification and tolerate moderate frustration. As a result, toddlers react differently to strangers than do infants. The appearance of unfamiliar persons does not represent such a significant threat to their attachment to the mother. They have learned from experience that parents still exist when physically absent. Repetition of events such as going to bed without the parents but waking to find them there again (in the household) reinforces the reliability of such brief separations. Consequently, toddlers are able to venture away from their parents for brief periods because of the security of knowing that the parents will be there when they return.

The separation–individuation phase encompasses the phenomenon of rapprochement; as the toddler separates from the mother and begins to make sense of experiences in the environment, the child is drawn back to the mother for assistance in verbally articulating the meaning of the experiences. Developmentally the term *rapprochement* means the child moves away and returns for reassurance. If the mother's response to the toddler is inappropriate, the toddler may experience insecurity and confusion.

Fig. 37.3 Transitional objects such as a fuzzy stuffed animal are sources of security to a toddler. (iStock.com/fizkes)

Transitional objects, such as a favourite blanket or toy, provide security for children, especially when they are separated from parents, dealing with a new stress, or just fatigued (Figure 37.3). Security objects often become so important to toddlers that they refuse to have them taken away. Such behaviour is normal; there is no need to discourage this tendency. During separations such as day care, hospitalization, or even overnight stays with relatives, transitional objects should be provided to minimize any feelings of fear or loneliness.

Learning to tolerate and master brief periods of separation is an important developmental task of children in this age group. In addition, it is a necessary component of parenting, since brief periods of separation allow parents to regain their energy and patience and to minimize any tendency to direct their irritations and frustrations at the children.

Language. The most striking characteristic of language development during early childhood is the increasing level of comprehension (see Table 37.1). Although the number of words acquired—from about 4 at 1 year of age to approximately 300 at age 2 years—is notable, the ability to comprehend and understand speech is much greater than the number of words the child can say. Bilingual children also achieve their early linguistic milestones in each of the languages at the same time and produce a substantial number of semantically corresponding words in each of their two languages from the very first words or signs.

At age 1 year the child uses one-word sentences, or *holophrases*. The word "up" can mean "pick me up" or "look up there." For the child, the one word conveys the meaning of a sentence, but to others it may mean many things or nothing. At this age about 25% of the vocalizations are intelligible. By the age of 2 years the child uses multiword sentences by stringing together two or three words, such as the phrases "mama go bye-bye" or "all gone," and approximately 65% of the speech is understandable. By 3 years of age the child puts words together into simple sentences, begins to master grammatical rules, acquires five or six new words daily, knows their age and gender, and can count three objects correctly. Looking at books during this period provides an ideal setting for further language development (Carter & Feigelman, 2020). While early evidence suggests that interactive apps may help to build literacy by providing practice with words, phonics, and letters (Radesky et al., 2015), toddlers learn best from expressive interactions with caring adults. While these interactions may include the use of apps, reading, storytelling, and conversation should be encouraged (Courage & Setliff, 2010).

Gestures precede or accompany each of the language milestones up to 30 months of age (putting phone to ear, pointing). After sufficient language development, gestures phase out and the pace of word learning increases.

Personal-Social Behaviour. One of the most dramatic aspects of development in the toddler is personal-social interaction. Parents often wonder why their manageable, docile, lovable infant has turned into a determined, strong-willed, volatile little tyrant. In addition, the tyrant of the terrible twos can swiftly and unpredictably revert to the adorable, cuddly child. All of this is part of growing up and is evident in such areas as dressing, feeding, playing, and establishing self-control.

Toddlers are developing skills of independence, and these are evident in all areas of behaviour. By 15 months children feed themselves, drink well from a covered cup, and manage a spoon with considerable spilling. By 24 months they use a spoon well and by 36 months may be using a fork. Between ages 2 and 3 years they like to help with chores, such as setting the table or removing dishes from the dishwasher. However, they lack appropriate table etiquette at times and may find it difficult to sit through the family's entire meal.

In dressing, toddlers also demonstrate strides in independence. The 15-month-old child helps by putting the arm or foot out for dressing and pulls shoes and socks off. The 18-month-old child removes gloves, helps with pullover shirts, and may be able to unzip. By age 2 years the toddler removes most articles of clothing and puts on socks, shoes, and pants without regard to right or left and back or front. Help is still needed to fasten clothes.

Toddlers also begin to develop concern for the feelings of others and develop an understanding of how adult expectations for behaviour apply to specific situations (e.g., causing a sibling to cry while playing rough). As their understanding increases, they are able to develop control. Age-appropriate discipline contributes to healthy social and emotional development. Positive reinforcement, redirecting, and time-out are appropriate for most toddlers. Early screening and intervention promote more positive developmental outcomes as the young child grows and develops.

Play. Play magnifies the toddler's physical and psychosocial development. Interaction with people becomes increasingly important. The solitary play of infancy progresses to **parallel play**—the toddler plays alongside, not with, other children (see Figure 32.7). Although sensorimotor play is still prominent, there is much less emphasis on the exclusive use of one sensory modality. The toddler inspects the toy, talks to the toy, tests its strength and durability, and invents several uses for it. Imitation is one of the more distinguishing characteristics of play and enriches the child's opportunity to engage in **fantasy**. With less emphasis on gender-stereotyped toys, play objects such as dolls, carriages, dollhouses, dishes, balls, clay, cooking utensils, child-size furniture, trucks, and dress-up clothes (Figure 37.4) are suitable for both genders. However, some children may be more interested in activities associated with the opposite gender.

Fig. 37.4 Young children enjoy dressing up. (iStock.com/chameleonseye)

Increased locomotive skills make push-pull toys, straddle trucks or cycles, a small gym and slide, balls of various sizes, and rocking horses appropriate for the energetic toddler. Finger paints, thick crayons, chalk, a blackboard, paper, and puzzles with large, simple pieces engage the child's developing fine motor skills. Interlocking blocks in various sizes and shapes provide hours of fun and, during later years, are useful objects for creative and imaginative play. The most educational toy is the one that fosters the interaction of an adult with a child in supportive, unconditional play. Toys are never substitutes for the attention of devoted caregivers, but toys can enhance these interactions. Parents and other providers are encouraged to allow children to play with a variety of simple toys that foster creative thinking (e.g., blocks, dolls, and clay) rather than passive toys that the child observes (battery-operated or mechanical toys). Active play time should also be encouraged over the use of computer or video games, which are more passive.

Certain aspects of play are related to emerging linguistic abilities. Talking is a form of play for toddlers who enjoy musical toys, such as age-appropriate music players, "talking" dolls and animals, and toy telephones. Toddlers also enjoy "reading" stories from a picture book and imitating the sounds of animals. Children's television programs are appropriate for some children over 2 years of age who learn to associate words with visual images. However, total media or screen time should be limited to less than 1 hour of quality programming per day for children ages 2 to 5 years and, if possible, parents should watch programs with their child (CPS, 2020). Screen time for children under 2 years is not recommended (CPS, 2020). Caregivers need to be mindful of all screen use in the home, and model positive habits screen time with children mindfully by choosing media purposefully—for example, "Let's watch this content at this time for this reason" (CPS, 2020). Excessive television watching can affect children's sleep, cause behaviour issues, and leaves less time for active play. Screen time 1 hour before bedtime is not recommended.

Tactile play is also important for the exploring toddler. Water toys, a sandbox with pail and shovel, finger paints, soap bubbles, and clay provide excellent opportunities for creative and manipulative recreation. Adults sometimes forget the fascination of feeling slippery cream, mud, or pudding; catching airy bubbles; squeezing and reshaping clay; or smearing paints. These types of unstructured activities are as important as educational play to allow children freedom of expression.

The selection of appropriate toys must involve safety factors, especially in relation to size and sturdiness. Toddlers' oral activity puts them at risk for aspirating small objects or for ingesting toxic substances. Parents need to be especially careful to keep toys of older siblings or those played with in other children's homes away from toddlers. Toys are a potential source of serious bodily damage to toddlers, who may have the physical strength to manipulate them but not the knowledge to appreciate their danger (see Family-Centred Teaching box: Guidance During Toddler Years later in this chapter). Government agencies do not inspect and regulate all toys on the market. Therefore, adults who purchase play equipment, supervise purchases, or allow children to use play equipment (including toys that are gifts or are purchased by the children themselves) need to evaluate their safety. Adults should also be alert to notices of toys determined to be defective and recalled by the manufacturers.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Toilet Independence

One of the major tasks of toddlerhood is toilet learning (previously called *toilet training*). Anticipatory guidance and clinical interventions for families regarding toilet learning should begin during routine

well-child visits, before the toddler has the readiness to start the learning. Preparation and education reveal and allay misconceptions, lead to the development of appropriate expectations, and provide information, guidance, and support to parents for managing this potentially frustrating process.

Voluntary control of the anal and urethral sphincters is achieved sometime after the child is walking, probably between ages 18 and 24 months. However, complex psychophysiological factors are required for readiness. The child must be able to recognize the urge to let go and hold on and be able to communicate this sensation to the parent. In addition, there may be some necessary motivation in the desire to please the parent by holding on, rather than pleasing oneself by letting go. Cultural beliefs may also affect the age at which children demonstrate readiness (Clifford et al., 2000/2018).

Five markers signal a child's readiness to learn toilet independence: motor, language, social milestones, demeanour, and relationship with the parents (Clifford et al., 2000/2018). According to some experts, physiological and psychological readiness is not complete until age 28 months. By this time, the child has mastered the majority of essential gross motor skills, can communicate intelligibly, is in less conflict with parents in terms of self-assertion and negativism, and is aware of the ability to control the body and please the parent. There is no universal right age to begin toilet learning or an absolute deadline for a child to become toilet independent. One of the nurse's most important responsibilities is to help parents identify the readiness signs in their child, such as showing interest, and in how to facilitate toilet learning (see Guidelines box: Assessing Toilet Learning Readiness). On average, girls are developmentally ready to begin toilet learning before boys. The CPS has a helpful parent guide to toilet independence (see Additional Resources at the end of this chapter).

GUIDELINES

Assessing Toilet Learning Readiness

Physical Readiness

- Voluntary control of anal and urethral sphincters, usually by 24 to 30 months of age
- Ability to stay dry for 2 hours; decreased number of wet diapers; waking dry from nap
- Regular bowel movements
- Gross motor skills of sitting, walking, and squatting
- Fine motor skills to remove clothing

Cognitive Readiness

- Recognizing urge to defecate or urinate
- Verbal or nonverbal communicative skills to indicate when wet or has urge to defecate or urinate
- Cognitive skills to imitate appropriate behaviour and follow directions

Psychological Readiness

- Expressing willingness to please parent
- Ability to sit on toilet for 5 to 10 minutes without fussing or getting off
- Curiosity about adults' or older sibling's toilet habits
- Impatience with soiled or wet diapers; desire to be changed immediately

Parental Readiness

- Recognizing child's level of readiness
- Willingness to invest time required for toilet learning
- Absence of family stress or change, such as a divorce, moving, new sibling, or imminent vacation

Nighttime bladder control normally takes several months to years after daytime training. This is because the sleep cycle needs to mature to the point that the child can awaken in time to urinate. Carter and Feigelman (2020) indicate that bed-wetting is normal in girls up to age 4 years and boys up to age 5 years. Few children will have night wetting episodes after daytime dryness is achieved; however, those children who do not have nighttime dryness by the age of 6 years are likely to require intervention (see Chapter 39 for further discussion of enuresis).

Bowel training is sometimes accomplished before bladder training because of its greater regularity and predictability. The sensation for defecation is stronger than that for urination and easier for children to recognize. A well-balanced diet that includes dietary fibre helps keep stools soft and supports the development and maintenance of regular bowel movements.

A number of techniques can be helpful when initiating toilet learning, and cultural differences should be considered in this process. The following discussion of toilet-learning methods includes suggestions from the child-oriented approach to toilet independence. Parents should begin the readiness phase of toilet learning by teaching the child how the body functions in relation to voiding and having a bowel movement. They should keep toilet learning as easy and simple as possible. Important considerations are the selection of the child's clothing and the potty chair or use of the toilet. A freestanding potty chair allows children a feeling of security (Figure 37.5, *A*). Planting the feet firmly on the floor also facilitates defecation. Another option is a portable seat attached to the regular toilet, which may ease the transition from potty chair to regular toilet. Placing a small bench under the feet helps stabilize the child's position. It is probably best to keep the potty chair in the bathroom and to let the child observe the excreta being flushed down the toilet to associate these activities with usual practices. If a potty chair is not available, having the child sit facing the toilet tank provides added support (see Figure 37.5, *B*). Practice sessions should be limited to 5 to 8 minutes, and a parent should stay with the child, practising sanitary habits after every session. Children should be praised for their behaviour and successful evacuation. Dressing children in easily removed clothing; using training pants, "pull-on" diapers, or underwear; and encouraging imitation by watching others can be helpful. Another method emerging in the literature involves early assisted toilet learning of infants around 2 to 3 weeks of age, but there are no studies assessing this method (Kiddoo, 2012).

When the child begins to experience regular daytime dryness, parents may experiment with the child wearing underwear during the day. Daytime accidents are common, particularly during periods of intense activity. Young children become so engrossed in play that if they are not reminded, they will wait until it is too late to reach the bathroom. Therefore, frequent reminders and trips to the toilet are necessary. Parents often forget to plan ahead when the toddler is learning to use the toilet; before trips outside the house it is important to remind the child to at least try to urinate, to decrease the chance of needing to use the toilet while the car is stuck in traffic.

As the child develops each step of toileting (discussion, undressing, going, wiping, dressing, flushing, and hand washing), they gain a sense of accomplishment that parents should reinforce. If the parent–child relationship becomes strained, both may need a break from toilet learning to focus on enjoyable activities together. Regression may coincide with a stressful family situation or may occur if the child is being pushed too hard and too fast. Regression is a normal part of toilet independence and does not mean failure but should be viewed as a temporary setback to a more comfortable place for the child.

Day care providers also play a role in the support and education of parents regarding toilet-learning practices. It is important for parents to

Fig. 37.5 **A:** Children may begin the process of toilet independence sitting on a small potty chair. (iStock.com/Orbon Alija) **B:** Sitting on a seat on a toilet. (iStock.com/yaoinlove)

inform all caregivers of their individual family values and the child's specific needs when planning for toilet learning away from home. Ensuring consistency in care of the toddler and healthy practices in a sanitary environment allows for safe and effective toilet practices in all settings.

Once the child has been successfully become toilet independent for bladder control, sudden wetting accidents and frequent urinating urges may require further investigation for a possible urinary tract infection (UTI), especially in girls. Younger children often have a UTI without accompanying fever or painful urination.

Temper Tantrums

Toddlers may assert their independence by violently objecting to discipline. They may lie down on the floor, kick their feet, and scream as loud as possible. Some have learned the effectiveness of holding their breath until the parent relents. Although holding one's breath may cause fainting from lack of oxygen, the accumulation of carbon dioxide will stimulate the respiratory control centre, resulting in no physical harm. Tantrums are an indication of the child's inability to control emotions; toddlers are particularly prone to tantrums because their strong drive for mastery and autonomy is frustrated by adult figures or lack of motor and cognitive skills.

The best approach toward tapering temper tantrums requires consistency and developmentally appropriate expectations and rewards. Ensuring consistency among all caregivers in expectations, prioritizing what rules are important, and developing consequences that are reasonable for the child's level of development can help manage the behaviour. For example, a popular time for a tantrum is before bed. Active toddlers often have trouble slowing down and, when placed in bed, resist staying there. Parents can reinforce consistency and expectations by stating, "After this story, it is bedtime." Starting at 18 months, timeouts work well for managing temper tantrums. One key to handling the child's behaviour is to demonstrate consistency in dealing with both the behaviour and the situation that seemingly precipitated the tantrum; inconsistency reinforces the negative behaviour because the child cannot cognitively comprehend the ambiguous messages being received from the parents. During tantrums, parents should stay calm and ignore the behaviour, provided it is not injurious to the child, such as violently banging the head on the floor. Parents should continue to be present, to provide a feeling of control and security to the child once the tantrum has subsided. When the child starts demonstrating appropriate behaviour, positive feedback can be provided about that behaviour. During periods of no tantrums, the child should receive developmentally appropriate positive reinforcement. The Family-Centred Care box: Temper Tantrums outlines other behaviour strategies that parents can use to manage their toddler's tantrums.

FAMILY-CENTRED CARE

Temper Tantrums

Suggestions for handling tantrums include the following:

- Give your child plenty of positive attention by rewarding good behaviour with praise.
- Try to give toddlers some control over little things.
- Keep off-limits objects out of sight and out of reach to make struggles less likely to develop over them.
- Distract your child.
- Set the stage for success when the child is playing or trying to master a new task.
- Consider the request carefully when your child wants something.
- Know your child's limits.

Source: Kids Health. (2018). *Temper tantrums*. http://kidshealth.org/parent/emotions/behavior/tantrums.html.

Temper tantrums are common during the toddler years and essentially represent normal developmental behaviours. However, temper tantrums can be signs of serious concerns. Nurses should be alert to situations that require further evaluation.

Negativism

One of the more difficult aspects of rearing children in this age group is their persistent "no" response to every request. The negativism is not an expression of being stubborn or insolent but a necessary assertion of self-control. Children test limits in order to gain understanding of the world and to learn to modify their behaviour to fit the expectations of society. Negativism begins to subside as most children prepare to enter kindergarten.

One method of dealing with negativism is to reduce the opportunities for a "no" answer. Asking the child, "Do you want to go to sleep now?" is an almost certain example of a question that will be answered with an emphatic "no." Instead, the parent should tell the child that it is time to go to sleep and proceed accordingly. In their attempt to exert control, children like to make choices. When confronted with appropriate choices, such as "You may have a peanut-butter-and-jelly sandwich or chicken-noodle soup for lunch," they are more likely to choose

one rather than automatically say "no." However, if their response is negative, parents should make the choice for the child.

Nurses working with children and parents can help parents understand this concept by role modelling. For example, when the nurse approaches the toddler to take vital signs, instead of asking, "Can I listen to your heart?" the nurse can say, "I'm going to listen to your heart." Because of normal developmental behaviour, toddlers vigorously resist first attempts at taking vital signs because it is an intrusion on their bodies. They are most likely going to answer "no," not because they necessarily fear the procedure itself but because of the tendency to answer all questions with a negative response. If the nurse asks the question and the toddler says "no" but the nurse proceeds anyway, the toddler starts to mistrust the nurse's actions because they contradict their words.

Sibling Rivalry

The natural jealousy and resentment of children to a new child in the family is referred to as *sibling rivalry*. The arrival of a newborn represents a crisis for even the best-prepared toddlers. It is not the newborn that toddlers resent but the changes that this additional sibling produces, especially the separation from the mother during the birth. The parents now share their love and attention with someone else, the usual routine is disrupted, and toddlers may lose their crib or room, all at a time when they thought they were in control of their world. Sibling rivalry tends to be most pronounced in the firstborn, who experiences *dethronement* (i.e., loss of sole parental attention). It also seems to be most difficult for young children, particularly in terms of mother–child interaction.

Preparation of children for the birth of a sibling is individual, but age influences some important considerations. Time for toddlers is a vague concept. Tomorrow could be yesterday or next week, and a month from now could be never. Preparing children too soon for the birth may lessen their interest by the time the event occurs. A good time to start talking about the new baby is when the toddler becomes aware of the pregnancy and the changes taking place in the home in anticipation of the new member (see Chapter 11, Family-Centred Care: Tips for Sibling Preparation).

Toddlers need to have a realistic idea of what the newborn will be like. Telling them that a new playmate will come home soon sets up unrealistic expectations. Rather, parents should stress the activities that will take place when the baby arrives home, such as diapering, feeding, bathing, and dressing. At the same time, parents should emphasize which routines will stay the same, such as reading stories or going to the park. The disruption of the toddler's routine is significant but can be restored with some effort by the parents. It may be helpful for the father or partner to spend more quality time with the toddler in anticipation of the mother's time being occupied with the new baby. If toddlers have had no contact with an infant, it is a good idea to introduce them to one, if feasible.

A new sibling in the home is stressful, so any additional stresses for the toddler should be avoided or minimized. For example, moving the toddler to a regular bed or to a different room should be done well in advance of the newborn's arrival.

When the newborn arrives, toddlers keenly feel the changed focus of attention. Visitors may initiate conflicts when they inadvertently shower the newborn with attention and presents while neglecting the older child. Parents can minimize this friction by alerting visitors to the toddler's needs and by including the child in the visits as much as possible. The toddler can also help with the care of the newborn by getting diapers and doing other small tasks (Figure 37.6).

How children exhibit jealousy is complex. Some will overtly hit the infant, push the child off the mother's lap, or pull the breast or bottle from the infant's mouth. For this reason, infants must be protected by parental supervision of the interaction between the siblings. More often the expressions of hostility and resentment are more subtle and covert. Toddlers may verbally express a wish that the infant "go back inside mommy," or they will revert to more infantile forms of behaviour, such as demanding a bottle, soiling their underpants, clinging for attention, using baby talk, or aggressively acting out toward others.

Fig. 37.6 To minimize sibling rivalry, parents should include the toddler during caregiving activities.

Regression

The retreat from one's present pattern of functioning to past levels of behaviour is referred to as *regression*. It usually occurs in instances of discomfort or stress when one attempts to conserve psychic energy by reverting to patterns of behaviour that were successful in earlier stages of development. Regression is common in toddlers because almost any additional stress hinders their ability to master present developmental tasks. Any threat to their autonomy, such as illness, hospitalization, separation from parents, or adjustment to a new sibling, represents a need to revert to earlier forms of behaviour, such as increased dependency; refusal to use the potty chair; temper tantrums; demand for the bottle, stroller, or crib; and loss of newly learned motor, language, social, and cognitive skills.

At first, such regression appears acceptable and comfortable for children, but the loss of newly acquired achievements is actually frightening and threatening because children are aware of their helplessness. Parents become concerned about regressive behaviour and often, in their efforts to deal with it, force the child to cope with an additional source of stress—the pressure to live up to expected standards. Brazelton (1999) suggests that these predictable times of regression, or *touchpoints*, are an opportunity to prepare parents for the next step in their child's development.

When regression does occur, the best approach is to ignore it while praising existing patterns of appropriate behaviour. Regression is a child's way of saying, "I can't cope with this present stress and perfect this skill as well, but I will if given patience and understanding." For this

reason, it is advisable not to attempt new areas of learning when an additional crisis is present or expected, such as beginning toilet learning shortly before a sibling is born or attempting new areas of learning during a brief period of hospitalization.

Mental Health

A child with mental health concerns can have symptoms in this age group that may need to be carefully investigated. For example, there is evidence that autism spectrum disorders (ASDs) can sometimes manifest between 12 and 24 months (Zwaigenbaum et al., 2019/2021). Early treatment is critical to all mental health disorders in order to optimize interventions successfully.

The well-baby visits and developmental screening tools are very important for picking up any unusual developmental delays or behaviours that would indicate a mental health issue. The CPS recommends that all children have an enhanced well-baby visit at 18 months; this is a critical time when signs or symptoms of ASD often emerge (Williams et al., 2011; Zwaigenbaum et al., 2019/2021). See Chapter 33 for more information on developmental assessment tools and Chapter 55 for more information on ASD. Nurses play an important role in assessing the child and the family and in helping families understand the developmental norms for age of the child.

ANTICIPATORY GUIDANCE FOR FAMILIES

Understanding toddlers' development, abilities, and limits is fundamental to successful child-rearing. Nurses, particularly those in ambulatory or child health centres, are in a favourable position to assist parents in facilitating the tasks and meeting the needs of children in this age group. Prevention yields better results than treatment. Anticipatory guidance is paramount to preventing future difficulties and injuries (see Family-Centred Care box: Guidance During Toddler Years and Chapter 35 for discussion on health promotion topics).

Advice, however, is sometimes not the only answer. Actual assistance, such as being available for telephone consulting, should be part of the nurse's flexible repertoire of interventions. Whether parents are experiencing the child-rearing dilemmas of a first or subsequent child, they benefit from sharing their feelings, frustrations, and satisfactions. They need adult companionship, occasional freedom from child-rearing responsibilities, and periodic separations from their children. Part of a nurse's responsibility is to provide opportunities for parents to express their feelings and support them in meeting their physical, mental, and spiritual needs.

FAMILY-CENTRED CARE

Guidance During Toddler Years

Ages 12 to 18 Months

Prepare parents for expected behavioural changes of the toddler, especially negativism and ritualism.

Assess present feeding habits and encourage gradual weaning from the bottle and increased intake of solid foods.

Stress expected feeding changes of picky eating habits, food fads and strong taste preferences, the need for scheduled routine at mealtimes, the child's inability to sit through an entire meal, and their lack of table manners.

Prepare parents for potential dangers of the home, particularly those contributing to motor vehicle injuries, poisoning, and falling injuries; give appropriate suggestions for safety proofing the home.

Discuss the need for firm but gentle discipline and ways to deal with negativism and temper tantrums; stress positive benefits of appropriate discipline.

Emphasize the importance for both the child and parents of brief, periodic separations.

Discuss new toys that involve developing gross and fine motor, language, cognitive, and social skills.

Emphasize the need for dental supervision, the types of basic dental hygiene at home, and food habits that predispose to caries; stress the importance of supplemental fluoride when required.

Ages 18 to 24 Months

Stress the importance of peer companionship in play.

Explore the need for preparation for an additional sibling (as appropriate); stress the importance of preparing the child for new experiences.

Assess sleep patterns at night, particularly the habit of a bedtime bottle, which is a major cause of dental caries, and behaviours that delay the hour of sleep.

Discuss present discipline methods, their effectiveness, and parents' feelings about the child's negativism; stress that negativism is an important aspect of developing self-assertion and independence and is not a sign of parental spoiling.

Discuss signs of readiness for toilet learning; emphasize the importance of waiting for physical and psychological readiness.

Discuss development of fears, such as fear of darkness or loud noises, and of habits, such as having a security blanket or thumb-sucking; stress normalcy of these transient behaviours.

Prepare parents for signs of regression in time of stress.

Assess the child's ability to separate easily from parents for brief periods under familiar circumstances.

Allow parents the opportunity to express their feelings of weariness, frustration, and exasperation; be aware that it is often difficult to love toddlers when they are not asleep!

Point out some of the expected changes of the next year, such as longer attention span, somewhat less negativism, and increased concern for pleasing others.

Ages 24 to 36 Months

Discuss the importance of imitation and domestic mimicry and the need to include the child in activities.

Discuss approaches toward toilet learning, particularly realistic expectations and the parents' attitude toward accidents.

Stress uniqueness of toddlers' thought processes, especially through their use of language, poor understanding of time, view of causal relationships in terms of proximity of events, and inability to see events from another's perspective.

Stress that discipline still must be structured and concrete and that relying solely on verbal reasoning and explanation leads to injuries, confusion, and misunderstanding.

Discuss investigation of preschool or a day care centre toward completion of the child's second year (see Preschool and Kindergarten in Chapter 38 for more information).

KEY POINTS

- The toddler stage, extending from 12 to 36 months, is a period of intense exploration of the environment.
- Biological development during the toddler years is characterized by the acquisition of fine and gross motor skills that allow children to master a wide range of activities.
- Although most of the physiological systems are mature by the end of toddlerhood, development of certain areas of the brain is still occurring, allowing for greater intellectual capacity.
- Locomotion is the major gross motor skill acquired during toddlerhood, followed by increased eye–hand coordination.

- Specific tasks in the psychosocial development of a toddler include differentiating self from others, tolerating separation from the parent, coping with delayed gratification, controlling bodily functions, acquiring socially acceptable behaviour, communicating verbally, and interacting with others in a less egocentric manner.
- According to Erikson, the major developmental task of toddlerhood is acquiring a sense of autonomy while overcoming a sense of doubt and shame.
- In Piaget's sensorimotor and preconceptual phases of development, the toddler experiments by incorporating the old learning of secondary circular reactions with new skills and applies this knowledge to new situations. There is the beginning of rational judgement, an understanding of causal relationships, and discovery of objects as objects.
- Preconceptual thought is characterized by egocentrism, centration, global organization of thought processes, animism, and irreversibility.
- Language is the major cognitive achievement in toddlerhood.
- The most striking characteristic of language development during early childhood is the increasing level of comprehension.
- Development of body image occurs with increasing motor ability, at which point toddlers recognize the importance and capacity of body parts.
- The two phases of differentiation of self from significant others are separation and individuation.
- Parental concerns during the toddler years include toilet independence; coping with sibling rivalry; limit setting and discipline; and dealing with temper tantrums, negativism, and regression.
- Effective discipline techniques for toddlers include reward, ignoring, and time-out.

The Preschooler and Family

Constance O'Connor
Originating US Chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the major biological, psychosocial, cognitive, moral, spiritual, and social developments that occur during the preschool years.
2. List the benefits of imaginary playmates.
3. Discuss how to prepare preschoolers for preschool or day care experience.
4. Provide parents with guidelines for coping with a child's fears, stresses, aggression, and sleep issues.
5. Recognize causes of stuttering during preschool years.
6. Offer parents suggestions for preventing speech difficulties.

PROMOTING OPTIMUM GROWTH AND DEVELOPMENT

The combined biological, psychosocial, cognitive, and social achievements during the preschool period (3 to 4 years of age) prepare preschoolers for their most significant change in lifestyle: entrance into school. Their control of bodily functions, experience of brief and prolonged periods of separation, ability to interact cooperatively with other children and adults, use of language for mental symbolization, and increased attention span and memory prepare them for the next major period, school years. Successful achievement of previous levels of growth and development is essential for preschoolers in order to refine many of the tasks that were mastered during the toddler years.

Biological Development

The rate of physical growth slows and stabilizes during the preschool years. See Table 38.1 for preschooler heights and weights. The World Health Organization (WHO) Child Growth Standards 2006 and WHO Growth Reference charts are used to measure and track Canadian preschoolers' growth patterns and were revised in 2016 by the Dietitians of Canada, Canadian Paediatric Society (CPS), College of Family Physicians, Community Health Nurses of Canada, and Canadian Pediatric Endocrine Group (Dietitians of Canada, 2019).

The physical proportions of the preschooler no longer resemble the squat, pot-bellied toddler. The preschooler is slender but sturdy, graceful, agile, and posturally erect. There is little difference in physical characteristics according to gender.

Most organ systems can adjust to moderate **stress** and change. During this period, most children have achieved toilet independence. Motor development consists mainly of increases in strength and refinement of previously learned skills. Muscle development and bone growth are still not mature. Excessive activity and overexertion can injure delicate tissues. Good posture, appropriate exercise, and adequate nutrition and rest are essential for optimum development of the musculoskeletal system.

Gross and Fine Motor Skills. Walking, running, climbing, and jumping are well established by age 36 months. Refinement in eye–hand and muscle coordination is evident in several areas (see Table 38.1 and Figure 38.1). Fine motor development is evident in these children's increasingly skillful manipulation, such as in drawing and dressing. These skills provide readiness for **learning** and independence for entry into school.

Psychosocial Development

Developing a Sense of Initiative (Erikson). After preschoolers have mastered the tasks of the toddler period, they are ready to face the developmental endeavours of the preschool period. Erikson (1963) maintained that the chief psychosocial task of this preschool period is acquiring a sense of *initiative*. Children are in a stage of energetic learning. They play, work, and live to the fullest and feel a real sense of accomplishment and satisfaction in their activities. Conflict arises when children overstep the limits of their ability and inquiry and experience a sense of guilt for not having behaved appropriately. Feelings of guilt, anxiety, and fear may also result from thoughts that differ from expected behaviour.

A particularly stressful thought for the preschooler is wishing one's parent dead. As a sense of rivalry or competition develops between the

TABLE 38.1 Growth and Development During Preschool Years

Physical	Gross Motor	Fine Motor	Language	Socialization	Cognition	Family Relationships
Age 3 Years						
Usual yearly weight gain of 1.8–2.7 kg Average weight of 14.5 kg Usual gain in height of 5 to 7.5 cm per year Birth length doubles by age 4 Average height of 95 cm May have achieved nighttime control of bowel and bladder	Rides tricycle Jumps off bottom step Stands on one foot for a few seconds Goes up stairs using alternate feet; may still come down using both feet on step Broad jumps May try to dance, but balance may not be adequate	Builds tower of 9–10 cubes Builds bridge with 3 cubes Adeptly places small pellets in narrow-necked bottle In drawing, copies a circle, imitates a cross, names what has been drawn; cannot draw stick figure but may make circle with facial features	Has vocabulary of about 900 words Uses primarily telegraphic speech Uses complete sentences of three or four words Talks incessantly regardless of whether anyone is paying attention Repeats sentence of six syllables Asks many questions	Dresses self almost completely if helped with back buttons and told which shoe is right or left Pulls on shoes Has increased attention span Feeds self completely Can prepare simple meals, such as cold cereal and milk Can help to set table; can dry dishes without breaking any May have fears, especially of dark and going to bed Knows own gender and gender of others Play is parallel and associative; begins to learn simple games, but often follows own rules; begins to share	Is in preconceptual phase Is egocentric in thought and behaviour Has beginning understanding of time; uses many time-oriented expressions, talks about past and future as much as about present, pretends to tell time Has improved concept of space, as demonstrated by understanding of prepositions and ability to follow directional command Has beginning ability to view concepts from another perspective	Attempts to please parents and conform to their expectations Is less jealous of younger sibling; may be opportune time for birth of additional sibling Is aware of family relationships and gender-role functions Boys tend to identify more with father or other male figure Has increased ability to separate easily and comfortably from parents for short periods
Age 4 Years						
Pulse and respiration rates decrease slightly Growth rate is similar to that of previous year Average weight of 16.7 kg Average height of 103 cm Length at birth is doubled Maximum potential for development of amblyopia	Skips and hops on one foot Catches ball reliably Throws ball overhead Walks down stairs using alternate footing	Uses scissors successfully to cut out picture following outline Can lace shoes but may not be able to tie bow In drawing, copies a square, traces a cross and diamond, adds three parts to stick figure	Has vocabulary of 1 500 words or more Uses sentences of four or five words Questioning is at peak Tells exaggerated stories Knows simple songs May be mildly profane if associates with older children Obeys four prepositional phrases, such as *under, on top of, beside, in back of,* or *in front of* Names one or more colours Comprehends analogies, such as, "If ice is cold, fire is _____"	Very independent Tends to be selfish and impatient Aggressive physically and verbally Takes pride in accomplishments Has mood swings Shows off dramatically, enjoys entertaining others Tells family tales to others with no restraint Still has many fears Play is associative Imaginary playmates are common Uses dramatic, imaginative, and imitative devices Sexual exploration and curiosity demonstrated through play, such as being "doctor" or "nurse"	Is in phase of intuitive thought Causality is still related to proximity of events Understands time better, especially in terms of sequence of daily events Unable to conserve matter Judges everything according to one dimension, such as height, width, or order Immediate perceptual clues dominate judgement Is beginning to develop less egocentrism and more social awareness May count correctly but has poor mathematical concept of numbers Obeys because parents have set limits, not because of understanding of right and wrong	Rebels if parents expect too much, such as impeccable table manners Takes aggression and frustration out on parents or siblings Do's and don'ts become important May have rivalry with older or younger siblings; may resent older sibling's privileges and younger sibling's invasion of privacy and possessions May "run away" from home Identifies strongly with parent of opposite sex Is able to run simple errands outside home

Fig. 38.1 A 4-year-old child has sufficient balance to stand or hop on one foot.

child and the same-sex parent, the child may think of ways to get rid of the interfering parent. In most situations this rivalry is resolved when the child strongly identifies with the same-sex parent and peers during the school years. However, if that parent dies before the identification process is completed, the preschooler may be overwhelmed with guilt for having wished for and therefore "caused" the death. Clarifying for children that wishes cannot and do not make events occur is essential in helping them overcome their guilt and anxiety.

Development of *superego*, or *conscience*, begins toward the end of the toddler years and is a major task for preschoolers (see Cultural Awareness box). Learning right from wrong and good from bad is the beginning of a sense of morality (see Moral Development section).

CULTURAL AWARENESS

Learning Sociocultural Mores

Developing a conscience implies learning sociocultural mores of the family's heritage. Depending on the type of attitudes conveyed, children will learn not only appropriate behaviours but also tolerance-based, biased, or prejudicial values concerning their ethnic, religious, and social background and those of other groups. Much of this influence may remain dormant until they associate with children or adults of a different heritage. Depending on the particular group, they may be accepted or ostracized for their attitudes.

Cognitive Development

One task related to the preschool period is readiness for school and scholastic learning.

Preoperational Phase (Piaget). Piaget's cognitive theory (1952) does not include a period specifically for children who are preschool age. The *preoperational phase* covers the age span from 2 to 7 years and is divided into two stages: *preconceptual phase*, ages 2 to 4, and the phase of *intuitive thought*, ages 4 to 7. One main transition during these two phases is the shift from totally egocentric thought to social awareness and the ability to consider other viewpoints. However, egocentricity is still evident.

Language continues to develop during the preschool stage. Speech remains primarily a vehicle of egocentric communication. Preschoolers assume that everyone thinks as they do and that a brief explanation of their thinking makes the entire thought understood by others. Because of this self-referenced, egocentric verbal communication, it is often necessary to explore and understand a young child's thinking through other, nonverbal approaches. For children in this age group, the most enlightening and effective method is *play*, which becomes the child's way of understanding, adjusting to, and working out life's experiences.

Preschoolers increasingly use language without comprehending the meaning of words, particularly concepts of right and left, causality, and time. Children may use the concepts correctly but only in the circumstances in which they have learned them. For example, they may know how to put on shoes by remembering that the buckle is always on the outside of the foot. If different shoes have no buckles, they cannot reason which shoe fits which foot. In other words, they do not understand the concepts of right and left.

Superficially, causality resembles logical thought. Preschoolers explain a concept as they heard it described by others, but understanding is limited. An example is the concept of time. Because time is still incompletely understood, children interpret it according to their own frame of reference. Consequently, time is best explained in relationship to an event, such as "Your mother will visit you after you finish your lunch." Avoiding words such as *yesterday*, *tomorrow*, *next week*, or a named day of the week to express when an event is expected to occur and instead associating time with expected daily events can help children learn about temporal relationships while increasing their trust in others' predictions.

Preschoolers' thinking is often described as *magical thinking*. Because of their egocentrism and **transductive reasoning**, they believe that thoughts are all-powerful. Such thinking places them in the vulnerable position of feeling guilty and responsible for bad thoughts, which may coincide with the occurrence of a wished event. Their inability to logically reason cause and effect of an illness or injury makes it especially difficult for them to understand such events.

Preschoolers believe in the power of words and accept their meaning literally. An example of this type of thinking is when children are called "bad" because they did something wrong: In preschoolers' minds, calling them "bad" means they are a bad person; it is better to say that their actions were bad by saying, for example, "That was a bad thing to do."

! NURSING ALERT

Counselling children whose parents are going through a divorce or separation should involve a discussion with the child about their role. Because of magical thinking the child may believe that they wished the other parent away. The child should be reassured that this is not the case.

Moral Development

Preconventional or Premoral Level (Kohlberg). Young children's development of moral **judgement** is at the most basic level. They have little, if any, concern about why something is wrong. They behave because of freedom or restriction that is placed on actions. In the *punishment and obedience orientation*, children (from about 2 to 4 years) judge whether an action is good or bad depending on whether it results in reward or punishment. If children are punished for it, the action is bad. If they are not punished, the action is good, regardless of the meaning of the act. For example, if parents allow hitting, children will perceive that hitting is good because it is not associated with punishment.

From approximately 4 to 7 years of age, children are in the stage of *naive instrumental orientation*, in which actions are directed toward satisfying their needs and, less frequently, the needs of others. They have a concrete sense of justice and fairness during this period of development.

Spiritual Development

Children generally learn about faith and religion from significant others in their environment, usually from parents and their religious beliefs and practices. However, young children's understanding of spirituality is influenced by their cognitive level. Preschoolers have a concrete concept of a God or other deity with physical characteristics, often like an imaginary friend. They understand simple religious stories and memorize short prayers, but their understanding of the meaning of these rituals is limited. Preschoolers benefit from concrete representations of religious practices, such as picture books, small statues, and other related objects. They will imitate religious practices of their parents without fully understanding the significance of these acts.

Observing religious traditions and participating in a religious community can help children cope during stressful periods, such as illness, hospitalization, and other traumatic events. In many religious faiths and belief systems, cultural practices and religion are closely intertwined and are an important part of the child's and family's life.

Development of Body Image

The preschool years play a significant role in the development of **body image**. With increasing comprehension of language, preschoolers recognize that individuals have undesirable and desirable appearances. They are aware of the meaning of words such as *pretty* or *ugly*, and they reflect opinions of others regarding their own appearance. By 5 years of age, children compare their size with that of their peers and can become conscious of being large or short, especially if others refer to them as "so big" or "so little" for their age. Research indicates that girls as young as preschool age already show concern about appearance and weight (Skouteris et al., 2010). Because these are formative years for boys and girls, parents should make the effort to instill positive attitudes about body image, give their children encouraging feedback regarding their appearance, and emphasize the importance of accepting individuals no matter how their appearances differ. Children at this age should be educated about the benefits of physical activity and nutrition on health instead of focusing on weight.

Despite advances in body image development, preschoolers have poorly defined body boundaries and little knowledge of their internal anatomy. Intrusive experiences are frightening, especially those that disrupt the integrity of the skin, such as injections and surgery. They fear that if their skin is "broken," all of their blood and "insides" can leak out. Bandages are critical to "keep everything from coming out."

Development of Gender and Sexuality

Sexual development during these years is an important phase in the formation of a person's overall sexual identity and beliefs. *Sex-typing*, or the process by which an individual develops behaviour, personality, attitudes, and beliefs appropriate for their culture and sex, occurs through several mechanisms during this period. Probably the most powerful mechanisms are child-rearing practices and imitation.

Gender identification is a result of complex prenatal and postnatal psychological factors and biological or genetic factors. Most children are aware of their gender and the expected sets of related behaviours by 1.5 to 2.5 years. Many preschool age children have a stable gender identity; however, this may change later in life. Children may express their gender by using female or male pronouns, such as "I am a she," when describing themselves, or through their choice of hairstyle, clothing, toys, or preferred name (Canadian Paediatric Society [CPS], 2021).

Gender-creative children may express their gender differently from what are often considered social norms—for example, boys who love to paint their nails or wear pink, or girls who wear their hair very short or play with traditionally "male" toys. Gender diversity, and its expression, is not a medical or psychological illness (CPS, 2021).

As sexual identity develops beyond gender recognition, modesty may become a concern. Sexual exploration may be more pronounced now than ever before, particularly in terms of exploring and manipulating genitalia. Questions about sexual reproduction may surface in preschoolers' search for understanding (see Sex Education section in Chapter 35).

Social Development

During the preschool period, the *separation–individuation process* is completed. Preschoolers have overcome much of the anxiety associated with strangers and the fear of separation of earlier years. They relate to unfamiliar people easily and tolerate brief separations from parents, with little or no protest. However, they still need parental security, reassurance, guidance, and approval, especially when entering preschool or elementary school. Prolonged separation, such as that imposed by illness and hospitalization, is difficult, but preschoolers respond to anticipatory preparation and concrete explanation. Maintaining an established routine is still important for early preschoolers regardless of home, school, or hospital environment. They can cope with changes in daily routine much better than toddlers, although they may develop more imaginary fears. Preschoolers gain security and comfort from familiar objects, such as toys, dolls, or photographs of family members. They are able to work through many of their unresolved fears, fantasies, and anxieties through play, especially if guided with appropriate play objects (e.g., dolls, puppets) that represent family members, other adults, and other children.

Language. During preschool years, language becomes more sophisticated and complex and the major mode of communication and social interaction (Figure 38.2). Through language, preschool children learn to express feelings of frustration or anger without acting them out. Both cognitive ability and environment, particularly consistent role models, influence vocabulary, speech, and comprehension. Vocabulary increases dramatically from 300 words at age 2 years to more than 2 100 words at the end of 5 years. Sentence structure, grammatical usage, and intelligibility also advance to a more adult level. Language development during these early years predicts school readiness (Harrison & McLeod, 2010) and sets the stage for later success in school (Reilly et al., 2010).

Children between 3 and 4 years of age form sentences of about three or four words and include only the most essential words to convey a

Fig. 38.2 Preschool children enjoy friends and often use nonverbal messages to communicate. (iStock.com/kali9)

meaning. Such speech is often termed *telegraphic* for its brevity. Three-year-old children ask many questions and use plurals, correct pronouns, and the past tense of verbs. They name familiar objects such as animals, parts of the body, relatives, and friends. They can give and follow simple commands. They talk incessantly regardless of whoever is listening or answering them. They enjoy musical or talking toys or dolls and imitate new words proficiently. Preschoolers also benefit from "reading" picture books with a parent or adult figure; this provides immediate feedback to the child and helps develop vocabulary as the child hears the pronunciation of words from adults (Carter & Feigelman, 2020). There is evidence that reading and speaking to a child in early life establishes words in the child's memory bank for use at a later time.

From ages 4 to 5 years, preschoolers use longer sentences of four or five words and more parts of speech to convey a message (e.g., prepositions, adjectives, and a variety of verbs). They can follow simple directional commands, such as "Put the ball on the chair," but can carry out only one request at a time. They answer questions such as "What do you do when you're hungry?" by describing the appropriate action. The pattern of asking questions is at its peak, and children usually repeat a question until they receive an answer. Preschoolers also are incapable of understanding figurative speech and are very literal in their understanding of the meaning of words (Carter & Feigelman, 2020). For example, saying that an intravenous cannula to be inserted for hydration is a straw is interpreted by the preschoolers as literally a drinking straw because that is their common frame of reference for that object.

While Canada is bilingual with two official languages, English and French, a multitude of other languages are also spoken in this multicultural country. Children can learn two languages at home, at school, or in the community. Often children will learn both languages well but may have a dominant language depending on how often the languages are practised. Learning two languages does not cause difficulties with speech or language. If there is a concern about the child's language skills, the child likely has a speech or language delay that is not related to bilingualism and needs an assessment (Byers-Heinlein & Lew-Williams, 2013).

Personal-Social Behaviour. The pervasive **ritualism** and **negativism** of toddlerhood gradually diminish during the preschool years. Although self-assertion is still a major theme, preschoolers demonstrate their sense of autonomy differently. They are able to verbalize their request for independence and carry out activities independently because of their much-refined physical and cognitive development. By 4 or 5 years of age, they need little if any assistance with dressing, eating, or toileting (Figure 38.3). They can also be trusted to obey warnings of danger, although 3- or 4-year-old children may exceed their boundaries at times.

Preschoolers are much more sociable and willing to please than toddlers. They have internalized many standards and values of family and culture. By the end of early childhood they begin to question parental values and compare them with those of their peer group and other authority figures. As a result, they may be less willing to abide by the family's code of conduct. Preschoolers become increasingly aware of their position and role within the family. Although this is a more secure age for experiencing the addition of another sibling, relinquishing the position of only or youngest child is still difficult and requires special parental attention to prevent feelings of desertion and resentment (see Chapter 37, Sibling Rivalry).

Play. While various types of play are typical of this period, preschoolers especially enjoy **associative** play—group play in similar or identical activities but without rigid organization or rules (see Figure 32.8). Play should foster physical, social, and mental development.

Fig. 38.3 Most preschoolers are able to dress themselves but need help with more difficult items of clothing.

Fig. 38.4 Preschoolers enjoy play activities that promote motor skills such as jumping and running. (iStock.com/FatCamera)

Play activities for physical growth and refinement of motor skills include jumping, running, and climbing. Tricycles, wagons, gym and sports equipment, sandboxes, wading pools, and activities at water parks can help develop muscles and coordination (Figure 38.4). Activities such as swimming and skating teach safety and enhance muscle development and coordination. Children involved in the work of play do not require expensive toys and gadgets to keep them entertained but often enjoy playing with common household items such as a broom handle or even items that adults consider junk (boxes, sticks, rocks, and dirt). The imaginative mind of the preschooler enjoys playing for playing's sake.

Manipulative, constructive, creative, and educational toys provide for quiet activities, fine motor development, and self-expression. Easy construction sets, large blocks of various sizes and shapes, a counting frame, alphabet or number flash cards, paints, crayons, simple

carpentry tools, musical toys, illustrated books, simple sewing or handicraft sets, large puzzles, and clay are suitable toys. Electronic games and computer programs are especially valuable in helping children learn basic skills such as letters and simple words.

Probably the most characteristic and pervasive preschool activity is imitative, imaginative, and dramatic play. Dress-up clothes, dolls, housekeeping toys, dollhouses, play store toys, telephones, toy farm animals and equipment, village sets, trains, trucks, cars, planes, hand puppets, and toy medical kits provide hours of self-expression (Figure 38.5). Probably at no other time is reproduction of adult behaviour as faithful and absorbing as in an older preschooler. Toward the end of the preschool period, children are less satisfied with make-believe or pretend objects and enjoy doing the actual activity, such as cooking and carpentry, with the aid of an adult.

Play is so much a part of a young child's life that reality and fantasy can become blurred. Make-believe is reality during play and only becomes fantasy when toys are put away or dress-up clothes are removed. It is no wonder that imaginary playmates are so much a part of this age period. The appearance of imaginary companions usually occurs between ages 2½ and 3 years, and, for the most part, such playmates are relinquished when the child enters school. Birth order and number of siblings may influence the creation of imaginary companions, with firstborn and only children being more likely to create imaginary playmates (Trionfi & Reese, 2009).

Imaginary companions serve many purposes: they become friends in times of loneliness, they accomplish what the child is still attempting, and they experience what the child wants to forget or remember. It is not unusual for the "friend" to have myriad vices and be blamed for wrongdoing. Sometimes the child hopes to escape punishment by saying, "My friend George broke the glass." At other times the child may fantasize that the companion misbehaved and play the role of the parent. This becomes a way of assuming control and authority in a safe situation.

Parents often worry about imaginary playmates, not realizing how normal and useful they are. Parents need to be reassured that the child's fantasy is a sign of health that helps differentiate make-believe and reality. Parents can acknowledge an imaginary companion's presence by calling them by name and even agreeing to simple requests, such as setting an extra place at the table, but they should not allow the child to use the "playmate" to avoid punishment or responsibility. For example, if the child blames the companion for messing up a room, parents need to state clearly that the child is the only one they see; therefore, the child is responsible for cleaning up.

Television and other media also have their place in children's play, although each should be only one part of children's total repertoire of social and recreational activities (see Chapter 35). Parents and other caregivers should supervise the selection of programs, watch and discuss programs with their children, schedule limited time for television and screen viewing, and set a good example of television viewing (CPS, 2020). Children enjoy and learn from educational programs; however, television and screen viewing may limit time spent in other meaningful activities such as reading, physical activity, and socialization (Lipnowski et al., 2012/2021). Health routines, including media use, are established more easily in early childhood, and early overexposure increases the likelihood of overuse in later life (CPS, Digital Health Task Force, 2017). Prolonged television viewing among young children has been linked to an increase in psychological distress and decreased time spent in active playing, which can increase the risk for obesity among certain children (CPS, Digital Health Task Force, 2017). Watching fast-paced television cartoons can lead to a temporary decrease in executive functioning (self-regulation and working memory), and these effects may be cumulative (CPS, Digital Health Task Force, 2017). Because of the significant increase in media accessibility through the various portable electronic devices and cell phones, parents need to be aware of the potential positive and negative effects of media exposure. The CPS recommends that children under the age of 5 years be limited to under 1 hour per screen (television, computers, and video games) per day (CPS, 2020).

Fig. 38.5 Imaginative and imitative play is typical of preschoolers. (iStock.com/Nikola Stojadinovic)

Although the potential negative effects of television and screen viewing have been well documented in literature, research has also shown that prosocial behaviour and later academic achievement can result from viewing educational media during the preschool years. However, positive effects depend on the media content, the age of the viewer, the length of viewing time, and the presence of a co-viewing parent (CPS, Digital Health Task Force, 2017). When parents view media with their children, the activity can become interactive, with parents and children discussing program content.

Children benefit from play that occurs between them and a parent. *Mutual play* fosters development from birth through the school years and provides enriched opportunities for learning. Through mutual play, parents can provide tactile and kinesthetic experiences, maximize verbal and language abilities, and offer praise and encouragement for exploration of the world. In addition, mutual play encourages positive interactions between parent and child, strengthening their relationship.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

Preschool and Kindergarten Experience

While some children are home-schooled, many children attend some type of early childhood program, usually preschool or a day care centre. Group care has become commonplace with large numbers of parents being employed outside the home or working full-time remotely from home. Approximately 65% of Canadian children under 5 years of age rely on nonparental child care (Findlay, 2019). The effects of early education and stimulation on children have increasingly gained recognition. Because social development widens to include age-mates and other significant adults, preschool provides an excellent vehicle for expanding children's experiences with others. It is also excellent preparation for entrance into elementary school.

In preschool or day care centres, children are exposed to opportunities for learning group cooperation, adjusting to sociocultural differences, and coping with frustration, dissatisfaction, and anger. If activities are tailored to provide mastery and achievement, children increasingly have feelings of success, self-confidence, and personal competence. Whether structured learning is imposed is less important than the social climate, type of guidance, and attitude toward children that is fostered by the teacher or leader. With a teacher who is aware of

preschoolers' developmental abilities and needs, children will learn from the activity that is provided. Most programs incorporate a daily schedule of quiet play, active outdoor activity, group activities such as games and projects, creative or free play, and snack and rest periods. Preschool is particularly beneficial for children who lack a peer-group experience and for children from impoverished homes.

One issue that all parents face is their child's readiness for preschool or kindergarten. While there are no absolute indicators for school readiness, the child's social maturity, especially attention span, is as important as their academic readiness. A developmental screening tool that addresses cognitive (especially language), social, and physical milestones can be used to identify children who may benefit from diagnostic testing and early intervention programs before starting school (e.g., Nipissing District Developmental Screen [NDDS]) (see Table 33.2 and Additional Resources). Parents should promote a positive attitude toward learning, read to their children, provide opportunities for social and emotional growth, and choose programs or schools that will partner with the family to foster learning. Family income and the availability of quality child care and early childhood education can be factors in such choices. Nurses and other health care providers can guide parents in selecting enriched social and educational early intervention programs.

An Aboriginal Head Start preschool program for Indigenous families has demonstrated that locally controlled early-intervention strategies can improve the health of Indigenous children by providing supports for them to gain confidence toward attaining life goals. Such strategies include support for physical, personal, and social development (Indigenous Services Canada, 2020). In 2017, the Government of Canada developed the Indigenous Early Learning and Child Care Framework. The framework recognizes the importance of distinct Indigenous knowledge and language, supports the training and education of Indigenous child care providers, and is family centred (Government of Canada, 2017/2021).

Nurses and other health care workers can guide parents in selecting enriched social and educational early intervention programs, schools, and child care centres. Careful selection of early childhood education is intrinsic to future learning and development. Licensed and regulated programs are mandated to abide by established standards, which represent minimum requirements and safeguards. Regulation is important to protect children from harm and promote the conditions essential for a child's healthy development and learning. The Association of Day Care Operators of Ontario (see Additional Resources) serves as the model for optimal care of small children. Areas for parents to evaluate include the facility's daily program, teacher qualifications, staff-to-student ratio, discipline policy, environmental safety precautions, provision of meals, sanitary conditions, adequate indoor and outdoor space per child, safety and injury prevention, and fee schedule. While references from other parents help in evaluating a facility, personal observation of the facility is recommended. Parents need to meet the director and some of the employees at a few facilities to make an informed choice.

One of the areas that is increasingly important in selecting child care is the day care centre's health practices; however, parents often do not check the centre for health and safety features. Children in day care centres, especially those under 3 years of age, tend to have more illnesses—especially diarrhea, otitis media, respiratory tract infections (especially if the caregiver smokes), hepatitis A, meningitis, and cytomegalovirus—than children cared for in their own home (Lang & CPS, Community Paediatrics Committee, 2009). The strongest predictor of risk of illness is the number of unrelated children in the room. Proactive infection control measures and education of staff have been effective in reducing the incidence of upper respiratory tract infections, diarrhea, and rotavirus in day care centres (Figure 38.6). Families who have children in out-of-home child care may lose several days of work per year as a result of childhood infections. Parents should inquire about the centre's policy regarding the attendance and care of sick children.

Fig. 38.6 Thorough hand hygiene is the single most effective method of preventing infection.

Children need preparation for the preschool or kindergarten experience. For young children, it represents a change from their usual home environment and a prolonged separation from parents. Before children begin school, parents should present the idea as exciting and pleasurable. Talking to children about activities such as painting, building with blocks, or enjoying swings and outdoor equipment allows children to fantasize about the event in a positive manner. When the first day of school arrives, parents should behave confidently. Such behaviour requires parents to have resolved their own feelings regarding the experience.

Parents should introduce their child to the teacher and the facility. In some instances, it is helpful for parents to remain with the child for at least part of the first day until the child is comfortable and at ease. Other specific actions that can help reduce separation anxiety include providing the school with detailed information about the child's home environment, such as familiar routines, favourite activities, food preferences, names of siblings or pets, and personal habits. Such information helps the teacher make the child feel familiar in strange surroundings. When schools automatically request this information, the parent has a valuable clue to the quality of the program—the request represents the staff's awareness of each child's needs. Transitional objects, such as a favourite toy, may also help the child bridge the gap from home to school.

Fears

A great number and variety of real and imagined fears are present during the preschool years, including fear of the dark, being left alone (especially at bedtime), animals (particularly large dogs), ghosts, sexual matters (castration), and objects or persons associated with pain. The exact cause of children's fears is often unknown. Parents often become perplexed about handling these fears because no amount of logical persuasion, coercion, or ridicule will send away the ghosts, boogeymen,

monsters, and devils. Inappropriate television viewing by preschoolers may increase fears and anxieties because of their inability to separate reality-based experiences from fantasy portrayed on television.

The concept of *animism*, ascribing lifelike qualities to inanimate objects, helps explain why children fear objects. For example, a child may refuse to use the toilet after watching a television commercial in which the toilet bowel is portrayed as turning into a monster.

Preschoolers also experience fear of annihilation. Because of poorly defined body boundaries and improved cognitive abilities, young children develop concerns related to the loss of body parts. They fear losing body parts with certain medical procedures, such as an intravenous insertion or cast application on a limb, and may see these procedures as real threats to their existence. Preschoolers are often fearful when approaching the health care environment (office or hospital) and are especially fearful of pain. Because of their inability to sometimes discern reality from the imagined, a painful procedure such as a vaccination may be perceived as the end of existence (death) to the child; the preschooler is often unable to see beyond that experience. It is helpful to discuss the child's fears but maintain honesty and openness when working with preschoolers in the health care setting.

The best way to help children overcome their fears is by actively involving them in finding practical methods to deal with the frightening experience. This may be as simple as keeping a night light on in child's bedroom for assurance that no monsters lurk in the dark. Exposing children to the feared object in a safe situation also provides a type of conditioning, or desensitization. For instance, children who are afraid of dogs should never be forced to approach or touch one, but they may be gradually introduced to the experience by watching other children play with an animal. This type of modelling, with others demonstrating fearlessness, can be effective if the child is allowed to progress at their own rate.

Usually by 5 or 6 years of age, children relinquish many fears. Explaining the developmental sequence of fears and their gradual disappearance may help parents feel more secure in handling preschoolers' fears. Sometimes fears do not subside with simple measures or developmental maturation. When children experience severe fears that disrupt family life, professional help is required.

Stress

Although for parents preschool years generally are less troublesome than toddlerhood, this period of life presents children with many unique stresses. Some, such as fears, are innate and stem from preschoolers' unique understanding of the world. Others, such as beginning school, are imposed. Although minimal amounts of stress are beneficial during the early years to help children develop effective coping skills, excessive stress is harmful. Young children are especially vulnerable because of their limited capacity to cope. Expression of frustration, fear, or anxiety is hampered by inadequate expressive language.

To help parents deal with stress in their child's life, they must be aware of the signs of stress (see Chapter 32, Stress and Coping) and be helped to identify the source. Any number of stressors may be present, such as the birth of a sibling, marital discord, divorce and separation, relocation, food insecurity, or illness.

The best approach to dealing with stress is prevention—monitoring the amount of stress in children's lives so that levels do not exceed their coping ability. In many instances, structuring children's schedules to allow rest and preparing them for change, such as entering school, are sufficient measures.

Aggression

The term *aggression* refers to behaviour with the intent to hurt a person or destroy property. Aggression differs from anger, which is a temporary emotional state, but anger may be expressed through aggression. Hyperaggressive behaviour in preschoolers is characterized by unprovoked physical attacks on other children and adults, destruction of others' property, frequent intense temper tantrums, extreme impulsivity, disrespect, and noncompliance. Aggression is influenced by a complex set of biological, sociocultural, and familial variables. Factors that tend to increase aggressive behaviour are gender, frustration, modelling of such behaviour, and reinforcement.

Evidence indicates that types of aggression differ between genders. Boys exhibit more physical aggression than girls during preschool years (Lussier et al., 2012). Relational aggression is exhibited at similar rates in boys and girls of this age group; however, differences in the frequency of relational aggression between genders can vary depending on peer interactions in various situations and settings (McEachern & Snyder, 2012).

Frustration, or continual thwarting of self-satisfaction by disapproval, humiliation, punishment, or insults, can lead children to act out against others as a means of release. Especially if they fear their parents, these children will displace their anger onto others, particularly peers and other authority figures. This type of aggression often applies to the child who is well behaved at home but has a discipline issue at school or is a bully among playmates.

Modelling, or imitating the behaviour of significant others, is a powerful influencing force in preschoolers. Children who see their parents as physically abusive are observing behaviour that they come to know as acceptable, and they may exhibit this behaviour with others (Benzies et al., 2009). Another aspect of modelling is the "double standard" for acceptable conduct. For example, in some families, aggression is synonymous with masculinity, and boys are encouraged to defend themselves. Television is also a significant source for modelling at this age. Research indicates that there is a direct correlation between media exposure, both violent and educational media, and preschoolers exhibiting physical and relational aggression; therefore, parents should be encouraged to supervise programming, especially for children with aggressive tendencies (Fitzpatrick et al., 2012).

Reinforcement can also shape aggressive behaviour. Sometimes reward for aggression is negative (e.g., punishment) yet reinforcing because it brings attention. For example, children who are ignored by a parent until they hit a sibling or the parent learn that this act garners attention.

When children exhibit extreme behaviours, such as aggression, parents may be concerned about the need for professional help. Generally, the difference between "normal" and "problematic" behaviour is not behaviour itself but its *quantity* (number of occurrences), *severity* (interference with social or cognitive functioning), *distribution* (different manifestations), *onset* (when behaviour started), and *duration* (at least 4 weeks).

Speech Issues

The most critical period for speech development occurs between 2 and 4 years of age. During this period, children are using their rapidly growing vocabulary faster than they can produce the words. Failure to master sensorimotor integrations results in stuttering or stammering as children try to say the word they are already thinking about. This **dysfluency** in speech pattern is a normal characteristic of language development in children ages 2 to 5 years, affects boys more frequently than girls, and usually resolves during childhood (Lowry, n.d.). When parents or other significant persons place undue emphasis on a child's dysfluency, an abnormal speech pattern may develop. Parents and caregivers of children who stutter are encouraged to speak slowly, refrain from correcting or criticizing the child's speech, resist the temptation to complete the child's sentences, provide the opportunity for the child to speak frequently, and take time to listen attentively.

The best therapy for speech issues is prevention and early detection. Common causes of speech disorders include hearing impairment, oropharyngeal structural anomalies, developmental disorders such as autism, brain injuries and other neuromotor impairments, lack of environmental stimulation, and physical conditions that impede normal speech production (McLaughlin, 2011). Referral for further evaluation and treatment may be necessary to prevent an impairment from interfering with learning. Anticipatory preparation of parents for expected developmental norms may allay caregiver concerns.

Children pressured into producing sounds ahead of their developmental level may develop *dyslalia* (articulation difficulties) or revert to using infantile speech. Prevention involves educating parents about the usual achievement of speech production during childhood. The NDDS is an excellent tool for assessing articulation skills in the child and for explaining to parents the expected progression of sounds (see Additional Resources at the end of the chapter).

Most provinces and territories have newborn hearing screening, which enables early identification of children with hearing impairment (see Chapter 26, Newborn Hearing Screening); treatment can then begin at birth. Referral for further evaluation and treatment may be necessary to prevent an impairment from interfering with learning. Anticipatory preparation of parents for expected developmental norms may allay caregiver concerns.

Mental Health

Various mental health issues can begin in early childhood, including depression, anxiety, attention-deficit/hyperactivity disorder (ADHD), autism spectrum disorders (ASD), and disruptive behaviour such as aggression, opposition, and defiance. It can be difficult for parents to differentiate between normal growth and development behaviours and early mental health concerns. Developmental screenings tools detailed in Chapter 33 may help nurses and other health care providers pick up on potential mental health issues. Early intervention may improve treatment outcomes.

The early signs of mental health issues include ongoing changes in behaviours that have an impact on how children function, such as fluctuations in mood, energy levels, sleep patterns, attitude, and appetite. For example, ASD symptoms usually appear before age 3 years. The signs vary in severity, but ASD often affects children's ability to communicate and interact with others. Mental health concerns in children are covered in more detail in Chapter 55.

ANTICIPATORY GUIDANCE—CARE OF FAMILIES

The preschool years present fewer child-rearing difficulties than do earlier years. This stage of development is facilitated by appropriate anticipatory guidance in the areas discussed in previous sections, as well as in health promotion, discussed in Chapter 35 (see Family-Centred Care box: Guidance During Preschool Years). During preschool years, child-rearing practices shift from protection of the child to education, as preschoolers can now understand why things happen.

During this period, an emotional transition between parent and child occurs. Although children are still attached to their parents and accept all their values and beliefs, they are nearing the period of life when they will question previous teachings and prefer the companionship of peers. Entry into school marks a separation for parents and for children. Parents may need help in adjusting to this change, particularly if one parent has focused their daily activities primarily on home responsibilities. All family members must adjust to changes, which is part of the process of growth and development.

FAMILY-CENTRED CARE

Guidance During Preschool Years

Age 3 Years

Prepare parents for child's increasing interest in widening relationships.

Encourage enrollment in preschool.

Emphasize the importance of setting limits.

Prepare parents to expect exaggerated tension-reduction behaviours, such as the need for a "security blanket."

Encourage parents to offer the child choices.

Prepare parents to expect marked changes at 3½ years, when the child becomes insecure and exhibits emotional extremes.

Prepare parents for normal dysfluency in speech and advise them to avoid focusing on the pattern.

Prepare parents to expect extra demands on their attention as a reflection of the child's emotional insecurity and fear of loss of love.

Warn parents that the equilibrium of a 3-year-old will change to the aggressive, out-of-bounds behaviour of a 4-year-old.

Age 4 Years

Prepare parents for more aggressive behaviour, including motor activity and offensive language.

Prepare parents to expect resistance to parental authority.

Explore parental feelings regarding the child's behaviour.

Suggest some type of respite for primary caregivers, such as placing the child in preschool for part of the day.

Explore parental feelings about the child's expression of gender identity.

Prepare parents for the child's increasing sexual curiosity.

Emphasize the importance of realistic limit setting on behaviour and appropriate disciplinary techniques.

Prepare parents for the highly imaginative 4-year-old who indulges in "tall tales" (to be differentiated from lies) and develops imaginary playmates.

Help parents prepare children for entrance into the school environment.

Prepare parents to expect their child to have nightmares or an increase in them.

Provide reassurance that a period of calmness begins at about 5 years of age.

KEY POINTS

- The preschool years consist of the period from 3 to 4 years of age, a time considered critical for emotional and psychological development.
- Biological development in the preschool period is characterized by mature body systems and refinement in gross and fine motor behaviour, as evidenced by activities such as running, riding a tricycle, and drawing.
- According to Erikson, acquiring a sense of initiative is the chief psychosocial task of the preschooler. Development of the superego occurs during this period, as conscience begins to emerge.
- According to Piaget, the preschool age is characterized by intuitive (or prelogical) thinking and a move toward logical thought processes through advanced, complex learning; language; and understanding of causality.
- The seeds of moral development are planted during the preschool period. According to Kohlberg, these children are in the stage of naive instrumental orientation, in which they are concerned with satisfying their own needs and, less frequently, the needs of others.
- Social development includes further separation–individuation; more sophisticated language; greater independence; and more complex, imaginative forms of play.

- In selecting an early learning program, parents should inquire about daily activities, teacher qualifications, accreditation, student–staff ratio, safety, meals, fees, and health practices.
- Fears constitute a great part of the preschool period; fear of objects or potential annihilation and parent-induced fears are common.
- Preschool aggression may result from frustration, modelling behaviour, and reinforcement.
- Hesitancy or dysfluency in speech patterns is a normal characteristic of language development. Speech issues can occur when parents express excessive concern over this pattern.
- Preschoolers can exhibit early signs of mental health issues, which include ongoing behaviour changes that affect how children function, such as fluctuations in mood, energy levels, sleep patterns, attitude, and appetite.

The School-Age Child and Family

Cheryl Dika

Originating US Chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the physical, cognitive, and moral changes that take place during the middle childhood years.
2. Describe ways to help a child develop a sense of accomplishment.
3. Demonstrate an understanding of the changing interpersonal relationships of school-age children.
4. Discuss the role of the peer group in the socialization of the school-age child.
5. Discuss the role of schools in the development and socialization of the school-age child.
6. Describe the most common causes of growth and maturation failure in later childhood.
7. Provide parents with guidelines for coping with normal growth and development issues that occur in a school-age child.

PROMOTING OPTIMUM GROWTH AND DEVELOPMENT

The segment of the lifespan that extends from age 5 years to approximately 11 years has a variety of labels, each of which describes an important characteristic of the period. These middle years are most often referred to as *school-age* or the *school years*. This period begins with entrance into the school environment, which has a significant impact on children's development and relationships. While the biological, social, emotional, and cognitive changes discussed throughout the chapter help us understand development during the school-age years, limiting our attention to these aspects of children's lives may divert attention from vital differences affecting health and well-being. School-age children vary in many ways according to race, gender, ethnicity, and class, and these differences have important implications. Thus, in this chapter, **growth** and development in the school-age years are discussed within the context of these differences. Also addressed is how nurses can support children and their families in ways that attend to diversity while acknowledging the developmental changes that are ongoing in these children's lives.

Indigenous Child Development Life Stages

Various Indigenous cultural teachings about child development exist across Canada. One is the life cycle teaching, in which the developmental stages of life are viewed through the medicine wheel as a holistic perspective of family wellness. Using the medicine wheel, the fast life is from 7 to 14 years of age. During this time, the child is prepared for puberty and rites of passage ceremonies celebrating the transition to adulthood. The youth may challenge their belief system, with patience being an important lesson. As their bodies are changing physically youths are taught respect for their bodies (Best Start, 2010).

Biological Development

Before 5 or 6 years of age, children have progressed from helpless infants to sturdy, complicated individuals with an ability to communicate, conceptualize in a limited way, and become involved in complex social and motor behaviours. Physical growth is also rapid during the preschool-age years. In contrast, the period of middle childhood, between the rapid growth of early childhood and the prepubescent growth spurt, is a time of gradual growth and development with more even progress in both physical and emotional aspects.

During middle childhood, growth in height and weight assumes a slower but steady pace compared with that of the earlier years. Between ages 5 and 12, children will grow an average of 5 cm per year to gain 30 to 60 cm in height and will almost double their weight, increasing 2 to 3 kg per year. During this period, girls and boys differ little in size, although boys tend to be slightly taller and heavier than girls. Toward the end of the school-age years, both boys and girls begin to increase in size, although most girls begin to surpass boys in both height and weight.

Physical Changes. School-age children are more coordinated than they were as preschoolers and are steadier on their feet. Their body proportions take on a slimmer look, with longer legs, varying body proportion, and a lower centre of gravity. Posture improves over that of the

preschool period to facilitate locomotion and efficiency in using the arms and trunk. These proportions make climbing, bicycle riding, and other activities easier. Fat gradually diminishes, and its distribution patterns change, contributing to the thinner appearance of the child during the middle years.

Accompanying the skeletal lengthening and fat diminution is an increase in the percentage of body weight represented by muscle tissue. By the end of this age period, both boys and girls double their strength and physical capabilities, and their steady and relatively consistent development of coordination increases their poise and skill. However, this increased strength can be misleading. Although strength increases, muscles are still functionally immature compared with those of the adolescent, and they are more readily damaged by muscular injury caused by overuse.

The most pronounced changes that indicate increasing maturity in children are a decrease in head circumference in relation to standing height, a decrease in waist circumference in relation to height, and an increase in leg length in relation to height. These observations often provide a clue to a child's degree of physical maturity and are useful in predicting readiness for meeting the demands of school.

Specific physiological and anatomical characteristics are typical of children in middle childhood. Facial proportions change as the face grows faster in relation to the remainder of the cranium. The skull and brain grow very slowly during this period and increase little in size. Because all of the primary (deciduous) teeth are lost during this age span, middle childhood is sometimes known as the age of the loose tooth (Figure 39.1). In the early years of middle childhood, the new secondary (permanent) teeth appear to be too large for the face.

Maturation of Systems. Maturity of the gastrointestinal system is reflected in fewer stomach upsets, better maintenance of blood glucose levels, and an increased stomach capacity, which permits retention of food for longer periods. The school-age child does not need to be fed as promptly or as frequently as the preschool-age child. Caloric needs are less than those in the preschool years and lower than what are needed during the coming adolescent growth spurt.

Physical maturation is evident in other body tissues and organs. Bladder capacity, although differing widely among individual children, is generally greater in girls than in boys. The heart grows more slowly during the middle years and is smaller in relation to the rest of the body than at any other period of life. Heart and respiratory rates steadily decrease, and blood pressure increases from ages 5 to 12 (see Appendix C).

Fig. 39.1 Middle childhood is the stage of development when deciduous teeth are shed. (iStock.com/Yelena Rodriguez Mena)

The immune system becomes more competent in its ability to localize infections and to produce an **antibody–antigen** response. However, children may have several infections in the first 1 to 2 years of school because of increased exposure to other children with infectious diseases.

Bones continue to ossify throughout childhood but yield to pressure and muscle pulls more readily than with mature bones. Children need ample opportunity to move around and should observe caution in carrying heavy loads. For example, they should shift books or tote bags from one arm to the other or consider using backpacks that distribute weight more evenly.

Wider differences between children are observed at the end of middle childhood than at the beginning. These differences become increasingly apparent and, if they are extreme or unique, may create emotional issues. The associated characteristics of height and weight relationships, rapid or slow growth, and other important features of development should be discussed with children and their families.

Prepubescence. *Preadolescence* is the period of approximately 2 years that begins at the end of middle childhood and ends with the thirteenth birthday. Because puberty or pubescence signals the beginning of the development of secondary sex characteristics, prepubescence typically occurs during preadolescence.

Toward the end of middle childhood, the discrepancies in growth and maturation between boys and girls become apparent. On average, there is a difference of approximately 2 years between girls and boys in age of onset of **pubescence**. This is a period of rapid growth in height and weight, especially for girls.

There is no universal age at which children assume the characteristics of prepubescence. The first physiological signs appear at about 9 years of age (particularly in girls) and are usually clearly evident in 11- to 12-year-old children. Although preadolescent children do not want to be different, variability in physical growth and physiological changes between children of the same sex and between the two sexes is often striking at this time. This variability, especially in relation to the onset of **secondary sexual characteristics**, can be a great concern to the preadolescent. Either early or late appearance of these characteristics can be a source of embarrassment and uneasiness to both sexes.

Preadolescence is a period of considerable overlapping of developmental characteristics of both middle childhood and early adolescence. However, several unique characteristics set this period apart from others. Generally, puberty begins at age 10 years in girls and 12 years in boys, but it can be normal for either sex after the age of 8 years. Boys experience little visible sexual maturation during preadolescence.

Table 39.1 summarizes the major developmental achievements of the school-age years.

Psychosocial Development

Freud described middle childhood as the *latency period*, a time of tranquility between the Oedipal phase of early childhood and the eroticism of adolescence. During this time, children experience relationships with same-sex peers following the indifference of earlier years and preceding the sexual fascination that occurs for most boys and girls in puberty.

Developing a Sense of Industry (Erikson). Successful mastery of Erikson's first three stages of psychosocial development is important in terms of development of a healthy personality. Successful completion of these stages requires a loving environment within a stable family unit. These initial experiences have prepared the child to engage in experiences and relationships beyond the intimate family group.

TABLE 39.1 Growth and Development During School-Age Years

Physical and Motor	Mental	Adaptive	Personal-Social
Age 5 Years			
Height is 110 cm Weight is 18.7 kg Eruption of permanent dentition Pulse and respirations decrease slightly Handedness is established (about 90% are right-handed)	Begins to question what parents think by comparing them with age-mates and other adults May notice prejudice and bias in the outside world Is more able to view others' perspective but tolerates differences rather than understands them Begins to understand conservation of numbers through counting objects regardless of arrangement Uses time-oriented words with increased understanding Cautious about accepting or believing information	Skips and hops on alternate feet Throws and catches ball well Jumps rope Skates with good balance Walks backward with heel to toe Jumps from height of 30 cm and lands on toes Balances on alternate feet with eyes closed Ties shoelaces Uses scissors, simple tools, or pencil very well In drawing copies a diamond and triangle, adds seven to nine parts to stick figures Prints a few letters numbers, or words, such as first name Has vocabulary of 2 100 words Uses sentences of six to eight words, with all parts of speech Knows coins' names Knows four or more colours Describes drawing or picture with much comment and elaboration Knows days of week, months, and other time-associated words Knows composition of object, such as a shoe Follows three commands in succession	Less rebellious and quarrelsome, more settled and gets down to business Not as open or accessible in thought and behaviour as in earlier years Independent but trustworthy, not foolhardy, more responsible Has fewer fears, relies on outer authority to control world Eager to do things right and to please; tries to "live by the rules" Has better manners Cares for self totally, occasionally needs supervision in dress or hygiene Not ready for concentrated close work or small print because of slight farsightedness Still unrefined eye–hand coordination Play is associative; tries to follow rules but may cheat to avoid losing Gets along with parents and may seek out parents more often for reassurance and security, especially when entering school Begins to question parents' thinking and principles Strongly identifies with parent of same sex, especially boys with their fathers Enjoys activities such as sports, cooking, and shopping with parent of same sex
Age 6 Years			
Height and weight gain continues slowly Weight gain is 2 to 3 kg per year Height gain is 5 cm per year after age 7 and birth length triples by about age 13 Central mandibular incisors erupt Loss of first tooth Gradual increase in dexterity Active age; constant activity Often returns to finger feeding More aware of hand as a tool Likes to draw, print, colour Vision reaches maturity	Develops concept of numbers Easily counts 13 pennies Knows whether it is morning or afternoon Defines common objects such as fork and chair in terms of their use Obeys three commands in succession Knows right and left hands Says which is pretty and which is ugly of a series of face drawings Describes objects in a picture rather than simply enumerating them Attends first grade	At the table, uses knife to spread butter or jam on bread At play, cuts, folds, pastes paper; sews crudely if the needle is threaded Takes a bath without supervision; performs bedtime activities alone Reads from memory; enjoys oral spelling game Likes table games, checkers, simple card games Giggles a lot Sometimes steals money or attractive items Has difficulty owning up to misdeeds Tries out own abilities	Can share and cooperate better Has great need for children of own age Will cheat to win Often engages in rough play Often jealous of younger brother or sister Does what adults are seen doing May have occasional temper tantrums Is a boaster Is more independent, probably influenced by school Has own way of doing things Increases socialization
Age 7 Years			
Begins to grow at least 5 cm in height per year Weight 17.7–30 kg Height 112–130 cm	Notices that certain items are missing from pictures Can accurately copy a diamond Repeats three numbers backward	Uses table knife for cutting meat; may need help with tough or difficult pieces Brushes and combs hair acceptably without help	Is becoming an active member of the family group Takes part in group play Most boys prefer playing with boys; most girls prefer playing with girls

Continued

TABLE 39.1 Growth and Development During School-Age Years—cont'd

Physical and Motor	Mental	Adaptive	Personal-Social
Maxillary central incisors and lateral mandibular incisors erupt More cautious in approaches to new activities Repeats performances to master them Jaw begins to expand to accommodate permanent teeth	Develops concept of time; reads ordinary clock or watch correctly to nearest quarter hour; uses clock for practical purposes Attends second grade More mechanical in reading; often does not stop at the end of a sentence; skips words such as "it," "the," and "he"	Likes to help and have a choice Is less resistant and stubborn	Spends a lot of time alone; does not require a lot of companionship
Ages 8–9 Years			
Continues to gain 5cm in height per year Weight 19.5–39.5kg Height 117–142cm Lateral incisors (maxillary) and mandibular cuspids erupt Movement is fluid; often graceful and poised Always on the go; jumps, chases, skips Increased smoothness and speed in fine motor control; uses cursive writing Dresses self completely Likely to overdo; hard to quiet down after recess More limber; bones grow faster than ligaments	Gives similarities and differences between two things from memory Counts backward from 20 to 1; understands concept of reversibility Repeats days of the week and months in order; knows the date Describes common objects in detail, not merely their use Makes change out of a quarter Attends third and fourth grades Reads more; may plan to wake up early just to read Reads classic books, but also enjoys comics More aware of time; can be relied on to get to school on time Can grasp concepts of parts and whole (fractions) Understands concepts of space, cause and effect, nesting (puzzles), conservation (permanence of mass and volume) Classifies objects by more than one quality; has collections Produces simple paintings or drawings	Makes use of common tools such as a hammer, saw, screwdriver Uses household and sewing utensils Helps with routine household tasks such as dusting and sweeping Assumes responsibility for share of household chores Looks after all of own needs at the table Buys useful articles; exercises some choice in making purchases Runs useful errands Likes pictorial magazines Likes school; wants to answer all the questions Is afraid of failing a grade; is ashamed of bad grades Is more critical of self Takes music and sport lessons	Is easy to get along with at home Likes the reward system Dramatizes Is more sociable Is better behaved Is interested in relationships with person of the same sex and/or opposite sex but will not admit it Goes about home and community freely, alone or with friends Likes to compete and play games Shows preference in friends and groups Plays mostly with groups of own sex but is beginning to mix Develops modesty Compares self with others Enjoys organizations, clubs, and group sports
Ages 10–12 Years			
Weight 24.5–58kg Height 127–162.5cm Posture is more similar to an adult's; will overcome lordosis Remainder of teeth will erupt and tend toward full development (except wisdom teeth) Girls—Pubescent changes may begin to appear; body lines soften and round out Boys—Slow growth in height and rapid weight gain; may become obese in this period	Writes brief stories Attends fifth to seventh grades Writes occasional short letters to friends or relatives on own initiative Responds to magazine, television, or other advertising Reads for practical information or own enjoyment—stories of adventure, fantasy, science fiction, or romance	Makes useful tools or does easy repair work Cooks or sews in small way Raises pets Washes and dries own hair; is responsible for a thorough job of cleaning hair, but may need reminding to do so Is sometimes left alone at home for an hour or so Is successful in looking after own needs or those of other children left in child's care	Loves friends; talks about them constantly Chooses friends more selectively; may have a "best friend" Enjoys conversation Develops beginning interest in opposite sex (if heterosexual) or same sex (if gay) Is more diplomatic Likes family; family has significant meaning Likes mother and wants to please her in many ways Demonstrates affection Likes father, who is admired and may be idolized Respects parents

A *sense of industry*, or a *stage of accomplishment*, is achieved somewhere between age 5 and adolescence. School-age children are eager to develop skills and participate in meaningful and socially useful work. They acquire a sense of personal and interpersonal competence, receive the systematic instruction prescribed by their individual cultures, and develop the skills needed to become useful, contributing members of their social communities. Failure to develop a sense of accomplishment may result in a sense of inferiority.

Interests expand in the middle years, and with a growing sense of independence, children want to engage in tasks that can be carried through to completion (Figure 39.2). They gain satisfaction from independent behaviour in exploring and manipulating their environment and from interaction with peers. Often the acquisition of skills provides a way to achieve success in social activities. Reinforcement in the form of grades, material rewards, additional privileges, and recognition provides encouragement and stimulation.

A sense of accomplishment also involves the ability to cooperate, to compete with others, and to cope effectively with people. Middle childhood is the time when children learn the value of doing things with others and the benefits derived from division of labour in the accomplishment of goals. Peer approval is a strong motivating power.

The danger inherent in this period of development is that children may encounter situations in which they feel a sense of inferiority. Children with physical and cognitive limitations may be at a disadvantage in the acquisition of certain skills. When the reward structure is based on evidence of mastery, children who are less capable of developing these skills are at risk of feeling inadequate and inferior. Even children without chronic disabilities may experience feelings of inadequacy in some areas. No child is able to do everything well, and children must learn that they will not be able to master every skill they attempt. Children, even children who usually have positive attitudes toward work and their own abilities, will feel some degree of inferiority when they encounter specific skills they cannot master.

Children need and want a sense of real achievement. Children attain a sense of industry when they have access to tasks that need to be done and when they are able to complete the tasks well despite individual differences in their innate capacities and emotional development.

Cognitive Development

When children enter the school years, they begin to acquire the ability to relate a series of events to mental representations that can be expressed both verbally and symbolically (see Table 39.1). This is the stage Piaget (1952) describes as "concrete operations," when children are able to use thought processes to experience events and actions. The rigid, **egocentric** view of the preschool years is replaced by mental processes that allow children to see things from another's point of view.

Fig. 39.2 School-age children are motivated to complete tasks working alone. (iStock.com/Imgorthand)

During this stage, children develop an understanding of relationships between things and ideas. They progress from making **judgements** based on what they see (perceptual thinking) to making judgements based on what they reason (conceptual thinking). They are able to master symbols and to use their memories of past experiences to evaluate and interpret the present.

One cognitive task of school-age children is mastering the concept of conservation (Figure 39.3), which occurs through a developmental sequence toward understanding. At an early age (≈5 to 6 years of age), children grasp the concept of conservation of numbers. For example, they recognize that 5 remains 5 whether it is represented by 3 + 2, 4 + 1, five balls, or five buttons. Conservation of liquids, mass, and length usually is accomplished at about 6 to 7 years of age. They recognize that changing the shape of a substance such as a lump of clay does not alter its total mass. They learn conservation of weight sometime later (9 to 10 years of age) and conservation of volume or displacement last (9 to 12 years of age). For example, they no longer perceive a tall, thin glass of water as containing a greater volume than a short, wide glass; they can distinguish between the weight of items regardless of their size.

School-age children also develop classification skills. They can group and sort objects according to the attributes they share, place things in a sensible and logical order, and hold a concept in mind while making decisions based on that concept. Another characteristic of middle childhood is that children derive enjoyment from classifying and ordering their environment. They become occupied with collections of objects, such as stickers, shells, dolls, cars, cards, and stuffed animals. Depending on their cultural background, they may even begin to order friends and relationships (e.g., best friend, second-best friend).

They also develop the ability to understand relational terms and concepts, such as bigger and smaller; darker and paler; heavier and lighter; to the right of and to the left of; first, last, and intermediate relationships; and more than and less than. They view family relationships in terms of reciprocal roles (e.g., to be a brother, one must have a sibling).

School-age children learn the alphabet and the world of symbols called words, which can be arranged in terms of structure and their relationship to the alphabet. They learn to tell time, to see the relationship of events in time (history) and places in space (geography), and to combine time and space relationships (geology and astronomy).

The ability to read is usually achieved during the school years and becomes the most significant and valuable tool for independent inquiry. Children's capacity to explore, imagine, and expand their knowledge is enhanced by reading.

Moral Development

As children move from **egocentrism** to more logical patterns of thought, they also move through stages in the development of conscience and moral standards (Kohlberg, 1968). Young children do not believe that standards of behaviour come from within themselves but that rules are established and set down by others. During the preschool years, children adopt and internalize the moral values of their parents. They learn standards for acceptable behaviour, act according to these standards, and feel guilty when they violate them. Although children 5 or 6 years of age know the rules and behaviours expected of them, they do not understand the reasons behind them. Rewards and punishments guide their judgement; a "bad act" is one that breaks a rule or causes harm. This description of moral development includes the aspect that young children believe that what other people tell them to do is right and that what they themselves think is wrong.

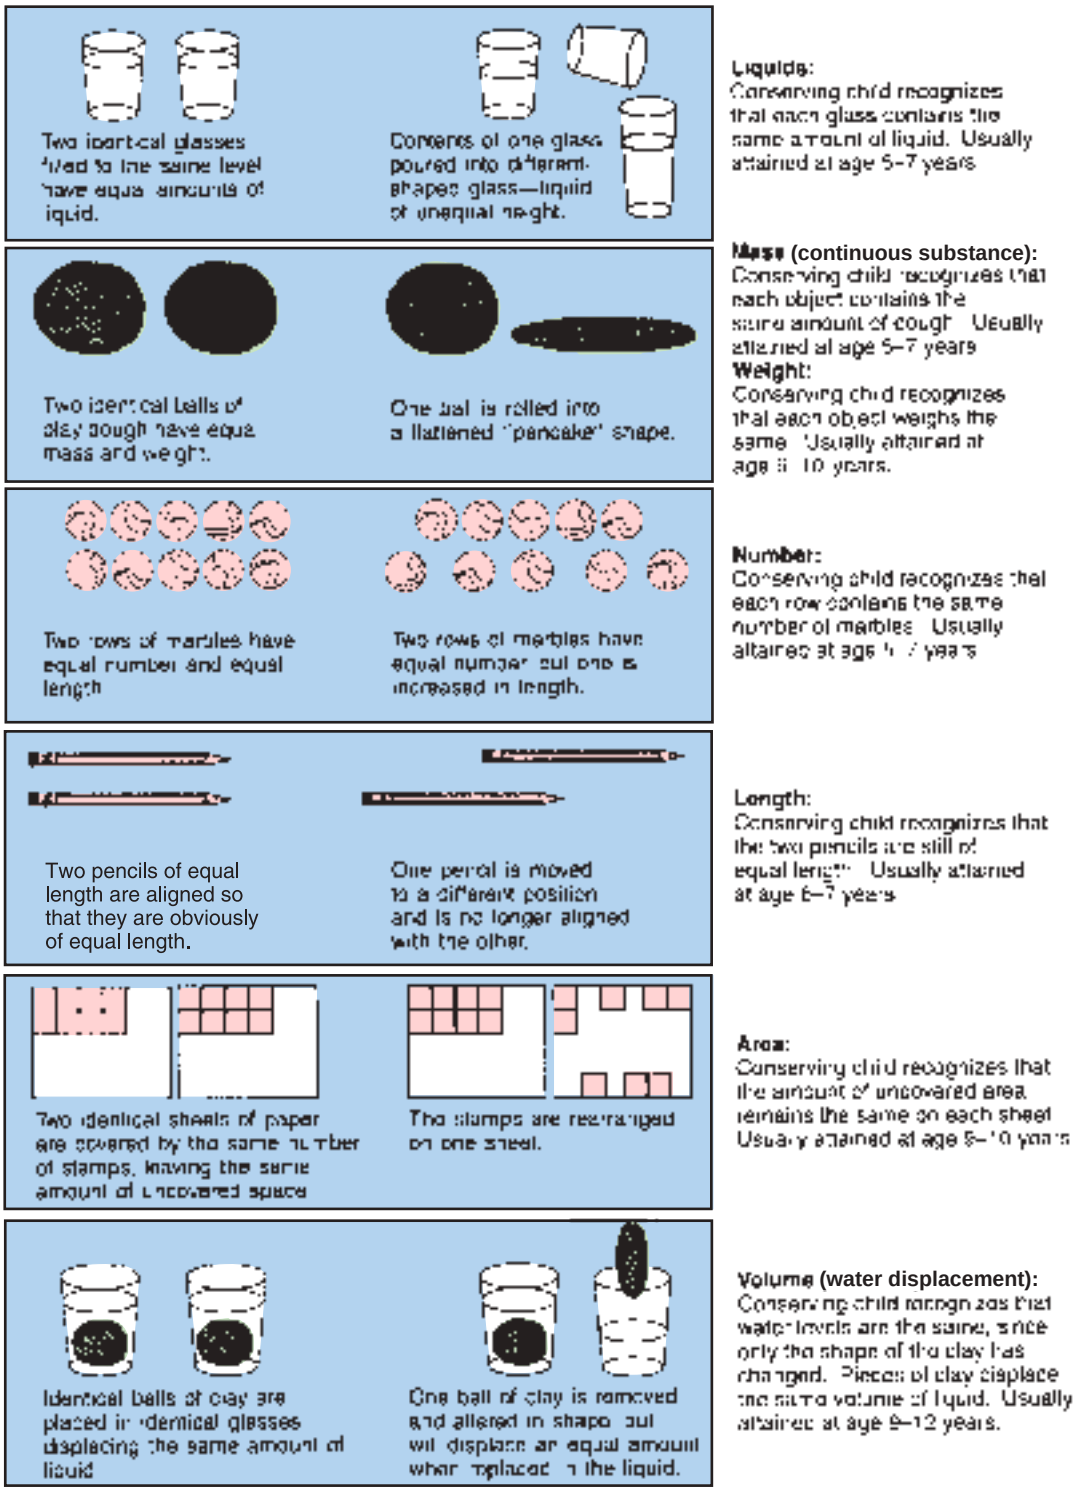

Fig. 39.3 Common examples that demonstrate the child's ability to conserve (ages are only approximate).

Consequently, children 5 or 6 years old may interpret accidents or misfortunes as punishment for "bad" acts.

Older school-age children are able to judge an act by the intentions that prompted it rather than just by its consequences. Rules and judgements become less absolute and authoritarian and begin to be founded on the needs and desires of others. For older children, a rule violation is likely to be viewed in relation to the total context in which it appears. The situation, as well as the morality of the rule itself, influences reactions. Although younger children judge an act only according to whether it is right or wrong, older children take into account a different point of view. They are able to understand and accept the concept of treating others as they would like to be treated.

Spiritual Development

Children at this age think in concrete terms but are avid learners and have a great desire to learn about their God or deity. They picture their God as human and use adjectives such as "loving" and "helping" to describe their deity. They are fascinated by the concepts of

hell and heaven, with a developing conscience and concern about rules. They may fear going to hell for misbehaviour. School-age children want and expect to be punished for misbehaviour and, when given the option, tend to choose a punishment that "fits the crime." However, they may view illness or injury as a punishment for a real or imagined misdeed. The beliefs and ideals of family and religious people are more influential than those of their peers in matters of faith.

School-age children begin to learn the difference between the natural and the supernatural but have difficulty understanding symbols. Consequently, religious concepts must be presented to them in concrete terms. Prayer or other religious rituals comfort them, and if these activities are a part of their daily lives, they may help them cope with threatening situations. Their petitions to their God in prayers tend to be for tangible rewards. Although younger children expect their prayers to be answered, as they get older, they begin to recognize that this does not always occur and become less concerned when prayers are not answered. They are able to discuss their feelings about their faith and how it relates to their lives (see Cultural Awareness box: Religious Orientation).

CULTURAL AWARENESS

Religious Orientation

Many schools and communities in Canada have a Christian or Jewish orientation toward prayer, holidays, and values. For children of other religious backgrounds, the predominance of these practices and values may result in their feeling conflict and discomfort. In Canada, awareness of and openness to the spiritual diversity of Indigenous groups is important and many schools are supporting curriculum revisions to incorporate such teachings. It is also important that schools and communities exercise sensitivity so as not to offend and confuse children from other religious backgrounds, such as Buddhism, Hinduism, and Islam, or those with no religious background.

Social Development

One of the most important socializing agents in the school-age years is the peer group. In addition to parents and the schools, the peer group conveys a substantial amount of information to its members. Peer groups have a culture of their own, with secrets, traditions, and codes of ethics that may promote feelings of solidarity and detachment from adults. Through peer relationships, children often learn how to deal with dominance and hostility, how to relate to persons in positions of leadership and authority, and how to explore ideas and the physical environment.

Peer group identification is an important factor in gaining independence from parents. The aid and support of the group provide the child with enough security to risk the moderate parental rejection brought about by small victories in the development of independence.

A child's concept of gender role is also influenced by relationships with peers. During the early school years, few gender differences exist in the play experiences of children. Both girls and boys share games and other activities. In the later school years the differences in the play of boys and girls may become more marked.

Social Relationships and Cooperation. Daily relationships with peers provide important social interactions for school-age children. Now children join group activities with unrestrained enthusiasm and steady participation. Previous interactions were limited to short periods under considerable adult supervision. With increased skills and wider opportunities, school-age children become involved with one or more peer groups in which they can gain status as respected members.

Valuable lessons are learned from daily interaction with age-mates. First, children learn to appreciate the numerous and varied points of view that are represented in the peer group. As children interact with peers who see the world in ways that are somewhat different from their own, they become aware of the limits of their own point of view. Because age-mates are peers and are not forced to accept each other's ideas as they are expected to accept those of adults, other children have a significant influence on decreasing the egocentric outlook of the child. Consequently, children learn to argue, persuade, bargain, cooperate, and compromise to maintain friendships.

A second lesson that children learn is increasing sensitivity to the social norms and pressures of the peer group. The peer group establishes standards for acceptance and rejection, and children are often willing to modify their behaviour to be accepted by the group. The need for peer approval becomes a powerful influence toward conformity. Children learn to dress, talk, and behave in a manner acceptable to the group. A variety of roles, such as class joker or class hero, may be assumed by individual children to gain approval from the group.

Finally, the interaction among peers leads to the formation of intimate friendships between peers—the school-age period is the time when children may have "best friends" with whom they share secrets, private jokes, and adventures; they come to one another's aid in times of trouble. In the course of these friendships children also fight, threaten each other, break up, and reunite. These relationships, in which the child experiences love and closeness for a peer, may be important as a foundation for relationships in adulthood (Figure 39.4).

Clubs and peer groups. One of the outstanding characteristics of middle childhood is the formation of formalized groups, or clubs. A prominent feature of these groups is the rigid rules imposed on the members. There is exclusiveness in the selection of persons who have the privilege of joining. Acceptance in the group is often determined on a pass-fail basis according to social or behavioural criteria. Conformity is the core of the group structure. There are often secret codes, shared interests, and special modes of dress, and each child must abide by a standard of behaviour established by the members. Conforming to the rules provides children with feelings of security and relieves them of the responsibility of making decisions. By merging their identities with those of their peers, children are able to move from the family group to an outside group, as a step toward seeking further independence. Peer groups and clubs allow children to substitute conformity to a peer group for conformity to a family at a time when children are still too insecure to function independently.

During the early school years, groups are usually small and loosely organized, with changing membership and no formal structure. The

Fig. 39.4 School-age children enjoy engaging in activities with a "best friend." (iStock.com/Jacob Lund)

clubs and groups usually do not display elements of cooperation and order that are seen in groups of older children. Although there may be a mixture of both sexes in the early school years, the groups of later school years are composed predominantly of children of the same sex. Common interests are the basis around which the group is structured.

Bullying. Peer-group identification and association are essential to a child's socialization. Poor relationships with peers and a lack of group identification can contribute to bullying. *Bullying* is any recurring activity and targeted aggression that is intended to harm or bother, either physical or otherwise (PREVNet, 2019). The bully establishes a perceived power differential over the victim (Public Safety Canada, 2018).

Between the ages of 4 and 11, bullying often begins when children are forming their self-identities at school and through other social activities. During middle school and high school, boys practise and are the victims of bullying almost twice as much as girls (Government of Canada, 2015). As children grow and develop into adolescence and adulthood, the nature of bullying changes, but the incidence does not decrease unless appropriate interventions are taken (PREVNet, 2019). Although bullying can occur in any setting, it most often occurs at school or during times or places where children gather, such as the school bus or community locations (PREVNet, 2019). Among adult Canadians, 38% of males and 30% of females report having experienced occasional or frequent bullying during their school years (Canadian Institutes of Health Research [CIHR], 2012).

Bullies are generally defiant toward adults, antisocial, and likely to break school rules. Bullies have not developed pro-social behaviours to regulate their frustrations and resolve interpersonal conflict (Public Safety Canada, 2018). They have dominant personalities, may come from homes where parental involvement and nurturing are lacking, and may experience or witness violence or abuse at home (Hensley, 2013). Boys who bully tend to use physical force, referred to as *direct bullying*, whereas girls usually use indirect bullying methods, such as exclusion, gossip, or rumours (Shetgiri, 2013). *Cyberbullying* involves the use of information and communication technologies such as cellular telephones, digital cameras, or social networking Internet sites to cause distress or harm to others through threatening, exclusion, or damaging reputations (PREVNet 2019; Public Safety Canada, 2018). It can be more harmful than traditional bullying, because the attack can instantly reach a wider audience, be available 24 hours a day, and allow the bully to remain anonymous (Carter & Wilson, 2015). The use of social media for mass communication has escalated the gravity of many methods of bullying.

Children who are targeted for bullying may have internalizing characteristics such as withdrawal, anxiety, depression, and low self-esteem, and in some cases this may lead to suicide (Public Safety Canada, 2018). Children who are bullied may experience headaches, stomachaches, as well as school absenteeism (Public Safety Canada, 2018). Of particular concern are LGBTQ2 students, who are bullied three times more than heterosexual students (CIHR, 2012).

Canada does not have a good record of effectively managing bullying. The World Health Organization global survey of health behaviours of school-age children ranks Canada twenty-sixth out of 35 countries for number of bullying incidents (CIHR, 2012). A Canadian federal network, called PREVNet (Promoting Relationships and Eliminating Violence), has been established to prevent bullying, by bridging the gap between research and practice (see Additional Resources at the end of this chapter). Through PREVNet partnerships, the Healthy Relationships Training Module (HRTM), co-developed with the Canadian Red Cross, Big Brothers Big Sisters of Canada, and Scouts Canada, has improved professional practices in approximately 100 organizations that train more than 35 000 adults and reach more than 1 million children and youth (PREVNet, 2019).

Bullying needs to be managed directly by adults who will acknowledge the problem and step in to stop it. Children also need empowerment strategies that can give them peer support and that help them in bullying situations. School personnel can play an important role in implementing antibullying interventions in elementary schools, before bullying becomes a part of the school culture.

Relationships With Families. Although the peer group is influential and necessary for normal child development, parents are usually the primary influence in shaping the child's personality, setting standards for behaviour, and establishing value systems. Family values usually take precedence over peer value systems. Although children may appear to reject parental values while testing the new values of the peer group, ultimately they retain and incorporate into their own value systems the parental values they have found to be of worth to them.

In the middle school years, children want to spend more time in the company of peers and often prefer peer-group activities to family activities. This can be disturbing to parents. Children may become intolerant and critical of their parents, especially when their parents' ways deviate from those of the group. They discover that parents can be wrong, and they begin to question the knowledge and authority of their parents, who were previously often considered to be all-knowing and all-powerful. Parents can best serve the interests of their children through tolerant understanding and support.

Play. Play takes on new dimensions that reflect a new stage of development in the school years (see Table 39.1). Play involves increased physical skill, intellectual ability, and fantasy. In addition, children develop a sense of belonging to a team or club by forming groups and cliques.

Rules and rituals. The need for conformity in middle childhood is strongly manifested in the activities and games of school-age children. In the preschool years, children's games were either invented for them or played in the company of a friend or an adult. Now children begin to see the need for rules, and their games have fixed and unvarying rules that may be bizarre and extraordinarily rigid. Part of the enjoyment of the game is knowing the rules because knowing means belonging. Conformity and ritual permeate their play and are also evident in their behaviour and language. Childhood is full of chants and taunts, such as "Eeeny, meeny, miney, mo," "Last one is a rotten egg," and "Step on a crack, break your mother's back." Children derive a sense of pleasure and power from such sayings, which have been handed down with few changes through generations.

Team play. A more complex form of play that evolves from the need for peer interaction is team games and sports. A referee, umpire, or person of authority may be required so that the rules can be followed more accurately. Team play teaches children to modify or exchange personal goals for goals of the group; it also teaches them that division of labour is an effective strategy for attaining a goal.

Team play can also contribute to children's social, intellectual, and skill growth. Children work hard to develop the skills needed to become team members, to improve their contribution to the group, and to anticipate the consequences of their behaviour for the group. Team play helps stimulate cognitive growth because children are called on to learn many complex rules, make judgements about those rules, plan strategies, and assess the strengths and weaknesses of members of their own team and members of the opposing team.

Quiet games and activities. Although play at this age is highly active, school-age children also enjoy quiet and solitary activities. The middle years are a time for collections, which constitute another ritual. Young school-age children's collections can be an odd assortment of unrelated objects in messy, disorganized piles. Collections of later school years tend to be more orderly, selective, and may be organized in scrapbooks, on shelves, or in boxes.

School-age children become fascinated with complex board, card, video, or computer games that they can play alone, with a best friend,

Fig. 39.5 School-age children enjoy reading books. (iStock.com/Tim Macpherson)

or with a group. As in all games, adherence to the rules is strict. Disagreements over rules can cause much discussion and argument, but may be easily resolved by reading the rules of the game.

The newly acquired skill of reading becomes increasingly satisfying as school-age children expand their knowledge of the world through books (Figure 39.5). School-age children never tire of stories and, as with preschool children, love to have stories read aloud. They also enjoy sewing, cooking, carpentry, gardening, and creative activities such as painting. Many creative skills, such as music and art, as well as athletic skills, such as swimming, karate, dancing, and skating, are learned during these years and continue to be enjoyed into adolescence and adulthood (Figure 39.6).

Development of a Self-Concept

The term *self-concept* refers to a conscious awareness of self-perceptions, such as one's physical characteristics, abilities, values, self-ideals and expectations, and idea of self in relation to others. It also includes one's body image, sexuality, and self-esteem. Although primary caregivers continue to exert influence on children's self-evaluation, the opinions of peers and teachers provide valuable input during middle childhood. With the emphasis on skill building and broadened social relationships, children are continually engaged in the process of self-evaluation.

Significant adults can often manage to unobtrusively manipulate the environment so that children experience success. Each small success increases a child's self-image. The more positive children feel about themselves, the more confident they will remain in trying for success in the future. All children profit from feeling that they are in some way special to a significant adult. A positive self-concept makes children feel likable, worthwhile, and capable of significant contributions. These feelings lead to self-respect, self-confidence, and happiness.

Fig. 39.6 School-age children take pride in learning new skills. (iStock.com/Weekend Images Inc.)

Body Image. School-age children have a relatively accurate and positive perception of their physical selves, but in general they like their physical selves less as they grow older. The head appears to be the most important part of the school-age child's perceived image of self, with hair and eye colour being the characteristics used most frequently to describe the physical self.

Body image is influenced, but not solely determined, by significant others. The number of significant others who influence children's perception of themselves increases with age. Children are acutely aware of their own body, the bodies of their peers, and those of adults. They are also aware of deviations from the norm. It is important that children learn about bodily functions and that adults provide correct information. Physical impairments, such as hearing or visual defects, ears that "stick out," or birthmarks, assume great importance during this age span. Increasing awareness of these differences, especially when accompanied by unkind comments and taunts from others, may cause a child to feel inferior and less desirable. This is especially true if the defect interferes with the child's ability to participate in games and activities.

COPING WITH CONCERNS RELATED TO NORMAL GROWTH AND DEVELOPMENT

School Experience

School constitutes an important part of the experience of children 5 to 11 years of age. Schools serve as a significant agent in the transmitting

of values of society to children. School is also the setting for building relationships with peers. After the family, schools are the second-most important socializing agent in the lives of children.

Entrance into school causes a sharp break in the structure of the child's world. For many children, it is their first experience with conforming to a group pattern imposed by an adult who is not a parent and who often has responsibility for too many children to be constantly aware of each child as an individual. Most children want to go to school and usually adapt to the new conditions with little difficulty. Successful adjustment is related to the child's physical and emotional maturity and the parent's readiness to accept the separation associated with school entrance. Unfortunately, some parents express their unconscious attempts to delay the child's maturity through clinging behaviour, particularly with their youngest child.

By the time they enter school, most children have a fairly realistic concept of what school involves. They receive information regarding the role of a student from parents, siblings, playmates, and the media. In addition, most children have had some experience with day care or preschool. Middle-class children generally have fewer adjustments to make and less to learn about expected behaviour, since schools tend to reflect dominant middle-class customs and values. If the child has attended a preschool program, the focus of the preschool program also affects the child's adjustment. Some preschool programs provide custodial care only, whereas others emphasize emotional, social, and intellectual development.

Some children in Canada are home-schooled. There are many reasons why parents choose this type of education, including educational liberty to form their own curriculum; religious freedom to integrate their values and beliefs into their child's learning; formation of a closer family relationship; potential for less peer pressure and bullying; and flexible scheduling. Some disadvantages include the amount of time required for parents to teach, less income if one parent has to stay at home to teach, and possible limited access for the child to organized sports. The children must be able to meet the legal conditions and pass standardized tests in accordance with the individual province's or territory's educational requirements. It is essential for home-schooled children to have opportunities to socialize and build peer relationships in order to foster their social development. Organized sports, play dates with neighbourhood children, and group swimming lessons are examples of common ways to help children develop friendships and social skills with others.

Role of Teachers. Children respond best to teachers who possess the characteristics of a warm, loving parent. Teachers in the early grades perform many of the activities formerly assumed by the parent, such as recognizing the child's personal needs (e.g., the need to go to the bathroom, need for help with clothing) and helping to develop their social behaviour (e.g., manners).

Teachers, like parents, are concerned about the child's psychological and emotional welfare. Although the functions of teachers and parents differ, both place constraints on behaviour, and both are in a position to enforce standards of conduct. However, unlike parents, the teacher's primary responsibility involves stimulating and guiding children's intellectual development, not providing for their physical welfare beyond the school setting.

Teachers serve as models that children often try to emulate. Children tend to seek their teachers' approval and avoid their disapproval. The teacher is a significant person in the life of the early schoolchild, and hero worship of a teacher may extend into late childhood and preadolescence. Teachers who make supportive statements that reassure or commend children, use accepting and clarifying statements that help children refine ideas and feelings, and provide assistance that aids children with their own problem solving contribute to the development of a positive self-concept in the school-age child.

Role of Parents. Parents share responsibility for helping children develop innate capabilities and social awareness. Parents can supplement academic education in numerous ways (see Family-Centred Care box: Helping Children in School). Cultivating responsibility is one goal of parental assistance, as being responsible for schoolwork helps children learn to keep promises, meet deadlines, and succeed at their jobs as adults. Children may occasionally ask for help (e.g., with a spelling list), but usually they prefer to think through their work by themselves. Excessive pressure or lack of encouragement from parents may inhibit development of these desirable traits.

FAMILY-CENTRED CARE

Helping Children in School

General Guidelines

- Be supportive—Provide companionship; share ideas and thoughts.
- Be positive—Every child should experience some success each day.
- Share an interest in reading—Use the library; discuss books they are reading.
- Support and encourage activity rather than passivity.
- Encourage originality—Help children make their own projects from discarded articles or other available materials.
- Foster the development of hobbies and collections.
- Encourage children to wonder and reflect during free time.
- Initiate family trips to places of interest.
- Encourage asking of questions—Help children discover sources for information or places to explore and investigate.
- Stimulate creative thinking and problem solving—Help children try out new solutions to problems without fear of making mistakes.
- Use rewards rather than punishment.

Specific Guidelines

- Meet the teacher at the beginning of school and plan to visit the school to see what is taught and expected.
- Demonstrate an interest in what the child is learning.
- Demonstrate an interest in content of school education and in the child's growth, more than in grades.
- Make it clear to the child that schoolwork is between the child and the teacher; the teacher and child should set goals for better school performance so that the child feels responsible for school successes and failures.
- Take advantage of situations that support and reinforce school learning.
- Share information with teachers that will help them understand the child better.
- Communicate with the teacher if there appears to be an issue; avoid waiting for a scheduled conference.
- Provide a quiet, well-lit area for study that is safe from interruption.
- Avoid dictating a study time, but do enforce rules, such as no television until homework is done; accept the child's word that work is complete.
- Help with homework should focus on explaining the question, not giving the answer.
- Teach the child to break large tasks (e.g., a report) down into smaller, manageable tasks spread over the allotted time rather than attempting the entire project the night before it is to be completed.
- Request special help for children with learning challenges.
- Support the school staff by showing respect for both the school system and the teacher, especially in the child's presence.

Latchkey Children

The term *latchkey children* is used to describe children in elementary school who are left to care for themselves before or after school without the supervision of an adult. The increasing numbers of lone-parent families and families in which both parents work outside the home, together with the lack of available child care, have created a stress-provoking situation for many school-age children.

Inadequate adult supervision after school leaves children at greater risk for injury and delinquent behaviour. In some instances, outside activities are curtailed and relationships with peers may be significantly diminished. Latchkey children may feel more lonely, isolated, and fearful than children who have someone to care for them. To cope with their fears and anxieties while alone, these children may devise strategies such as hiding, playing the television at loud volume, or using pets for comfort.

Many communities and persons concerned about the welfare of latchkey children are trying to help these children and their parents deal with this potentially serious issue. Some communities and employers have implemented after-school programs. Other types of programs include those designed to teach self-help skills to children, hotlines to provide telephone check-in and reassurance for children, and programs that link latchkey children with reassuring older people in their community. Nurses should be aware of these community services and encourage parents to teach self-help skills to their children.

Limit-Setting and Discipline

Many factors influence the amount and manner of discipline and limit-setting imposed on school-age children. Some of these factors are the parents' psychosocial maturity, the parents' childhood and child-rearing experiences, the children's temperament, the context of the children's misconduct, and the children's response to rewards and punishments. Discipline serves many purposes: (1) to help the child interrupt or inhibit a forbidden action; (2) to point out a more acceptable form of behaviour so that the child knows what is right in a future situation; (3) to provide some reason, understandable to the child, that explains why one action is inappropriate and another action is more desirable; and (4) to stimulate the child's ability to empathize with the victim of a misdeed.

To be effective, discipline should take place in a positive, supportive environment with the use of strategies to instruct and guide desired behaviours and eliminate undesired behaviours. Parents can set the stage for this environment and encourage good behaviour by establishing the following: (1) a calm, organized and comfortable space; (2) age-appropriate toys; (3) routine with scheduled time that includes some quiet activities and some outdoor and other physical activities; (4) standard sleep routines that ensure adequate nighttime sleep; and (5) regular mealtimes and healthy snacks to avoid irritability from hunger. Peer relationships affect a child's behaviour, so parents should get to know the child's friends and explain the house rules and expect respectful behaviour from everyone. Parents also need to limit screen time to high-quality shows and limit viewing of violent video games and shows that can make a child feel anxious or encourage aggressive behaviour. Parents need to respect their child's feelings, thoughts, ideas, and contributions and be honest with and listen to their child.

Physically aggressive practices, such as spanking, are detrimental to both parent and child health and well-being (Williams et al., 2019). Reasoning is an effective technique for older school-age children. With advancing cognitive skills, they are able to benefit from more complex disciplinary strategies. For example, withholding privileges, requiring compensation, imposing penalties, and contracting can be used with great success. Problem solving is the best approach to limit-setting, and children themselves can be included in the process of determining appropriate disciplinary measures.

Dishonest Behaviour

During middle childhood, children may engage in what is considered to be antisocial behaviour. Previously well-behaved children may engage in lying, stealing, and cheating. Such behaviours are disturbing and challenging to parents.

Lying can occur for a number of reasons. By the time children enter school, they still "tell stories," often exaggerating a story or situation as a means of impressing their family or friends. However, during middle childhood, children become able to distinguish between fact and fantasy. If children do not develop this characteristic, parents need to teach them what is real and what is make-believe.

Young children may lie to escape punishment or to get out of some difficulty even when their misbehaviour is evident. Older children may lie to meet expectations set by others to which they have been unable to measure up. However, most children know that lying and cheating are wrong, and they are concerned when it is observed in their friends. They can be quick to report others when they detect cheating.

Parents need to be reassured that all children lie occasionally and that sometimes children may have difficulty separating fantasy from reality. Parents should be helped to understand the importance of being truthful in their relationships with children.

Cheating is most common in children who are 5 to 6 years of age. They find it difficult to lose at a game or contest, so they may cheat to win. They have not yet realized that this behaviour is wrong, and they do it almost automatically. This behaviour usually disappears as they mature. However, because children model observed behaviours, parents need to be aware of their own behaviour. When parents set examples of honesty, children are more likely to conform to these standards.

As with other ethically related behaviour, stealing is not unexpected in the younger child. Between 5 and 8 years of age, children's sense of property rights is limited, and they tend to take something simply because they are attracted to it or to take money for what it will buy. They are equally likely to give away something valuable that belongs to them. When young children are caught and punished, they are penitent—they "didn't mean to" and "promise to never do it again"—but they are likely to repeat the action the following day. Often they not only steal but also lie about their behaviour or attempt to justify it with excuses. It is seldom helpful to trap children into admission by asking directly if they committed the offence. Children do not take responsibility for these types of behaviours until the end of middle childhood. Stealing can be an indication that something is seriously wrong or lacking in the child's life. For example, children may steal to make up for love or another satisfaction that they feel is lacking. Or if they are not receiving adequate food, they may steal food because they are hungry. In most situations it is wise not to attempt to attach a hidden or deep meaning to the stealing. An admonition, together with an appropriate and reasonable punishment, such as having the older child pay back the money or return the stolen items, takes care of most cases. Most children can be taught to respect the property rights of others with little difficulty despite numerous temptations and opportunities. If children's personal rights are respected, they are likely to respect the rights of others. Some children simply need more time to learn the rules regarding private property.

Stress and Fear

Children today experience significant amounts of **stress**, which can cause long-term adjustment and health issues. Stress in childhood comes from a variety of sources, such as conflict within the family, interpersonal relationships, poverty, and chronic illness. The school environment and participation in multiple organized activities can be additional sources of stress. The demands from coaches and parents, in addition to school requirements and pressure from teachers to do

well on proficiency testing, can place unrealistic expectations on the school-age child. With increasing exposure to sexuality and provocative clothing and behaviours, children of this age group may feel pressured to have a girlfriend or boyfriend, which their maturity level cannot handle and which can cause additional stress (McLeod & Knight, 2010).

Increasing **violence** in society has also spilled over into the school setting. In the present information age, in which tragedy is broadcast daily in the media, children come to school knowing more about the latest world events than any previous generation of children. Today's children are often personally aware of violence in their families or communities. Some children know other children who have been killed or children who have brought weapons to school. School-age children can be victims of teasing, bullying, and physical abuse in the school environment.

To help children cope with stress, parents, teachers, and health care providers must recognize signs that indicate a child is undergoing stress, identify the source of the stress promptly, work to reduce the source of stress, and refer those children who need specialized treatment. They need to frequently reassure children that they are safe, have honest and open communication, encourage children to express their feelings, and provide time for unstructured play. It is important that adults help children build coping strategies to foster self-confidence and overcome fears, by providing practical solutions, encouraging a sense of self-control, praising accomplishments, avoiding criticism, and advocating for social and family conditions that reduce stress.

! NURSING ALERT

The nurse who observes the following signs of stress in a child should explore the situation further:

- Stomach pains or headache
- Changes in sleep patterns or nightmares
- Bedwetting
- Changes in eating habits
- Aggressive or stubborn behaviour
- Withdrawal or reluctance to participate
- Regression to earlier behaviours (e.g., thumb-sucking)
- Trouble concentrating or changes in academic performance

Children 7 to 11 years of age are capable of identifying their own physiological responses to stress with terms that have meaning to them. They may describe their body's reaction to stress in terms of having tight muscles; being hot or red in the face; tingling; having chills or goose bumps; or experiencing shakiness, a heart beating fast, headache, or stomachache. Some children may experience headaches or get angry more easily. Children should be taught to recognize these signs as indicators of stress and to use techniques to manage their stress. Children can learn relaxation techniques such as deep-breathing exercises, progressive relaxation of muscle groups, and positive imagery to immediately reduce stress. Encouraging them to "blow off steam" through physical activity can reduce tension and anxiety. Children can also be encouraged to observe effective coping strategies in others and adopt them for their own use. When an effective strategy has been developed for one situation, parents can show the child how to transfer the coping strategy or technique to other situations.

In addition to stress, school-age children experience a wide variety of fears, including fear of the dark, excessive worry about past behaviour, self-consciousness, social withdrawal, and an excessive need for reassurance. These fears are considered normal for children this age. During the middle range of the school-age years, children become less fearful of body safety than they were as preschoolers, but they still fear being hurt, being kidnapped, or having to undergo surgery. They also fear death and are fascinated by all aspects of death and dying. Fears of noises, darkness, storms, and dogs lessen, while new fears related predominantly to school and family can bother children at this age.

Sports

Considerable controversy surrounds the trend toward early participation in competitive athletics and the amount and type of competitive sports that are appropriate for children in the elementary grades. The current view is that virtually every child is suited for some sport, and authorities do not discourage participation if children are matched to the type of sport appropriate to their abilities and to their physical and emotional constitution. School-age children tend to enjoy competition (Figure 39.7). However, teachers and coaches must understand the physical limitations of children this age and teach them the proper techniques and safety measures needed to avoid injuries. A safe and appropriate sport can be identified for even the most unskilled and uncompetitive child, including children with chronic illnesses and cognitive impairments. Common activities for school-age children include hockey, skiing, softball, soccer, gymnastics, and swimming. Equipment must be maintained in safe condition, and protective gear should be worn to prevent serious injury, such as helmets and wrist splints (see Chapter 35 and Chapter 53).

During the school-age years, girls have the same basic body structure as that of boys and have a similar response to systematic exercise training. However, at puberty, boys become larger and have more

Fig. 39.7 The activities engaged in by school-age children vary according to interest and opportunity. **A:** Little League competitors. (iStock.com/monkeybusinessimages) **B:** Playing tug-of-war. (iStock.com/BraunS)

muscle mass, and at this stage it is usually recommended that girls compete only against other girls, in most sports. Before puberty there is no essential difference in strength and size between girls and boys, making these precautions unnecessary.

Preadolescence is a time to teach fundamental motor skills; develop fitness in a practical, safe, and gradual manner; and promote healthy attitudes and values. Activities should include both practice sessions and unstructured play; the actual game or event should be managed in a manner that stresses mastery of the sport, fun, and enhancement of self-image rather than winning or pleasing others. All children should have an opportunity to participate, and special ceremonies should recognize all participants, not just individuals who excel in sports or athletics.

Acquisition of Skills

School-age children demonstrate increasing fine-motor abilities and complex artistic skills. Handedness is well established by the beginning of the school years, and children make great strides in writing and drawing during this period. It is a time of energetic and vibrant creative productivity. With the tools of language and reading, children create poems, stories, and plays. With more advanced fine-motor skills, they are able to master an unlimited variety of handicrafts, such as ceramics, needlework, wood carving, and beadwork. They avidly pursue these skills in solitude, with a friend, or through organized groups, such as boys' or girls' clubs, or special interest groups that use crafts or other activities as a means to occupy, entertain, and educate children.

School-age children are capable of assuming responsibility for their own needs. School-age children can and want to assume their share of household tasks, which may be related to male and female roles defined by their culture. Parents may choose to role model open and flexible gender expectations. Many children also assume responsibility for tasks outside the home, such as babysitting, mowing lawns, or having paper routes.

Use of Social Media and the Internet

Children are very familiar with different forms of media, and this contact with the media brings benefits as well as risks. Social media sites abound, including Facebook, Twitter, Instagram, Snapchat, blogs, gaming sites, and virtual worlds such as Club Penguin, Second Life, and The Sims. Children also frequent video sites such as YouTube. The benefits of social media and Internet use to children include entertainment as well as development of communication and technical skills. However, there are also risks to children with these media sites, such as cyberbullying. Sexual predators lurk on the Internet and can make dangerous contact with children.

It is recommended that parents talk to their children about their use of the Internet and the dangers that children may face online. Parents also need to address cyberbullying, "sexting," and time management of using social media. Families can create a "family online-use plan" that emphasizes good citizenship and healthy behaviour. Children need parental monitoring with participation and discussion of their online activity (Ponti & Canadian Paediatric Society [CPS] Digital Health Task Force, 2019). (See Additional Resources at the end of the chapter for a guide for parents.)

School Health

Child health maintenance is ultimately the responsibility of the parents; however, public schools and health departments in Canada have contributed to the improvement of child health by providing a healthful school environment, health services, and health education that emphasize sound health practices. Varying by province, territory, and school district, most of these functions constitute major components of community health services and involve public funding and health care providers, including nurses. School health programs are involved in ongoing health maintenance through assessment, screening, and referral activities. Health services provided by some schools include health appraisal by consultation, emergency care, safety education, communicable disease control, counselling, and follow-up care. Health education of school-age children is directed toward providing knowledge of health and influencing habits, attitudes, and conduct in relation to health promotion and injury prevention. School districts may allocate their money to programs aimed at improving learning by improving nutrition; for example, some inner city schools in Vancouver and Toronto have breakfast programs for all children.

Community health nurses may manage and coordinate care required by regular students and students with special health care needs. In many settings, school health services have enlarged into community health centres that meet the needs of not only school-age children but also their families and the community. In these settings, schools provide health care that includes assessment of physical, psychological, emotional, behavioural, and learning issues, as well as comprehensive well-child care.

The level of integration of children with chronic illness or disability into regular classrooms varies among the provinces and territories in Canada. Community health nurses are usually available for consultation on integrating the child into the classroom, although the individual parent may need to make arrangements with their local community health nursing organization if their child requires nursing care at school. Community health nurses can develop, implement, and evaluate individualized health care plans for these children. Most health jurisdictions aim to provide unregulated care providers such as special education assistants (EAs) to be with all children who require such assistance. Delegation and supervision of unregulated care providers requires skillful nursing assessment, effective communication, and professional judgement.

SPECIAL HEALTH CONCERNS

Altered Growth and Maturation

The absence of physical or sexual maturation at a time when other children are experiencing positive evidence of sexual development and its associated spurt in growth and physical strength can be a concern to both the parents and their affected child. Fortunately, in most instances, the delay in development is a simple physiological or constitutional delay that represents one end of the normal genetically influenced variation of pubertal growth. These children will go through a delayed but normal puberty and finally catch up, in their late teens, with their more rapidly developing age-mates. Less benign causes of delayed development may be the result of endocrine disorders or chromosomal abnormalities. Delayed development can also be a result of chronic diseases (such as malabsorption or chronic asthma) that are serious enough to slow development or a result of environmental factors (such as stress or poor nutrition).

Rates of maturation are important during the school years, but at puberty they assume larger proportions to both teens and their parents. Girls or boys who lag behind their peers in physical maturation are painfully aware of their difference in growth. Manifestations of sexual development before 9 years of age in boys and before 8 years of age in all children may signal precocious puberty and need to be investigated (see Chapter 51).

Tall Stature. Despite the fact that the average height of boys and girls is steadily increasing, there is a small group of children who, because of some organic disorder or a familial tendency, are excessively tall compared with their peers.

When the rate of height change before puberty suggests the probability of excessive adult height, treatment with hormones may be considered, although there is considerable controversy regarding the use of hormones for this purpose. The use of estrogens is effective in controlling height when therapy is initiated before menarche and before the end of the adolescent growth spurt that normally precedes menarche. The selection of children for hormonal therapy is made on the basis of a careful evaluation of physical, psychological, and social factors.

Short Stature. Short stature is a nonspecific finding that may be the first manifestation of a serious disorder, or it may be of no consequence medically. On a worldwide scale, the most common cause of short stature or delayed development is inadequate nutrition. The major physical disorders that produce delayed development are chronic diseases, endocrine dysfunction, and syndromes of primary **gonad** failure.

Chronic diseases can interfere with growth, but unless the illness is unduly prolonged, catch-up growth occurs. Diseases and disorders that cause some degree of growth delay include asthma, cystic fibrosis, gastrointestinal diseases (such as parasitic infections), celiac disease, malabsorption syndromes, cardiac anomalies, and chronic renal disturbances. The duration of the illness is more significant than the intensity in terms of the effect on growth, although the precise length of time necessary to affect growth permanently has not been determined.

Skeletal disorders that affect growth in stature are those described as *dwarfism*. Most disorders are caused by congenital defects and disorders, such as achondroplasia, and by inborn errors of metabolism, such as Hurler's syndrome or Hunter's syndrome.

Psychosocial or deprivation dwarfism is a stress-induced growth failure. It is defined as growth restriction in children over 2 years of age that is caused by environmental (emotional) stress and is associated with a marked delay in physical growth, delayed developmental skills, and immature behaviour. When these children are removed from the deprived environment, their growth proceeds at a normal or increased rate. (See also Growth Failure [Failure to Thrive] in Chapter 36, and Child Maltreatment in Chapter 35.)

Management involves continued medical observation, attention to general health and nutrition, and psychological support. When growth delay is accompanied by poor self-esteem, many authorities recommend hormonal therapy. Testosterone in carefully regulated doses is effective in some cases. Growth hormone is capable of increasing height and is used to treat growth hormone deficiency (see Chapter 51, Hypopituitarism). Its use in children with constitutional delay is highly controversial.

Nursing Care. One difficulty related to size being incongruent with chronological and mental age is the manner in which others relate to the child. Physical maturity is not necessarily correlated with emotional and social maturity. Seven-year-old children who look like 10-year-old children will think and act like 7-year-old children. To expect behaviours appropriate for the older age is unrealistic and can be detrimental to their development of competence and self-esteem. Conversely, to treat 10-year-old children who look young physically as though they were younger is an equal disservice to them.

Listening to distressed children and conveying interest in and concern about them are important interventions. Counselling and therapy need to be individualized for each youth. Encouraging these children to focus on the positive aspects of their bodies and personalities and to adopt sound health practices and practise good grooming foster a more positive self-image.

Enuresis

Enuresis is defined as involuntary urination. *Nocturnal enuresis* (bedwetting) is a common and troublesome disorder that is defined as the involuntary passage of urine at night by children who are beyond the age when voluntary bladder control should normally have been acquired. Children should not be labelled enuretic unless regular (more than twice per week) wetting persists beyond the age of 5 years (Feldman & CPS, Community Paediatrics Committee, 2005/2016).

Enuresis can also be defined as primary (bedwetting in children who have never been dry for extended periods) or secondary (the onset of wetting after a period of established urinary continence) (Feldman & CPS, Community Paediatrics Committee, 2005/2016). Primary nocturnal enuresis is more common in boys. Bedwetting is found in 10 to 15% of 5-year-old children and 6 to 8% of 8-year-old children, and it declines to 1 to 2% by 15 years of age (Feldman & CPS, Community Paediatrics Committee, 2005/2016). The passage of urine may be monosymptomatic and occur only during nighttime sleep, with the child remaining dry during the day, or it may be polysymptomatic, in which the child has daytime urinary urgency and an occasional daytime accident in conjunction with other conditions, such as sleep apnea, urinary tract infection, neurological impairment, constipation, or emotional stressors (Elder, 2020). The nocturnal, monosymptomatic type is most common. The condition may be particularly distressing to adolescents, who may refuse therapy. Although enuresis may occur during the daytime (*diurnal enuresis*), the following discussion focuses primarily on nocturnal enuresis.

Organic causes that may be related to enuresis should be ruled out before psychogenic factors are considered. Organic causes include structural disorders of the urinary tract; urinary tract infection; neurological deficits; disorders that increase the normal output of urine, such as diabetes; and disorders that impair the concentrating ability of the kidneys, such as chronic renal failure or sickle cell disease.

The following recommendations are suggested by the Canadian Paediatric Society for the treatment of primary nocturnal enuresis (Feldman & CPS, Community Paediatrics Committee, 2005/2016):

- Clarify the goal of getting up at night and using the toilet.
- Assure the child's access to the toilet.
- Avoid caffeine-containing foods and excessive fluids before bedtime.
- Have the child empty the bladder at bedtime.
- Take the child out of diapers (training pants may be acceptable).
- Include the child in morning cleanup in a nonpunitive manner.
- Preserve the child's self-esteem.
- Children for whom primary nocturnal enuresis is not distressing should not receive treatment.
- Parents should be reassured about their child's physical and emotional health and should be counselled about eliminating guilt, shame, and punishment.
- A conditioning alarm system is the most efficacious therapy, but it will be successful in the long term in less than 50% of children. Alarms may be the most appropriate initial line of therapy for primary nocturnal enuresis for older children in highly motivated families.
- Pharmacological therapy with desmopressin acetate has a place in special situations, such as at camp and sleepovers, or when the alarm system is impractical or not effective.
- Treatment of primary nocturnal enuresis should be aimed at minimizing the emotional impact on the child.

Nursing Care. No matter what techniques are used, the nurse can help both children and parents to understand the issue of enuresis, the treatment plan, and the difficulties they may encounter in the

process. Essential to the success of any method is the supportive care of parents and their children. Both need encouragement and patience. The issue is discussed with both the parent and child because all treatments involve and require the child's active participation. In some treatment interventions, the child is in charge of the intervention; therefore, parents must learn to support the child rather than intervene themselves. For example, children can strip their wet covers, limit fluids, and use the toilet before bedtime. Parents should encourage the child to maintain a regular bowel evacuation regimen; constipation can contribute to nocturnal enuresis (Elder, 2020). A calendar with wet and dry nights may be helpful to motivate the child to stay dry and to maintain a positive perspective on the issue; positive rewards are also helpful.

Parents need to understand that punishment such as scolding, shaming, and threatening is contraindicated because of its negative emotional impact and limited success in reducing the behaviour. Positive reinforcement of the desired behaviour may be beneficial. Children need to believe they are helping themselves, and they need to sustain feelings of confidence and hope. Many parents believe enuresis is caused by an emotional disturbance and fear that they have somehow produced the situation by using improper child-rearing practices. They need reassurance that bedwetting is not a manifestation of an emotional disturbance and does not represent willful misbehaviour. Parents need to be encouraged to be patient and understanding and to communicate love and support to the child.

Communication with children is directed toward eliminating the emotional impact of enuresis, relieving feelings of shame and guilt and the burden of parental disapproval, building self-confidence, and motivating children toward independent control. More important, the nurse can provide consistent support and encouragement to help children through the inconsistent and unpredictable treatment process. Parents should also be taught to observe for adverse effects of any medications used.

Sex Chromosome Abnormalities

Most **sex chromosome** abnormalities are caused by an alteration in sex chromosome number (Table 39.2). Most of these conditions are due to nondisjunction. An alteration in the number of sex chromosomes usually does not produce the profound defects associated with the autosomal trisomies. Intelligence may be normal or low normal or the child may have some learning disabilities. Moderate or severe cognitive impairment is less common.

Turner Syndrome. Turner syndrome is caused by absence of one of the X chromosomes. Most girls with this disorder have one X chromosome missing from all cells (45,X). This disorder is often recognized at birth if the newborn has a webbed neck, low posterior hairline, widely spaced nipples, and edema of the hands and feet. It can also be diagnosed at puberty because of three features: short stature, sexual infantilism, and **amenorrhea**. Girls with Turner syndrome are generally infertile. They may also have difficulty with peer relationships and understanding social cues. They frequently exhibit behavioural issues, especially in relation to their immature, socially isolated behaviour. Diagnosis is confirmed on the basis of a negative sex chromatin test.

Therapy is individualized for these girls and consists primarily of hormone treatment and psychological counselling for both the child and parents. Linear growth can be increased by the administration of growth hormone if therapy is begun early. Estrogen therapy is initiated during the usual time for puberty to promote the development of secondary sex characteristics. Responses to estrogen therapy vary from girl to girl, but gradual feminization is accomplished to some degree in most individuals.

Klinefelter Syndrome. Klinefelter syndrome, the most common of all sex chromosome abnormalities, is caused by the presence of one or more additional X chromosomes. Most males with this syndrome have a chromosome complement of 47,XXY. The disorder is seldom recognized before puberty, at which time varying degrees of failure of adolescent virilization occur. Some males are not diagnosed until they appear for evaluation for infertility. All have absence of sperm in the semen (azoospermia), small testes, and defective development of secondary sex characteristics. In 80% of these boys there is a chromatin-positive buccal smear, and the extra chromosome is apparent on chromosome analysis.

Cognitive impairment is a frequent clinical finding and appears to be related to the number of X chromosomes. Boys may also have gross motor skill difficulties, a developmental language delay, poor verbal skills, reduced auditory memory, shyness, passivity, behavioural issues, and school difficulties. Therapy is directed toward enhancing the masculine characteristics through administration of testosterone.

Nursing Care. The nursing care of children with Turner syndrome or Klinefelter syndrome is primarily supportive. Nurses can assist in diagnosis, explain tests and therapies, and provide support and encouragement to the child and the family. Because the disorders render the

TABLE 39.2 Common Sex Chromosome Abnormalities

Syndrome	Chromosomal Nomenclature	Phenotype	Incidence (Live Births)	Clinical Manifestations
Turner	45,X or 45XO	Female	1:2 500 to 1:5 000 female births*	Short stature; webbed neck; low posterior hairline; shield-shaped chest with widely spaced nipples; sterile; no development of secondary sex characteristics
Triple X, or superfemale	47,XXX (can also be 48, XXXX or 49,XXXXX)	Female	1:1 000 female births	Normal female characteristics; usually tall; variable mental capacity and behaviour; at risk for impaired language, learning difficulties; fertile
XYY male	47,XYY (can also be 48, XYYY or mosaic)	Male	1:800 to 1:1 000 male births*	Usually normal sexual development; tendency to be tall with long head; poor coordination; may demonstrate aberrant behaviour
Klinefelter	47,XXY (48,XXYY, 48, XXXY, 49,XXXXY, and so on, mosaics)	Male	1:580 male births*	Tall with long legs; hypogenitalism; sterile; male secondary sex characteristics may be deficient; may demonstrate aberrant behaviour; learning disabled; possible gynecomastia

individual unable to reproduce, psychological counselling is an important aspect of care. Marriage and sexual relationships are possible, but alternative reproductive options, such as artificial insemination and adoption, should be discussed.

ANTICIPATORY GUIDANCE FOR FAMILIES

Although increased independence is the goal of middle childhood, children are not prepared to abandon all parental control. They need and want restrictions placed on their behaviour, and they are not prepared to cope with all the challenges of their expanding environment. They feel more secure knowing there is an authority figure to implement controls and restrictions. Children may complain loudly about restrictions and try to break down parental barriers, but they are uneasy if they succeed in doing so. They respect adults who prevent them from acting on every urge. Children view this behaviour as an expression of love and concern for their welfare.

Children need stable, secure guidance provided by mature adults to whom they can turn during troubled relationships with peers or stressful changes in their world (see Family-Centred Care box: Guidance for Parents During School Years). Children also need their parents to be adults, not friends. Sometimes parents, hurt by their children's rejection, attempt to maintain their love and gratitude by assuming the role of a friend.

FAMILY-CENTRED CARE

Guidance for Parents During School Years

Ages 5 to 6 Years

Prepare parents for potential strong food preferences and potential refusal of specific food items.
Prepare parents to expect an increasingly ravenous appetite.
Prepare parents for emotionality as the child experiences mood changes.
Help parents anticipate the child's continued susceptibility to illness.
Review the immunization schedule with parents—if tetanus schedule of four initial doses is completed before age 4, a fifth dose of tetanus toxoid is recommended at school entry by age 6 (Government of Canada, 2021).
Teach injury prevention and safety, especially bicycle safety (see Chapter 35).
Encourage parents to respect the child's need for privacy.
Prepare parents for the child's increasing interests outside the home.
Help parents understand the need to support the child's interactions with peers.

Ages 7 to 10 Years

Prepare parents to expect an improvement in their child's health with fewer illnesses, although allergies may increase or become apparent.
Prepare parents to expect an increase in minor injuries in their child.
Advise parents to use caution in selecting and maintaining sports equipment, and re-emphasize focus on safety (see Chapter 35).
Prepare parents to expect increased involvement with peers and interest in activities outside the home.
Emphasize the need to encourage independence in the child while maintaining limit-setting and discipline.
Prepare maternal figure to expect more demands from the child at age 8 years.
Prepare paternal figure to expect increasing admiration from the child at age 10 years; encourage father–child activities.
Prepare parents for prepubescent changes in girls.

Ages 11 to 12 Years

Help parents prepare the child for body changes of pubescence.
Prepare parents to expect a growth spurt in girls.
Make certain the child's sex education is adequate with accurate information.
Prepare parents to expect energetic and stormy behaviour at age 11 years, possibly becoming more even-tempered at age 12 years.
Encourage parents to support the child's desire to "grow up" but to allow regressive behaviour when needed.
Prepare parents to expect an increase in the child's masturbation.
Instruct parents that the amount of rest the child needs may increase.
Help parents educate the child regarding experimentation with potentially harmful activities.

Health Guidance

Provide information regarding human papilloma virus (HPV) immunization. Health Canada recommends HPV immunization in girls and women between ages 9 and 26, preferably before sexual activity has commenced (see Chapter 35). Health Canada is now recommending the HPV vaccine for males between 9 and 26 years as well. The vaccine is covered by all provincial and territorial health plans for females and males (see Chapter 35) (Government of Canada, 2021).
Help parents understand the importance of regular health and dental care for the child.
Encourage parents to teach and model sound health practices, including diet, rest, activity, and exercise.
Stress the need to encourage children to engage in appropriate physical activities.
Emphasize the importance of providing a safe physical and emotional environment.

KEY POINTS

- Middle childhood, also known as the school years, is the period of life that extends from 5 to 12 years of age.
- Although growth is slower than in previous years, there is a steady gain in height and weight, with maturation of body systems; primary teeth are lost and replaced by permanent teeth.
- A major task during the middle school years is developing a sense of industry or accomplishment (Erikson).
- Piaget's period of concrete operations refers to the school-age period, when children are able to use their thought processes to experience events and actions and make judgements based on reasoning.
- The child develops a conscience and is able to understand and adhere to rules and standards set by others.
- Entertaining different points of view, becoming sensitive to cultural norms, and forming peer friendships are important features of social development during the school years.
- Cooperative play, team activities, and the acquisition of skills are prime elements of play during the school years; rules and rituals assume greater importance.
- Parental concerns during middle childhood include lying, cheating, stealing, bullying, and school achievement.
- Activities involving physical movement should be encouraged; sedentary activities, such as watching television or playing video games for long periods of time, contribute to health issues in this age group.
- Ideally, school health programs include health appraisal, emergency care, safety education, lifestyle support, recommended immunizations, communicable disease control, counselling, guidance, and health education with adjustment to individual student needs.
- Education related to appropriate uses of social media is important.
- Alterations in growth and maturation may be manifested as short or tall stature or as delayed sexual development.

The Adolescent and Family

Constance O'Connor
Originating US Chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the usual physical changes that occur throughout the adolescent years.
2. Discuss the reactions of adolescents to the physical changes that take place at puberty.
3. Demonstrate an understanding of the processes by which adolescents develop a sense of identity.
4. Discuss the significance of changing interpersonal relationships and the role of peer groups during adolescence.
5. Outline a health teaching plan for adolescents.
6. Demonstrate an understanding of common disorders of the male and female reproductive systems.
7. Demonstrate an understanding of health challenges related to adolescent sexuality.

PROMOTING OPTIMUM GROWTH AND DEVELOPMENT

Adolescence is a period of transition between childhood and adulthood. The precise boundaries of adolescence are difficult to define, but this period is customarily viewed as beginning with the gradual appearance of secondary sex characteristics at about 11 or 12 years of age and ending with cessation of body growth at 18 to 20 years. Several terms are used to refer to this stage of growth and development. **Puberty** refers to the maturational, hormonal, and growth process that occurs when the reproductive organs begin to function and the secondary sex characteristics develop. This process is sometimes divided into three stages: *prepubescence*, the period of about 2 years immediately before puberty when the child is developing preliminary physical changes that herald sexual maturity; *puberty*, the point at which sexual maturity is achieved, marked by the first menstrual flow in girls but by less obvious indications in boys; and *postpubescence*, a 1- to 2-year period following puberty during which skeletal growth is completed and reproductive functions become fairly well established. Adolescence, which literally means "to grow into maturity," is generally regarded as the psychological, social, and maturational process initiated by the pubertal changes. It involves three distinct subphases: early adolescence (ages 11 to 14), middle adolescence (ages 15 to 17), and late adolescence (ages 18 to 20). The term *teenage years* is used synonymously with *adolescence* to describe ages 13 through 19. The changes that occur during the early, middle, and late phases of adolescence are summarized in Table 40.1.

Biological Development

The physical changes of puberty are primarily the result of hormonal activity under the influence of the central nervous system, although all aspects of physiological functioning are mutually interacting. The obvious physical changes are noted in increased physical growth and in the appearance and development of secondary sex characteristics; less obvious are physiological alterations and neurogonadal maturity, accompanied by the ability to procreate. Physical distinction between the sexes is made on the basis of distinguishing characteristics. **Primary sex characteristics** are the external and internal organs that carry out the reproductive functions (e.g., ovaries, uterus, breasts, penis). **Secondary sex characteristics** are the changes that occur throughout the body as a result of hormonal changes (e.g., voice alterations, development of facial and pubertal hair, fat deposits) but that play no direct part in reproduction.

Hormonal Changes of Puberty. The events of puberty are caused by a cluster of events that trigger the production of gonadotropin-releasing hormone (GnRH) by the hypothalamus. GnRH travels to the anterior pituitary gland, where it stimulates the production and secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Increasing levels of FSH and LH stimulate a gonadal response, which for females consists of growth of ovarian follicles, production of estrogen, and initiation of ovulation, and for males consists of maturation of the testicles and testosterone and stimulation of sperm production.

TABLE 40.1 Growth and Development During Adolescence

Early Adolescence (11–14 Years)	Middle Adolescence (15–17 Years)	Late Adolescence (18–20 Years)
Growth		
Rapidly accelerating growth Reaches peak velocity Secondary sex characteristics appear	Growth decelerating in girls Stature reaches 95% of adult height Secondary sex characteristics are well advanced	Physically mature Structure and reproductive growth are almost complete
Cognition		
Explores newfound ability for limited abstract thought Groping for new values and energies Comparison of "normality" with peers of same sex	Develops capacity for abstract thinking Enjoys intellectual powers, often in idealistic terms Concern with philosophical, political, and social issues	Established abstract thought Can perceive and act on long-range options Able to view issues comprehensively Intellectual and functional identity established
Identity		
Preoccupied with rapid body changes Trying out of various roles Measurement of attractiveness by acceptance or rejection of peers Conformity to group norms	Modifies body image Very self-centred; increased narcissism Tendency toward inner experience and self-discovery Has a rich fantasy life Idealistic Able to perceive future implications of current behaviour and decisions; variable application	Body image and gender-role definition are nearly secured Mature sexual identity Phase of consolidation of identity Stability of self-esteem Comfortable with physical growth Social roles defined and articulated
Relationships With Parents		
Defining independence–dependence boundaries Strong desire to remain dependent on parents while trying to detach No major conflicts over parental control	Major conflicts over independence and control Low point in parent–child relationship Greatest push for emancipation; disengagement Final and irreversible emotional detachment from parents; mourning	Emotional and physical separation from parents completed Independence from family with less conflict Emancipation nearly secured
Relationships With Peers		
Seeks peer affiliations to counter instability generated by rapid change Upsurge of close, idealized friendships with members of the same sex Struggle for mastery takes place within peer group	Strong need for identity to affirm self-image Behavioural standards set by peer group Acceptance by peers extremely important—fear of rejection Exploration of ability to attract sexual partner	Peer group recedes in importance in favour of individual friendship Testing of romantic relationships against possibility of permanent alliance Relationships characterized by giving and sharing
Sexuality		
Self-exploration and evaluation Limited dating, usually group Limited intimacy	Multiple plural relationships Internal identification of heterosexual, same-sex, or bisexual attractions Exploration of "self appeal" Feeling of "being in love" Tentative establishment of relationships	Forms stable relationships and attachment to another Growing capacity for mutuality and reciprocity Dating as a romantic pair May publicly identify as gay, lesbian, bisexual, transgender, or queer Intimacy involves commitment rather than exploration and romanticism
Psychological Health		
Wide mood swings Intense daydreaming Anger outwardly expressed with moodiness, temper outbursts, and verbal insults and name-calling	Tendency toward inner experiences; more introspective Tendency to withdraw when upset or feelings are hurt Vacillation of emotions in time and range Feelings of inadequacy common; difficulty in asking for help	More constancy of emotion Anger more apt to be concealed

The ovaries, testes, and adrenals secrete sex hormones. These hormones are produced in varying amounts by both sexes throughout the lifespan. The adrenal cortex is responsible for the small amounts secreted before the pubescent years, but the sex hormone production that accompanies maturation of the gonads is responsible for the biological changes observed during puberty.

Estrogen, the feminizing hormone, is found in low quantities during childhood. Beginning in early puberty, FSH stimulates estrogen production by the ovaries; however, estrogen levels are not high enough to cause ovulation until mid-puberty. The increasing quantity of estrogen in early puberty causes a building of the endometrial lining of the uterus and first menstruation, or menarche. As puberty progresses, one ovarian follicle becomes dominant during each menstrual cycle and produces increasing amounts of estrogen that releases an ovum, a process called *ovulation*. After ovulation, the follicle involutes and estrogen production decreases. The pituitary gland responds to the decreased estrogen production by increasing production of FSH, which initiates a new menstrual cycle.

Androgens, the masculinizing hormones, are also secreted in small and gradually increasing amounts up to about 7 or 9 years of age, at which time there is a more rapid increase in both sexes, especially boys, until about age 15 years. These hormones have tremendous growth-promoting properties that result in rapid increases of muscle mass, skeletal growth, and bone density. Androgens are responsible for the development of pubic, axillary, facial, and body hair; acne; body odour; and an increase in height. The capacity to ejaculate occurs approximately 1 year after initial testicular enlargement and pubic hair appearance. The production of viable sperm tends to follow boys' first ejaculation.

Sexual Maturation. The visible evidence of sexual maturation is achieved in an orderly sequence, and the state of maturity can be estimated on the basis of the appearance of these external manifestations. The age at which these changes are observed and the time required to progress from one stage to another vary among children. The time from the appearance of breast buds to full maturity may be up to 6 years for adolescent girls. It may take 2 to 5 years for male genitalia to reach adult size. The stages of development of secondary sex characteristics and genital development have been defined as a guide for estimating sexual maturity and are referred to as the *Tanner stages*. The usual sequence of appearance of maturational changes is presented in Box 40.1.

Sexual maturation in girls. In most girls the initial indication of puberty is the appearance of breast buds, an event known as *thelarche*, which occurs after 8 years of age (Figure 40.1). This is followed in approximately 2 to 6 months by the growth of pubic hair on the mons pubis, known as *adrenarche* (Figure 40.2). In a minority of normally developing girls, however, pubic hair may precede breast development. The average age for thelarche varies depending on many factors.

The initial appearance of menstruation, or **menarche**, occurs about 2 years after the appearance of the first pubescent changes, approximately 9 months after attainment of peak height velocity and 3 months after attainment of peak weight velocity. Among various ethnicities girls develop secondary sex characteristics at a younger age. The explanation for this is not yet clear but appears to be influenced by being overweight as well as by environmental factors (Currie et al., 2012). The normal age range of menarche is usually 10½ to 15 years, with the average age of onset of menarche in Canadian girls being 12.72 years (Al-Sahab et al., 2010). Ovulation and regular menstrual periods usually occur 6 to 14 months after menarche. Girls may be considered to have pubertal delay if breast development has not occurred by 13 years of age (Villanueva & Argente, 2014).

BOX 40.1 Usual Sequence of Maturational Changes

Girls

Breast changes
Rapid increase in height and weight
Growth of pubic hair
Appearance of axillary hair
Menstruation (usually begins 2 years after first signs)
Abrupt deceleration of linear growth

Boys

Enlargement of testicles
Growth of pubic hair, axillary hair, hair on upper lip, hair on face and elsewhere on body (facial hair usually appears about 2 years after appearance of pubic hair)
Rapid increase in height
Changes in the larynx and consequently the voice (usually take place along with the growth of the penis)
Nocturnal emissions
Abrupt deceleration of linear growth

Sexual maturation in boys. The first pubescent changes in boys are testicular enlargement accompanied by thinning, reddening, and increased looseness of the scrotum (Figure 40.3). These events usually occur between 9½ and 14 years of age. Early puberty is also characterized by the initial appearance of pubic hair. Penile enlargement begins, and testicular enlargement and pubic hair growth continue throughout midpuberty. During this period increasing muscularity, early voice changes, and development of early facial hair also occur. Temporary breast enlargement and tenderness, called *gynecomastia*, are common during midpuberty, occurring in up to 70% boys (Ali & Donohoue, 2020). The spurts in height and weight occur concurrently toward the end of midpuberty. For most boys, breast enlargement disappears within 2 years. By late puberty there is a definite increase in the length and width of the penis, testicular enlargement continues, and first **ejaculation** occurs. Axillary hair develops, and facial hair extends to cover the anterior neck. Final voice changes occur secondary to the growth of the larynx. Concerns about pubertal delay should be considered for boys who exhibit no enlargement of the testes or no scrotal changes by 14 years of age (Villaneuva & Argente, 2014).

Physical Growth. A constant phenomenon associated with sexual maturation is a dramatic increase in growth. The final 20 to 25% of height is achieved during puberty, and most of this growth occurs during a 24- to 36-month period—the adolescent growth spurt. This accelerated growth occurs in all children but, as in other areas of development, is highly variable in age of onset, duration, and extent. The growth spurt begins earlier in girls, usually between ages 9½ and 14½ years; on average it begins between ages 10½ and 16 years in boys. During this period, the average boy gains 10 to 30 cm in height and 7 to 30 kg in weight. The average girl, in whom the growth spurt is slower and less extensive, gains 5 to 20 cm in height and 7 to 25 kg in weight. Growth in height typically ceases 2 to 2½ years after menarche in girls and at age 18 to 20 years in boys.

This increase in size is acquired in a characteristic sequence. Growth in length of the extremities and neck precedes growth in other areas, and since these parts are first to reach adult length, the hands and feet appear larger than normal during adolescence. Increases in hip and chest breadth take place in a few months, followed several months later by an increase in shoulder width. These changes are followed by

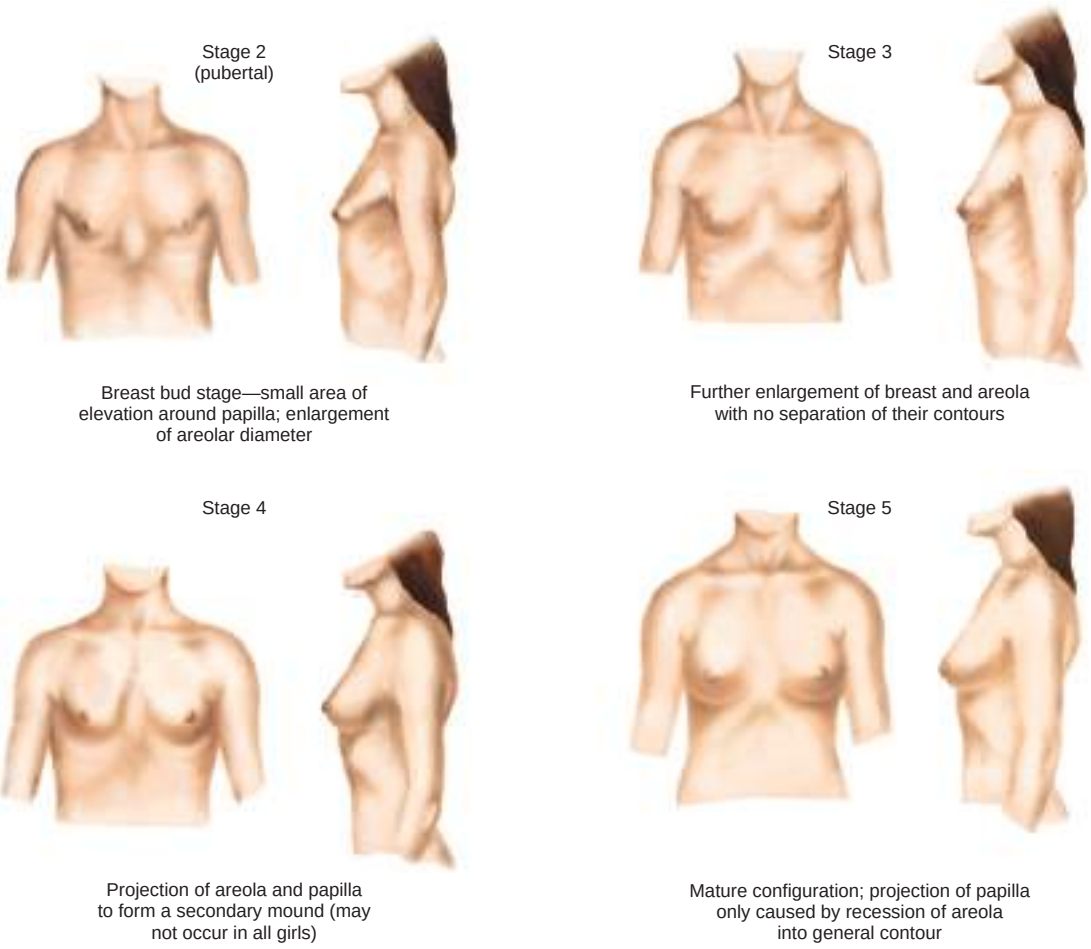

Fig. 40.1 Development of the breast in girls—average age span: 9 to 13½ years. Stage 1 (prepubertal, elevation of papilla only) is not shown. (Modified from Daniel, W. A., & Paulshock, B. Z. [1979]. A physician's guide to sexual maturity. *Patient Care, 13,* 122–124; Marshall, W. A., & Tanner, J. M. [1969]. Variations in pattern of pubertal changes in girls. *Archive of Diseases in Childhood, 44*, 291.)

A physician's guide to sexual maturity. *Patient Care, 13*, 122–124; Marshall, W. A., & Tanner, J. M. [1969]. Variations in pattern of pubertal changes in girls. *Archive of Diseases in Childhood, 44*, 291.)

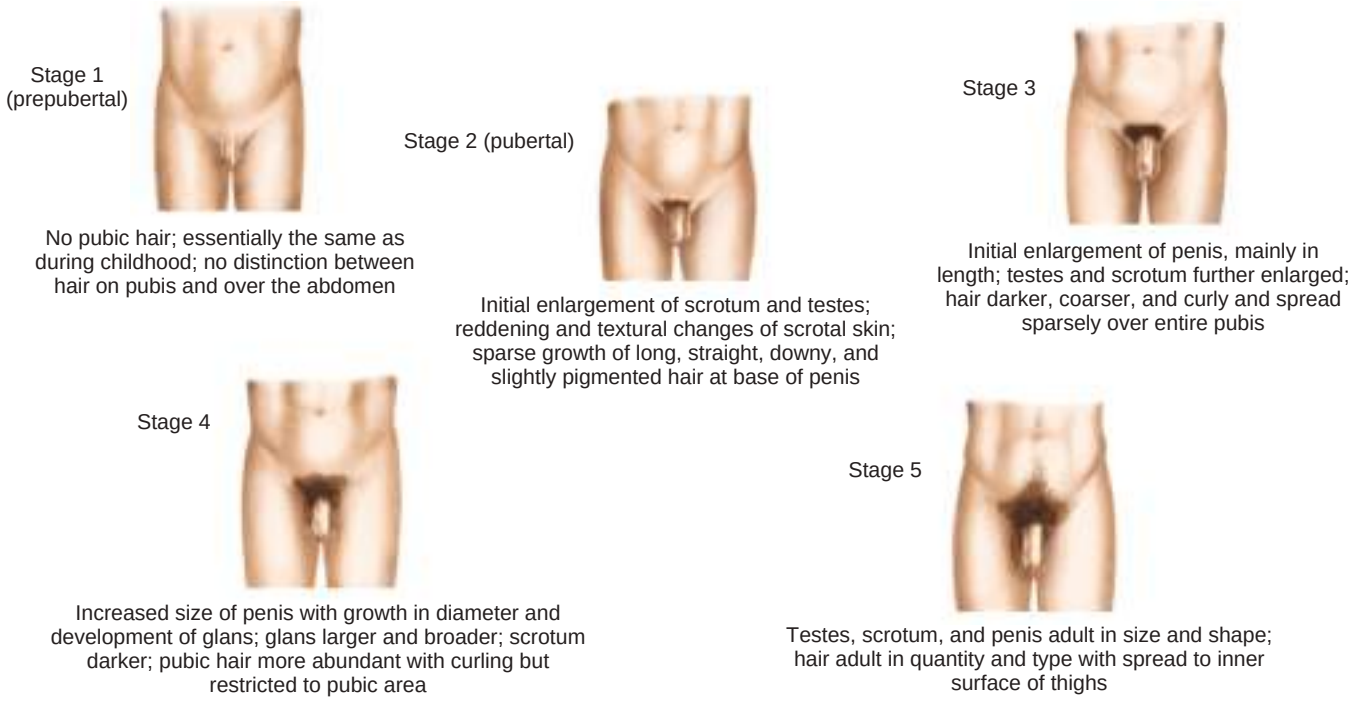

Fig. 40.3 Developmental stages of secondary sex characteristics and genital development in boys—average age span, 9½ to 14 years. (Modified from Daniel, W. A., & Paulshock, B. Z. [1979]. A physician's guide to sexual maturity. *Patient Care, 13*, 122–124; Marshall, W. A., & Tanner, J. M. [1969]. Variations in pattern of pubertal changes in girls. *Archive of Diseases in Childhood, 44*, 291.)

increases in the length of the trunk and depth of the chest. This sequence of changes is responsible for the characteristic long-legged, gawky appearance of the early adolescent child.

Sex differences in general growth patterns. Sex differences in general growth and distribution patterns are apparent in skeletal growth, muscle mass, adipose tissue, and skin. Skeletal growth differences between boys and girls are apparently a function of hormonal effects at puberty and are evident primarily in limb length. The earlier cessation of growth in girls is caused by epiphyseal unity under the potent effect of estrogen secretion, and the hormonal effect on female bone growth is much stronger than the similar effect of testosterone in boys. In boys the prolonged growth period before puberty and the less rapid epiphyseal closure are reflected in their greater overall height and longer arms and legs. Other skeletal differences are increased shoulder width in boys and broader hip development in girls.

Hypertrophy of the laryngeal mucosa and enlargement of the larynx and vocal cords occur in both boys and girls to produce voice changes. Girls' voices become slightly deeper and considerably fuller. The effect in boys is particularly striking, occurring as boys mature, with the voice often shifting uncontrollably from deep to high tones in the middle of a sentence.

Growth of lean body mass, principally muscle, which tends to occur after the bone growth spurt, takes place steadily during adolescence. Lean body mass is both quantitatively and qualitatively greater in boys than in girls at comparable stages of pubertal development. Nonlean body mass, primarily fat, is also increased but follows a less orderly pattern. There may be a transient increase in subcutaneous fat just before the skeletal growth spurt, especially in boys. This is followed 1 to 2 years later by a modest to marked decrease, which is again more notable in boys. Later, variable amounts of fat are deposited to fill out and contour the mature physique in patterns characteristic of the adolescent's sex, particularly in the regions over the thighs, hips, and buttocks and around the breast tissue.

Obesity can change the timing of puberty in females, thus with pediatric obesity steadily on the increase in Canada more adolescents may be affected. An association, not a causal relationship, has been noted between obesity and onset of early puberty; other factors such as hormones and insulin resistance may also account for early-onset puberty. No correlations between body fat and earlier puberty in boys have been reported (Biro et al., 2012). Pediatric obesity may also increase the risk for adult adiposity and obesity.

Hormonal influences during puberty cause acceleration in growth and maturation of the skin and its structural appendages. Sebaceous **glands** become extremely active at this time, especially those on the genitalia and in the "flush areas" of the body (i.e., face, neck, shoulders, upper back, and chest). This increased activity and the structural nature of the glands are important in the pathogenesis of a common condition of puberty: acne (see Chapter 52). The eccrine sweat glands, present almost everywhere on the human skin, become fully functional and respond to emotional and thermal stimulation. Heavy sweating appears to be more pronounced in boys than in girls. The apocrine sweat glands, nonfunctional in childhood, reach secretory capacity during puberty. Unlike the eccrine sweat glands, the apocrine glands are limited in distribution and grow in conjunction with hair follicles in the axillae, around the areola of the breast, around the umbilicus, on the external auditory canal, and in the genital and anal regions. Apocrine glands secrete a thick substance as a result of emotional stimulation that, when acted on by surface bacteria, becomes highly odorous.

Body hair assumes very characteristic distribution patterns and changes texture during puberty. Under the influence of gonadal and adrenal androgens, hair coarsens, darkens, and lengthens at sites related to secondary sex characteristics. Pubic and axillary hair appears in both sexes, although pubic hair is more extensive in boys than in girls. Beard, moustache, and body hair on the chest, upward along the linea alba, and sometimes on other areas (e.g., back and shoulders)

appears in boys and is androgen dependent. Extremity hair appears in varying amounts in both sexes but is also more prolific in boys.

Other Physiological Changes. A number of physiological functions are altered in response to some of the pubertal changes. The size and strength of the heart, blood volume, and systolic blood pressure increase, whereas the pulse rate and basal heat production decrease (see Appendix C). Blood volume, which increases steadily during childhood, reaches a higher value in boys than in girls, a fact that may be related to the increased muscle mass in pubertal boys. Adult values are reached for all formed elements of the blood. Respiratory rate and basal metabolic rate, which decrease steadily throughout childhood, reach the adult rate in adolescence. Respiratory volume and vital capacity are increased and to a far greater extent in males than in females. During this period, physiological responses to exercise change drastically: performance improves, especially in boys, and the body is able to make the physiological adjustments needed for normal functioning after exercise is completed. These capabilities are a result of the increased size and strength of muscles and the increased level of cardiac, respiratory, and metabolic functioning.

Responses to Puberty. The response to the physical changes of pubertal growth and development is manifested differently depending on the stage of development. During early adolescence, young adolescents may be preoccupied with the rapid changes in their body and are interested in the anatomy, physiology, and function of their sexual organs. Boys must also confront the sexual feelings and tensions that accompany puberty, and the appearance of nocturnal emissions may be puzzling, troublesome, or embarrassing. Unless the boy has been prepared in advance, he may find it difficult to discuss his feelings with his parents and may turn to his friends for information and guidance. Many girls also find the rapid changes in their body to be sources of concern. Some girls perceive the increase in weight and associated fat deposition as evidence of obesity and may indulge in fad diets. Although many girls look forward to menstruation and take this event in stride, others may find the first menstrual period a distressing and frightening event. All teenagers, regardless of gender, are concerned with the question, "Am I normal?" To answer this question, they compare their body with those of their peers and with images in the media. This can lead to a great deal of uncertainty about their appearance and attractiveness.

If an adolescent does not enter puberty at the same time as their peers, considerable inner conflict may occur. Nurses who work with adolescents must provide teaching and health care interventions that are appropriate for the adolescent's chronological and cognitive development rather than the stage of physical maturation.

Psychosocial Development

Developing a Sense of Identity (Erikson). Traditional psychosocial theory holds that the developmental crisis of adolescence leads to the formation of a sense of identity (Erikson, 1963). Adolescents come to see themselves as distinct individuals, somehow unique and separate from every other individual.

Adolescence begins with the onset of puberty and extends to relative physical and emotional stability at or near graduation from high school. During this time, the adolescent is faced with the crisis of group identity versus alienation. In the period that follows, the individual strives to attain autonomy from the family and develop a sense of personal identity instead of role diffusion. A sense of group identity appears to be essential to developing a sense of personal identity. Young adolescents need to resolve questions concerning relationships with a peer group before they are able to resolve questions about who they are in relation to family and society.

Group identity. During the early stage of adolescence, pressure to belong to a group is intensified. Teenagers find it essential to have a group to which they can belong and that provides them with status. They dress as the group dresses and wear makeup and hairstyles according to group criteria, all of which are different from those of the parental generation. Language, music, and dancing reflect a culture that is exclusive to the adolescent. Adolescent conformity to the peer group and nonconformity to the adult group provides teenagers with a frame of reference in which they can display their own self-assertion while rejecting the identity of their parents' generation. To be different from the group, however, can mean to be unaccepted and alienated from the group.

Individual identity. The quest for personal identity is an ongoing process. As adolescents establish identity within a group they also attempt to incorporate multiple body changes into a concept of the self. In addition, as part of their search for identity, adolescents will take stock of their current and past relationships, as well as the directions they hope to take in the future.

Significant others hold expectations for the adolescent's behaviour. Often these expectations or demands are persistent enough to result in certain decisions that might be made differently or not at all if the individual could be solely responsible for identity formation. It is all too easy to slip into the roles that are expected by these external influences without incorporating personal goals or questioning these decisions. Thus individuals may become what parents or others wish them to be, based on these premature decisions. Adolescents might form a negative identity when society or their culture provides them with a self-image that is contrary to the values of the community.

The evolving of a personal identity is fraught with periods of confusion, excitement, depression, and discouragement. Determining an identity and a place in the world is a critical feature of adolescence (see Clinical Reasoning Case Study: Discussing the Future). As the pieces gradually shift and settle into place, an identity eventually emerges. Role diffusion results when the individual is unable to formulate a satisfactory identity from the multiplicity of aspirations, roles, and influences.

CLINICAL REASONING CASE STUDY

Discussing the Future

Jeremy is 17 years of age and will be graduating from high school in the spring. His mother, a single parent, tells the nurse that she is concerned because graduation is quickly approaching and Jeremy has made no plans for what he will do with his life after graduation. Whenever Jeremy mentions the topic, his mother tells him, "This is what you must do," and begins to outline the steps he must take. Jeremy just walks away. She asks, "What should I do?" What advice should a nurse give Jeremy's mother?

1. Evidence—Is there sufficient evidence to draw any conclusions about what advice the nurse should give Jeremy's mother?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Adolescents and the search for personal identity
   b. The influence of others on the adolescent's search for personal identity
   c. Ways to communicate with adolescents
3. What implications and priorities for nursing care can be drawn at this time?

Development of Self-Concept and Body Image. The sudden growth that takes place in early adolescence can create feelings of confusion. The security of a familiar body is lost and the adolescent may

feel uncomfortable within their altered body. Consequently, some adolescents may try to either hide their body or advertise it, or they may alternate between the two extremes. Teenagers tend to be acutely aware of their appearance as they begin to acquire images of themselves as adults, but they see discrepancies between their ideal and actual skills and abilities.

Adolescents are continually comparing themselves with their peers and making judgements about their own normality based on these observations. Most youth feel most comfortable when they are just like their friends and age-mates. Perceived defects or deviations from the group average can threaten their idealized image. Any blemish may be magnified out of proportion, and any delay of the visible evidence of maturity is cause for worry. Unfortunately, this is also the time when the hormonal effect of the sebaceous glands produces acne, and even the most insignificant pimple may be viewed as a disfigurement. The diagnosis of chronic disease or a permanent physical disability has special significance during adolescence and creates additional stresses for both adolescents with the condition and health care providers.

The body image that is established during adolescence is the one that individuals retain throughout life. Much of adolescents' search for identity takes a variety of forms. For some, much of this process unfolds in front of a mirror as they try to read from the reflected features just who they are and what they look like to other people. Adolescents may practise facial expressions and postures, try out hair arrangements, worry about a pimple, and in other ways attempt to assess the best means to achieve a maximum effect—to reveal the "true self."

The self-concept becomes more differentiated as adolescents acquire a more complex picture of themselves, one that takes situational factors into account. The self-concept gradually becomes more individualized and more distinct from the concepts of others. Although younger teenagers describe themselves in terms of similarities with peers, as adolescence advances, young people tend to describe themselves in terms of their special characteristics. By late adolescence, the heightened concern with body image has ended and is replaced by a general comfort with the body.

Sexual orientation and gender-role identity. One of the important goals of adolescence is to incorporate sexuality successfully into close, intimate relationships. This process involves advanced cognitive abilities that emerge over the course of adolescence. During early adolescence the peer group will begin to communicate expectations regarding relationships, and as development progresses, adolescents will encounter expectations for mature gender-role behaviour from both peers and adults. Adolescents will explore both their sexual orientation and gender identity. Many teenagers begin to make a shift toward intimate relationships during middle adolescence. The type and degree of seriousness of partner relationships vary by age and maturity level.

An integrated sexual identity often emerges during late adolescence as individuals incorporate sexual experiences, feelings, and knowledge. For most, this identity is consistent with their own physical and mental capacities and with societal limits and expectations. Adolescents have a sexual orientation even if they are not yet sexually active. They may identify their sexual orientation in one or more of the following ways: heterosexual, lesbian, gay, bisexual, pansexual, demisexual, or asexual (Canadian Paediatric Society [CPS], 2018b). Whatever their sexual orientation, many older teenagers possess the capacity to have intimate relationships that satisfy the emotional and sexual needs of both partners.

During adolescence, individuals commonly begin to identify their sexual orientation as part of their developing sexual identity. Sexual orientation encompasses several dimensions, including attraction, fantasy, actual sexual behaviour, and self-labelling or group affiliation. In individuals, the direction and intensity of each dimension are not necessarily consistent with any of the others. For example, individuals may be attracted most strongly to their same gender, fantasize about both genders, have sexual activity only with the opposite gender, and identify as gay or lesbian. Other individuals may engage in same-gender sexual behaviour and fantasize about both genders but identify as heterosexual. As with all aspects of sexual identity, the dimensions of sexual orientation are influenced by cultural meaning and expectation, by gender, by peer groups, and by other environmental contexts. For adolescents whose orientation encompasses any same-sex dimensions, the identity process during adolescence can be complicated, especially when community norms disapprove of orientations other than heterosexual.

The development of sexual orientation as part of sexual identity includes several developmental milestones during late childhood and throughout adolescence. These milestones do not necessarily occur in the same order for everyone, nor are they completed in the same amount of time. They include (1) the realization of romantic or erotic attraction to people of one or both genders; (2) erotic daydreaming about one or both genders; (3) romantic partners or dates without sexual activity; (4) sexual activity with people of the preferred gender or genders (also, for some teens, sexual activity with a nonpreferred gender, out of curiosity or through social pressure); (5) self-identification of the orientation that best fits one's current circumstances and understanding; (6) publicly self-identifying as that orientation, usually to intimate friends and family first, then to the wider social group; and (7) an intimate, committed, sexual relationship with a person of the gender appropriate to one's orientation.

Gender identification refers to how an individual sees themselves as a man, a woman, both, or neither; this is separate from sexual orientation. *Transgender* is an umbrella term to describe individuals with diverse gender identities that differ from traditional gender norms (Ontario Human Rights Commission, 2014).

Adolescents encounter many social issues related to sexual orientation and gender identity, particularly if the adolescent identifies in a way that contradicts typical social, cultural, familial and religious expectations (Canadian Bar Association, 2020). These issues include:

- Rejection or estrangement from family
- Social rejection and exclusion
- Physical, social, or emotional harassment, including cyberbullying
- Pressure to "change" their sexual orientation or gender identity
- Lack of positive role models and representation in educational materials or in the media
- Lack of respect for chosen names and gender pronouns

It is important for health care providers to be cognizant of the significant psychological, psychosocial, and medical challenges that may confront young people whose sexual orientation or gender identity are perceived as being outside what may be expected by their cultural, peer and familial groups. Nurses need to have specific strategies to approach all youth in a nonjudgmental, sensitive, and respectful manner when discussing sexuality and gender identity. For example, using the preferred pronouns of the individual, "he", "she" or "they", can convey respect and care. See Clinical Reasoning Case Study: Discussing Sexual Orientation With Adolescents.

CLINICAL REASONING CASE STUDY

Discussing Sexual Orientation With Adolescents

John, a 17-year-old adolescent, comes into the school-based clinic and tells the nurse practitioner that he thinks he is gay. What is the most appropriate response for the nurse practitioner?

1. Evidence—Is there sufficient evidence to draw any conclusions about John's sexual orientation at this time?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Sexual orientation in adolescents
   b. Societal reactions toward self-identifying as gay
   c. Health care providers and sexuality
3. What implications and priorities for nursing care can be drawn at this time?

Cognitive Development

Cognitive thinking culminates with the capacity for abstract thinking. This stage, the period of formal operations, is Piaget's (1952) fourth and last stage. Adolescents are no longer restricted to the real and actual, which was typical of the period of concrete thought. They now have the capacity to think beyond the present. Without having to centre attention on the immediate situation, they can imagine a sequence of events that might occur, such as college and occupational possibilities; how things might change in the future, such as relationships with parents; and the consequences of their actions, such as dropping out of school. At this time their thoughts can be influenced by logical principles rather than just their own perceptions and experiences. They become increasingly capable of scientific reasoning and formal logic.

Adolescents are capable of mentally manipulating more than two categories of variables at the same time. For example, they can consider the relationship between speed, distance, and time in planning a trip. They can detect logical consistency or inconsistency in a set of statements and evaluate a system or set of values in a more analytical manner. For instance, they question the parent who insists on honesty in the teenager but at the same time cheats on an income tax report or expense account.

In adolescence, young people begin to think about both their own thinking and the thinking of others. They wonder what opinion others have of them, and they are able to imagine the thoughts of others. With this capacity comes the ability to differentiate between others' thoughts and their own and to interpret the thoughts of others more accurately. They are able to understand that few concepts are absolute or independent of other influencing factors. As they become aware that other cultures and communities have different norms and standards from their own, it becomes easier for them to accept members of these other cultures, and the decision to behave in their own culture in an accepted manner becomes a more conscious commitment.

Moral Development

Although younger children tend to accept the decisions or point of view of adults, adolescents, in their efforts toward autonomy, must substitute their own set of morals and values. According to Kohlberg (1968), when old principles are challenged but new independent values have not yet emerged to take their place, young people search for a moral code that preserves their personal integrity and guides their behaviour, especially in the face of strong pressure to violate the old beliefs. Their decisions involving moral dilemmas must be based on an internalized set of moral principles that provides them with the resources to evaluate the demands of the situation and to plan actions that are consistent with their ideals.

Late adolescence is characterized by serious questioning of existing moral values and their relevance to society and the individual. They understand duty and obligation based on the reciprocal rights of others, as well as the concept of justice that is founded on making amends for misdeeds and repairing or replacing what has been spoiled by wrongdoing. However, they seriously question established moral codes, often as a result of observing that adults verbally ascribe to a code but do not adhere to it.

Spiritual Development

Adolescents are capable of understanding abstract concepts and of interpreting analogies and symbols. They are able to empathize, philosophize, and think logically. Most teens search for ideals and speculate about illogical statements and conflicting ideologies. Their tendency toward introspection and emotional intensity often makes it difficult for others to know what they are thinking. They tend to keep their thoughts private, fearing that no one will understand these feelings that they perceive to be unique and special. However, they may reveal deep spiritual concerns. They need support and encouragement in their struggle for understanding as well as the freedom to question without censure.

Generally, the stated importance of participation in organized religions declines somewhat during the adolescent years. More high school students than post–secondary school young people attend religious services regularly, and, not surprisingly, the younger the adolescents, the more likely they are to view religion as being important to them. Among older adolescents, the importance of organized religion declines more among college students than among those not in college. Late adolescence appears to be a time when individuals re-examine and re-evaluate many of the beliefs and values of their childhood. Consistent with developmental changes in values and autonomy, the religious beliefs of young people are likely to become more personalized and less bound to the traditional religious practices they may have been exposed to when they were younger. As adolescents mature and form an identity, they may either reject their family's traditional beliefs or they may decide to conform to those beliefs. Religious beliefs in adolescence are also strongly influenced by interpersonal relationships with peers as well as adults in their environment.

Greater levels of religiosity and spirituality are associated with fewer high-risk behaviours and more health-promoting behaviours (Michaelson et al., 2015). Nurses can play an important role in providing an opportunity to discuss issues dealing with spirituality with this age group.

Social Development

The biological, cognitive, and social changes of adolescence are shaped by the social environment in which the changes take place. The social environment provides opportunities, barriers, role models, and support for individuals' development and health. Systems within the social environment, including family, peers, schools, community (including the Internet-based community), and the larger society, all contribute uniquely to an adolescent's development and health.

Relationships With Parents. During adolescence the parent–child relationship changes from one of protection and dependency to one of mutual affection and equality. The process of achieving independence often involves turmoil and ambiguity as both parent and adolescent learn to play new roles and work toward this end while, at the same time, resolving the often painful series of rifts essential to establishing the ultimate relationship.

As teenagers assert their rights for grown-up privileges, they frequently create tensions within the home. They resist parental control, and conflicts can arise from almost any situation or any subject. Favourite topics of dispute include Internet and cell phone use, manners, dress, chores, homework, friendships, dating, money, automobiles, alcohol and substance use, and time schedules. Adolescents' earliest attempts

to achieve emancipation from parental controls are manifested in a period of rejection of the parents. They absent themselves from home and family activities and spend increasing time with the peer group. They confide less in their parents, but parents continue to play an important role in their personal and health-related decision making.

With advancing adolescence, teenagers become more competent, and with this competence comes a need for more autonomy. Although they may be psychologically prepared for independence, they are often thwarted in their efforts by lack of money or other barriers. Conflict may arise in relation to the teenager's independent activities as well as the needs of privacy and trust. Parental supervision remains important throughout adolescence and may have a direct influence on adolescent sexual and **substance use** behaviour. Parents should be guided toward a style of parenting in which authority is used to guide the adolescent while allowing developmentally appropriate levels of freedom and providing clear, consistent messages about expectations. Consistency in guidance and establishing ground rules is important for adolescents, even though they may fiercely reject the parents' wishes. However, to gain the trust of adolescents, parents must respect their adolescent's privacy and show an honest and sincere interest in what the adolescent believes and feels.

Communicating with teens. Conflicts between parents and their adolescents are often a result of a natural characteristic of parenthood: the desire to protect one's children from harm or from simply doing something "stupid" or embarrassing or something they may later regret. Teenagers sometimes bounce their thoughts and ideas off adults. At times they really want some feedback; at other times they simply want to elicit a reaction. Mindful parenting, an approach where parents consciously manage their own emotions and behaviours when communicating with their adolescent child, has been found to improve both parent–child communication and a sense of well-being in the adolescent (Moreira et al., 2018).

Relationships With Peers. For the majority of teenagers, peers assume a more significant role in adolescence than they did during childhood. The peer group serves as a strong support to teenagers, individually and collectively, providing them with a sense of belonging and a feeling of strength and power. The peer group forms the transitional world between dependence and independence.

Adolescents are usually social, gregarious, and group minded. Thus the peer group has an intense influence on adolescents' self-evaluation and behaviour. To gain acceptance by a group, younger teenagers tend to conform completely in such things as mode of dress, hairstyle, taste in music, and vocabulary. Peers can also be a positive force in health promotion by encouraging healthy behaviours, serving as role models, and promoting positive health norms. Adolescents use the peer group as a standard measure of what is normal.

School. The school is psychologically important to adolescents as a focus of social life. Teenagers usually distribute themselves into a relatively predictable social hierarchy. They know to which groups they and others belong. A sense of school connectedness and optimal social connectedness is associated with positive outcomes for school completion, positive mood, and decreased high-risk behavior in adolescents (Chapman et al., 2014). School connectedness is correlated with caring teachers and the absence of prejudice or discrimination from peers.

Within the larger peer groups are smaller, distinct, and rather exclusive crowds or cliques of selected close friends who are emotionally attached to each other (Figure 40.4). The selection tends to follow common tastes, interests, and background. Although cliques may become formalized, most of them remain informal and small. However, each has an identifying feature that proclaims its difference from others and its solidarity within itself, in much the same manner as the adolescent generation as a whole sets itself apart from the adult generation. Cliques are usually made up of one gender. Within the intimacy of the group, adolescents gain support in learning about themselves, consideration for the feelings of others, and increased ego development and self-reliance. To belong is of utmost importance; thus adolescents behave in ways that will ensure their establishment in a group. Adolescents are highly susceptible to social approval, acceptance, and demands. Being ignored or criticized by peers can create feelings of inferiority, inadequacy, and incompetence.

Fig. 40.4 Teenagers often like to gather in small groups. (iStock.com/Jacob Lund)

Close friendships. Personal friendships between individuals usually develop between same-sex and opposite-sex adolescents. These relationships tend to be closer and more stable than those of middle childhood and are important in the quest for identity. A best friend is the best audience on whom to try out possible roles and identities that an adolescent wants to test. Best friends may try a social role together, each supporting the other. Each cares about what the other thinks and feels. Because a sense of intimacy grows within a permanent relationship, the stability of this friendship is an important link in the progress toward intimate relationships in young adulthood.

Interests and Activities. Adolescents spend a large amount of time engaging in leisure-time activities—sports, video games, parties, and nonstructured time spent with friends. As teenagers progress through the developmental stages of adolescence, these leisure-time activities move from being family centred to being peer centred. In addition to providing teenagers with fun and enjoyment, leisure-time activities assist in the development of social, physical, and cognitive skills. Leisure-time activities also allow teenagers the opportunity to learn to set priorities and structure their time.

Many adolescents must learn to juggle their time between school, extracurricular activities, and the responsibilities of a job. Adolescent work experiences can provide the benefits of time management, teamwork skills, and increased income. It is generally recommended that adolescents limit their work to no more than 20 hours per week during the school year.

The role of social media and advanced technology is nowhere more prominent than in the lives of today's adolescents. Most adolescents in Canada are connected to others through electronic means: cell phones, gaming consoles, personal tablets, and computers (Figure 40.5). The large availability of social media through Snapchat, Instagram, Facebook, and Twitter have created virtual communities and ways for young people to interact with others, occasionally anonymously; Web cameras allow those interactions to include real-time video communication. Cellular telephones offer more mobile opportunities to talk on the phone, send text messages or instant messaging, send photos, or use video phone capabilities.

Fig. 40.5 Cell phones and social media create ways for adolescents to communicate with peers. (iStock.com/Leo Patrizi)

Social networking websites have created a more public arena for trying out identities and developing interpersonal skills with a wider network of people, occasionally with anonymity. This can create opportunities for young people who have limited access to friends (because of rural location, shyness, or rare chronic conditions) to interact with people like themselves. However, most adolescents appear to be using the online social environment to interact with the same peers that they spend their day with at school.

Text messaging and instant messaging via cell phones have become a common activity and can be disruptive at school. In addition, these activities can be used for cyberbullying, in which teens engage in insults, harassment, and publicly humiliating statements online or on cell phones. There is also increased danger of adolescents coming in contact and sharing personal information with sexual predators who pose as adolescents in an attempt to make contact with underage victims or engage them in sexting (sending sexually explicit or suggestive pictures or messages online). Adolescent sexting, rather than being an innocent anonymous activity, has been associated with high-risk sexual behaviour, such as lack of contraception use and multiple sexual partners, and mental health concerns like anxiety and depression and alcohol, drug, and tobacco use (Mori et al., 2019; Van Ouytsel, 2015). Recommendations for parents include having a discussion with their children about what is safe to post online, following their teen's social accounts, showing an interest in the online life of their adolescent child, and, in some cases, using parental controls to block or monitor the website use of the adolescent (CPS, 2018a).

PROMOTING OPTIMUM HEALTH DURING ADOLESCENCE

For adolescents, health promotion involves helping them acquire the power (including knowledge, attitudes, and skills), authority (permission to use their power), and opportunities to make choices that increase the likelihood of positive expressions of health for themselves. Adolescence provides an opportunity for teenagers to incorporate healthy lifestyle behaviours that will benefit them not only during the teenage years but also throughout the lifespan.

When focusing on health issues with adolescents it is important to address the major sources of mortality and morbidity for this age group. In 2018, the leading cause of mortality for children aged 1 to 14 in Canada was unintentional injuries (Statistics Canada, 2021). The sources of morbidity among adolescents include injury (primarily motor vehicle related), cancer, depression, eating disorders, substance use, sexually transmitted infections (STIs), and pregnancy. Obesity may begin in childhood or adolescence, with secondary health consequences becoming evident in adolescence.

Effective health promotion for adolescents requires a developmentally appropriate, multifaceted approach and should incorporate adolescents' perspectives on what health means. One strategy for health promotion used by nurses and other professionals in health care settings is the one-on-one health screening. Through a health screening interview, the health care provider can identify both assets and threats to an adolescent's health and well-being and foster building a trusting relationship with the adolescent. As adolescents develop, they are able to assume additional responsibility for their own health, including maintaining health practices, taking prescribed medications, keeping appointments, and performing procedures when necessary. Health care providers who work with adolescents should consider the adolescent's increasing independence and responsibility while at the same time maintaining privacy and ensuring confidentiality (see Guidelines box: Interviewing Adolescents, and Clinical Reasoning Case Study: Respecting Privacy). Parents should also respect their teenager's independence and move toward the role of consultant about health issues while maintaining some level of parental involvement in their child's care.

GUIDELINES

Interviewing Adolescents

- Ensure confidentiality and privacy; interview the adolescent without their parents.
- Ask which pronouns the adolescent would prefer be used during your discussion.
- Show concern for the adolescent's perspective with statements such as "First, I'd like to talk about your main health concerns" and "I'd like to know what you think is happening."
- Offer a nonthreatening explanation for the questions you ask: "I'm going to ask a number of questions to help me better understand your health."
- Maintain objectivity; avoid assumptions, judgements, and lectures.
- Ask open-ended questions when possible; move to more directive questions if necessary.
- Begin with less sensitive issues and proceed to more sensitive ones.
- Use language that both the adolescent and you understand. Clarify terms, such as "having sex" or "hooking up."
- Restate: Reflect back to the adolescent what they said, along with feelings that may be associated with their descriptions.
- Ask the adolescent if the practitioner may share general (or specific) information gathered in the health examinations and interview with their parents. Reiterate that the teen's confidentiality will be maintained if they refuse to give permission (unless life-threatening information is shared).

CLINICAL REASONING CASE STUDY

Respecting Privacy

Jamie, a 17-year-old girl, arrives at the adolescent clinic with her mother, Mrs. S, for a routine history and physical examination with the nurse practitioner. As the nurse practitioner walks with Jamie to an examination room, Mrs. S whispers to the nurse practitioner, "I need to speak with you in private." What principles should guide the nurse practitioner's response to Mrs. S's request?

1. Evidence—Is there sufficient evidence to formulate a response to Jamie's mother?
2. Assumptions—Describe an underlying assumption about each of the following topics:
   a. The role of the adolescent in health care
   b. The role of parents in the health of their adolescent
   c. Adolescents and confidentiality
3. What implications for nursing care should be established at this time?

Bright Futures (2019) emphasizes that the following issues be addressed with adolescents over the course of multiple visits:

- Emotional well-being (coping, mood regulation, mental health, sexuality)
- Physical growth and development (physical and dental health, body image, healthy nutrition, physical activity, hearing screening)
- Social and academic competence (relationships with peers and family, school performance, interpersonal relationships)
- Risk reduction (tobacco, alcohol, other drugs, pregnancy, STIs)
- Violence and injury prevention (safety belt and helmet use, substance use and riding in a vehicle, use of guns, interpersonal violence, bullying) (see Chapter 35)

Other topics that should be addressed that are related to the adolescent's individual health care needs include:

- Nutrition (see Chapter 35)
- Physical activity (see Chapter 35)
- Safety (see Chapter 35)
- Substance use (see Chapter 55)
- Suicide and depression (see Chapter 55)

The following discussion of adolescent health will focus on some of the topics not covered in other chapters.

Emotional Well-Being

Adolescents vacillate in their emotional states between considerable maturity and childlike behaviour. One minute they are exuberant and enthusiastic; the next minute they are depressed and withdrawn. Unpredictable, but essentially normal, **mood** swings are common during this time. As the tension is relieved, individuals can bring the emotion under control and individuals may retreat to review what has happened, to attempt to master their anger, and to increase their ability to control their emotions and gain from the new experience. Because of these mood swings, adolescents are frequently labelled unstable, inconsistent, and unpredictable. Little things can cause an emotional upheaval and, depending on the teenager's interpretation, can mean a great deal.

Teenagers are generally better able to control their emotions in later adolescence. They can approach problems more calmly and rationally, and although they are still subject to periods of sadness, they have fewer mood swings and begin to demonstrate more mature emotions. Whereas younger adolescents react immediately and emotionally, older adolescents can control their emotions until socially acceptable times and places for expression present themselves. They are still subject to heightened emotion, and when it is expressed, their behaviour can reflect feelings of insecurity, tension, and indecision.

As sources of credible information, support, and encouragement, nurses can help adolescents cope with the changes and challenges they face. To promote both emotional health and psychosocial adjustment, nurses and other health care providers can encourage adolescents to develop skills to cope with stress and change, as well as become involved in personally meaningful activities.

Eating Habits and Behaviour

Eating and attitudes toward food are primarily family centred during early and middle childhood, and food habits are largely related to cultural and individual family preferences and patterns. With adolescence and the move toward independence, family influences on the individual may diminish. Adolescents' interests, attitudes, and routines are altered as an increasing number of meals are eaten away from home. These changes are largely a result of the high value that teenagers place on peer acceptability and sociability. Their peers may easily influence the adolescent's eating habits.

Pressure for time and commitments to activities can adversely affect the teenager's eating habits. Snacks, usually selected on the basis of accessibility rather than nutritional merit, can become a greater part of the habitual eating pattern during adolescence (Figure 40.6). Excess intake of calories, sugar, fat, cholesterol, and sodium is common among adolescents, regardless of income or ethnicity group and in both genders. Overeating or undereating during adolescence presents special issues. When teenage girls experience the normal increase in weight and fat deposition of a growth spurt, they often resort to dieting. The desire for a slim figure and a fear of becoming "fat" can prompt teenage girls to embark on nutritionally inadequate weight-reducing regimens that drain their energy and deprive their growing bodies of essential nutrients. They may resort to diets on their own or with peers in an effort to conform to a body ideal. Many adopt current fad diets and are victims of food misinformation. Boys may be less inclined to undereat; they are more concerned about gaining size and strength. However, they tend to eat foods high in calories but low in other essential nutrients.

Fig. 40.6 Snacking on empty calories is common among adolescents, especially during inactivity. (iStock.com/Juan Monino)

Obesity has increased significantly among children and adolescents in Canada. The obesity currently seen is not a result of metabolic disturbances but of poor dietary habits and sedentary lifestyles. A contributing factor to the increase in obesity is the fact that, over the past two decades, the overall portion size for foods has increased, the largest portions for most foods being at fast-food restaurants. In addition, the amount of physical activity many adolescents are getting has decreased (see Chapter 35, Physical Activity).

Health conditions traditionally thought of as adult comorbidities of obesity, including type 2 diabetes mellitus, obstructive sleep apnea, and nonalcoholic steatohepatitis, are occurring in adolescents. Thus routine nutrition screening for all adolescents should include questions about meal patterns, dieting behaviours, consumption of high-fat and high-salt foods, and recent changes in weight. Healthy dietary habits should be discussed with all adolescents, including the benefits of a healthy diet; ways to consume foods rich in calcium, iron, and other vitamins and minerals; and safe weight management. Lifestyle changes necessary for adolescents to lose weight require the involvement of family members who can provide support and encouragement.

Nursing Care. Adolescents should receive an annual assessment of weight, height, and body mass index (BMI) for age, plotted on a standard growth chart. Healthy dietary habits should be discussed with all adolescents. The frequency of eating at fast-food restaurants, consumption of sweetened beverages, and consumption of excessive portion sizes should be identified. A growing concern regarding child and

adolescent health is the availability and consumption of high-fat, high-carbohydrate snack foods and drinks within the school environment, which may further contribute to obesity. Such foods may be chosen over the school meals that are offered. In addition to food intake, the nurse should assess the adolescent's level of physical activity and sedentary behaviours. Readiness to change; environmental supports and barriers; and family history of diabetes, heart disease, and early stroke must be considered when planning nutritional education and guidance.

In general, adolescents are body conscious and concerned about their appearance. Concrete messages about the relationship between an attractive appearance and the benefits of a healthy lifestyle are most effective. However, helping adolescents arrive at a decision for change is more difficult than providing information. They respond best when the counsellor provides straightforward information, uses instructional methods that actively involve them, talks with them and not at them, and listens to what they have to say.

Hypertension and Dyslipidemia

As adolescents experience sexual maturation, along with increases in height and weight, blood pressure increases from the onset of adolescence and continues to rise until the end of pubertal growth. This trend is especially apparent among males. Approximately 1% of adolescents have sustained **hypertension**, defined as a blood pressure greater than the ninety-fifth percentile of standards. The detection of hypertension during adolescence is important because hypertension is one of the major preventable risk factors for adult cardiovascular disease. With increasing levels of obesity, there have been reports of increasing incidence of hypertension among adolescents (Gurnani et al., 2015). All children older than 3 years of age need to have their blood pressure checked and be followed during episodic practitioner office visits, using the Canadian Heart and Stroke Foundation guidelines (see Chapter 47 for more information; see Appendix C for normal values). Along with hypertension, smoking, and obesity, elevated serum cholesterol and triglyceride levels are major risk factors for the development of adult cardiovascular disease (see Chapter 47 for discussion of guidelines for cholesterol screening).

Personal Care

Body-conscious teenagers are highly amenable to discussion and counselling about personal care and hygiene. Body changes associated with puberty bring special needs for cleanliness. The hyperactive sebaceous glands and newly functioning apocrine glands make frequent bathing or showering a necessity, and underarm deodorants and antiperspirants assume an important place in personal care. Adolescents discover that hair requires more frequent shampooing, and girls often have questions about hair removal, use of cosmetics, and menstrual hygiene. Peer group discussions on personal care may centre on the advantages of particular products or methods. Adolescents are continually bombarded with messages from the media regarding the best way to enhance their popularity and attractiveness. Nurses are in a position to help them evaluate the relative merits of commercial products.

Vision

Regular vision testing is an important part of health care and supervision during adolescence. During this time, visual refractive difficulties reach a high level that is not exceeded until the fifth decade of life. The increased demands of schoolwork make adequate vision essential for academic success. Consequently, teenagers are more likely to be referred for visual evaluation. The need for corrective lenses can create psychological issues for teenagers if they believe that glasses spoil their appearance or do not fit their body image. Contact lenses may be a preferred solution; a wide variety of lenses are now available at fairly reasonable prices.

Hearing

Considerable concern has focused on current teenage practices that cause hearing damage. Cochlear damage from relatively continuous exposure to loud sound levels of music has been documented. The popularity of handheld devices with ear bud earphones are of particular concern. When these units are used for extended periods, permanent hearing impairment can occur. Although appeals for more judicious use are not always successful, teenagers should be informed of the risk. Efforts directed toward legislating legal limits of noise exposure that can be achieved through earphones may be another possible solution. (See Chapter 42 for a discussion of noise-related hearing impairment.)

Posture

Many adolescents demonstrate altered posture. Rapid skeletal growth is often associated with slower muscular growth, and as a result, some teenagers may appear awkward or slump and fail to stand or sit upright. However, some postural defects of adolescence require early medical intervention. Scoliosis is a defect of the spine that occurs frequently in adolescence and is more common in girls than in boys (see Scoliosis, Chapter 53). Most cases are idiopathic, and the defect manifests as a painless curvature of the spine. Fortunately, most of these spinal curvatures will not require treatment. However, because there is no way to predict which curvatures will progress, all curvatures of the spine should be referred for further evaluation.

Body Art

The presence of body art in the form of tattoos, piercing, and branding is common among adolescents and young adults. Body art is generally associated with adolescents' alignment with particular groups and reflects their shifting sense of identity. Adolescents often seek body art as an expression of their personal identity and style. Tattoos may mark significant life events such as new relationships, births, and deaths. Piercing of the ear, nose, nipple, eyebrow, navel, labia, penis, or tongue may sometimes create a health issue. Nurses need to caution adolescents against having piercings performed by friends, parents, or themselves. Although in most cases piercings have few, if any, serious adverse effects, there is always a danger of complications such as infection, abscess formation, cyst or keloid formation, bleeding, dermatitis, or metal allergy. Using the same unsterilized needle to pierce body parts of multiple persons presents the same risk for human immunodeficiency virus (HIV), hepatitis C, and hepatitis B virus transmission as occurs with other needle-sharing activities.

A qualified, licensed operator using proper sterile technique should perform the procedure. This is especially important if the adolescent has a history of diabetes, allergies, or skin disorders. Adolescents should be informed about the approximate time for healing after body piercing and the care of the pierced area during and after healing. Some body sites require extra precautions. For example, cartilage (ear, nose) has a poor blood supply and heals slowly and scars easily; nipple piercing puts the adolescent at risk for breast abscess. Penile piercing often penetrates the urethra. Finally, migration of the piercing is common with navel and other flat skin surface piercing. Piercing guns should not be used for piercing anything other than the earlobe because guns place the piercing too deeply.

Professionals as well as amateur artists administer tattoos. The risk to the adolescent receiving a tattoo is low. The greatest risk is for the tattoo artist who comes in contact with the patient's blood. Adolescents who are amateur tattoo artists benefit from discussions about **routine**

practices and the hepatitis B vaccination. Many provinces and territories either have no regulations or do not enforce existing regulations for piercing and tattooing facilities. The Government of Canada (2018) regulates the dyes used for tattoos or permanent makeup, which are considered to be cosmetic products and must meet the requirements of the *Food and Drugs Act* and its cosmetics regulations. The definition of a cosmetic is "any substance or mixture of substances manufactured, sold, or represented for use in cleansing, improving or altering the complexion, skin, hair or teeth, and includes deodorants and perfumes." The local health department is a source of information about local regulatory requirements.

The Government of Canada (2015) has issued a health warning to alert consumers to the potential risks of using tattoo removal products, which include gels, creams, or solutions, applied topically or injected through the skin using a tattoo needle. Incident reports concerning adverse reactions related to the use of tattoo removal products have included skin irritation and scarring. Health Canada does not recommend the use of any tattoo-removing product.

Tanning

The quest for an attractive appearance leads many teenagers to excessive sunbathing and artificial means for tanning. However, this practice has serious long-term risks, and adolescents should be educated regarding the detrimental effects of sunlight on the skin (see Sunburn, Chapter 52). Long-term effects include premature aging of the skin, increased risk of skin cancer, and, in susceptible individuals, phototoxic reactions. Cutaneous melanoma, the most common fatal form of skin cancer, is associated with ultraviolet light exposure and affects an increasing number of Canadians (Canadian Dermatology Association, 2021).

The popularity of artificial tanning has prompted concern from health care providers regarding the use of sunlamps and tanning machines. The long-term effects of tanning machines are similar to those of the sun; dermatologists do not recommend tanning by these means. The Government of Canada (2020) suggests that people under the age of 18 years not use tanning equipment; however, a minor may have restricted access to tanning equipment if allowed by provincial or territorial regulations. Those who insist on using tanning equipment should be warned that goggles must be worn in tanning booths to prevent serious corneal burning (Taddeo et al., 2012/2018). The Canadian federal government has mandated since 2014 that warning labels of radiation exposure be placed on all tanning beds in Canada.

Adolescents require education on the use of sunscreens, including hypoallergenic products, with a sun protective factor (SPF) of at least 30 and a nonalcohol base without lanolin, parabens, or fragrance. Broad-spectrum sunscreens that protect against both ultraviolet A and B are most effective. Self-tanning creams safely simulate the appearance of a tan; however, teens using these products should be cautioned that sun protection is still required. The Canadian Dermatology Association (CDA) has provided a list of sunscreens that are CDA approved and have the CDA logo on their label (see Additional Resources at the end of this chapter). Targeting health education messages to adolescents and incorporating education relating to sun protection behaviours into school health curricula and health care visits can help increase knowledge and awareness of the health risks related to unprotected sun exposure.

Mental Health

During this time of transition from childhood to becoming an adult, adolescents experience many physiological and emotional changes. This age group often will have a sense of pressure to achieve success at home, school, and in social groups yet lack the experience required to help them realize that these challenges can be overcome as they gain that life experience (Canadian Mental Health Association, 2016). With these changes and pressures, some adolescents may be more vulnerable to developing an **emotional disorder**.

It is important for nurses to not only assess the mental health of adolescent patients but also support those who struggle with mental disorders (see Chapter 55). Given the varied emotions of adolescents, identifying mental health concerns can be a challenge.

A significant number of young people and their families are affected by mental, emotional, or behavioural disorders, which can be caused by biology, environment, or a combination of the two. In Canada, it is estimated that as many as one in five children and adolescents have a mental health disorder that requires interventional treatment. These disorders include anxiety disorders, severe depression, bipolar disorder, attention-deficit/hyperactivity disorder (ADHD), learning disorder, conduct disorder, eating disorders, autistic spectrum disorders, and schizophrenia. It is thus important for nurses to incorporate mental health assessment into their practice. See Table 33.2 for mental health assessment tools that can help nurses comprehensively screen for these mental health disorders and Chapter 55 for the care of children with common mental health challenges.

Stress Reduction. The multiple changes occurring in adolescence can result in much stress (Box 40.2). Adolescents are faced with pressures from peers that often involve flouting adult authority and taking serious health risks, including pressures for sexual experimentation and use of drugs, alcohol, and tobacco, as well as potentially dangerous physical activities.

Early-maturing girls and late-maturing children are especially sensitive to the stresses of being different from their peers. Many feel intense anxiety over their identity. Both early- and late-maturing children can feel out of place among their classmates, but slow-maturing children appear to suffer the most pronounced inner turmoil and may be hesitant to voice their concerns. Slow-maturing adolescents need support and reassurance that they are not abnormal and need only be patient until the time comes when they, too, will mature physically.

School and Learning Issues

In 2016, approximately 340 000 young Canadians between the ages of 25 to 34 years had less than a high school diploma, representing a drop-out rate of 8.5% in men and 5.4% in women. Indigenous adults in the same age groups have significantly higher rates of incomplete secondary level education, with 20.1% of men and 28.7% of women not obtaining a high school diploma (Uppal, 2017). Young adults with lower levels of education are more likely to experience unemployment or

BOX 40.2 Areas of Stress in Adolescence

- Body image
- Sexuality conflicts
- Academic pressures
- Competitive pressures
- Relationships with parents
- Relationships with siblings
- Relationships with peers
- Dating
- Finances
- Decisions about present and future roles
- Career planning
- Ideological conflicts

underemployment, and lone parenthood is more prevalent among women with less than a high-school diploma; both of these factors may lead to financial insecurity and increased need for social supports (Uppal, 2017).

Among in-school adolescents, a low grade point average has been associated with higher levels of emotional distress; cigarette, alcohol, and cannabis use; and earlier onset of sexual activity. School challenges and dropping out of school can be markers for difficulties, such as learning disabilities, language barriers, family issues, lack of supportive relationships at school, and employment needs.

Questions about recent grades, school absences, suspensions, and any history of repeating a grade in school can be used to screen for school-related issues. Specific management plans for an adolescent who experiences school challenges should be coordinated with school personnel and with the adolescent's parents or caregivers, if possible.

Sexual Health

The World Health Organization (WHO) defines sexual health as "a state of physical, mental and social well-being in relation to sexuality [requiring] a positive and respectful approach to sexuality and sexual relationships, as well as the possibility of having pleasurable and safe experiences, free of coercion, discrimination and violence" (WHO, 2021). Sexual health is a critical consideration for nurses working directly with adolescents and for those involved in creating programs and shaping policy that affects services to this age group. In assessment and counselling of adolescents, STIs, pregnancy, birth control, abortion, and sexual practices need to be considered.

Sexuality Education. The responsibility for providing sexuality education has been assumed by parents, schools, religious communities, community agencies such as Action Canada for Sexual Health and Rights, and health care providers, including nurses. Guidelines for sexual health education, including information on STIs, have been developed by the Public Health Agency of Canada (2016). These guidelines are based on an understanding that sexual health education should be culturally sensitive and respectful of sexual diversity, abilities, and choices. Other resources for information about sexuality, STIs, sexual health, and sexuality education are the Sex Information and Education Council of Canada (SIECCAN) and Sexandu.ca (sponsored by the Society of Obstetricians and Gynaecologists of Canada) (see Additional Resources section).

Many adolescents perceive nurses, especially school nurses, as individuals who possess important information and who are willing to discuss sex with them. To be able to discuss the topic adequately, nurses must have not only an understanding of the physiological aspects of sexuality and a knowledge of cultural and societal values but also an awareness of their own attitudes, feelings, and biases about sexuality. Sexuality education should consist of instruction concerning normal body functions and should be presented in a straightforward manner using correct terminology. When discussing sex and sexual activities, nurses should use simple but correct language, not street language (although it may be helpful to know), highly scientific terminology, or evasive jargon. Once the meanings of biological terms such as *uterus, testicles*, and *vagina* are understood, most teenagers prefer to use them in their discussions.

Teenagers need to discuss intercourse, alternative methods of sexual satisfaction, and how to resist peer pressure. With the increased incidence of STIs, especially HIV infection, the topic of "safer sex," especially abstinence or the use of condoms, is essential. Role-playing may help teenagers learn effective approaches to dealing with difficult situations. Sex and sexuality cannot be taught without discussions of mature decision making, sexual responsibility, and values clarification. Adolescents may receive inaccurate and ambiguous messages regarding sexual behaviour; for example, an adolescent may be told that abstinence from vaginal intercourse will prevent transmission of an STI. Accurate and unbiased information about sexual practices should be provided in a setting where the adolescent feels comfortable asking questions without being degraded or made to feel uncomfortable for seeking information.

Most importantly, adolescents need problem-solving experience and decision-making skills so that they can anticipate the positive and negative outcomes of a decision. These types of experience can help teenagers become sexually responsible young adults. Adolescents who receive comprehensive sexual education are less likely to become pregnant or get someone else pregnant; programs that focus only on abstinence have not reduced rates of sexual abstinence. Adolescents can receive information on contraception and abortion from community health units, community health clinics, and Planned Parenthood Centres.

Pregnancy, Abortion, and Birth Control. In Canada, the rate of teenage pregnancy and abortion has decreased significantly (McKay, 2013). Many factors shape the likelihood of whether a young woman who is sexually active will become pregnant. Nearly 1 in 10 sexually active teens surveyed in 2016 said they do nothing to prevent pregnancy, up from less than 1 in 20 in 2006 (Vogel, 2017). A study by the Society of Obstetricians and Gynecologists of Canada found that more than a third of women who had unplanned pregnancies said they did not use contraception because they did not think they could get pregnant, and almost one third of women said they were unprepared in the heat of the moment. Moreover, 17.8% said they did not use contraceptives because of the adverse effects (Vogel, 2017). Many sexually active adolescents may be reluctant to buy condoms because they feel embarrassed. Alcohol or drug use may also lead to unplanned or unintentional sex or sexual risk taking. Nurses and other health care providers need to be aware of the importance of these issues when planning health care to adolescents.

Safety Promotion and Injury Prevention

Physical injuries are the greatest single cause of death among Canadian youth, claiming more lives than all other causes combined. In 2015, unintentional injuries were the leading cause of death for children aged 1 to 19 years (Yao et al., 2020). In addition, for every youth that dies from trauma, many more have serious injuries.

Injury prevention during adolescence requires a multidimensional approach. To begin, education of adolescents about potential risks is vital (Box 40.3). Education, however, is not enough; engaging with youth about the motivations for risk-taking behaviour is useful. For such discussions to be effective, the adult must be seen as credible and the tone must be nonjudgemental. Finally, advocating for provincial, territorial, and federal legislation is another avenue through which nurses can work to reduce injuries among adolescents (see Motor Vehicle–Related Injuries below). See Chapter 35 for more discussion of specific injury prevention.

Motor Vehicle–Related Injuries. The adolescent's newly acquired ability to drive and the normal developmental need for independence and freedom make the automobile an attractive but potentially dangerous part of many adolescents' lives. Motor vehicle collisions (MVC) continue to be the leading cause of injury-related deaths for this age group (Yanchar et al., 2012/2020). Many factors contribute to the higher rate of crashes among teen drivers, including lack of driving

BOX 40.3 Injury Prevention During Adolescence

Developmental Abilities Related to Risk for Injury

Need for independence and freedom
Testing independence
Age permitted to drive a motor vehicle (varies)
Inclination for risk-taking behaviours
Feeling of indestructibility
Need for discharging energy, often at expense of logical thinking and other control mechanisms
Strong need for peer approval
Desire to attempt hazardous feats
Peak incidence for practice and participation in sports
Access to more complex tools, objects, and locations
Can assume responsibility for own actions

Injury Prevention

Pedestrian

Emphasize and encourage safe pedestrian behaviour.

- At night, walk with a friend.
- If someone is following you, go to the nearest place with people.
- Do not walk in secluded areas; take well-travelled walkways.
- Reinforce the pedestrian risks when using cell phones and listening to music with earphones when walking.

Motor or Nonmotor Vehicles

Passenger—Promote appropriate behaviour while riding in a motor vehicle.
Driver—Provide competent driver education; encourage judicious use of vehicle; discourage drag racing, "playing chicken"; discourage cell phone usage and text messaging while driving; maintain vehicle in proper condition (brakes, tires, etc.).
Reinforce not to drink and then drive or to get into a vehicle driven by someone who has been drinking.
Teach and promote safety and maintenance of two-wheeled vehicles.
Encourage wearing of safety apparel such as helmet and long trousers.
Reinforce the dangers of drugs, including alcohol, when operating a motor vehicle.

Falls

Teach and encourage general safety measures in all activities.

Drowning

Teach nonswimmers to swim.
Teach basic rules of water safety:

- Select carefully a place to swim.
- Ensure sufficient water depth for diving.
- Swim with a companion.
- Wear a life vest during water sports (e.g., boating, skiing).
- Avoid swimming, boating, or other water sports after alcohol consumption or illicit drug use.

Burns

Reinforce proper behaviour in areas involving contact with burn hazards (gasoline, electric wires, and fires).
Advise regarding protection from excessive exposure to natural or artificial sunlight (ultraviolet burn).
Discourage smoking.
Encourage use of sunscreen.
Discourage use of tanning beds.

Poisoning

Educate in hazards of drug use, including alcohol.

Other Sources of Physical Harm

Promote proper instruction in sports and use of sports equipment.
Instruct in safe use of and respect for firearms and other devices with potential danger (e.g., power tools, fireworks).
Provide and encourage use of protective equipment when using potentially hazardous devices (e.g., motorcycles, ATVs, power tools) or when engaging in sports activities such as skateboarding.
Promote access to and provision of safe sports and recreational facilities.
Be alert for signs of depression (potential suicide).
Instruct in proper use of corrective devices (e.g., glasses, contact lenses, hearing aids).
Encourage judicious application of safety principles and prevention.

experience and maturity, following too closely, driving too fast, having other teen passengers in the car, texting or answering a cell phone while driving, and driving under the influence of alcohol (Parachute, 2021). Recent attention has focused on teens driving while distracted, and talking or texting on their cell phones while driving. A recent survey found that 90% of college and university students use their cell phone to talk while driving, 50% text while on a highway, 60% text in stop-and-go traffic, and 87% text at traffic lights (Hill et al., 2015). All provinces and territories have outlawed the use of handheld mobile devices while actively operating a vehicle (Hands Free Info, 2021), and all-driver texting bans have significantly lowered the odds of texting while driving (Qiao & Bell, 2016).

Several provinces have enacted graduated driver licence laws with restrictions on younger adolescent driving. In most provinces, adolescents may obtain a learner's licence by successfully passing a knowledge test. Upon passing a road test, the teen may drive supervised with certain imposed conditions (only one other nonfamily member in the car, zero blood alcohol level, no electronic devices). The age at which an adolescent can first drive varies among provinces and territories.

Nurses need to educate teenagers and their parents about the risk of driving while drinking alcohol or of riding in an automobile with a drunk driver. Many families arrange a no-questions-asked ride home to prevent an adolescent from riding with a drunk driver. Families should also require adolescents to log several hours of supervised practice in driving before taking the car out alone. Educational efforts should convey that the major risk for death in a motor vehicle accident is failure to use a safety restraint.

Nursing Care

Both adolescents and their parents are often confused and perplexed about the changes and behaviour of this stage of development. Parents need support and guidance to help them through this trying time. They need to understand the changes taking place in their teenage children and to accept the expected behaviours that accompany the process of detachment. Parents may need help in "letting go" and in promoting the changed relationship from one of dependence to one of mutuality. Suggestions for anticipatory guidance of parents of adolescents are listed in the Family-Centered Care box: Parent Strategies for Adolescent Support.

FAMILY-CENTRED CARE

Parent Strategies for Adolescent Support

Encourage Parents To Do the Following:

- Accept the adolescent as a unique individual.
- Respect the adolescent's ideas, likes and dislikes, and wishes.
- Be involved with school functions and attend the adolescent's performances, whether it be a sporting event or a school play.
- Listen and try to be open to the teenager's views, even when they disagree with parental views.
- Avoid criticism about no-win topics.
- Provide an opportunity for choosing options and accept natural consequences of these choices.
- Allow the young person to learn by doing, even when choices and methods differ from those of adults.
- Provide the adolescent with clear, reasonable limits.
- Clarify house rules and consequences for breaking them.
- Allow increasing independence within limitations of safety and well-being.
- Be available but avoid pressing the teenager too far.
- Respect the adolescent's privacy.
- Try to share in the adolescent's feelings of joy or sorrow.
- Respond to feelings, as well as words.
- Be available to answer questions, give information, and provide companionship.
- Try to make communication clear.
- Avoid comparisons with siblings.
- Assist the adolescent in selecting appropriate career goals and preparing for an adult role.
- Welcome the adolescent's friends into the home and treat them with respect.
- Provide unconditional love.
- Be willing to apologize when mistaken.

Be Aware That Adolescents:

- Are subject to turbulent, unpredictable behaviour
- Are struggling for independence
- Are extremely sensitive to feelings and behaviour that affect them
- May receive a different message from what was sent
- Consider friends extremely important
- Have a strong need to belong to a peer group of friends and not necessarily to family (except in certain circumstances)

SPECIAL HEALTH CONCERNS

For discussion regarding obesity see Chapter 35. See Chapter 55 for discussion of eating disorders, substance use, and other mental health concerns.

Disorders of the Female Reproductive System

Disorders related to the female reproductive system, such as amenorrhea and dysmenorrhea, are discussed in Chapter 7. STIs are also discussed in Chapter 7.

Disorders of the Male Reproductive System

Many of the obvious anomalies, such as hypospadias, hydrocele, phimosis, and cryptorchidism, are identified with corrective measures instituted during early childhood. The most frequent issues related to the reproductive organs in adolescence are as follows:

- Infections, such as urethritis (see Urinary Tract Infection, Chapter 49)
- Hematuria
- Penile conditions, such as drug-induced priapism, carcinoma, and trauma
- Scrotal conditions, such as varicocele (elongation, dilation, and tortuosity of the veins superior to the testicle)
- Testicular torsion (a condition in which the testicle hangs free from its vascular structures, which can result in partial or complete venous occlusion with rotation)

Tumours of the testes are not common, but when manifested in adolescence they are generally malignant and demand immediate evaluation. The usual presenting symptom for testicular cancer is a heavy, hard mass (either smooth or nodular) that is palpated on the testis; approximately 40% of men present with a painful mass. If a firm swelling is noted, the adolescent should be evaluated by ultrasonography and immediately referred for direct biopsy if the mass is found to be solid. Treatment involves surgical removal of the affected testicle (orchiectomy) and adjacent lymph nodes (if affected) and possibly chemotherapy and radiation following surgery. Fertility may be regained after chemotherapy and surgery; however, sperm banking before the initiation of chemotherapy is recommended. Recurrence of testicular cancer in the contralateral testis may occur; therefore, follow-up is essential.

Nursing Care. Most adolescent boys are self-conscious about their changing bodies. Preparation is crucial before performing a genital examination. Generally, the most effective approach is to assume a matter-of-fact attitude toward the examination, explain precisely what will take place, and maintain a continuous commentary about what is being done and the findings at each phase of the examination.

The routine health assessment of every adolescent boy should include teaching about testicular cancer. The Canadian Cancer Society (2021) recommends that young men age 15 years and older be taught the signs and symptoms of testicular cancer. They should also know how their testicles normally look and feel. Testicular tumours may be detected by the individual male. While there is not enough evidence to recommend regular testicular exams, it is important for men to know what is normal for them (see Additional Resources for an effective video from the Canadian Cancer Society that can be used in teaching). This is particularly important if the male adolescent may be at a higher risk of developing testicular cancer (undescended testicle[s], a family member with testicular cancer, or a history of testicular cancer). Young men should be taught to examine their testes while they are in a warm shower or bath, which relaxes the scrotum and helps testes to descend (Canadian Cancer Society, 2021). The normal testicle is a firm organ with a smooth, egg-shaped contour; the epididymis is palpated as a raised swelling on the superior aspect of the testicle and should not be confused with an abnormality.

Gynecomastia. The male breast, although not strictly part of the male reproductive system, responds to hormonal changes. Some degree of bilateral or unilateral breast enlargement occurs frequently in boys during puberty. It is estimated that approximately 70% of adolescent boys have transient gynecomastia, which subsides spontaneously in less than 1 year with achievement of male development (Ali & Donohoue, 2020). A careful assessment of the pubertal stage at the onset of gynecomastia; medication history, including anabolic steroids, calcium, channel blockers, cancer chemotherapy, histamine receptor blockers, and oral ketoconazoles; and the exclusion of renal, liver, thyroid, and endocrine disorders or dysfunction indicate that the changes are pubertal gynecomastia and the examiner can reassure the adolescent that no further assessment is indicated. Gynecomastia may also be drug induced; calcium channel blockers, cancer chemotherapeutic agents, histamine$_2$ receptor blockers, and oral ketoconazoles have all been shown to cause the condition.

If the condition persists or is extensive enough to cause embarrassment or to produce doubts about gender identity in the boy, plastic

surgery may be indicated for cosmetic and psychological considerations. Administration of testosterone has no effect on breast development or regression and may aggravate the condition.

Nursing care. Treatment usually consists of assuring the adolescent and his parents that this is a benign and temporary situation. A physical examination with palpation is necessary to differentiate gynecomastia from increased adiposity caused by being overweight. Adolescents who are distressed about physical integrity and masculinity may benefit from the knowledge that this condition is not uncommon in adolescent boys.

KEY POINTS

- The pubescent growth spurt that begins around age 10 years in girls and age 12 years in boys signals the beginning of adolescence.
- Biological development during puberty is characterized by increased activity of the pituitary gland, which results in sexual maturity and the appearance of secondary sex characteristics.
- Development of body image is closely tied to body changes and social interactions.
- According to Erikson, the major developmental crisis of adolescence is establishing a sense of identity.
- Cognitive development in adolescence includes abstract thought, thinking beyond the present, logical reasoning, and a sense of idealism.
- According to Kohlberg's theory of moral development, adolescents begin to question existing moral values and learn to make their own choices.
- Spiritual development is characterized by the questioning of one's family's values and ideals and a move toward more philosophical thinking.
- Adolescent relationships with parents may be strained; the influence of the peer group increases and intimate relationships assume importance.
- Teenagers demonstrate a wide variety of interests, and their increased physical and cognitive skills allow them to engage in increasingly difficult and complex activities.
- Adolescents' emotions fluctuate.
- The rapid changes, growth, and stress accompanying the transition to adulthood may predispose adolescents to faulty problem solving.
- The most common health issues related to the female reproductive system during adolescence involve menstrual dysfunction; male reproductive health issues include testicular cancer and gynecomastia.

Caring for the Child With a Chronic Illness and at the End of Life

Laura Pilla
Originating US chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the scope of and changing trends in the care of children with special needs.
2. Identify the major reactions of and effects on the family of a child with special needs.
3. Define the stages of adjustment to the diagnosis of a chronic or complex medical condition.
4. Recognize the impact of the illness or condition on the developmental stages of childhood.
5. Outline nursing interventions that promote the family's optimum adjustment to the child's chronic illness or complex condition.
6. Describe the importance of home care in the life of a family with a medically complex child.
7. Describe care coordination and its importance in home care.
8. List general principles of a family-centred assessment and planning process.
9. Identify key characteristics of collaborative relationships.
10. Describe approaches to promoting optimum development, self-care, and education in home care.
11. Outline nursing interventions that support the family at the time of the child's death.
12. Describe the usual symptoms of grief.

CARE OF CHILDREN AND FAMILIES LIVING WITH CHRONIC OR COMPLEX CONDITIONS

Scope of the Issue

Advances in medical and nursing care, such as the increasing viability of extremely preterm infants, the portability of life-sustaining technology (e.g., total parental nutrition, ventilatory support), and life-extending treatments for children with conditions that previously would have led to an early death (e.g., malignancies, genetic conditions), have led to an increase in the prevalence of children with complex and chronic diseases. These children often live with complex conditions involving several organ systems and require multiple specialists, technological supports, and community services to assist them to function to their healthiest potential; this group of children is referred to as *children with medical complexity*. An example of such a child is one with a genetic disorder affecting multiple organ systems. The complex, high level of skill required to meet their daily health care needs and the continuous nature and potential volatility of the condition sets this group apart from the broader population of children with special health care needs (Cohen et al., 2011; Kuo et al., 2011).

Canadian children with chronic and complex conditions have the highest survival rates this group has ever experienced, with many now living well into adulthood and beyond. These higher survival rates have led to greater numbers of children with special needs who are likely to be in poorer health than their unaffected counterparts (Halfon & Newacheck, 2010). It is estimated that children with medical complexity account for less than 1% of the pediatric population that seeks health care, yet the expenditures for their care comprise approximately one-third of all pediatric health care dollars (Cohen et al., 2012).

The nature and the severity of childhood chronic and complex conditions are widely heterogeneous. However, these children and their families are similar in the vulnerability they experience due to the health and developmental consequences of these diagnoses on the child, such as ongoing functional impairment, neurodevelopmental disability, dependence on medical technology, and the need for ongoing skilled, supportive care from health care providers and family members. Parents of children with complex care needs play a unique and special role in supporting their child to live a healthy and productive life at home. The often complicated health and social systems require parents and other family members to learn a variety of skills and develop special skills to enable their child to remain safe at home and active in the community (Canadian Home Care Association, 2016). To help provide this care, nurses are moving into highly specialized community roles.

The impact of chronic and complex conditions in children is wide ranging. For some families, the impact is minimal, but for many other families, chronic conditions in their children present families with

additional tasks, responsibilities, and concerns. The family may experience significant challenges related to the child's care requirements (Goudie et al., 2014). A child's activity level and developmental opportunities can be affected. Days attending school can be lost. Children with complex chronic conditions may be at increased risk for behavioural or emotional issues.

Families with children with special needs and who live in rural or remote locations in Canada have the additional stressors of trying to access services that are far away or of obtaining resources and assistance within their own communities (Chambers & Burnett, 2017; Hoogsteen & Woodgate, 2013). Strategies for addressing these challenges include building partnerships to optimize local resources and build capacity; mobilizing systems integration by accessing resources outside the community; and using technology to train, provide guidance, and support family caregivers and health care teams. Options available to families living in rural or remote areas are travelling to a major health care facility that will coordinate all appointments in a clustered approach (which may not be an option for children with more severe disabilities and multiple services involved), accessing travelling services such as satellite clinics from specialty hospitals, or using telehealth services, which have been shown to extend access to care (Rutledge et al., 2014). Another option is for the family to move closer to an urban centre. This option can be particularly challenging for Indigenous children, who may reside in remote communities in Canada. Some programs have been developed to help mitigate this issue, such as Jordan's Principle, created in 2007 by the federal government to ensure access to care and funding for Indigenous children requiring specialized medical care (Chambers & Burnett, 2017).

Trends in Care

Developmental Focus. Focusing on the child's developmental level rather than their **chronological age** or diagnosis places emphasis on the child's abilities and strengths rather than on disabilities. Attention is directed toward normalizing experiences, adapting the environment, and promoting **coping** skills. Nurses are often in a vital position to redirect efforts away from the pathological model, with its focus on weaknesses and challenges, and toward the developmental model to meet the unique needs of the child and family.

A developmental approach also takes into account family development. The life cycle of the family unit reflects changing ages and needs of family members as well as changing external demands. The chronic or complex illness or disability of a family member can cause significant stress or crisis at any stage of the family life cycle. Just as with individual development, family development may be interrupted or even regress to an earlier level of functioning. By using the concept of family development nurses can plan meaningful interventions and evaluate care.

Family-Centred Care. Children's physical and emotional health, as well as cognitive and social functioning, is strongly influenced by how well their families function. The importance of family-centred care, a philosophy that considers the family as the constant in the child's life, is especially evident in the care of children with special needs (see Chapter 30, Family-Centred Care). As parents learn about their child's health care needs, they often become experts in providing care. Health care providers, including nurses, are adjuncts to the child's care and need to form partnerships with parents. Through these partnerships the parents are integral to communicating the child's typical responses and actions to assist the health care team. Effective communication and negotiation between parents and nurses are essential to forming trusting and effective partnerships and finding the best ways to meet the needs of the child and family (Giambra et al., 2014). Collaborative relationships are characterized by communication, dialogue, **active listening**, awareness, and acceptance of differences.

Family–health care provider communication. The disclosure of a child's serious chronic or complex condition is one of the most stressful aspects of communication between families and health care providers. Often, parents and caregivers have suspected for some time that something is amiss with the child. After a diagnosis is made, factors that can lead to parents being dissatisfied with the way that relevant information is communicated include a disrespectful attitude, breaking difficult news in an insensitive manner, withholding information, and changing a treatment course without preparing the child and family (Barnes et al., 2012). Conversely, parents report satisfaction when they perceive that health care providers are available, demonstrate competence, and engage the child and parent in care decision making (Barnes et al., 2012; Kuo et al., 2012). Similar factors are important in communicating changes in the child's condition throughout the course of the illness.

Providing information to families with a chronically ill child should be a process of repeated discussions, to enable the family to process the information and their reactions to that information and allow them to ask for clarification and further information. Nurses play an important role in ensuring that families' needs are met during discussions related to a child's diagnosis, condition, and treatment. The family should be assessed regarding how much information they are comfortable with, what they understand of the information already given to them, and how they are coping with the information, both cognitively and emotionally. Nurses should ensure that the appropriate health care providers address any concerns or further questions that families may have.

When parents not fluent in the health care provider's language are informed of their child's chronic illness, interpreters familiar with both cultures and languages should be used during clinic visits and hospitalization (see Chapter 2, Use of Interpreters). Children, family members, and friends of the family should not be used as translators because their presence may prevent parents from openly discussing issues, or they may not be able to accurately translate the medical terminology used or the meaning of what the health care provider is trying to relay. Also, parents with limited proficiency in the health care provider's language who receive inadequate communication are at increased risk of feeling dissatisfied with care and experiencing a lack of partnership in care (Eneriz-Wiemer et al., 2014). The ability to interpret mainstream medical culture to the family is also important. Furthermore, every effort should be made to incorporate a family's traditional cultural beliefs into the treatment plan. Developing a care plan in conjunction with the family that considers their preferences and priorities is an important first step in formulating a plan that best meets the family's needs (Canadian Home Care Association, 2017b; Wiener et al., 2013).

Establishing therapeutic relationships. Another important aspect of family-centred care of children with chronic and complex conditions is establishing a therapeutic relationship with the child and family, which can improve health-related outcomes. Families, often the primary caregiver, take on enormous responsibility in providing technical care and symptom management of their child's condition outside the health care institution. To build successful therapeutic relationships with families, nurses need to recognize parents' expertise in their child's condition and needs. Health care environments for children with serious illnesses are fraught with obstacles that can serve as barriers to successful therapeutic relationships with families. Individual discussions, especially with the case manager, primary nurse, clinical nurse specialist, or nurse practitioner, aid in establishing a consistent and flexible care plan that can prevent conflicts or, if needed, address conflicts before they disrupt care.

Shared Decision Making. Shared decision making among the child, family, and health care team can result from open, honest, culturally sensitive communication and the establishment of a therapeutic

relationship between the family and health care providers. In a shared decision-making model, the health care providers provide honest, clear information regarding the diagnosis, prognosis, treatment options, and risk–benefit assessment. The patient and family share information with the health care team about important family values, acceptable levels of discomfort or inconvenience, and their ability to adhere to treatments being recommended (Kon, 2010; Wyatt et al., 2015). This process enables them to discuss all options in terms of the risks and benefits to the child and family, the prognosis or expected course of the illness, and the impact on the family's resources (Box 41.1). Together the parents and health care team can make decisions that are best for the family and child at the time the decision is made (Kon, 2010).

Normalization. **Normalization** refers to the efforts that family members make to create a normal family life, their perceptions of the consequences of these efforts, and the meanings they attribute to their management efforts (Knafl et al., 2010). For chronically ill children, such tasks could include attending school, pursuing hobbies and recreational interests, and achieving employment and a level of independence. For their families, it may entail adapting the family routine to accommodate the child's health and physical needs.

Children with chronic illness and complex conditions and their families face numerous challenges in achieving normalization. Families move between the "normal" of living with the experience of chronic childhood illness and the "normal" of the outside world; they often redefine "normal" on the basis of their particular experiences, needs, and circumstances. Normalization may be an important mediator of illness-related stressors (e.g., treatment demands, uncertainty) on family outcomes.

Nurses can assist families in normalizing their lives by assessing the family's everyday life, social support systems, coping strategies, family cohesiveness, and family and community resources. Interventions could include encouraging families to reduce stress through delegation of care and family tasks, identifying ways to incorporate care into current routines, structuring the home environment to foster the child's engagement in age-appropriate activities, and ensuring that families have access to appropriate community support services. Being supportive of the child living with illness and its treatment and actively including the family in all aspects of care can improve their self-esteem and promote further development (Knafl & Santacroce, 2010).

Paralleling normalization is the process of *mainstreaming*, or integrating children with special needs into regular classrooms. Just as the home is the natural environment for children, the school must be included as an essential component of children's overall physical, intellectual, and social development. Children who attend school have the advantages of learning and socializing with a wide group of peers. With increased focus on individualization, plans are made to meet the academic needs of these children along with those of the rest of the students.

BOX 41.1 Facilitating Shared Decision Making

- Continually assess the impact of the child's illness and treatment on the family.
- Provide honest, accurate information regarding the trajectory of the disease, anticipated complications, and prognostic information.
- Discuss what the family desires for the child's quality of life.
- Avoid personal opinion or judgement of the family's questions and decisions.
- Be aware of nurses' personal and cultural assumptions and the ways these assumptions affect communication, decision making, and judgement.

A variety of supplemental programs have been designed in school systems to accommodate the special needs of children of school age and younger through *early intervention*. These programs consist of any sustained and systematic effort to assist children from birth to age 3 years who are disabled and developmentally vulnerable. These programs, as well as increasing opportunities for normalization for children with special needs, resulted in large part from enactment of the *Charter of Rights and Freedoms*; Canada signed the United Nations *Convention on the Rights of the Child* on May 28, 1990, and ratified it on December 13, 1991 (United Nations, 1989). The *Charter* continues to be used as a basis for supporting children with disabilities. Each province and territory has different laws that govern education and health care for children. It is important for nurses to be aware of the laws within their jurisdiction and how these laws might affect their patients. Nurses can provide parents with information about the relevant laws and rights and, in some cases, may participate in the development of individualized educational programs (IEPs) or individualized family service plans for children with special needs.

THE FAMILY OF THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

A major goal in working with the family of a child with a chronic or complex illness is to support the family's effective coping and promote their optimal functioning throughout the child's life. Long-term, comprehensive care involves forming parent–health care provider partnerships that can support a family's adaptations across the trajectory of the illness to the many changes that may be necessary in day-to-day life, determine expectations of and for the child, and provide a long-term perspective (Box 41.2).

Often the impact of a child's medical or developmental condition is first experienced as a crisis at the time of diagnosis, which may occur at birth, after a long period of diagnostic testing, or immediately after a tragic injury. But the impact may also be felt before the diagnosis is made, when parents are aware that something is amiss with their child but before its medical confirmation (Smaldone & Ritholz, 2011).

The diagnosis and initial discharge home can be a critical time for parents. Several factors can make this time difficult, including a long duration of uncertainty in the diagnostic process, negative perceptions of chronic illness and complex conditions, insufficient information, and lack of trust between parents and their child's health care team (LeGrow et al., 2014). Parental feelings of shock, helplessness, isolation, fear, and depression are common. Throughout the first year, parents may struggle to accept the child's diagnosis and care needs and the uncertainty of the future. The provision of explicit and uncomplicated information to parents using an empathic approach tends to yield more positive outcomes along with the development of a collaborative

BOX 41.2 Adaptive Tasks of Parents Who Have Children With Chronic Conditions

1. Accept the child's condition.
2. Manage the child's condition on a day-to-day basis.
3. Meet the child's normal developmental needs.
4. Meet the developmental needs of other family members.
5. Cope with ongoing stress and periodic crises.
6. Assist family members to manage their feelings.
7. Educate others about the child's condition.
8. Establish a support system.

From Canam, C. (1993). Common adaptive tasks facing parents of children with chronic conditions. *Journal of Advanced Nursing, 18,* 46–53.

relationship. When parents are provided adequate information they may be better able to come to terms emotionally with their child's diagnosis and to provide care for them at discharge (Adler et al., 2015). Providing optimal support at the time of diagnosis and initial discharge home includes assessment of the family's daily routines, living conditions, background knowledge, skills and abilities, coping behaviours, and their understanding of the information provided. It is also necessary to reassess parental needs for information and support on a regular basis.

Impact of the Child's Chronic Illness and Complex Conditions

Each member in the family of a child with a chronic or complex illness is affected by the experience (Goudie et al., 2014; Kuo et al., 2011). The effects on the parents and their responses may be so intense that they directly influence the other members' reactions and the child's own coping.

Parents. In addition to the stress of grieving the loss of hope for a "perfect" child, parents are affected by whether or not they receive positive feedback from interactions with their child. Parents may grieve for the loss of the child they expected. Many parents of children with special needs feel satisfaction and fulfillment from their role as parents. For others, parenting may be a series of unrewarding experiences that contribute to feelings of inadequacy and failure (Box 41.3). These responses may be most evident in the parents who are most responsible for the child's care. For example, parents may become preoccupied with their ability to carry out certain procedures, overlooking the child's personal comfort and satisfaction or failing to offer praise for anything less than perfect cooperation or performance. They may pursue a frustrating activity until they achieve "success"—long after the child has become irritable and uncooperative. As a result, parents can become caught in a pattern of interaction that is mutually unrewarding and minimally productive. This situation may become exacerbated by disagreements with or lack of support from other family members and judgement from caregivers and others in the community. For these parents, several strategies may be helpful: education regarding what can reasonably be expected of their child, assistance in identifying the child's strengths, praise for a parental job well done, and respite care so that parents can renew their energy.

Parental roles. Parenting a child with a complex chronic condition requires attending to the routine aspects of parenting, with the added responsibility of performing complex technical care and symptom management, advocating for their child, and seeking and coordinating health and social services for their child who is ill or has a disability. These added responsibilities must then be balanced with the needs of other family members, extended family and friends, personal health, and obligations to minimize consequences to the overall functioning of the family (Woodgate et al., 2015).

Often one parent or partner remains at home to manage existing family responsibilities while the other remains with the ill child in the hospital or other care facility. The parent who is not included in the caregiving activities may feel neglected because all of the attention is directed toward the child. The partner may feel resentful that they are not sufficiently informed to be competent in the child's care. Without active participation in the child's care, this parent has little appreciation of the time and energy involved in performing these activities. When this partner does attempt to participate, the other parent may criticize the less skillful efforts. As a result, communication and support for one another can be adversely affected.

The nurse can assist parents in avoiding role conflicts by providing anticipatory guidance early on. Teaching should address stressors often identified as having an impact on the relationship: (1) the burden of care at home assumed by primarily one parent, (2) the financial burden, (3) fear of the child dying, (4) pressure from relatives, (5) the hereditary nature of the disease (if applicable), (6) fear that the parents may become ill and unable to care for their child, and (7) fear of pregnancy. Other causes of tension may centre on the inconveniences associated with care, such as long waits for an appointment, lack of parking near care facilities, or lack of affordable overnight accommodations.

Parents in the same family often adjust to and cope with caring for a child with special needs differently; thus it is important to treat each individual as having their own coping style. Some parents may not have a social network of people who can help with child care, adding to their feelings of isolation. Extensive stresses in the family can leave parents feeling depressed, weak, guilty, powerless, isolated, embarrassed, and angry. Some parents may escape in their work as a means of coping with a difficult situation. Nurses need to assess parental coping strategies and provide strategies to enhance coping.

A key intervention for caregivers of a child with a complex medical condition is to encourage the use of respite care. This may involve scheduling time for the family to leave the ill child in the homelike setting of a hospice while they go on a holiday or more time with a partner or siblings that may not be possible when caring directly for the ill child. Respite care may also be offered on an emergency basis, such as when the primary caregiver becomes ill, until other arrangements can be made for care of the ill child. Parents report that provision of respite care benefits the entire family and contributes to maintaining relationships and personal health so they can continue to care for the ill child in the future (Widger et al., 2016).

Respite care for ventilator-dependent children and for those requiring skilled technological care is in short supply in some provincial and territorial jurisdictions, given the lack of skilled care providers, early discharge from the hospital, and high health needs (Canadian Healthcare Association [CHA], 2012). Nurses can play an important role in advocating for the provision of high-quality respite care, which enables families and caregivers to maintain appropriate family function, care for themselves, and continue to provide care for their child, as necessary. Family-focused respite care is considered most effective when various cultural and ethnic practices and values are taken into consideration (CHA, 2012).

Lone-parent families. Lone-parent families are of special concern. As the only parent of a child who may require extensive, sophisticated, and lifelong care, lone parents may feel an enormous burden. Available financial and emotional resources may already be stretched to the

BOX 41.3 Anticipated Parental Stress Points

Diagnosis of the condition—Parents require considerable education while dealing with an emotional response.

Developmental milestones—Times that children normally achieve walking, talking, and self-care are delayed or impossible for the child.

Start of schooling—Particularly stressful are situations in which appropriate schooling will not be in a regular class placement.

Reaching the ultimate attainment—Parents must deal with difficult situations, such as realizing that ambulation will be impossible or that the child will not learn to read.

Adolescence—Issues such as sexuality and independence become prominent.

Future placement—Decisions about placement must be made when the child becomes an adult or when the parents can no longer care for the child.

Death of the child—Parents coping with the death of a child can suffer enormous loss with physical and psychological effects, including higher levels of depression.

limit. A special effort should be made to assist lone parents in finding financial and support services that can ease the burden of care. Lone parents may have fewer opportunities to get involved in community and outside activities, contributing to diminished support networks and feelings of social isolation. This and the burden of care can lead to negative physiological effects, further increasing stress responses when caring for a child with special needs (Knafl et al., 2013). Nurses can involve social workers and assist the parent in seeking out support options, such as online support networks. Nurses can also assist the lone parent in identifying helping roles that may be acceptable to relatives and friends.

Siblings. Results of studies are less clear regarding the ways that siblings are affected by having a brother or sister with a complex condition (Dykens, 2015; Emerson & Giallo, 2014). Generally, the evidence indicates a negative effect on siblings of children with a chronic illness when compared with siblings of healthy children (Gold et al., 2011). More recently, this effect has appeared to decrease in significance—most likely because of changes in public attitudes toward ill and disabled persons. Newer research has shown that being a sibling of a child with special needs can have a positive impact on the sibling's life, in being generally more mature and independent and accepting of individual differences. A number of factors increase the risk of negative effects for siblings of ill children, such as responsibility for caregiving, differential treatment by parents, and decreased family resources and recreational time (Emerson & Giallo, 2014) (Box 41.4). Being mindful of the potential harmful effects that some siblings can experience, health care providers need to provide interventions that support siblings' physical and emotional well-being.

An important factor in sibling adjustment and coping is information and knowledge regarding their brother's or sister's illness or complex condition. What siblings piece together or overhear is often much worse than the truth. Often they imagine gruesome things regarding the experiences related to the illness, treatment, and hospitalization (Knafl & Santacroce, 2010). Parents are usually in the best position to impart information. Nurses can encourage parents to talk with the siblings about how they perceive their sick brother or sister and to be accepting of the siblings' feelings. Nurses can be ideal educators and counsellors of siblings during the course of their brother's or sister's illness. Parents should be encouraged to provide siblings with knowledge about the chronic condition, facilitate attendance at camps or therapeutic groups, and spend alone time with the ill child's siblings (Incledon et al., 2015).

Coping With Ongoing Stress and Periodic Crises

Health care providers can help families cope with stress by providing anticipatory guidance and emotional support, assisting the family in assessing and identifying specific stressors, aiding the family in developing coping mechanisms and problem-solving strategies, and working collaboratively with parents so that they become empowered in the process.

Concurrent Stresses Within the Family. The ability to deal with the overwhelming stress of a chronic illness is challenged further when additional stresses are present. Stressors may be situational or developmental. They may be related to relationship difficulties, sibling needs, financial strain, homelessness or food insecurity, or social isolation. Even relatively minor stressors, such as arranging care for siblings, managing the home, and travelling to distant treatment centres, can challenge a family's ability to cope successfully.

BOX 41.4 Supporting Siblings of Children With Special Needs

Promote Healthy Sibling Relationships

- Value each child individually and avoid comparisons. Remind each child of their positive qualities and contributions to other family members.
- Help siblings see the differences and similarities between themselves and the child with special needs. Create a climate in which children can achieve successes without feeling guilty.
- Teach siblings ways to interact with the child.
- Seek to be fair in terms of discipline, attention, and resources; require the affected child to do as much for themselves as possible.
- Let siblings settle their own differences; intervene only to prevent siblings from hurting one another.
- Legitimize reasonable anger. Even children with special needs behave badly sometimes.
- Respect a sibling's reluctance to be with or to include the child with special needs in activities.

Help Siblings Cope

- Listen to siblings to let them know that their thoughts and suggestions are valued.
- Praise siblings when they have been patient, have sacrificed, or have been particularly helpful. Do not expect them to always act in this manner.
- Acknowledge the personal strengths that siblings have and their ability to cope with stress successfully.
- Provide age-appropriate information about the child's condition and update it when appropriate.
- Let teachers know what is happening so they can be understanding and helpful.
- Recognize special stress times for siblings and plan to minimize negative effects.
- Schedule special time with siblings; have a friend or family member substitute when the parent is unavailable.
- Encourage siblings to join or help establish a sibling support group.
- Use the services of professionals when needed. If a parent thinks that such a service is necessary, it should be provided in as timely a manner as a service for the child with special needs.

Involve Siblings

- Seek out ways to realistically include siblings in the care and treatment of the child with special needs.
- Limit caregiving responsibilities and give recognition when siblings perform them.
- Develop a library of children's books on special needs.
- Invite siblings to attend meetings to develop plans for the child with special needs (e.g., individualized educational program, individualized family service plan).
- Discuss future plans with the siblings.
- Solicit their ideas on treatment and service needs.
- Have them visit professionals who work with the child.
- Help them develop competencies to teach the child new skills.
- Provide opportunities for siblings to advocate for the child.
- Allow siblings to set their own pace for learning and involvement.

Tips for dealing with siblings. *Candlelighters Childhood Cancer Foundation—A Newsletter, 11*(3,4), 7; Carlson, J., Leviton, A., & Mueller, M. (1993). Services to siblings: An important component of family-centered practice. *Association for the Care of Children's Health Advocate, 1*(1), 53–56.

Most families, regardless of their income or insurance coverage, have financial concerns. The costs of caring for a child with special needs can be overwhelming. Nurses and social workers can help a family review options for financial assistance, including insurance and other financial resources, disease-related associations and support groups, and local philanthropic organizations.

Coping Mechanisms. *Coping mechanisms* are behaviours aimed at reducing the tension caused by a crisis. *Approach behaviours* are coping mechanisms that result in movement toward adjustment and resolution of the crisis. *Avoidance behaviours* result in movement away from adjustment and represent maladaptation to the crisis. Several approach and avoidance behaviours used in coping with a chronic or complex condition are listed in the Guidelines box: Assessing Coping Behaviours. Each behaviour must be viewed in the context of all of the variables affecting the family. For example, the observation of several avoidance behaviours in an emotionally healthy family with a solid support system may denote significantly less risk to the successful resolution of the crisis than an equal number of avoidance behaviours in an individual who has few available supports.

GUIDELINES

Assessing Coping Behaviours

Approach Behaviours

- Asks for information regarding diagnosis and child's present condition
- Seeks help and support from others
- Anticipates future issues; actively seeks guidance and answers
- Endows the illness or disability with meaning
- Shares burden of disorder with others
- Plans realistically for the future
- Acknowledges and accepts child's awareness of diagnosis and prognosis
- Expresses feelings such as sorrow, depression, and anger and realizes reason for the emotional reaction
- Realistically perceives child's condition; adjusts to changes
- Recognizes own growth through passage of time, such as earlier denial and nonacceptance of diagnosis
- Verbalizes possible loss of child

Avoidance Behaviours

- Fails to recognize seriousness of child's condition despite physical evidence
- Refuses to agree to treatment
- Intellectualizes about the illness, but in areas unrelated to child's condition
- Is angry and hostile to members of the staff, regardless of their attitude or behaviour
- Avoids staff, family members, or child
- Entertains unrealistic future plans for child, with little emphasis on the present
- Is unable to adjust to or accept a change in progression of the disease
- Continually looks for new cures with no perspective toward possible benefit
- Refuses to acknowledge child's understanding of disease and prognosis
- Uses magical thinking and fantasy; may seek "occult" help
- Places complete faith in religion to the point of relinquishing own responsibility
- Withdraws from outside world; refuses help
- Punishes self because of guilt and blame
- Makes no change in lifestyle to meet needs of other family members
- Resorts to excessive use of alcohol or drugs to avoid difficulties
- Expresses suicidal intent
- Is unable to discuss possible loss of child or previous experiences with death

Parental Empowerment. *Empowerment* can be seen as a process of recognizing, promoting, and enhancing competence. For parents of children with chronic conditions, empowerment may occur gradually as strength and capabilities are drawn on to master the child's care, manage family life, and plan for the future. Advocating for the child and developing parent–professional partnerships are part of the promotion of empowerment. Families of children with special health care needs want to be active members of the health care team and to be actively engaged in decision making. Nurses can ensure that they are included in meetings related to their child's care as well as all aspects of their child's care, as they are able (Adler et al., 2015; LeGrow et al., 2014).

Parents of children with complex medical conditions are very aware of their child's needs and should be partners in making all decisions for their child. In addition, studies have shown that health care providers can learn much from listening to and partnering with parents in the planning and provision of health care for children with disabilities (Kube et al., 2013).

Assisting Family Members in Managing Their Feelings

Although previous research has postulated stages of adaptation to a chronic or complex condition, there is a great deal of variation in individuals' responses to their child's diagnosis, in the adjustments they make, and in the time frame for coming to terms with a diagnosis. It is important that health care providers recognize and respect a wide range of reactions and coping mechanisms. Members of the family of a child with a complex chronic condition may experience a number of difficult emotions, including fear, guilt, anger, resentment, and anxiety. Learning to manage these emotions enables adaptive coping (see Guidelines box: Assessing Coping Behaviours). Support from health care providers, other family members, and friends can assist family members in managing their feelings. The following discussion examines some common phases of adjustment and emotional reactions.

Shock and Denial. The initial diagnosis of a chronic illness or complex condition is often met with intense emotion and is characterized by shock, disbelief, and sometimes **denial**. Denial as a defence mechanism is necessary to prevent disintegration and is a normal response to grieving for any type of loss. Probably all family members experience various degrees of adaptive denial as they learn of the impact that the diagnosis has and will have on their lives.

Shock and denial can last from days to months, sometimes even longer. Examples of denial that may be exhibited at the time of diagnosis include the following:

- Health care provider shopping
- Attributing the symptoms of the actual illness to a minor condition
- Refusing to believe the diagnostic tests
- Delaying consent for treatment
- Acting happy and optimistic despite the revealed diagnosis
- Refusing to share with or talk to anyone about the condition
- Insisting that no one is telling the truth regardless of others' attempts to do so
- Denying the reason for admission
- Asking no questions about the diagnosis, treatment, or prognosis

Generally, these mechanisms should be respected as short-term responses that allow individuals to distance themselves from the emotional impact of the news and to collect and mobilize their energies toward goal-directed, problem-solving behaviours.

In children, the importance of denial has repeatedly been demonstrated as a factor in their positive coping with the diagnosis. Denial allows the child to maintain hope in the face of overwhelming odds and to function adaptively and productively. Like hope, denial may

be an adaptive mechanism for dealing with loss that persists until a family or patient is ready for or needs other responses.

Denial is probably the least understood and most poorly dealt-with reaction. If denial is labelled as maladaptive, it can lead to inappropriate attempts to strip it away by giving repeated and sometimes blunt explanations of the prognosis. Denial becomes maladaptive only when it prevents recognition of treatment or rehabilitative goals necessary for the child's optimal survival or development.

Adjustment. For most families, adjustment gradually follows shock and is usually characterized by an open admission that the condition exists. This stage may be accompanied by several responses, which are normal parts of the adaptation process. Probably the most universal of these feelings are guilt and self-accusation. Guilt is often greatest when the cause of the disorder is directly traceable to the parent, as in genetic diseases or accidental injury. It can occur even without any scientific or realistic basis for parental responsibility. Frequently the guilt stems from a false assumption that the illness is a result of personal failure or wrongdoing, such as not doing something correctly during the pregnancy or birth. Guilt may also be associated with cultural or religious beliefs. Some parents are convinced that they are being punished for some previous misdeed. Others may see the disorder as a test of their religious strength and faith. With correct information, support, and time, most parents master guilt and self-accusation.

Children, too, may interpret their serious illness as retribution for past misbehaviour. The nurse should be particularly sensitive to the child who passively accepts all painful procedures. This child may believe that such acts are inflicted as deserved punishment. It is vital that parents and health care providers reassure children that their illness is not their fault.

Other common and normal reactions to a diagnosis are bitterness and anger. Anger directed inward may be evident as self-reproaching or punitive behaviour, such as neglecting one's health and verbally degrading oneself. Anger directed outward may be manifested in either open arguments or withdrawal from communication and may be evident in the person's relationship with any number of individuals, such as their partner, the child, and siblings. Passive anger toward the ill child may be evident in decreased visiting, refusal to believe how sick the child is, or an inability to provide comfort. Health care providers are among the most common targets for parental anger. Parents may complain about the nursing care, the insufficient time physicians spend with them, or the lack of skill of those who draw blood or start intravenous infusions.

Children are apt to respond with anger as well, and this includes the affected child and the well siblings. Children are aware of the loss engendered by their illness or complex condition and may react angrily to the restrictions imposed or the feelings of being different. Siblings may also feel anger and resentment toward the ill child and parents for the loss of routine and parental attention. It is difficult for older children and almost impossible for younger children to comprehend the plight of the affected child. Their perception is of a brother or sister who has the undivided attention of their parents, is showered with cards and gifts, and is the focus of everyone's concern.

During the period of adjustment, four types of parental reactions to the child influence the child's eventual response to the disorder:

1. Overprotection, in which the parents fear letting the child achieve any new skill, avoid all discipline, and cater to every desire to prevent frustration
2. Rejection, in which the parents detach themselves emotionally from the child but usually provide adequate physical care or constantly nag and scold the child
3. Denial, in which parents act as if the disorder does not exist or attempt to have the child overcompensate for it
4. Gradual acceptance, in which parents place necessary and realistic restrictions on the child, encourage self-care activities, and promote reasonable physical and social abilities

Reintegration and Acknowledgement. For many families the adjustment process culminates in the development of realistic expectations for the child and reintegration of family life with the illness or disability in a manageable perspective. Because a large portion of this phase is one of grief for a loss, total resolution is not possible until the child dies or leaves home as an independent adult. Therefore, one can regard adjustment as "increased comfort" with everyday living rather than a complete resolution.

This adjustment phase also involves social reintegration in which the family broadens its activities to include relationships outside the home, with the child as an accepted and participating member of the group. This last criterion often differentiates the reaction of gradual acceptance during the adjustment period from total acceptance, or perhaps is more descriptive of the acknowledgement process.

Many parents of children with chronic illnesses experience **chronic sorrow**, feelings of sorrow and loss that recur in waves over time. If the child's condition progresses, parents may experience repeated losses that represent further declines and new caregiving demands. Consequently, families must be assessed on an ongoing basis and offered appropriate support and resources as their needs change over time (Doig et al., 2009). This represents a critical period of time, as the approach and support provided by the nursing and medical team during this period can directly affect the experience of complicated grief after the death of the child. *Complicated grief,* which is characterized as persistent distress and a chronic stress response, may last 6 months or longer after the death of a child and has a significant impact on quality of life of the family left behind (Meert et al., 2011).

Establishing a Support System

The diagnosis of a child with a complex chronic condition is a major **situational crisis** that affects the entire family system. However, families can experience positive outcomes as they successfully work with the many challenges that accompany a child with chronic illness.

One nursing goal is to assess which families are at greater or lesser risk for succumbing to the effects of the crisis. Several variables—available support system, perception of the event, coping mechanisms, reactions to the child, available resources, and concurrent stresses within the family—influence the resolution of a crisis. Although most families cope well, the needs of families at risk are great. If they receive emotional support and guidance early, there is an increased likelihood that they will also cope successfully.

Although it is easy to assume that families of children with the most severe illnesses or disabilities would have the poorest adjustment, the severity of the condition reflects only one part of the overall picture. The level of adjustment is significantly influenced by the *functional burden* on the individual family (Baillargeon & Bernier, 2010). This concept involves the issues related to caring for and living with the child in relation to the family's resources and ability to cope (Box 41.5). If a family of a child with a high level of technology dependence who demands complex care has many resources and coping skills, they may adjust more successfully to the child's situation than the family of a child with a less serious condition and few resources to counterbalance.

Intrafamilial resources, social support from friends and relatives, parent-to-parent support, parent–professional partnerships, and community resources interweave to provide a flexible web of support for the family of a child with a chronic condition.

BOX 41.5 Concept of Functional Burden

Impact of Child With Special Needs on the Family

Child's need for medical and nursing care
Child's fixed deficits
Child's age-appropriate dependency in activities of daily living
Disruptions in family routine caused by the child's care
Psychological burden of the prognosis on the family

Family Resources and Ability to Cope

Family's physical resources
Family's emotional resources
Family's educational resources
Family's social supports and available help
Competing demands for family members' time and energy

Data from Doig, J. L., McLennan, J. D., & Urichuk, L. (2009). "Jumping through hoops": Parents' experiences with seeking respite care for children with special needs. *Child: Care, Health and Development, 35*(2), 234–242; Dewan, T., & Cohen, E. (2013). Children with medical complexity in Canada. *Paediatrics & Child Health, 18*(10), 518–522.

THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

The child's reaction to chronic illness depends to a great extent on their developmental level, temperament, and available coping mechanisms; on the reactions of family members or significant others; and, to a lesser extent, on the condition itself. A child's conceptual understanding of their own illness is based not only on age and developmental level but also on the duration and type of experience accumulated with the disease. Knowledge of these variables is essential in providing the kind of information and support these children need in order to cope with a sometimes overwhelming situation.

Developmental Aspects

The impact of a chronic complex illness is influenced by the age at onset. While chronic illness affects children of all ages, the developmental aspects of each age group determine particular stresses and risks for the child. The nurse must recognize that children need to redefine their condition and its implications as they develop and grow. For example, appearance, skills, and abilities are highly valued by peers (Figure 41.1); a teenager who is limited in any of these qualities may be subject to rejection or bullying. While bullying is a large topic at any developmental age, the need to address it in the special needs population is of particular importance, yet there are few resources available on bullying and the child with special needs (Lund & Vaughn-Jensen, 2012). Some children with special needs are aware of the bullying behaviour, while others may not realize it is occurring, because of their limited developmental capacity. Parents can ask their child about daily interactions with other children through inquiry such as "Tell me some of the nicknames the other children have for you at school," in order to detect potential bullying. (See Additional Resources at the end of this chapter for further information on bullying and the child with special needs.)

Fig. 41.1 Children with any type of impairment should have the opportunity to develop their skills. (iStock.com/SDI Productions)

Coping Mechanisms

Children with chronic conditions tend to use five distinct patterns of coping (Box 41.6). Children with more positive and accepting attitudes about their chronic illness use a more adaptive coping style characterized by optimism, competence, and compliance. They show fewer behavioural issues at home and at school. The two maladaptive coping patterns—"Feel different and withdraw" and "Are irritable and moody and act out"—are associated with poorer adaptation; children using these strategies have poorer self-concepts, more negative attitudes about their conditions, and more behavioural issues at home and at school.

Well-adapted children gradually learn to accept their physical limitations and find achievement in a variety of compensatory motor and intellectual pursuits. They function well at home, at school, and with peers. They understand their disorder, which allows them to accept their limitations, assume responsibility for care, and assist in treatment and rehabilitation regimens. They express appropriate emotions, such as sadness, anxiety, and anger, at times of exacerbation, but confidence and guarded optimism during periods of clinical stability (Figure 41.2). They are able to identify with other similarly affected individuals, promoting positive self-images and displaying pride and self-confidence in their ability to lead a productive, successful life despite their illness.

Children, particularly adolescents, are sensitive to the presence or absence of hope. Hopefulness is an internal quality that mobilizes humans into goal-directed action that may be satisfying and life

BOX 41.6 Coping Patterns Used by Children With Special Needs

Develop competence and optimism—They accentuate the positive aspects of the situation and concentrate more on what they have or can do than on what is missing or on what they cannot do; are as independent as possible

Feel different and withdraw—They see themselves as being different from other children because of the chronic health condition; view being different as negative; see self as less worthy than others; focus on things they cannot do and sometimes over-restrict activities needlessly

Are irritable and moody, act out—They use proactive and self-initiated coping behaviours, although usually counterproductive in that the behaviours are not ego enhancing or socially responsible and do not result in desired outcomes; act out irritably, which may or may not be associated with the condition's symptoms

Adhere to treatment—They take necessary medications, treatments; adhere to activity restrictions; also use behaviours that indicate developing independence (e.g., assume responsibility for taking medication)

Seek support—They talk with adults, children, physicians, and nurses; develop plans to handle issues as they occur; use downward comparison (i.e., realize that others have it worse)

Fig. 41.2 Periods of sadness and anger are appropriate in the child's adjustment to a chronic illness or complex condition, especially during exacerbations of the disorder.

sustaining. A sense of hopefulness can produce increased participation in health-seeking behaviours and an improved sense of well-being.

Health Education and Self-Care. Health education is an intervention that promotes coping. Children need information about their condition, the therapeutic plan, and how the disease or therapy might affect their particular situation. Children nearing puberty also need to understand the maturation process and how their medical condition may alter it. For example, a youngster with Crohn disease should understand that this disorder is associated with growth failure and delayed puberty; a child with diabetes needs to know that hormonal changes and increased growth will alter food and insulin requirements at this time; and a sexually active girl with sickle cell anemia or systemic lupus erythematosus needs to be aware of the risks of pregnancy. The information should not be given all at once but be timed appropriately to meet the changing needs of the youth, and it should be described and repeated as often as the situation requires.

NURSING CARE OF THE FAMILY AND CHILD WITH A CHRONIC OR COMPLEX CONDITION

Performing an Assessment

Because the nurse may meet a family during any phase of the adjustment process, several assessment areas are important. The family's ability to cope with previous stresses will influence the current situation, and answers to questions about their usual coping skills can provide insight into their ability to cope with having a child with special needs. Knowledge of concurrent stresses, such as financial, marital, and career or unemployment, will help the nurse identify families who may have fewer resources to cope with their child's needs.

Finally, awareness of family members' reactions to the child and the illness is important. Sample questions that the nurse and family can use to evaluate the support system, perception of the illness, coping mechanisms, resources, and concurrent stresses are listed in Table 41.1.

TABLE 41.1 Assessment of Factors Affecting Family Adjustment

Factors Affecting Adjustment	Assessment Questions
Available Support System	
Status of spousal or partner relationship	With whom do you talk when you have something on your mind? (If answer is not the partner, ask for the reason.)
Alternative support systems	When something is worrying you, what do you do?
	What helps you most when you are upset?
Ability to communicate	Does talking seem to help when you feel upset?
Perception of the Illness or Disability	
Previous knowledge of disorder	Have you ever heard the word (name of diagnosis) before? Tell me about it (if answer is yes).
Imagined cause of disorder	What are your thoughts about the causes of the disorder?
Effects of illness or disability on family	How has your child's illness or disability affected you and your family?
	How has your lifestyle changed?
Coping Mechanisms	
Reactions to previous crises	Tell me about a time when you've had another crisis (difficulty, bad time) in your family. How did you solve that problem?
Reactions to the child	Do you find yourself being a little more cautious with this child than with your other children?
Child-rearing practices	Do you feel as comfortable disciplining this child as your other children?
Influence of religion	Has your religion or faith been of help to you? Tell me how (if answer is yes).
Attitudes	How is this child different from the siblings or other children of similar age?
	Describe your child's personality.
	When you think of your child's future, what thoughts come to mind?
Available Resources	
	What parts of your child's care are causing the most difficulty for you or your family?
	What services are available to help?
	What services do you need that currently are not available?
Concurrent Stresses	
	What other issues are you facing now? (Be specific; ask about financial, spousal, or sibling stresses, and concerns around extended family or friends.)

Because factors affecting the family's response may change at any point during the illness, assessment must be a continuous process.

Communication. Special challenges exist in assessing the child's feelings about having a chronic condition. Chapter 30, Communicating with Children presents several approaches to encouraging a child to discuss feelings about the condition. The nurse should use a variety of communication techniques, such as drawing and play, as assessment tools rather than relying solely on parental reports. Often, children are neglected partners in their care, and their unique needs are not identified.

Children with a disability in communicating should be addressed directly whenever possible. The United Nations Convention on the Rights of the Child and People with Disabilities outlines the need for children with disabilities to be involved in discussions regarding them and their care (United Nations, 1989, 2006). Nurses can use methods of augmentative and alternative communication (for example, a communication switchboard) to speak directly with a child with communication challenges during an assessment or prior to a therapeutic intervention (Thunberg et al., 2016).

The needs of parents and siblings also should be assessed, a goal that requires flexibility in scheduling appointments to include these family members. When working parents know that their input is valuable, they will often change their work schedule to meet with a health care provider, but this may not always be possible and should be accommodated. Because siblings can be of any age, the use of appropriate communication strategies for assessment must be considered.

Providing Support at the Time of Diagnosis

The diagnosis is a critical time for parents and can influence how they perceive their health care providers throughout their child's care. Although they may not hear or remember all that is said to them, they can sense the health care provider's attitude—whether it is acceptance, rejection, hope, or despair—and this may influence their ability to absorb the shock and begin adapting to the family's altered future.

The informing session should take place in a private, comfortable setting free of distractions and interruptions, in an atmosphere where the parents feel free to express themselves. Their emotional needs can be acknowledged through acceptance of such expressions as crying, sadness, anger, and disappointment. Emotional support can be offered by having tissues available if a family member cries and demonstrating through facial and body language that this is a difficult and painful period. Although touching is a powerful expression of empathy, it must be used wisely. For example, it can prematurely inhibit free expression of feelings, especially when combined with statements such as "Everything will be all right." Nurses should be aware of cultural issues regarding touching and should always ask permission prior to providing touch.

Parents should receive the kind of information they desire; they can be asked questions such as "Do you prefer to hear detailed information?" Parents or other family members may have different preferences regarding the amount of information they wish to hear. Most parents want a clear, simple explanation of the diagnosis; a prediction of possible futures for the child; advice on what to do next; an opportunity to ask questions; a warm, sympathetic listener; and, most important, time. To determine their understanding of explanations the nurse can ask such questions as "Can you tell me in your own words what you think I told you?" or "Can you explain to me what you have heard so far? What questions do you still have at this time?" Technical terms should be clarified with simple, written definitions.

Finally, the informing conference does not end with the presentation of devastating news. Instead, the child's strengths, personality, and potential for development need to be stressed, as well as available rehabilitation efforts or treatment. Parents can be encouraged to view their experiences as a series of challenges that they are capable of handling, particularly with available professional feedback. Parents need to be assured that the nurse will be available to answer questions and provide further assistance. Because of the need for long-term follow-up, the initial informing interview is only one in a series of continuing discussions. In all interactions the family's input needs to be solicited and incorporated into the care plan.

Supporting the Family's Coping Methods

For the family to meet stresses while optimally adjusting to the child's condition, each member must be individually supported so that the family system is strong. Although the family can indefinitely support a member who is in need of assistance, its greatest strength lies in every member supporting each other. The nurse should bear in mind that the family member in greatest need is not necessarily the affected child but may be a parent or sibling who is encountering stresses that require intervention.

Parents. The nurse can provide support by being attentive to the family's responses to their child. Parents need to experience success, joy, and pride in their child in order to give the support they need. It is important for nurses to continuously examine their attitudes to determine their ability to engage in parent–professional partnerships. An essential characteristic for this partnership is the belief that parents are equal to professionals and are experts in caring for their child (see Guidelines box: Developing Successful Parent–Professional Partnerships). The nurse needs to regard parents as able, effective, competent, and capable of coping with the challenges they face.

GUIDELINES

Developing Successful Parent–Professional Partnerships

- Promote primary nursing; in nonhospital settings designate a case manager.
- Acknowledge parents' overall competence and their unique expertise with their child.
- Respect parents' time as having value equal to that of other members of child's health care team.
- Explain or define any medical, technical, or discipline-specific terms. Provide written information or diagrams to augment explanations.
- Tell families, "I am not sure" or "I don't know," when appropriate, then seek an answer if possible.
- Facilitate the family's effectiveness in team meetings (e.g., provide parents with the same information as that given other participants).

Parents can be encouraged to discuss their feelings toward their child, the impact of this event on their relationship with their spouse or partner, and associated stresses such as financial burdens. In addition, the family wage earner may have to sacrifice job opportunities to remain close to a medical facility or to avoid losing insurance benefits.

Numerous volunteer and community resources are available that provide assistance, rehabilitation, equipment, and funding for a variety of health conditions (see Additional Resources at the end of this chapter). National and local disease-oriented organizations may provide needed assistance and support to families that qualify. Staff in provincial and federal departments of health, mental health, social services, and labour may be able to help locate appropriate regional resources. Nurses should become acquainted with these resources in their communities and with vocational programs for special groups so that they can effectively guide the families who wish to access these resources.

Parent-to-parent support. Just being with another parent who has shared similar experiences can be helpful to parents. It may not need to be a parent of a child with the same diagnosis, since parents in the

process of adjusting to a child with special needs—or finding respite services, educational or rehabilitative services, special equipment vendors, and financial counselling—tread a common path.

A parent self-help group can be a means of promoting parent-to-parent support. Group members usually feel less alone and have the opportunity to observe both coping and mastery from other members. Parents' groups are also rich resources for information. Even if parents are unable to attend meetings, they can still benefit from group newsletters, blogs, and other resources that often accompany membership.

The nurse can foster parent participation in support groups by serving as a referral agent, a group advisory board member, a resource person, a group member, or an assistant in founding a group. Sometimes all that is required to start a group is identifying one or two parents as leaders; sharing with them the names, telephone numbers, and e-mail addresses of other families who have expressed both an interest and a willingness to release this information; and guiding them in how to initiate a first meeting.

The Child. Through ongoing contacts with the child, the nurse will be able to (1) observe the child's responses to the disorder, ability to function, and adaptive behaviours within the environment and with significant others; (2) explore the child's own understanding of their illness or condition; and (3) provide support while the child learns to cope with their feelings. Children should be encouraged to express their concerns rather than allowing others to express them for them, since open discussions may reduce anxiety.

One of the most important interventions is to alleviate the child's feeling of being different and normalize their life as much as possible (see Guidelines box: Promoting Normalization). Whenever possible, the nurse should assist the family in assessing the child's daily routine for indications of a need for normalizing practices. Children may also be deprived of social, recreational, and academic activities that can be accommodated by applying normalization practices. For example, home and out-of-home health-related treatments should be planned at times that interfere as little as possible with normal daily activities.

GUIDELINES

Promoting Normalization

Preparation—Prepare the child in advance for changes that may occur from the illness or disability.
Example—Tell the child in advance the possible adverse effects of medication therapy.

Participation—Include the child in as many decisions as possible, especially those relating to their care regimen.
Example—The child is responsible for taking medications or scheduling home treatments.

Sharing—Allow family members and the child's peers to be a part of the care regimen whenever possible.
Examples—Give the child their medication when the other siblings receive their vitamins.
The parent cooks the same menu for the whole family.
If the child is invited to another's home, the parent advises the family of the child's dietary restrictions.

Control—Identify areas where the child can be in control, to decrease feelings of uncertainty, passivity, and helplessness.
Example—The child identifies activities that are appropriate to their energy level and chooses to rest when fatigued.

Expectation—Apply the same family rules to the child with a chronic or complex condition as those used with the well siblings or peers.
Example—The child is disciplined, is expected to fulfill household responsibilities, and attends school in accordance with abilities.

Children who are concerned that their condition detracts from their physical attractiveness need attention focused on the positive or conventional aspects of appearance and capabilities. Health care providers can help strengthen and consolidate a child's self-image and help the child fit in with their peer group, while allowing the child to express anger, isolation, fear of rejection, feelings of sadness, and loneliness. Children need positive reinforcement for their efforts at enhancing their self-image and for any evidence of improvement. Anything that might improve a personal sense of attractiveness and contribute to a positive self-image should be used, such as makeup for a teenager with a scar, clothing that disguises a prosthesis, or a hairstyle, scarf, hat, or wig to cover a deformity or lost hair.

Siblings. The presence of a child with special needs may result in parents paying less attention to the other children in a family. Siblings may respond by developing negative attitudes toward the child or by expressing anger in different ways. The nurse can help in this situation by using anticipatory guidance—questioning the parents about what they believe is the best way to have siblings respond to the child and guiding them through ways to meet their other children's needs for attention.

Siblings may also experience embarrassment associated with having a brother or sister with a chronic illness or complex medical condition. Parents are then faced with the difficulty of responding to this embarrassment in an understanding and appropriate manner without punishing the siblings for how they feel. Parents should be encouraged to talk with the siblings about how they view their affected sibling. For example, siblings of a child who is cognitively impaired may express fears about their ability to bear normal children. Many siblings benefit from sharing their concerns with other young people who are in a similar situation. Support groups for siblings can help decrease isolation, promote expression of feelings, and provide examples of effective coping skills.

Parents may ask when and how to inform the other children in the family about a sibling's illness or disability. The answer depends on each child's level of sophistication and understanding. However, it is usually best to inform the siblings before a neighbour or other nonfamily member does so. Uninformed siblings may fantasize or develop apprehensions that are out of proportion to the child's actual condition. Furthermore, if parents choose to be silent or deceptive about the issue, they are setting a negative precedent for the siblings to follow rather than encouraging them to cope with the experience in a healthy and nurturing way.

The nurse needs to be sensitive to the reactions of siblings and, whenever possible, intervene to promote more positive adjustment. For example, siblings often mention that they are expected to take on additional responsibilities to help the parents care for the child. It is not unusual for them to express a positive reaction to assuming the extra duties but a negative response to feeling unappreciated for doing so. Such feelings can often be minimized by encouraging siblings to discuss this with their parents and by suggesting to parents ways of showing gratitude, such as an increase in allowance, special privileges, and, most significantly, verbal praise.

Teaching About the Disorder and General Health Care

Educating the family about the disorder is actually an extension of revealing the diagnosis. Teaching involves not only supplying technical information but also discussing how the condition will affect the child. Parents and other family members may be able to digest only so much information at a time. It may be helpful to provide essential information and then follow up by asking, "What else would you like to know about your child's condition?" Responding to the parents' and family's questions and concerns ensures that their information needs are met.

Activities of Daily Living. Parents also need guidance with how the condition may interfere with or alter activities of daily living, such as eating, dressing, sleeping, and toileting. One area frequently affected is nutrition. Common issues are undernutrition resulting from food being inappropriately restricted, or loss of appetite, vomiting, or motor deficits that interfere with feeding. Overnutrition may also occur, usually because of a caloric intake in excess of energy expenditure or boredom and lack of stimulation in other areas. Although the child requires the same basic nutrients as other children, daily requirements may differ. Special nutritional considerations are discussed as appropriate throughout the text.

Safe Transportation. Modifications may also be needed regarding car safety. Children with conditions such as low birth weight or orthopedic, neuromuscular, or respiratory challenges often cannot safely use conventional car restraints. For example, children with hip spica casts cannot sit properly in child safety seats (see Developmental Dysplasia of the Hip, Chapter 53). Special seating may be required or a specialized seatbelt adaptive device called an "EZ on vest." The adaptations must meet specific Canadian safety regulations. Alterations to standard car seats to accommodate the cast are not recommended because the structure may be adversely altered and fail to properly restrain the child.

If a child requires a wheelchair, the family should consult the wheelchair manufacturer for specific instructions regarding safe transportation by car. Considerations for wheelchairs used with vehicle transportation include securing both the wheelchair and the occupant in the wheelchair. Wheelchairs should be secured facing forward with tie downs at four points. The tie-down system should be dynamically crash tested, as should the occupant securement system that secures the child in the wheelchair. For example, the use of trays would not be recommended for transportation. Additional medical equipment (e.g., oxygen, monitors, or ventilators) required for travel should be anchored to the floor or underneath the vehicle seat or wheelchair. Soft padding should be added around the equipment to reduce movement. A second adult should be present to monitor the condition of a medically fragile child while travelling (Government of Canada, 2008/2013).

Primary Health Care. Children with special needs require all the usual health care recommended for any child. Attention to injury prevention, immunizations, dental health, and regular physical examinations is essential. Nurses can play an important role in reminding parents of these aspects that are so often neglected when the concern is focused on the child's chronic condition. Specific discussions of immunizations, nutrition, sleep, activity, dental health, and injury prevention are discussed in Chapter 35.

Dental and oral hygiene are even more important in children with chronic conditions such as cardiac failure, immunosuppressive disorders, and developmental disability such as cerebral palsy. Untreated dental caries can lead to painful abscesses and overwhelming infections. Parents should be referred within the child's first year of life to a qualified pediatric dental team with expertise in managing care for children with special health care needs. Some children may have developed oral aversion as a result of tube feeding or secondary to developmental conditions such as autism spectrum disorder, where they do not tolerate touch. Nurses in a hospital and community setting can help manage these challenges by ensuring oral care is part of the child's daily routine and helping parents develop ways to effectively provide oral health.

Parents also need to be aware of the importance of communicating the child's condition in the event of a medical emergency. Young children are unable to give information about their disorder, and although older children may be reliable sources, after an accident they may be physically unable to speak. Therefore, all children with any type of chronic illness or complex condition that may affect medical care should wear some type of identification, such as a MedicAlert bracelet (see Additional Resources at the end of the chapter), and carry a card in their wallet or bag that lists the medical condition(s) and a phone number as well as Internet links or instructions for accessing emergency medical records and other personal information.

Promoting Appropriate Development

Aside from having knowledge of the condition and its effect on the child's abilities, the parents need to foster appropriate development in their child. Although each stage may take longer to achieve, parents should be guided toward helping their child reach the child's full potential. Table 41.2 outlines developmental aspects of chronic illness or complex conditions along with supportive interventions. With planning and knowledge of strategies to improve the child's functional abilities, most children can live fulfilling and productive lives.

One important aspect of promoting development is to encourage the child's self-care abilities in both activities of daily living and the medical regimen. An assessment of the child's age and physical, emotional, and mental capacities, as well as the support and structure provided by the family, should be considered in determining the appropriate level of self-care in the medical regimen. Even toddlers can be involved in their own care, for example, by holding supplies for the parent during a procedure. Over time, children should be encouraged to practise greater autonomy in their own self-care.

The goal for self-care in activities of daily living should be the attainment of age-appropriate competence. Some modifications in the environment, the medical equipment, or the techniques for carrying out daily activities are often required to promote and support self-care. Effective teaching for self-care is focused at the child's own level of conceptual understanding and may be augmented by the use of dolls, other models and diagrams, simple explanations, and repetition.

Early Childhood. During infancy the child achieves basic trust through experiencing a satisfying, intimate, consistent relationship with their caregivers. However, affected children's early existence may be stressful, chaotic, and unsatisfying. Consequently, they may need more parental support and expressions of affection to achieve trust. Likewise, the parents may require assistance in finding ways to meet the infant's needs, such as how to hold a rigid or flaccid infant, how to feed a child with tongue thrust or episodes of dyspnea, and how to stimulate a child who seems incapable of achieving any skills. If hospitalizations are frequent or prolonged, every effort is made to preserve the parent–child relationship. Hospital policies should promote visitation by and involvement of families.

During early childhood the goal is to achieve separation from parents, autonomy, and initiative. The natural parental response to having a sick child is overprotection. Parents need help in realizing the importance of allowing brief separations of the child from them and from others involved in the child's care and of providing social experiences outside the home whenever possible. Respite care, which provides temporary relief for family members, can be essential in allowing caregivers time away from the daily burdens.

Young children also need the opportunity to develop independence. Frequently the child is able to learn self-help skills, such as holding the bottle, finger feeding, and removing simple articles of clothing, but the parent continues to perform the act. The nurse can guide parents to the usual milestones expected for the child. When a child is unable to perform a skill independently, functional aids should be used. With innovation, many adaptations can be implemented in children's environments to increase their mobility and independence and allow them to play like other children their age. For example, with slight

TABLE 41.2 Developmental Effects of Chronic Illness or Complex Conditions on Children

Developmental Tasks	Potential Effects of Chronic Illness or Complex Condition	Supportive Interventions
Infancy		
Develop a sense of trust	Multiple caregivers and frequent separations, especially if hospitalized	Encourage consistent caregivers in hospital or other care settings.
	Deprived of consistent nurturing	Encourage parental presence, rooming-in during hospitalization, and participation in care.
Bond, or attach, to parent	Delayed because of separation; parental grief for loss of "dream" child; parental inability to accept the condition, especially a visible defect	Emphasize healthy, perfect qualities of infant. Help parents learn special care needs of infant for them to feel competent.
Learn through sensorimotor experiences	More exposure to painful experiences than pleasurable ones	Expose infant to pleasurable experiences through all senses (touch, hearing, sight, taste, movement). Use skin-to-skin contact as appropriate.
	Limited contact with environment from restricted movement or confinement	Encourage age-appropriate developmental skills (e.g., holding bottle, finger feeding, crawling).
Begin to develop a sense of separateness from parent	Increased dependency on parent for care	Encourage all family members to participate in care to prevent overinvolvement of one member.
	Overinvolvement of parent in care	Encourage periodic respite from demands of care responsibilities.
Toddlerhood		
Develop autonomy	Increased dependency on parent	Encourage independence in as many areas as possible (e.g., toileting, dressing, feeding).
Master locomotor and language skills	Limited opportunity to test own abilities and limits	Provide gross motor skill activity and modification of toys or equipment, such as a modified swing or rocking horse.
Learn through sensorimotor experience; beginning preoperational thought	Increased exposure to painful experiences	Give choices to allow simple feeling of control (e.g., choice of what book to look at, what kind of sandwich to eat). Institute age-appropriate discipline and limit-setting. Recognize that negative and ritualistic behaviours are normal. Provide sensory experiences (e.g., water play, sandbox play, finger painting).
Preschool		
Develop initiative and purpose Master self-care skills	Limited opportunities for success in accomplishing simple tasks or mastering self-care skills	Encourage mastery of self-care skills. Provide devices that make task easier (e.g., self-dressing).
Begin to develop peer relationships	Limited opportunities for socialization with peers; may appear "like a baby" to age-mates Protection within tolerant and secure family causing child to fear criticism and withdraw	Encourage socialization (e.g., inviting friends to play, day care experience, trips to park). Provide age-appropriate play, especially associative play opportunities. Emphasize child's abilities; dress appropriately to enhance desirable appearance.
Develop sense of body image and sexual identification	Awareness of body centring on pain, anxiety, and failure Gender-role identification focused primarily on mothering skills	Encourage relationships with peers and adults.
Learn through preoperational thought (magical thinking)	Guilt (thinking they caused the illness or disability or are being punished for wrongdoing)	Help child deal with criticisms; realize that too much protection prevents child from learning to cope with realities of the world. Clarify that child's illness is not their fault or a punishment.
School Age		
Develop a sense of accomplishment	Limited opportunities to achieve and compete (e.g., many school absences, inability to join regular athletic activities)	Encourage school attendance; schedule medical visits at times other than school; encourage child to make up missed work.
Form peer relationships	Limited opportunities for socialization	Educate teachers and classmates about child's condition, abilities, and special needs. Encourage sports activities (e.g., Special Olympics). Encourage socialization (e.g., Girl Guides, Boy Scouts, 4-H Club; having a best friend or club membership).
Learn through concrete operations	Incomplete comprehension of the imposed physical limitations or treatment of the disorder	Provide child with information about their condition. Encourage creative activities.

Continued

TABLE 41.2 Developmental Effects of Chronic Illness or Complex Conditions on Children—cont'd

Developmental Tasks	Potential Effects of Chronic Illness or Complex Condition	Supportive Interventions
Adolescence		
Develop personal and sexual identity	Increased sense of feeling different from peers and reduced ability to compete with peers in appearance, abilities, special skills	Help child realize that many of the difficulties the teenager is experiencing are part of normal adolescence (rebelliousness, risk taking, lack of cooperation, hostility toward authority).
Achieve independence from family	Increased dependency on family; limited job or career opportunities	Provide instruction on interpersonal and coping skills. Encourage increased responsibility for care and management of the disease or condition (e.g., assuming responsibility for making and keeping appointment [ideally alone], sharing assessment and planning stages of health care delivery, contacting resources). Discuss planning for future and how condition can affect choices.
Form healthy sexual relationships	Limited opportunities for healthy sexual friendships; less opportunity to discuss sexual concerns with peers Increased concern with issues such as why the teen got this disorder, can they have a relationship and have a family	Encourage socialization with peers, including peers with special needs and those without special needs. Encourage activities appropriate for age (e.g., attending mixed-gender parties, sports activities, driving a car). Be alert to cues that signal readiness for information regarding implications of condition on sexuality and reproduction. Emphasize good appearance and wearing stylish clothes, use of makeup. Understand that the adolescent has the same sexual needs and concerns as any other teenager.
Learn through abstract thinking	Decreased opportunity for earlier stages of cognition impeding achievement of level of abstract thinking	Provide instruction on decision making, assertiveness, and other skills necessary to manage personal plans.

modifications, a child with physical limitations may be able to ride a tricycle (Figure 41.3).

Another critical component for normal child development is discipline. Discipline and guidance serve several purposes, such as providing children with boundaries at which to test their behaviour and teaching them socially acceptable behaviour. Resentment and hostility can arise among siblings if different standards are applied to each child. The nurse's responsibility is to help parents learn successful methods of managing a child's behaviours before they become problematic.

School Age. For school-age children, the major tasks are entry into school and achieving a sense of industry. Although the importance of school in the life of all children is well known, school absences are significantly higher among children with chronic illness than among their healthy peers. The more school absences the child experiences, the more difficult it is to resume attendance, and school phobia may result. The child should return to school as soon as possible after diagnosis or treatments.

Preparation for entry into or resumption of school is best accomplished through a team approach with the parents, child, teacher, community health nurse, and primary nurse in the hospital. Ideally, this planning should begin before hospital discharge. A structured plan should be developed, with attention to those aspects of care that must be continued during school hours, such as administration of medication or other treatments.

Children also need preparation before entering or resuming school. Having a tutor in the hospital or home as soon as children are physically able helps them realize that school will continue (Figure 41.4). They need to investigate possible answers to the many questions others will ask. One method of anticipatory preparation is to role-play, with the child as the "returned pupil" and the nurse or parent as "other

Fig. 41.3 A modified tricycle with self-adhesive straps for support, and modified seat and handle bars can help a child with disabilities gain mobility. (Disability Images/Science Source.)

Fig. 41.4 Children with special needs should continue their schooling as soon as their condition permits.

schoolmates." If the child returns to school with some obvious physical change, such as hair loss, amputation, or visible scar, the nurse might also ask questions about these alterations to prompt preparatory responses from the child.

Classroom peers also need preparation, and a joint plan involving the teacher, nurse, and child is best. At a minimum, classmates should be given a description of the child's condition, prepared for any visible changes in the child, and allowed an opportunity to ask questions. The child should have the option of attending this session. As the child's condition changes, particularly if the illness is potentially fatal, school personnel, including the students, need periodic appraisal of the child's status and preparation for what to expect.

Children with special needs should be encouraged to maintain or reestablish relationships with peers and to participate according to their capabilities in any age-appropriate activities. Programs such as the Special Olympics offer children an opportunity to compete with their peers and to achieve athletic skill. Summer camps give children with special needs the opportunity to associate with peers and develop a wide variety of skills (see Additional Resources at the end of this chapter). Children with special needs can derive enormous benefits from expressive activities, such as art, music, poetry, dance, and drama. With adaptive equipment and imagination, children can participate in a variety of activities.

Children need the opportunity to interact with healthy peers and to engage in activities with groups or clubs composed of similarly affected age-mates. Such organizations as ostomy clubs, diabetes clubs, and cerebral palsy groups share information and provide support related to the special issues the members face.

Adolescence. Adolescence can be a particularly difficult period for the teenager with special needs and for their family. All of the needs discussed previously apply to this age group as well. Developing independence or autonomy is a major task for the adolescent as planning for the future becomes a prominent concern. For these children, the emphasis in the past was on achieving independence from physical assistance. However, recent developments in the fields of special education, adolescent development, and family systems suggest that autonomy be redefined in terms of individuals' capacities to take responsibility for their own behaviour, make decisions regarding their own lives, and maintain supportive social relationships. Given this understanding, even individuals with severe impairment can be viewed as autonomous if they perceive their own needs and take responsibility for meeting them, either directly or by engaging the assistance of others. As adolescents become more autonomous, the nurse can help them articulate their needs, participate in developing their own care plan, and discover and express how others can be of greatest assistance.

Physical symptoms are high on the teenager's list of health-related concerns. Because adolescence is a time of enormous physical and emotional changes, it is important for the nurse to distinguish between body changes related to disability and those that are a result of normal body development. It can be a great comfort for teenagers with disabling conditions to know that many of the changes they experience are normal developmental outcomes.

A sense of feeling different from peers can lead to loneliness, isolation, and depression. Participation in groups of teenagers with chronic conditions or disabilities can help alleviate feelings of isolation and smooth the transition to meaningful relationships in adulthood.

Establishing Realistic Future Goals

One of the most difficult adjustments is setting realistic future goals for the child that are based on the child's own goals and values. Planning for the future should be a gradual process. All along, parents should cultivate realistic vocations for their child. For example, if children have physical disabilities, they could be directed toward undertaking intellectual, artistic, or musical pursuits. Children with developmental disabilities may need to be taught manual skills. In this way, the child's development proceeds in the direction of self-support through gainful employment.

With prolonged survival, young people with chronic illnesses must deal with new decisions and issues, such as marriage or other long-term relationships, employment, and insurance coverage. With appropriate guidance, many individuals with disabilities can attain gainful employment, marriage, and a family. For those with genetic conditions, counselling is needed regarding future offspring. Prospective partners often benefit from an opportunity to discuss their feelings about a relationship with an individual with continued health needs and possibly a limited lifespan. Health insurance coverage can be a critical issue if extra health care is needed, such as medications or treatments. Life insurance is another dilemma, especially when children have serious defects, such as congenital heart anomalies.

Transition to Adult Care

Transition to care from a pediatric- to adult-focused care environment can be stressful for the child and family. They will have developed strong relationships with the pediatric care team and must change to an environment that is more patient- than family-centric. Parents may be concerned about being left out of decisions, and the young adult may be stressed by the need to be more involved in decision making if not expected to do so up to this point. The nurse can play an important role in assisting with the transition from adherence and dependency to more independence in care (Schlucter et al., 2015). The Bristol-Myers Squibb Children's Hospital, in the United States, has developed a "My Healthy Transition Toolkit" as an aid in transitioning to increased

independence as the preadolescent-to-adolescent is ready. This model is used to help the parents and adolescent work together with the health care team so that the youth can move from being a recipient of care to being responsible for some self-management and then full management of care independently.

GENERAL CONCEPTS OF HOME CARE

Home Care Trends and Needs

In 2012, it was estimated that eight million Canadians were providing care for a family member with chronic health conditions (Sinha & Statistics Canada, Social and Aboriginal Statistics Division, 2013). Home care has become a routine option for the pediatric patient in today's health care environment, especially for the child with a chronic or complex condition. Home care involves a variety of services for people of all ages, provided in the home and community setting, that encompass health promotion and teaching, curative intervention, end-of-life care, rehabilitation, support and maintenance, social adaptation and integration, and support for family caregivers.

More importantly, home-based health care enables the family's valuable contribution to the child's overall health in their natural environment and can lead to greater parent satisfaction, improved quality of life, and a reduction in the length of hospital stays (Parab et al., 2013). A natural family environment optimizes growth and development when stress is minimal and support is optimal. Providing quality home health care for children requires professional assistance and community preparedness. The role of the community health or home care nurse in home care is to promote health and prevent disease; develop individual, family, and community relationships; build on the capacity of the individual and community; facilitate access and equity; and demonstrate professional responsibility and accountability (Community Health Nurses Association of Canada [CHNA], 2019).

The goals for home care include the following:

- Normalize the life of a child with special needs, including those with technologically complex care, in a family and community context and setting
- Minimize the disruptive impact of the child's condition on the family
- Foster the child's maximum growth and development

Improving the quality of life for both the child and the family is one of the driving forces in the effort to move technology-dependent children from the hospital to the home setting. Part of this process involves normalization, whereby, over time, families of children with chronic illness begin to perceive the child and their family life as normal (see discussion above, in the section Normalization).

Besides improved quality of life, another factor contributing to the increase in home care is the rising cost of institutionalized health care. Inpatient hospital stays have become shorter, in part because of the overwhelming cost of lengthy hospitalizations and because children who have been hospitalized have an increased risk of developing health care–acquired and antibiotic-resistant infections. Children may not be admitted to the hospital at all or are returned home as soon as possible after their illness. Likewise, a portion of the financial burden is shifted to the family. Third-party insurance may cover part or all of the costs at home. In some cases, the family may be forced to absorb the costs of certain medications, supplies, transportation, shelter, utilities, food, laundry, and housekeeping, as well as a portion of the nursing care.

Home care services are available to children and youth of a particular jurisdiction who hold valid health insurance coverage and are in possession of a valid health card for that province/territory, although services are provided on the basis of assessed need. There may be limits on the amount of service (maximum hours or visits) or type of services (e.g., respite, therapy) covered, as well as funding limits or maximum expenditures. Co-payment fees for service and income testing are a component of determining home care and community supports in several provinces and territories (Canadian Home Care Association, 2016).

High-quality home care should be universal, no matter where it is being delivered, who is delivering it, or who is receiving it (Canadian Home Care Association, 2017a). While the *Canada Health Act* does not mandate insurance coverage for home care services, the Canadian Home Care Association (2017a) has identified national harmonized principles necessary for home care. These principles provide a policy and program framework to support consistent, high-quality home care within and across jurisdictions and include the following:

- Patient- and family-centred care: Patients and their caregivers are at the centre of the planning and delivery of care.
- Accessible care: Patients and their caregivers have equitable and consistent access to appropriate care.
- Accountable care: Patient, provider, and system outcomes are managed, met, and reported.
- Evidence-informed care: Patients receive care that is informed by clinical expertise, personal values, and the best available research evidence.
- Integrated care: Patients' needs are met through coordinated clinical and service-level planning and delivery involving multiple providers and organizations.
- Sustainable care: Patients whose needs can reasonably be met in the home will receive the services and support to do so.

Home health care of children is not restricted to children with chronic and complex health care needs. Several short-term, intermittent therapies, such as dressing changes, phototherapy, chemotherapy, apnea monitoring, intravenous medication or fluid administration, and pain and symptom management, may be successfully delivered in a home setting, where the child may remain with the family, rather than in an acute care setting. In addition, home-based nutrition programs can provide a better quality of life, decrease cost of therapy, and improve survival.

Caregivers have the following four responsibilities when caring for a family member who has a chronic illness:

Managing the illness—Providing daily hands-on care, monitoring the child's medical condition, and educating others to care for the child

Identifying, accessing, and coordinating resources—Locating appropriate resources in the community to meet the needs of the child and of the family as the child's caregiver

Maintaining the family unit—Continuing to nurture the family unit: siblings' needs, partner relationships, and household maintenance

Maintaining self—Grieving the loss of the healthy child; balancing caregiver responsibilities with their own physical, emotional, mental, and personal needs; recognizing stressors and potential caregiver burnout.

Nurses need to understand the magnitude of responsibilities facing the caregiving family and assist them in finding resources to provide some respite from caring for the child in order to care for each other and maintain self and family integrity.

Effective Home Care

In providing home-based care for children, the nurse has an opportunity to assess and interact with the family in their own environment. This assessment can provide the health care team with valuable information about safety, support systems, nutrition, parenting stress, and health care practices. Such information will help determine future decisions regarding individualized care and realistic outcomes.

The pediatric home care nurse has two distinct arrangements for implementation of care. Nurses who perform *intermittent skilled nursing* visits may see different types and numbers of patients each day.

These nurses typically have an assigned patient caseload and accept responsibility for implementing the care plan. Most home visits focus on helping the patient and caregiver achieve independence with care in the home, including home care by therapists, home infusion teaching by nurses, and care management, instead of providing direct physical care. Nurses who perform *private-duty nursing*, or block nursing, are usually assigned individual patients, and they remain in the home for a predetermined time, such as an 8- or 12-hour block of time, to provide patient care. The care plan is implemented over the course of the time in the home. Required nursing skills are determined by patient needs, caregiver ability, complexity of family, and the home environment. In both types of home care, the pediatric nurse is responsible for patient and family assessment and evaluating the appropriateness of the care plan (Box 41.7).

It is vital to ensure that patients and families build a good support network and have access to resources such as social services (Box 41.8). An increasing concern in pediatric home health care is the need for a managing practitioner to oversee the home care. Shorter hospital stays have increased patients' rapid movement through the continuum of care; a patient may be seen in the emergency department or neonatal intensive care unit, then be discharged to home health without ever seeing a primary care physician. Thus, it is imperative that the provision of care for home patients involves interprofessional collaboration and communication among health care workers.

Discharge Planning

Identification of appropriate local community resources is critical to a successful transfer to home care. The ultimate goal of discharge planning is for the family to become familiar with the child's needs and to be competent in providing that care. A discharge plan should include emergency management and provision of social and emotional support.

Much of the success of home care, particularly for the child who is dependent on medical technology or who has complex medical conditions, depends on careful planning and preparation. Discharge planning must begin early; it should be based on the criteria of child and family readiness; it must be an interprofessional process, including representatives from acute care, home care, and community settings; and it must involve the family. Predischarge assessment (Box 41.9) and planning should include the following:

- The child's medical, nursing, educational, and other therapeutic needs
- Family members' (including siblings') education, coping skills, and adjustment needs
- Community readiness in areas such as accessibility of equipment, appropriate nursing and allied health personnel, educational and developmental services, respite care, and emergency plans
- Financial arrangements

BOX 41.7 Home Care Assessment

Health Care Need

Child at risk—Parental substance use; child's failure to thrive; social or family situation that is potentially detrimental to child's well-being

Chronically ill, but medically stable child with multiple care needs

Education for caregiver to provide skills

Skilled procedures—Regularly scheduled injections or infusions, dressing changes, reinforcement of home care teaching; evaluation of caregiver's skills

Technology-dependent child (e.g., ventilator or tracheostomy, home total parenteral nutrition, or enteral feedings by pump, peritoneal dialysis)

Chronically ill child with multiple skilled nursing needs, including pain symptom management and palliative care

Intervention

Regularly scheduled visits to assess patient status, evaluate home environment, teach care provider skills, determine status of growth and development, set goals with family for positive health outcomes

As-needed home visits during exacerbation of illness to assess physical status and determine appropriate intervention in collaboration with health care team

Assistance with transportation of child to ambulatory centre or practitioner's office for evaluation and diagnostic services

Regular visits of limited duration to perform skilled nursing intervention, assess parental ability and desire to perform procedure, teach procedure technique, supervise parental performance of procedure

Assessment of patient status; evaluation of safety of home environment; teaching, evaluation, and reinforcement of caregivers' skills; determination of status of growth and development; goal setting with family for positive health outcomes

Assessment of family status; evaluation of family coping skills and continued ability to manage care of child at home

BOX 41.8 Services That Support Effective Home Care

- Adequate family education and preparation
- Primary care provider willing to oversee medical aspects of home care
- Professional caregivers adequately trained in relevant nursing and communication skills
- Developmental intervention such as physiotherapy and occupational and speech therapy; early intervention
- Appropriately designed and well-maintained equipment
- Supportive therapies (e.g., respiratory therapy, pharmacy, rehabilitation services, parenteral therapy, physiotherapy, durable medical and infusion supplies, nutritional support) that are accessible and that families are able to contact when needed
- Adequate social and psychological support services
- High-quality respite care
- Appropriate home renovation
- Telephone service in the home
- Internet and computer access
- Appropriate transportation
- Appropriate locally available emergency facilities
- Competent case management services
- Safe environment (electricity, refrigeration, cleanliness)

Modified from Office of Technology Assessment (OTA), Congress of the United States. (1987). *Technology dependent children: Hospital v. home care—a technical memorandum* (OTA-TM-H-38). US Government Printing Office; Bakewell-Sachs, S., & Porth, S. (1995). Discharge planning and home care of the technology-dependent infant. *Journal of Obstetric, Gynecologic, & Neonatal Nursing 24*(1), 77–83.

BOX 41.9 Example of Predischarge Assessment for a Technology-Dependent Child

The Child's Family
Identification and training of primary caregivers
Identification and training of caregivers for respite and emergency care
Parent employment status while caring for child at home
Family financial picture, especially if one parent must stop working
Sibling preparation
Availability of psychosocial support services

Technical Equipment and Supplies for the Home
Home care company's availability and experience
Home care company's coordination of services with local health care provider and others
24-hour availability and coverage for unexpected situations

Community Nursing and Support Services
Availability, training, and experience
Adequacy of number of personnel to meet needs
Additional training of staff, if needed
24-hour availability of ambulance services and emergency medical services

Physical Environment of the Home
Adequacy of space for equipment and supplies
Heavy equipment (e.g., ventilator, oxygen tanks, compressor) accessibility
Layout of home (e.g., number of floors, stairways, room accessibility, room sizes)
Location and layout of bedrooms
Adequacy of apartment building elevator and fire escape
Telephone access
Type of transportation family uses
Possibility of modifying living space to minimize invasiveness of technology without isolating child
Adequacy of heating and cooling systems
Adequacy of electrical system to accommodate equipment

Emergency Plan
Identification and training of those involved
Written implementation plan: who, what, where, when, how (include telephone numbers)
Notification of utility companies for priority repairs and maintenance
Notification of local emergency medical facility or calling 911
Emergency drill

Primary Care Provider
Identification of local primary health care provider or pediatrician who is able to assume direct care responsibility and coordination of other care providers
Inclusion of local health care provider in discharge planning
Information needs of local health care provider before child's discharge

Creative financial planning, including negotiating arrangements with the insurance company and community programs, may be required.

! NURSING ALERT

If home care equipment is different from hospital equipment, have the portable equipment delivered to the hospital to allow family time to practise using it before discharge.

The preparation for hospital discharge and home care begins during the admission assessment. Short- and long-term goals are established to meet the child's physical and psychosocial needs. For children with complex care needs, discharge planning focuses on obtaining appropriate equipment and health care personnel for the home. It is also concerned with treatments that parents or children are expected to continue at home. In planning appropriate teaching, nurses need to assess (1) the actual and perceived complexity of the skill, (2) the parents' or child's ability to learn the skill, and (3) the parents' or child's previous or present experience with such procedures. See Family-Centred Care box: Preparation for Discharge on how to prepare the family for discharge.

FAMILY-CENTRED CARE

Preparation for Discharge

- For parents who choose to care for their child at home, planning for home care begins early in the recovery process.
- The family should become involved with the child's care as soon as they indicate an interest and ability to do so.
- They need education and support in learning to care for the child, regular follow-up observation and assessment of the home management, and planning for some respite care of the child.
- Parents need to understand that it is important to plan for periodic relief from the continual care of the child.

The teaching plan incorporates levels of learning such as observing, participating with assistance, and acting without help or guidance. The skill is divided into discrete steps, and each step is taught to the family member until it is learned. Return demonstration of the skill is requested before new skills are introduced. A record of teaching and performance provides an efficient checklist for evaluation. All families need to receive detailed *written* instructions about home care with telephone numbers for assistance before they leave the hospital. Communication between the nurse performing discharge planning and home health care is essential for ensuring a smooth transition for the child and family.

When the family member feels competent in performing the skill, they are given responsibility for the care. When possible, the family should have a transition or trial period to assume care with minimal health care supervision. This may be arranged on the unit, during a home pass, or in a facility such as a motel near the hospital. Such transitions provide a safe practice period for the family, with assistance readily available when needed, and are especially valuable when the family lives far from the hospital.

In many instances parents need only simple instructions and understanding of follow-up care. However, the often overwhelming care assumed by some families, coupled with other stressors they may be experiencing, necessitates continued professional support after discharge. A follow-up home visit or telephone call gives the nurse an opportunity to individualize care and provide information in perhaps a less stressful learning environment than the hospital. Early involvement of the home care agency in the discharge planning process promotes continuity of care and a smooth transition from hospital to home (Box 41.10). Before discharge, a care plan should be developed with interprofessional input and should address the range of needs identified as part of the comprehensive predischarge assessment. Sharing the important issues surrounding the child's and family's needs is essential. Referral summaries should be concise, specific, and factual. When numerous support services are required, periodic collaboration

BOX 41.10 Critical Home Care Referral Information

- Scheduled medications
- Durable medical equipment
- Medical supplies
- Transportation needs
- Adaptive equipment
- Respiratory therapy
- Rehabilitation therapies (occupational, physical, and speech therapy)
- Psychological counselling
- Social work referral
- Respite plans
- Key family members
- Demographic information
- Reimbursement information

among the professionals involved and the family is an excellent strategy to ensure efficient use and comprehensive delivery of services.

When providing education to the primary caregiver and family members, it is important to use materials that meet the needs and the ability of the learner. An excellent method of providing home care instructions is with video recordings. Once the family masters the procedures, consider video recording their performance; if they have a smartphone the recording can be made on the phone. Visual learning is most helpful for people who cannot read or who are not fluent in English. The video recording can also serve as a secondary support or follow-up to written instructions.

A predischarge home visit gives the home care nurse the chance to meet the family, help them assess their preparedness and the preparedness of the home environment, discuss plans for arranging the child's equipment at home (Figure 41.5), reinforce prior discharge teaching, and implement any additional teaching that may be necessary. Additional factors that should be considered in discharge planning include parents' work schedules, whether extended family are available to assist in the care, and child care arrangements for siblings.

Care Coordination (Case Management)

The concept of *care coordination* in home care for children is to link children with special home health care needs (and their families) to community services and resources in a coordinated effort to provide the child with optimum care. Care coordination has several purposes. Its primary goal is to ensure continuity for the child and family across hospital, home, educational, therapeutic, and other settings. Other goals involve facilitating timely access to services and enhancing child and family well-being (Canadian Home Care Association, 2016).

It can be challenging for parents and other caregivers of children with special health care needs to coordinate the many professionals, programs, and agencies that may be involved with their child's care (Kuo et al., 2018; Woodgate et al., 2015). The assistance of a knowledgeable case manager or service coordinator can ease the stress of navigating the various systems. Care should be coordinated among multiple providers to reduce the complexity of care for the child, reduce fragmentation of care, prevent duplication of services, and decrease the burden of care for the family. Care coordination should promote the family's role as primary decision maker and enhance the family's capability of meeting the special needs of the child and the family. Many parents take on increasing responsibility for care coordination over time; they should be encouraged and supported in this role.

In Canada there are three major issues facing children and youth who need home care: (1) lack of specialized pediatric professionals; (2) lack of timely access to services, which can result in long waits for treatment; and (3) geographic challenges to accessing service. Nurses can play a key role in helping families access the appropriate services in a way that causes as little disruption in health care as possible—for example, by acting as a key point of contact for families, connecting families to appropriate community resources, or clustering appointments with different services at a health care facility on the same day to avoid multiple visits for routine care (Dewan & Cohen, 2013).

Financial costs are another important consideration in this patient population. Families of children with special health care needs report an estimated $1 000 per year in out-of-pocket expenses related to their child's medical care, and some families pay far more (Canadian Home Care Association, 2016). Additional costs can accumulate from purchase of medical equipment and supplies, medication or nutrition requirements, travel and lodging expenses related to medical appointments, or lost days from work. Nurses can play an important role in seeking financial supports through government programs or local charitable organizations to help reduce this financial burden (Kuo et al., 2011).

A shortage of specialized home care providers for children with special medical needs is a common concern in many areas of Canada. This work has generally been devalued compared to hospital nursing care. Potential solutions to this issue include nurses maintaining close contact with a child's central care team (for example, through daily telephone consultation) and establishing stability in these roles through unionization, developing benefit plans, and providing opportunities

Fig. 41.5 **A:** An essential aspect of preparation for home care is the arrangement of equipment and supplies. **B:** The nurse in the home care setting requires expertise to care for a child who is technology dependent.

for full-time employment for community-based nurses (Manhas & Mitchell, 2012).

Role of the Nurse, Training, and Standards of Care

The home care nurse must share a level of technical expertise with the critical care nurse while being able to adapt equipment, procedures, and the nursing process to the home setting. The need for technical expertise must be matched with knowledge of child development and the ability to work creatively with the child challenged by chronic illness and technology dependence. When caring for patients in the home setting, the nurse must be comfortable making independent nursing judgements and solving problems with no immediate assistance, within the nursing scope of practice. At the same time, the nurse must have excellent interpersonal skills; an ability to work with other professionals and the family; and, most important, an ability to respect family autonomy. Being able to coordinate, facilitate, and advocate for appropriate resource allocation while considering broader determinants of health that influence the health of the child and family are vital qualities of a pediatric home care nurse. Patient outcomes are also more readily achievable with a balance of nursing skills demonstrating clinical excellence, adaptability, accountability, and the development of positive relationships with physicians, patients, and families.

FAMILY-CENTRED HOME CARE

Technology dependence, chronic illness, and complex care requirements cross social, cultural, spiritual, and economic boundaries. The goal for a home health care program for infants, children, or adolescents with chronic illness or complex conditions is the provision of community-based, culturally sensitive, comprehensive, and cost-effective health care within a nurturing home environment that maximizes the capabilities of the individual and minimizes the effects of the disabilities (Canadian Home Care Association, 2017a).

The home is the family's domain; the child is at home because the family's central role is to nurture and raise their child. The ultimate responsibility for managing the child's health, developmental, and emotional needs lies with the family. Roush and Cox (2000) have developed a framework for helping the home health care nurse understand the significance of home to the family. The three central concepts of the model are as follows:

Home as familiar—The environment where one is comfortable and at ease because of the familiarity with living arrangements and routines of home

Home as centre—The location of everyday experiences related to time, space, and one's social life

Home as protector—The environment that preserves privacy, safety, and identity

The philosophical basis for family-centred practice is the recognition that the family is the constant in the child's life, whereas the service systems and personnel within those systems fluctuate. Families have the most intimate knowledge of the child's strengths and abilities, the challenges of providing care, and the abilities and needs of other family members. Honouring the belief that no one knows the child better than the family is critical to the success of any health care plan.

Culturally Safe Care

Respect for varied family structures and for racial, ethnic, cultural, spiritual, and socioeconomic diversity among families is essential in home care (see also Chapter 2 and Chapter 31). Home care nurses work in close relationship with family members and in the family's own domain. The nurse shares in these relationships, participating in care throughout the course of illness.

The home care nurse, aware that personal values drive behaviour, must learn about the family's culture, ask questions without implying judgement, interpret the mainstream medical culture, and help families design interventions that meet their preferences (Canadian Nurses Association [CNA], 2018). When possible, culture-specific teaching materials should be used. Respect for family diversity and awareness of family developmental stages and the stages of a family's adjustment to illness in a child will assist the home care nurse in recognizing and promoting family strengths and in respecting varied coping mechanisms. Use of labels such as "dysfunctional," "difficult," and "noncompliant" can reinforce negative expectations and shape behaviours of both parents and professionals. By contrast, emphasizing, identifying, and building on family strengths and coping mechanisms can promote a central goal in nursing care of the child and family: family empowerment.

The provision of health and social supports for Indigenous children with complex care needs presents additional challenges, especially for those living on reserve. Such care involves a broad range of health care providers and government departments. On many reserves, access to health care is limited because of geography, lack of infrastructure, lack of funding for Indigenous health care, inadequate human resources, and language and cultural barriers (Canadian Home Care Association, 2017b). In order to receive appropriate medical care, Indigenous children may be forced to leave their community, family, and support networks for periods of time. The Pinaymootang First Nation community in Manitoba's Interlake Region has developed a program called "Niniijaanis Nide Program" (My Child, My Heart), which encompasses advocacy and intervention to support families of children with complex care needs between the ages of 10 months and 18 years living on reserve (Canadian Home Care Association, 2017b). Identified through the Pinaymootang First Nation's traditional belief of "love, respect and courage," the program is grounded in six key core values:

1. Children are best cared for at home and within families.
2. Special needs of children and families have to be met, as well as their basic needs.
3. Parents know their child better than anyone else and must be treated respectfully.
4. Professional supports must be coordinated and responsive to the needs of individual children and families.
5. Identified risks must be managed in ways that provide safety and good quality of life to the child and family.
6. Partnership working across disciplines and agencies is essential.

Building on these values, the goal of the My Child, My Heart program is to ensure that children with complex care needs and their families can access services without denial, delay, or disruptions (Canadian Home Care Association, 2017b). The results include improved care, socialization, and increased independence for these children with complex health needs. Parents and caregivers also have developed increased connection with their child and have learned new coping skills, and the community has experienced improvement in local capacity and enhanced access to care (Canadian Home Care Association, 2017b).

Parent–Professional Collaboration

Family-centred nursing practice is built on a foundation of parent–professional collaboration, which represents a shift from the traditional unidirectional relationships between health care providers and families. Communication with the family should be clear and respectful. The nurse should explain to families the reason for questions, particularly those they may perceive as intrusive, and should tell families who will have access to the information. The nurse must also assure families that they have a right to expect confidentiality in regard to the

data collected. When working in the home, the nurse must respect the privacy of family communications that may be overheard. It is essential that nurses adhere to the standards of practice related to privacy and confidentiality according to their provincial or territorial nursing regulatory body.

Communication with family members should include sharing with the family, in a supportive manner, complete and unbiased information about all aspects of the child's condition and care. Parents often feel overwhelming frustration related to obtaining accurate information about their child's illness and its management. Parents want information given slowly and repeated as necessary over time; they want explanations in terms they can understand; and they want the opportunity to ask questions, which should be answered in a straightforward manner. Stating "I don't know" or "I will find out" is better than pretending to know or giving excuses.

On occasion, disagreements may arise between parents and nurses over proper procedures for the child's care. Nurses should respect parental preferences in any situation that do not pose danger or risk for the child (see Family-Centred Care box: Knowledgeable Parents). It is important for the nurse to ensure that parents have adequate information in order to make an informed choice.

FAMILY-CENTRED CARE

Knowledgeable Parents

It is not unusual for parents, particularly those whose children have chronic illnesses or complex care regimens, to be more knowledgeable about their child's condition than a nurse who is assigned to the child's care. This can be disconcerting for both the parents and the nurse. It is important to remember and reinforce that, regardless of the condition, parents will always know more about their child than the professional caring for the child. The nurse and parents can set goals for care in an atmosphere of mutual respect. If the parents' goal is respite from prolonged caregiving, they are less likely to want to give long explanations about their child's care, and assistance from an experienced peer may be more appropriate for the nurse to seek. If the parents wish to maintain maximum participation in care delivery, the nurse and the parents can negotiate the collaboration.

When teaching parents to perform complex chronic care regimens at home, include teaching them to expect to know more about their child's care than professionals who may come to assist them, whether that be home health, hospital, or outpatient personnel. At the same time, assure them that various professionals who work with them will have a scientific knowledge base and a wealth of options for addressing and solving care issues from working with a multitude of families.

Teresa L. Hall, MS, RN

The Nursing Process

In the home, the family is a partner in each step of the nursing process. Assessment should address family strengths and resources. The principles of communication discussed previously need to guide data collection.

All the information gathered as part of the assessment process should be shared with the family. The nurse needs to recognize that the family's perception of their most important need will generally guide their behaviour and consume their attention and energy. Family priorities should guide the planning process.

Both short- and long-term goals should be outlined and agreed on by the child, family, and health care providers involved. The care plan should integrate various disciplines that may be involved with the child, to eliminate duplication and coordinate and consolidate care requirements. Cross-training of health care providers and an interprofessional mode of treatment can also be useful when a child has multiple and complex care requirements. For example, certain physiotherapy or occupational therapy routines may be incorporated into the child's morning nursing procedures, or speech therapy interventions may be conducted by the parent or nurse around eating times so that the entire day is not occupied by procedures. A written schedule of daily routines should be developed and followed by all caregivers.

Goals of care and achievement of established outcomes are supported by intervention strategies that reflect normalization and the interests and abilities of the child and family. Nurses can help the family explore a range of alternative strategies, services, and resources so that the family can choose the best match for their situation. Families can participate in evaluating a home care plan on several levels. Families and care providers should regularly review the goals of care and update the care plan as required. As part of the evaluation process, families should be acknowledged for their successes and accomplishments. Finally, families should be given an opportunity to evaluate individual home care nurses, the home care agency, and other service providers periodically. The evaluation should address the nurse's knowledge, skills, and respect for the family's choices. The agency should use the evaluations to improve the quality of care.

In addition to maintaining a sense of control over their child's care, families need to feel in control of their home and personal lives. For this reason, nurses should inquire about "house rules" with the family and address issues such as the physical environment, private areas in the home, responsibility for maintaining the child's environment, and interactions with siblings. One of the more important aspects of the nurse's relationship with the family is maintaining professional boundaries and a therapeutic role that is supportive but not intrusive.

Technological trends that influence the nursing process in home care include the use of laptop computers (notebooks) and personal tablets to document the home visit; smartphones or small hand-held computers that store large amounts of data, including addresses, appointments, patient tracking systems, textbooks, and pharmacological databases; Internet and e-mail services, which increase patient–practitioner accessibility and communication; and telemedicine or telehealth, which has various features, including electronic systems that can transmit physiological data directly to the practitioner via the telephone.

Safety Issues in the Home

Safety is an important consideration in child home care and should be addressed in the home care plan.

! NURSING ALERT

Arrangements should be made to ensure that, in an emergency, the family has adequate methods of communicating with properly trained emergency medical personnel, such as a telephone. A cellular phone may be used in place of a landline, but it is advisable to check with the local emergency facilities regarding policies for cell phone use and emergency 911 calls.

The telephone and electric companies (if the use of medical equipment requires electricity) must be notified that the family needs to be placed on a priority service list. In this way the family will learn of any anticipated interruptions in service and will receive priority in reinstatement of interrupted services. Prior contact with rescue squad and local emergency facility personnel can help ensure prompt and appropriate interventions if required. This is especially important if the family lives in a rural or remote location that may not be familiar to local emergency responders. It is recommended that local authorities be given a map marked with key landmarks and intersections for rapid access to the home.

Before hospital discharge, emergency protocols should be developed and reviewed with the parents and professional caregivers. Cardiopulmonary resuscitation (CPR) guidelines, if appropriate, should be posted near the child's bedside or in another accessible location. A list of emergency telephone numbers can be placed near each home phone and entered into cellular phone contact lists and should include those of the emergency medical services and fire department, emergency department, managing health care provider(s), nursing agency, and equipment vendor(s) or providers. Additional issues to consider are advance directives and out-of-hospital end-of-life care orders (which may vary by province or territory), as indicated. If the patient and family desire enforcement of an advance directive, they must follow specific guidelines, which could prevent undesired life-saving measures for children with terminal illnesses.

The activity level and curiosity of young children raise additional safety considerations in the provision of home care. All medications, needles, syringes, and contaminated materials must be securely stored well out of the reach of curious hands. Arrangements for the disposal of sharp items or contaminated materials can be made with the home health agency. Special attention should be given to childproofing the control panels on ventilators, pumps, monitors, and other equipment. The use of clear plastic tape, covers, or panels to cover control knobs or buttons reduces the risk of accidental changes in settings. Much of the medical equipment now in use has special lock-out capabilities that may be used to prevent accidentally altering settings. Electrical cords need to be kept short and out of reach, and safety covers should be used on any open outlets. Equipment should be unplugged when not in use and any wires (e.g., lead wires for an apnea monitor) stored out of reach.

Care at night poses other safety concerns. Parents or other caregivers need to be able to clearly hear monitor, ventilator, or pump alarms at night; an inexpensive intercom system or baby monitor can be used. Steps must be taken to prevent accidental strangulation by apnea, oximeter, or cardiac monitor wires or lengthy intravenous tubing during sleep.

! NURSING ALERT

Coiling extra tubing and taping it at the exit site, as well as running wires or tubes out the bottoms of pyjamas or one-piece infant suits, are precautions against strangulation.

Caregiver Stress

This burden of caregiving often leads to negative sequelae for caregivers and the family as a whole. It is not uncommon that a family member needs to stop working in order to care for their child, and significant financial burdens can also arise (Dewab & Cohen, 2013). A tool that might be helpful to assess for caregiver stress is the Caregiver Strain Index (CSI), a 13-item assessment tool designed to ascertain caregiver stress and subsequently develop appropriate strategies for individual and family coping (Onega, 2008) (see Additional Resources at the end of this chapter).

Families can be encouraged to develop coping strategies to decrease stress. Education regarding the need for and availability of respite care may assist families who have increased stress. The nurse can also assist the family to develop formal support networks in the form of involvement in online or local community social networks or informal support from other families who are in a similar situation.

PERSPECTIVES ON THE CARE OF CHILDREN AT THE END OF LIFE

Although most childhood illnesses and many injuries and other types of **trauma** respond favourably to treatment, some do not. When a child and family face a prolonged and possibly terminal illness, health care providers must confront the challenge of providing the best possible care to meet the physical, psychological, spiritual, and emotional needs of the child and family during the uncertain course of the illness and at the time of death. When death is sudden and unexpected, nurses are challenged to respond to the grief and shock that families experience and to provide comfort and support in the absence of a prior relationship.

A child who is diagnosed with a life-threatening illness or who is suffering serious, life-threatening trauma needs medical diagnosis and intervention, as well as nursing assessment and care—sometimes for a short time and sometimes over a lengthy period. Regardless of whether the child ultimately survives or dies from the condition, the principles of palliative care can and should be incorporated from the time of diagnosis, in order to provide the best possible care to both the child and family.

Principles of Palliative Care

Palliative care involves an interprofessional approach to the care of children living with or dying from chronic, complex, or potentially life-limiting conditions with a primary focus on symptom control, supportive care, and quality of life, rather than on cure or life prolongation in the absence of the possibility of a cure. The goal of palliative care is the achievement of the best possible quality of life for patients and their families.

The World Health Organization's (2021) definition of palliative care appropriate for children and their families is as follows:

- Palliative care for children is the active total care of the child's body, mind, and spirit and involves giving support to the family.
- It begins when illness is diagnosed and continues regardless of whether or not a child receives treatment directed at the disease.
- Health providers must evaluate and alleviate the child's physical, psychological, and social distress.
- Effective palliative care requires a broad interprofessional approach that includes the family and makes use of available community resources; it can be implemented successfully even if resources are limited.
- It can be provided in tertiary care facilities, in community health centres, and in children's homes.

A distinction can be made between palliative and end-of-life care. End-of-life care is a part of palliative care, but the goals of *palliative care* extend to all aspects of a patient's quality of life and can be established early in the trajectory of a patient's disease. *End-of-life care* refers to care provided in the last weeks, days, or hours of a person's life. Palliative care interventions do not serve to hasten death. Rather, they provide pain and symptom management, attention to issues faced by the child and family with regard to death and dying, and promotion of optimal functioning and quality of life during the time the child has remaining. The implementation of neonatal and pediatric palliative care consulting services within hospitals has led to enhanced quality of life and end-of-life care for children and their families and support for their care providers (Blume et al., 2014; Harrison et al., 2014).

Pediatric palliative care considers the child and family as the unit of care. The death of a child is an extremely stressful event for a family because it is out of the natural order of things. Children represent health and hope, and their death calls into question the understanding of life. An interprofessional team consisting of social workers, chaplains, nurses, personal care aides, and physicians skilled in caring for dying patients can assist the family by focusing care on the complex interactions among physical, emotional, social, and spiritual issues.

Practitioners of palliative care seek to create a therapeutic environment as homelike as possible, if not in the child's own home. Through

education and support of family members, an atmosphere of open communication is provided surrounding the child's dying process and its impact on all members of the family.

Decision Making at the End of Life

Discussions concerning the possibility that a child's illness or condition is not curable and that death is an inevitable outcome cause everyone involved a great deal of stress. Physicians, other members of the health care team, and families must consider all information regarding the child's situation in order to make decisions that all parties can agree to, particularly those that will have a profound impact on the child and family.

Ethical Considerations in End-of-Life Decision Making. A number of ethical concerns arise when parents and health care providers are deciding on the best course of care for the dying child. Many parents and health care providers are concerned that not offering treatment that would cause potential pain and suffering, but might extend life, would be considered euthanasia or assisted suicide. To eliminate such concerns, it is necessary to understand the various terms. *Euthanasia* involves an action carried out by a person other than the patient to end the life of the patient suffering from a terminal condition. This action is based on the belief that the act is "putting the patient out of their misery"; this action has also been called *mercy killing*. *Assisted suicide* is when someone provides the patient with the means to end their life and the patient uses that means to do so. The important distinction between these two actions involves who is actually acting to end the person's life.

In Canada, medical assistance in dying (MAID) is now a legal option for adult patients who have capacity to consent to end their life with assistance from a medical practitioner. According to the Canadian Criminal Code, MAID may occur in the setting of an irreversible medical condition that causes intolerable and enduring suffering or when death is "reasonably foreseeable." At present, MAID does not apply to infants, children, and adolescents in Canada. However, there may come a time when parents of children with life-limiting illnesses or severe disability and/or suffering seek the justice system's support in obtaining MAID for their child. In addition, mature minors with the capacity to consent may seek eligibility as well. If patients or parents are asking questions about MAID, nurses and other health care providers can provide factual information on the current legislation, while ensuring that consultation with palliative care providers and supportive services are being accessed to provide holistic care to families of a dying child (Davies, 2018). (For more information see Additional Resources section at the end of this chapter.)

The Canadian Nurses Association (2017) *Code of Ethics* discusses the role of the registered nurse when providing care to the dying patient, regardless of age. Such care involves:

- Fostering comfort, alleviating suffering, advocating for adequate relief of discomfort and pain, and assisting people in meeting their goals of culturally and spiritually appropriate care
- Working to relieve pain and suffering, including appropriate and effective symptom management, to allow persons receiving care to live and die with dignity
- Encouraging persons receiving care at the end of their life to be clear about what they want and listening to a person's stories to gain greater clarity about their goals and wishes

Health Care Team Decision Making. Decisions by health care providers regarding care are often made on the basis of the progression of the disease or amount of trauma, the availability of treatment options that would provide cure from disease or restoration of health, the impact of such treatments on the child, and the child's overall prognosis. Often the main determinants prompting health care providers to discuss end-of-life issues and options for children with critical illness include the child's age, premorbid cognitive condition and functional status, pain or discomfort, probability of survival, and quality of life. When the health care provider discusses this information openly with families, a shared decision-making process can occur regarding no CPR (also referred to as *do-not-resuscitate [DNR])* orders and care that is focused on the comfort of the child and family during the dying process (Tsai & Canadian Pediatric Society [CPS], Bioethics Committee, 2008/2018).

Unfortunately, many families are not given the option of terminating life-sustaining treatment and pursuing care focused on comfort and quality of life when cure is unlikely, and staff may be reluctant to raise the question of no CPR orders. This occurs for a number of reasons, including the belief that not being able to "save" a child is a "failure." Also, the physician and other members of the health care team may lack knowledge of and experience with the principles of palliative care (Sanderson et al., 2016; Tsai & CPS, Bioethics Committee, 2008/2018). At times, parental decisions do not match the health care team's recommendations. If this occurs, the team or family can request assistance from the hospital or institutional ethics committee or an ethics consultant (Coughlin & CPS, Bioethics Committee, 2018/2021).

Parental Decision Making. Rarely are families prepared to cope with the numerous decisions that must be made when a child is dying. When the death is unexpected, as in the case of an accident or trauma, the confusion of emergency services and possibly a critical care setting presents challenges to parents as they are asked to make difficult choices. If the child has either experienced a life-threatening illness such as cancer or lived with a chronic illness that has now reached its terminal phase, parents are often unprepared for the reality of their child's impending death. Numerous studies have found that families facing the impending death of a child depend on information provided to them by the health care team, particularly an honest appraisal of the child's prognosis, to make difficult decisions regarding care options for their child (Tsai & CPS, Bioethics Committee, 2008/2018).

Nurses are in an excellent position to ensure that families are presented with the relevant options available to them. The nurse's first responsibility is to explore the family's wishes related to goals of care. Nurses can explore with families what they might be hoping for in relation to the child's illness, as well as what they are worried or fearful about. Families who are hoping for a cure can also be guided to talk about other hopes, such as their child being pain free, spending more time at home, or getting to do a specific activity. Fears may include the child not being cured or being in pain. The discussion can move on to the specifics of where the family would like to receive care and the interventions that may or may not be used as part of the plan of care to both support hopes and address fears.

The Dying Child. Children need honest and accurate information about their illness, treatments, and prognosis; this information needs to be given in clear, simple language. In most situations this best occurs as a gradual process over time, characterized by increasingly open dialogue among parents, health care providers, and the child. Providing an atmosphere of open communication early in the course of an illness facilitates answering difficult questions as the child's condition worsens. Providing appropriate literature about the disease and the experience of illness and possible death is also helpful. Exactly how and when to involve children in decisions regarding care during their or a sibling's dying process and death is an individual matter. The child's age or developmental level is an important consideration in

the process (Table 41.3). In general, parents should be asked how they would like their child to be told of the prognosis, how siblings of the dying child should be informed, and how they all can be included in the child's care. Some parents may request that their child not be told that the child is dying, even if the child asks. This often places health care providers in a difficult situation. Children, even at a young age, are perceptive. Even if they are not told outright that they are dying, they realize that something is seriously wrong and that it involves them. Often, when parents are helped to understand that honesty and shared decision making between them and their child are important to the child and family's emotional health, the parents may then allow discussion of dying with their child. Parents may require professional support and guidance in this process from a nurse, social worker, or child life specialist who has a good relationship with the child and family.

TABLE 41.3 Children's Understanding of and Reactions to Death

Concepts of Death	Reactions to Death	Nursing Care
Infants and Toddlers		
Death has least significance to children less than 6 months of age. After parent–child attachment and trust are established, the loss, even if temporary, of the significant person is profound. Prolonged separation during the first several years is thought to be more significant in terms of future physical, social, and emotional growth than at any subsequent age. Toddlers are egocentric and can only think about events in terms of their own frame of reference—living. Their egocentricity and vague separation of fact and fantasy make it impossible for them to comprehend absence of life. Instead of understanding death, this age group is affected more by any change in lifestyle.	With the death of someone else, they may continue to act as though the person is alive. As children grow older, they will be increasingly able and willing to let go of the dead person. Ritualism is important; a change in lifestyle could be anxiety producing. This age group reacts more to the pain and discomfort of a serious illness than to the probable fatal prognosis. This age group also reacts to parental anxiety and sadness.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Encourage parents to remain as near to the child as possible, yet be sensitive to parents' needs. Maintain as normal an environment as possible to retain ritualism. If a parent has died, promote arrangements for a consistent caregiver for the child. Promote primary nursing.
