

Evolve®

YOU'VE JUST PURCHASED MORE THAN A TEXTBOOK!

Enhance your learning with Evolve Student Resources.

These online study tools and exercises can help deepen your understanding of textbook content so you can be more prepared for class, perform better on exams, and succeed in your course.

Activate the complete learning experience that comes with each NEW textbook purchase by registering with your scratch-off access code at

http://evolve.elsevier.com/Canada/Perry/maternal/

If your school uses its own Learning Management System, your resources may be delivered on that platform. Consult with your instructor.

If you rented or purchased a used book and the scratch-off code at right has already been revealed, the code may have been used and cannot be re-used for registration. To purchase a new code to access these valuable study resources, simply follow the link above.

Perry's Maternal Child Nursing Care in Canada

Third Edition

This page intentionally left blank

A tailored education experience — *Sherpath book-organized collections*

Sherpath is the digital teaching and learning technology designed specifically for healthcare education.

ELSEVIER

Sherpath book-organized collections offer:

Objective-based, digital lessons, mapped chapter-by-chapter to the textbook, that make it easy to find applicable digital assignment content.

Adaptive quizzing with personalized questions that correlate directly to textbook content.

Teaching materials that align to the text and are organized by chapter for quick and easy access to invaluable class activities and resources.

Elsevier ebooks that provide convenient access to textbook content, even offline.

Perry's Maternal Child Nursing Care in Canada

Third Edition

Lisa Keenan-Lindsay, RN, MN, PNC(C)
Professor, School of Nursing
Seneca College of Applied Arts and Technology
Toronto, Ontario

Cheryl A. Sams, RN, BScN, MSN
Professor Emerita, School of Nursing
Seneca College of Applied Arts and Technology
Toronto, Ontario

Constance (Connie) O'Connor, MN, RN(EC)
Nurse Practitioner
Ehlers-Danlos Syndrome (EDS)
Clinic & Connective Tissue Disorders Program
The Hospital for Sick Children (SickKids®)
Toronto, Ontario

US 6th Edition Authors

Maternity
Shannon E. Perry, RN, PhD, FAAN
Professor Emerita, School of Nursing
San Francisco State University
San Francisco, California

Deitra Leonard Lowdermilk, RNC, PhD, FAAN
Clinical Professor Emerita, School of Nursing
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Mary Catherine (Kitty) Cashion, RN-BC, MSN
Clinical Nurse Specialist, College of Medicine
Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine
University of Tennessee Health Science Center
Memphis, Tennessee

Kathryn Rhodes Alden, EdD, MSN, RN, IBCLC
Associate Professor, School of Nursing
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina

Associate Editor
Ellen F. Olshansky, PhD, RN, WHNP-BC, NC-BC, FAAN
Professor and Chair, Department of Nursing
Suzanne Dworak-Peck School of Social Work
University of Southern California
Los Angeles, California

Pediatrics
Marilyn J. Hockenberry, PhD, RN, PPCNP-BC, FAAN
Bessie Baker Professor of Nursing and Professor of Pediatrics
Associate Dean of Research Affairs, School of Nursing
Chair, Duke Institutional Review Board
Duke University
Durham, North Carolina

David Wilson, MS, RNC-NIC (deceased)
Staff
Children's Hospital at Saint Francis
Tulsa, Oklahoma

Cheryl C. Rodgers, PhD, RN, CPNP, CPON
Assistant Professor
Duke University School of Nursing
Durham, North Carolina

We are honoured to have received permission to reproduce the work "A Mother's Love," by Order of Canada award-winning Indigenous artist, Maxine Noel (Ioyan Mani), for the cover of this third Canadian edition of *Perry's Maternal Child Nursing Care in Canada.*

Maxine has lent her voice and art to projects to improve the health and well-being of Indigenous women and girls, in projects related to maternal and infant health and, in collaboration with the Native Women's Association of Canada (NWAC), in their work to raise awareness of the brutal dangers facing Indigenous women.

PART 1 Maternal Child Nursing

UNIT 1 Introduction to Maternal Child Nursing

1 Contemporary Perinatal and Pediatric Nursing in Canada, 2
Erica Hurley
- **Perinatal and pediatric nursing, 2**
- **The history and context of health care in Canada, 2**
- **Contemporary issues and trends, 3**
  - *Social Determinants of Health, 3*
  - *Trauma- and Violence-Informed Care, 6*
  - *Adverse Childhood Experiences, 7*
  - *Indigenous People, 7*
  - *Lesbian/Gay/Bisexual/Transsexual/Queer/2-Spirited (LGBTQ2) Health, 7*
  - *Culture, 8*
  - *Integrative Healing and Alternate Health Practices, 8*
  - *High-Technology Care, 8*
  - *Social Media, 8*
  - *Health Literacy, 9*
- **Specialization and evidence-informed nursing practice, 9**
  - *Evidence-Informed or Research-Based Practice, 9*
  - *Standards of Practice and Legal Issues in Delivery of Care, 10*
  - *Patient Safety and Risk Management, 10*
  - *Interprofessional Education, 10*
- **Global health, 10**
  - *Sustainable Development Goals, 10*
- **Ethical issues in maternal child nursing, 12**
  - *Ethical Guidelines for Nursing Research, 12*
- **Key points, 12**
- **References, 13**
- **Additional resources, 14**

2 The Family and Culture, 15
Karen MacKinnon
Originating US Chapter by *Shannon E. Perry*
- **The family in cultural and community context, 15**
  - *The Family in Society, 15*
  - *Defining Family, 15*
  - *Family Dynamics, 16*
- **Family nursing, 17**
  - *Theories as Guides to Understanding and Working With Families, 17*
  - *Family Assessment, 18*
  - *Family Nursing as Relational Inquiry, 19*
- **Cultural factors related to health, 20**
  - *Multiculturalism in Canada, 20*
  - *Cultural Context of the Family, 21*
  - *Providing Culturally Competent Nursing Care, 21*
  - *Spirituality, 23*
  - *Communication, 23*
  - *Personal Space, 24*
  - *Time Orientation, 24*
  - *Family Roles, 24*
- **Key points, 25**
- **References, 26**
- **Additional resources, 26**

3 Community Care, 27
Judy Buchan
- **Roles and Functions of Community Health Nurses, 28**
  - *Core Competencies, 28*
  - *Public Health Decision Making, 28*
  - *Community Health Promotion, 29*
- **Communities, 31**
  - *Community Nursing Process, 31*
  - *Implications for Nursing, 34*
- **Home Care in the Community, 35**
  - *Patient Selection and Referral, 35*
  - *Nursing Care, 35*
  - *Phone and Online Health Support, 37*
- **Key Points, 38**
- **References, 38**
- **Additional Resources, 39**

PART 2 Perinatal Nursing

UNIT 2 Introduction to Perinatal Nursing

4 Perinatal Nursing in Canada, 42
Lisa Keenan-Lindsay
- **Perinatal services in canada, 42**
- **Family-centred maternity and newborn care, 44**
  - *Promoting Healthy and Normal Birth, 44*
  - *Caring for Families, 45*
  - *Providing Care in a Culturally Safe Manner, 45*
  - *Care Environment, 47*
- **Perinatal health indicators: the canadian perinatal surveillance system, 48**
  - *Childbirth-Related Mortality Rate, 49*
  - *Maternal Morbidity, 49*
  - *Trends in Fertility and Birth Rate, 49*
  - *Multiple Birth Rate, 49*

Preterm Birth and Birth Weight, 49
Health Service Indicators, 50
Current issues affecting perinatal nursing practice, 50
Health Inequities Within Perinatal Populations, 50
Interprofessional Care, 51
Breastfeeding in Canada, 51
Community-Based Care, 51
Global Health, 52
Key points, 52
References, 52
Additional resources, 53

UNIT 3 Women's Health

5 Health Promotion, 54
Kerry Lynn Durnford
Originating US Chapter by *Ellen F. Olshansky*
Reasons for entering the health care system, 54
Wellness Care Across the Lifespan, 54
Approaches to care at specific stages during the lifespan, 56
Fertility Control and Infertility, 56
Preconception Counselling and Care, 56
Pregnancy, 56
Menstrual Concerns, 56
Perimenopause and Menopause, 56
Barriers to receiving health care, 56
Financial Issues, 57
Cultural Issues, 58
Gender Issues, 58
Risk factors that impact health, 58
Substance Use, 58
Nutrition, 61
Lack of Exercise, 62
Stress, 63
Depression, Anxiety, and Other Mental Health Conditions, 63
Sleep Disorders, 63
Environmental and Workplace Hazards, 64
Sexual Practices, 64
Medical Conditions, 64
Gynecological Conditions, 65
Female Genital Cutting, 65
Human Trafficking, 65
Intimate Partner Violence, 65
Health promotion and illness prevention, 68
Health Screening for Women Across the Lifespan, 68
Health teaching, 70
Domains of Learning, 70
Adult Learning, 70
Learning Styles, 70
Teaching Methods, 71
Factors That Influence Learning, 72
Key points, 72
References, 72
Additional resources, 74

6 Health Assessment, 75
Lisa Keenan-Lindsay
Originating US Chapter by *Ellen F. Olshansky*
Health assessment, 75
History, 75
Physical Examination, 77
Cultural Considerations and Communication Variations in History and Physical, 77
Adolescents (Ages 13 to 19), 78
Women With Disabilities, 78
Women at Risk for Abuse, 78
Transsexuality, 79
Breast Assessment, 79
Pelvic Examination, 79
Laboratory and Diagnostic Procedures, 84
Key points, 84
References, 84
Additional resources, 84

7 Reproductive Health, 85
Lisa Keenan-Lindsay
Originating US Chapter by *Ellen F. Olshansky*
Female reproductive system, 85
External Structures, 85
Internal Structures, 86
The Bony Pelvis, 88
Breasts, 89
Menstruation, 90
Menarche and Puberty, 90
Menstrual Cycle, 90
Concerns related to the menstrual cycle, 92
Amenorrhea, 92
Dysmenorrhea, 93
Premenstrual Syndrome, 96
Endometriosis, 97
Alterations in Cyclic Bleeding, 98
Abnormal Uterine Bleeding, 99
Perimenopause and menopause, 99
Infections, 100
Sexually Transmitted Infections, 100
Sexually Transmitted Bacterial Infections, 103
Sexually Transmitted Viral Infections, 107
Vaginal Infections, 112
Concerns of the breast, 114
Benign Problems, 114
Cancer of the Breast, 115
Key points, 118
References, 118
Additional resources, 120

8 Infertility, Contraception, and Abortion, 121
Lisa Keenan-Lindsay
Originating US Chapter by *Ellen F. Olshansky*
Infertility, 121
Incidence, 121
Factors Associated With Infertility, 121
Nursing Care, 123
Nonmedical Treatments, 126
Medical Therapy, 126

Assisted Human Reproduction, 127
LGBTQ2 Couples, 129
Adoption, 129
Contraception, 129
Nursing Care, 130
Methods of Contraception, 130
LGBTQ2 Issues Regarding Contraception, 145
Abortion, 145
Nursing Care, 145
First-Trimester Abortion, 146
Second-Trimester Abortion, 147
Emotional Considerations Regarding Abortion, 147
Key points, 147
References, 147
Additional resources, 148

UNIT 4 Pregnancy

9 Genetics, Conception, and Fetal Development, 149
Lisa Keenan-Lindsay
Originating US Chapter by *Ellen F. Olshansky*
Genetics, 149
Relevance of Genetics to Nursing, 150
Gene Identification and Genetic Testing, 150
Clinical Genetics, 151
Patterns of Genetic Transmission, 154
Genetic Counselling, 155
Nongenetic Factors Influencing Development, 157
Process of conception, 157
Cell Division, 157
Gametogenesis, 157
Conception, 159
Implantation, 160
The embryo and fetus, 160
Primary Germ Layers, 160
Development of the Embryo, 160
Membranes, 162
Amniotic Fluid, 163
Yolk Sac, 163
Umbilical Cord, 163
Placenta, 163
Fetal Maturation, 165
Multifetal Pregnancy, 169
Key points, 173
References, 174
Additional resources, 174

10 Anatomy and Physiology of Pregnancy, 175
Lisa Keenan-Lindsay
Originating US Chapter by *Kathryn R. Alden*
Obstetrical terminology, 175
Pregnancy tests, 176
Adaptations to pregnancy, 177
Signs of Pregnancy, 177
Reproductive System and Breasts, 177
General Body Systems, 182
Key points, 191
References, 191

11 Nursing Care of the Family During Pregnancy, 192
Nancy Watts
Originating US Chapter by *Kathryn R. Alden*
Confirmation of pregnancy, 192
Signs and Symptoms, 192
Estimating Date of Birth, 193
Adaptation to pregnancy, 193
Maternal Adaptation, 193
Paternal Adaptation, 195
Adaptation to Parenthood for the Nonpregnant Partner, 196
Sibling Adaptation, 196
Grandparent Adaptation, 197
Nursing care, 198
Initial Visit, 199
Follow-up Visits, 203
Nursing Interventions, 206
Variations in Prenatal Care, 219
Perinatal care choices, 222
Physicians, 222
Midwives, 223
Doula, 223
Birth Setting Choices, 223
Prenatal education, 225
Childbirth Education Classes, 225
Birth Plans, 226
Key points, 226
References, 226
Additional resources, 228

12 Maternal Nutrition, 229
Jennifer Buccino
Originating US Chapter by *Ellen F. Olshansky*
Preconception nutrition, 229
Nutrient needs during pregnancy, 230
Energy Needs, 230
Protein, 233
Fluids, 233
Omega-3 Fatty Acids, 233
Minerals, Vitamins, and Electrolytes, 234
Weight Gain, 236
Nutritional Concerns During Pregnancy, 238
Nursing Care, 239
Key points, 243
References, 243
Additional resources, 244

13 Pregnancy Risk Factors and Assessment, 245
Nancy Watts
Originating US Chapter by *Kitty Cashion*
Definition and scope of high-risk pregnancy, 245
Determinants of Health as Risk Factors, 246
Regionalization of Health Care Services, 246
Assessment of risk factors, 246
Mental Health Concerns, 246
Intimate Partner Violence (IPV) During Pregnancy, 248
Reducing Infant Morbidity and Mortality, 249

Antepartum testing in the first and second trimester, 249
Prenatal Screening, 249
Biochemical Assessment, 253
Third-trimester assessment for fetal well-being, 256
Fetal Movement Counting, 257
Antepartum Assessment Using Electronic Fetal Monitoring, 257
Ultrasound for Fetal Well-Being, 260
Nursing role in antenatal assessment for risk, 261
Psychological Considerations, 261
Key points, 263
References, 263
Additional resources, 264

14 Pregnancy at Risk: Gestational Conditions, 265
Melanie Basso
Originating US Chapter by *Kitty Cashion*
Hypertensive disorders in pregnancy, 265
Significance and Incidence, 265
Definition of Hypertensive Disorder of Pregnancy, 265
Morbidity and Mortality, 266
Classification, 266
Nursing Care, 270
Gestational diabetes mellitus, 276
Maternal and Fetal Risks, 276
Screening for Gestational Diabetes Mellitus, 276
Nursing Care, 276
Hyperemesis gravidarum, 278
Etiology, 278
Clinical Manifestations, 279
Nursing Care, 279
Hemorrhagic disorders, 280
Early Pregnancy Bleeding, 280
Late Pregnancy Bleeding, 288
Clotting Disorders in Pregnancy, 293
Infections acquired during pregnancy, 295
Sexually Transmitted Infections, 295
Urinary Tract Infections, 295
Nonobstetrical surgery during pregnancy, 296
Appendicitis, 296
Intestinal Obstruction, 297
Cholelithiasis and Cholecystitis, 297
Gynecological Concerns, 297
Nursing Care, 297
Trauma during pregnancy, 298
Maternal Physiological Characteristics, 298
Fetal Physiological Characteristics, 299
Mechanisms of Trauma, 300
Collaborative Care, 300
Cardiopulmonary Resuscitation of the Pregnant Patient, 302
Perimortem Caesarean Birth, 304
Key points, 304
References, 304
Additional resources, 306

15 Pregnancy at Risk: Pre-existing Conditions, 307
Melanie Basso
Originating US Chapter by *Kitty Cashion*
Metabolic disorders, 307
Diabetes Mellitus, 307
Pregestational Diabetes Mellitus (PGDM), 309
Thyroid Disorders, 317
Cardiovascular disorders, 318
Congenital Cardiac Diseases, 319
Acquired Cardiac Disease, 320
Ischemic Heart Disease, 321
Other Cardiac Conditions, 321
Nursing Care, 323
Antepartum, 323
Intrapartum, 324
Postpartum, 325
Obesity, 325
Antepartum Risks, 326
Nursing Care, 326
OTHER MEDICAL CONDITIONS IN PREGNANCY, 326
Anemia, 326
Pulmonary Disorders, 328
Integumentary Disorders, 330
Neurological Disorders, 331
Autoimmune Disorders, 333
Spinal Cord Injury, 335
Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome, 335
Substance use, 337
Barriers to Treatment, 337
Legal Considerations, 337
Nursing Care, 338
Key points, 339
References, 340
Additional resources, 342

UNIT 5 Childbirth

16 Labour and Birth Processes, 343
Lisa Keenan-Lindsay
Originating US Chapter by *Kitty Cashion*
Factors affecting labour, 343
Passenger, 343
Passageway, 346
Powers, 348
Position of the Labouring Patient, 350
Process of labour, 350
Signs Preceding Labour, 350
Onset of Labour, 351
Stages of Labour, 351
Mechanism of Labour, 351
Physiological adaptation to labour, 353
Fetal Adaptation, 353
Adaptation of Labouring Person, 353
Key points, 354
References, 355

17 Nursing Care of the Family During Labour and Birth, 356
Karen Pike
Originating US Chapter by *Kitty Cashion*
First stage of labour, 356
Nursing Care During Prelabour and the First Stage of Labour, 357
Supportive Care During Labour and Birth, 373
Emergency Interventions, 378
Second stage of labour, 378
Nursing Care During the Second Stage of Labour, 379
Mechanism of Birth: Vertex Presentation, 385
Perineal Trauma Related to Childbirth, 385
Water Birth, 389
Immediate Assessments and Care of the Newborn, 389
Third stage of labour, 390
Nursing Care During the Third Stage of Labour, 390
Umbilical Cord Blood Banking, 392
Fourth stage of labour, 393
Nursing Care During the Fourth Stage of Labour, 393
Family–Newborn Relationships, 394
Key points, 395
References, 395
Additional resources, 397
18 Maximizing Comfort During Labour and Birth, 398
Laura Payant
Originating US Chapter by *Kitty Cashion*
Pain during labour and birth, 398
Neurological Origins, 398
Perception of Pain, 399
Expression of Pain, 399
Factors Influencing Pain Response, 399
Nonpharmacological Pain Management, 402
Pharmacological Pain Management, 407
Nursing Care, 417
Key points, 422
References, 422
Additional resources, 423
19 Fetal Health Surveillance During Labour, 424
Lauren B. Rivard
Fetal health surveillance, 424
Basis for monitoring, 424
Fetal Response, 424
Uterine Activity, 425
Fetal Assessment, 426
Monitoring techniques, 426
Intermittent Auscultation, 427
Electronic Fetal Monitoring, 429
Admission Fetal Monitor Strips, 432
Fetal heart rate patterns, 432
Baseline Fetal Heart Rate, 432
Fetal Heart Rate Variability, 434
Periodic and Episodic Changes in Fetal Heart Rate, 434
Nursing Care, 440
Additional Methods of Assessment and Intervention, 442
Fetal Scalp Blood Sampling, 442
Umbilical Cord Acid–Base Determination, 443
Amnioinfusion, 443
Documentation, 443
Key points, 444
References, 445
20 Labour and Birth at Risk, 446
Jodie Bigalky
Originating US Chapter by *Kitty Cashion*
Preterm labour and birth, 446
Preterm Birth Versus Low Birth Weight, 446
Spontaneous Versus Indicated Preterm Birth, 447
Spontaneous Preterm Labour and Birth Risk Factors, 447
Predicting Spontaneous Preterm Labour and Birth, 448
Nursing Care, 448
Premature rupture of membranes, 454
Nursing Care, 454
Chorioamnionitis, 454
Post-term pregnancy, labour, and birth, 455
Post-Term Risks, 455
Collaborative Care, 455
Dystocia, 456
Abnormal Uterine Activity (Alteration in Power), 456
Alterations in Pelvic Structure (Passageway), 457
Fetal Causes (Passenger), 458
Position of the Labouring Patient, 459
Psychological Responses, 459
Nursing Care, 459
Precipitous labour, 460
Obesity, 460
Intrapartum and Postpartum Risks, 460
Nursing Care, 460
Multifetal pregnancy, 461
Obstetrical procedures, 461
Version, 461
Induction of Labour, 462
Augmentation of Labour, 468
Operative Vaginal Births, 469
Caesarean Birth, 470
Trial of Labour After Caesarean (TOLAC), 476
Obstetrical emergencies, 477
Meconium-Stained Amniotic Fluid, 477
Shoulder Dystocia, 478
Prolapsed Umbilical Cord, 479
Rupture of the Uterus, 479
Amniotic Fluid Embolism, 481
Key points, 481
References, 482
Additional resources, 483

UNIT 6 Postpartum Period

21 Physiological Changes in the Postpartum Patient, 484
Lisa Keenan-Lindsay
Originating US Chapter by *Kathryn R. Alden*
Reproductive system and associated structures, 484
Uterus, 484
Cervix, 486
Vagina and Perineum, 486
Abdomen, 486
Endocrine system, 486
Placental Hormones, 486
Metabolic Changes, 487
Pituitary Hormones and Ovarian Function, 487
Urinary system, 487
Urine Components, 487
Fluid Loss, 487
Urethra and Bladder, 488
Gastrointestinal system, 488
Breasts, 488
Breastfeeding Mothers, 488
Nonbreastfeeding Mothers, 488
Cardiovascular system, 488
Blood Volume, 488
Cardiac Output, 489
Varicosities, 490
Respiratory system, 490
Neurological system, 490
Musculoskeletal system, 490
Integumentary system, 490
Immune system, 490
Key points, 490
References, 491

22 Nursing Care of the Family During the Postpartum Period, 492
Keri-Ann Berga
Originating US Chapter by *Kathryn R. Alden*
Transfer from the recovery area, 492
Planning for discharge, 493
Nursing care, 494
Ongoing Physical Assessment, 494
Nursing Interventions, 494
Psychosocial Assessment and Care, 505
Discharge Teaching, 507
Follow-up After Discharge, 509
Key points, 510
References, 510
Additional resources, 511

23 Transition to Parenthood, 512
Keri-Ann Berga
Parental attachment, bonding, and acquaintance, 512
Assessment of Attachment Behaviours, 513
Parent–infant contact, 516
Early Contact, 516
Extended Contact, 516
Communication between parent and infant, 516
The Senses, 516
Entrainment, 517
Biorhythmicity, 517
Reciprocity and Synchrony, 518
Parental role after birth, 518
Transition to Parenthood, 518
Parental Tasks and Responsibilities, 518
Becoming a Mother, 519
Becoming a Father, 520
Adjustment for the Couple, 521
Infant–Parent Adjustment, 521
Rhythm, 521
Behavioural Repertoires, 522
Responsivity, 522
Sibling adaptation, 522
Grandparent adaptation, 523
Diversity in transitions to parenthood, 524
Age, 524
Parenting Among LGBTQ2 Couples, 525
Social Support, 526
Culture, 527
Indigenous Families, 527
Socioeconomic Conditions, 527
Personal Aspirations, 528
Parental sensory impairment, 528
Visually Impaired Parent, 528
Hearing-Impaired Parent, 528
Nursing care, 529
Key points, 530
References, 530
Additional resources, 531
Fathering resources, 531

24 Postpartum Complications, 532
Janet Andrews
Originating US Chapter by *Kathryn R. Alden*
Postpartum hemorrhage, 532
Definition and Incidence, 532
Etiology and Risk Factors, 533
Collaborative Care, 535
Hemorrhagic (Hypovolemic) Shock, 537
Venous thromboembolic disorders, 539
Incidence and Etiology, 540
Clinical Manifestations, 540
Collaborative Care, 540
Postpartum infections, 541
Endometritis, 541
Wound Infections, 541
Urinary Tract Infections, 542
Mastitis, 542
Nursing Care, 542
Perinatal mood disorders, 543
Perinatal Anxiety Disorders, 544
Perinatal Depression, 544
Postpartum Psychosis, 545
Interdisciplinary and Nursing Care, 545
Loss and grief, 551
Grief Responses, 552
Family Aspects of Grief, 554
Nursing Care, 555
Maternal death, 558

Key points, 559
References, 559
Additional resources, 560

UNIT 7 Newborn

25 Physiological Adaptations of the Newborn, 561
Jennifer Marandola
Originating US Chapter by *Kathryn R. Alden*
Transition to extrauterine life, 561
Physiological adjustments, 561
Respiratory System, 561
Cardiovascular System, 563
Hematopoietic System, 565
Thermogenic System, 566
Renal System, 568
Gastrointestinal System, 568
Hepatic System, 570
Immune System, 573
Integumentary System, 573
Reproductive System, 575
Skeletal System, 576
Neuromuscular System, 578
Behavioural adaptations, 578
Sleep–Wake States, 579
Other Factors Influencing Behaviour of Newborns, 580
Sensory Behaviours, 580
Response to Environmental Stimuli, 581
Key points, 581
References, 581
Additional resource, 582

26 Nursing Care of the Newborn and Family, 583
Jennifer Marandola
Originating US Chapter by *Kathryn R. Alden*
Birth through the first 2 hours, 583
Nursing Care, 583
Immediate Care After Birth, 583
Interventions, 584
Care of the newborn from 2 hours after birth until discharge, 588
Nursing Care, 588
Common Newborn Concerns, 608
Laboratory and Screening Tests, 612
Interventions, 615
Pain in the Newborn, 618
Promoting Parent–Newborn Interaction, 621
Discharge Planning and Teaching, 622
Key points, 630
References, 630
Additional resources, 632

27 Newborn Nutrition and Feeding, 633
Marina Green and Kim Dart
Originating US Chapter by *Kathryn R. Alden*
Recommended infant nutrition, 634
Breastfeeding Rates, 634
The Importance of Breastfeeding, 634
Contraindications to Breastfeeding, 634
The Baby-Friendly Initiative, 635
Informed Decisions About Infant Feeding, 636
Cultural Influences on Infant Feeding, 637
Lactation and LGBTQ2 Families, 638
Nutrient needs, 638
Fluids, 638
Energy, 638
Carbohydrates, 638
Fat, 638
Protein, 639
Vitamins, 639
Minerals, 639
Anatomy and physiology of lactation, 639
Breast Anatomy, 639
Lactogenesis, 640
Uniqueness of Human Milk, 641
Nursing care, 641
Pregnancy, 641
Early Postpartum, 641
Common Breastfeeding Concerns, 657
Follow-up After Hospital Discharge, 660
Formula-feeding, 660
Parent Education, 660
Readiness for Feeding, 660
Feeding Patterns, 660
Complementary feeding: introducing solid foods, 664
Key points, 664
References, 664
Additional resources, 666
Human Milk Banking Information, 666

28 Infants With Gestational Age–Related Conditions, 667
Jennifer Young
Originating US Chapter by *Debbie Fraser*
Preterm and post-term infants, 667
The Preterm Infant, 667
Late Preterm Infant, 667
Nursing Care, 668
Complications of Prematurity, 681
The Post-Term Infant, 684
Meconium Aspiration Syndrome, 684
Persistent Pulmonary Hypertension of the Newborn, 684
Other concerns related to gestation, 685
Small-for-Gestational-Age Infants and Intrauterine Growth Restriction, 685
Large-for-Gestational-Age Infants, 685
Infants of Diabetic Mothers, 685
Discharge planning and transport, 687
Discharge Planning, 687
Transport to a Regional Centre, 687
Key points, 688
References, 688
Additional resources, 690

29 The Newborn at Risk: Acquired and Congenital Conditions, 691
Jennifer Young
Originating US Chapter by *Debbie Fraser*
Injuries associated with birth, 691

Skeletal Injuries, 691
Peripheral Nervous System Injuries, 692
Central Nervous System Injuries, 693
Newborn infections, 695
Sepsis, 695
Nursing Care, 696
Congenital infections, 697
Chlamydia Infection, 697
Cytomegalovirus Infection, 697
Gonorrhea, 701
Group B Streptococcus, 701
Hepatitis B Virus (HBV), 701
Herpes, 701
Human Immunodeficiency Virus (Type 1), 701
Parvovirus B19, 702
Rubella Infection, 702
Syphilis, 702
Tuberculosis, 702
Varicella Zoster, 702
Zika, 702
Candidiasis, 702
Nursing Care, 703
Adverse exposures affecting newborns, 703
Neonatal Abstinence Syndrome, 703
Opioid Exposure, 704
Alcohol Exposure, 706
Tobacco and Nicotine Exposure, 707
Cannabis Exposure, 707
Cocaine Exposure, 707
Methamphetamine Exposure, 707
Selective Serotonin Reuptake Inhibitors, 708
Nursing Care, 708
Hematological disorders, 708
Blood Incompatibility, 708
Other Hemolytic Disorders, 710
Congenital anomalies, 711
Newborn screening for disease, 711
Inborn Errors of Metabolism, 711
Genetic Evaluation and Counselling, 713
Nursing Care of Parents and Family, 713
Key points, 713
References, 714

PART 3 Pediatric Nursing

UNIT 8 Children, Their Families, and the Nurse

30 Pediatric Nursing in Canada, 718
Cheryl Sams and Lisa Keenan-Lindsay
Children's health in canada, 718
Childhood Mortality, 719
Childhood Morbidity, 719
Social Determinants of Health, 719
Health Inequities Among Children, 720
Food Insecurity, 720
Health Promotion, 720
Immunizations, 720
Antimicrobial Resistance, 721
Childhood Injuries, 722
Violence, 722
Toxic Stress, 722
Mental Health, 722
Substance Use, 723
The art of pediatric nursing, 723
Philosophy of Care, 723
Family-Centred Care, 723
Atraumatic Care, 724
Therapeutic Relationships, 725
Family Advocacy and Caring, 730
Disease Prevention and Health Promotion, 730
Health Teaching, 730
Coordination and Collaboration, 732
Health Care Planning, 732
Future Trends, 733
Key points, 733
References, 733
Additional resources, 734

31 Family, Social, and Cultural Influences on Children's Health, 735
Valerie Bertoni
Originating US Chapter by *Marilyn J. Hockenberry*
Pediatric nursing and the family, 735
Family Nursing Interventions, 735
Families' Roles, Relationships, and Strengths, 735
Parental Roles, 736
Role Learning, 736
Special Parenting Situations, 737
Social and Cultural factors that impact health, 741
Social Determinant Influences, 741
The Child and Family in North America, 743
Understanding cultures in the health care encounter, 744
Bridging the Gap, 744
Health beliefs and practices, 745
Health Beliefs, 745
Health Practices, 745
Key points, 747
References, 747
Additional resources, 748

32 Developmental Influences on Child Health Promotion, 749
Constance O'Connor
Originating US Chapter by *Marilyn J. Hockenberry*
Foundations of growth and development, 749
Stages of Development, 749
Patterns of Growth and Development, 749
Biological Growth and Physical Development, 751
Physiological Changes, 753
Nutrition, 753
Temperament, 754
Development of personality and cognitive function, 755
Theoretical Foundations of Personality Development, 756

Development of Self-Concept, 759
Role of play in development, 759
Content of Play, 759
Social Character of Play, 760
Functions of Play, 761
Toys, 762
Selected factors that influence development, 762
Heredity, 762
Neuroendocrine Factors, 763

UNIT 9 Assessment of the Child and Family

33 Pediatric Health Assessment, 767
Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*
History taking, 767
Performing a Health History, 767
Identifying Information, 767
Presenting Health Issue or Concern, 767
History, 768
Family Health History, 770
Psychosocial History, 772
Review of Systems, 772
Performing a Nutritional Assessment, 773
Developmental assessment, 777
Health supervision guides, 778
Rourke Baby Record, 778
Greig Health Record, 778
General approaches toward examining the child, 778
Sequence of the Examination, 779
Preparation of the Child, 779
Physical Examination, 780
Vital Signs, 783
General Appearance, 788
Skin, 789
Lymph Nodes, 790
Head and Neck, 790
Eyes, 791
Ears, 794
Nose, 798
Mouth and Throat, 798
Chest, 799
Lungs, 800
Heart, 802
Abdomen, 803
Genitalia, 805
Anus, 807
Back and Extremities, 807
Neurological Assessment, 808
Key points, 811
References, 812
Additional resources, 812

34 Pain Assessment and Management, 813
Jennifer Tyrrell and Lorraine Bird
Originating US Chapter by *Marilyn J. Hockenberry*
Pain Assessment, 813
Assessment of Acute Pain, 813
Assessment of Chronic (Persistent) and Recurrent Pain, 820
Global Judgement of Improvement and of Satisfaction With Treatment, 821
Pain Assessment in Specific Populations, 821
Pain Management, 822
Physical Recovery, 822
Mind–Body Pain Management Strategies, 822
Complementary and Alternative Medicine (CAM), 824
Pharmacological Management, 824
Common Pain States in Children, 835
Painful and Invasive Procedures, 835
Procedural Sedation and Analgesia, 835
Postoperative Pain, 835
Burn Pain, 836
Recurrent Headaches in Children, 836
Recurrent Abdominal Pain in Children, 837
Pain in Children With Sickle Cell Disease, 837
Cancer Pain in Children, 837
Pain and Sedation in End-of-Life Care, 838
Key Points, 838
References, 839
Additional Resources, 841

UNIT 10 Health Promotion and Developmental Stages

35 Promoting Optimum Health During Childhood, 842
Cheryl Sams, Mollie Lavigne, Lisa Keenan-Lindsay, and With contributions from *Cheryl C. Rodgers*
Nutrition, 842
Nutrition Across the Lifespan, 843
Vegetarian Diets, 847
Obesity, 847
Etiology and Pathophysiology, 848
Diagnostic Evaluation, 849
Therapeutic Management and Nursing Care, 850
Complementary and alternative medicine, 852
Dental health, 852
Developmental Aspects of Dental Health, 852
Oral Health, 853
Other Dental Conditions, 855
Sleep, Rest, and Activity integration, 855
Infant, 856
Toddler, 856
Preschooler, 857
School-Age, 857
Adolescent, 858
Sexual health, 858
Sex Education, 859
Safety promotion and injury prevention, 860
Injury Prevention Throughout Childhood, 860

Motor Vehicle Safety, 862
Pedestrian Safety, 868
All-Terrain Vehicles, 868
Bicycles and Skateboards, 869
Aspiration and Suffocation, 870
Drowning, 870
Burns, 870
Accidental Poisoning, 871
Falls, 872
Firearms, 872
Sports Injuries, 872
Role of the Nurse in Prevention of Injury, 872
Child maltreatment, 874
Factors Predisposing to Child Maltreatment, 875
Child Neglect, 875
Emotional Abuse, 875
Physical Abuse, 875
Sexual Abuse, 876
Munchausen Syndrome by Proxy, 877
Nursing and Interprofessional Care, 877
Immunizations, 882
Vaccine Hesitancy, 882
Schedule for Immunizations, 882
Recommendations for Routine Immunizations, 884
Administration of Immunizations, 888
Reactions, 888
Contraindications, 889
Communicable diseases, 889
Nursing Care, 889
Key points, 901
References, 901
Additional resources, 905

36 The Infant and Family, 906
Constance O'Connor
Originating US Chapter by *Cheryl C. Rodgers*
Promoting Optimum Growth and Development, 906
Biological Development, 906
Psychosocial Development, 915
Cognitive Development, 916
Development of Body Image, 917
Social Development, 917
Language Development, 919
Temperament, 919
Coping with Concerns Related to Normal Growth and Development, 919
Separation and Fear of Strangers, 919
Alternative Child Care Arrangements, 920
Limit-Setting and Discipline, 920
Thumb-Sucking and Use of a Pacifier, 920
Teething, 921
Health Promotion and Anticipatory Guidance for Families, 922
Traumatic Head Injury due to Child Maltreatment, 922
Special Health Concerns, 923
Colic (Paroxysmal Abdominal Pain), 923
Failure to Thrive (Growth Failure), 924
Sudden Infant Death Syndrome, 926
Positional Plagiocephaly, 929
Brief Resolved Unexplained Events, 930
Key Points, 930
References, 931
Additional Resources, 932

37 The Toddler and Family, 933
Constance O'Connor
Originating US Chapter by *Cheryl C. Rodgers*
Promoting optimum growth and development, 933
Biological Development, 933
Psychosocial Development, 934
Cognitive Development, 936
Spiritual Development, 937
Development of Body Image, 938
Development of Gender Identity, 939
Social Development, 939
Coping with concerns related to normal growth and development, 940
Toilet Independence, 940
Temper Tantrums, 942
Negativism, 942

UNIT 11 Special Needs, Illness, and Hospitalization

41 Caring for the Child With a Chronic Illness and at the End of Life, 991
Laura Pilla
Originating US Chapter by *Marilyn J. Hockenberry*
Care of children and families living with chronic or complex conditions, 991
Scope of the Issue, 991
Trends in Care, 992
The family of the child with a chronic or complex condition, 993
Impact of the Child's Chronic Illness and Complex Conditions, 994
Coping With Ongoing Stress and Periodic Crises, 995
Assisting Family Members in Managing Their Feelings, 996
Establishing a Support System, 997
The child with a chronic or complex condition, 998
Developmental Aspects, 998
Coping Mechanisms, 998
Nursing care of the family and child with a chronic or complex condition, 999
Performing an Assessment, 999
Providing Support at the Time of Diagnosis, 1000
Supporting the Family's Coping Methods, 1000
Teaching About the Disorder and General Health Care, 1001
Promoting Appropriate Development, 1002
Establishing Realistic Future Goals, 1005
Transition to Adult Care, 1005
General concepts of home care, 1006
Home Care Trends and Needs, 1006
Effective Home Care, 1006
Discharge Planning, 1007
Care Coordination (Case Management), 1009
Role of the Nurse, Training, and Standards of Care, 1010
Family-centred home care, 1010
Culturally Safe Care, 1010
Parent–Professional Collaboration, 1010
The Nursing Process, 1011
Safety Issues in the Home, 1011
Caregiver Stress, 1012
Perspectives on the care of children at the end of life, 1012
Principles of Palliative Care, 1012
Decision Making at the End of Life, 1013
Treatment Options for Terminally Ill Children, 1015
Nursing Care of the Child and Family at the End of Life, 1016
Organ or Tissue Donation and Autopsy, 1018
Grief and Mourning, 1018
Nurses' Reactions to Caring for Dying Children, 1020
Key points, 1020
References, 1021
Additional resources, 1023

42 Impact of Intellectual Disability or Sensory Impairment on the Child and Family, 1024
Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*
Intellectual disability, 1024
General Concepts, 1024
Down Syndrome, 1029
Fragile X Syndrome, 1031
Communication impairment, 1032
Autism Spectrum Disorders, 1032
Sensory impairment, 1034
Hearing Impairment, 1034
Visual Impairment, 1038
Hearing–Visual Impairment, 1043
Retinoblastoma, 1044
Key points, 1045
References, 1045
Additional resources, 1046
43 Family-Centred Care of the Child During Illness and Hospitalization, 1047
Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*
Stressors of hospitalization and children's reactions, 1047
Separation Anxiety, 1047
Loss of Control, 1049
Effects of Hospitalization on the Child, 1049
Stressors and reactions of the family of the hospitalized child, 1050

ABOUT THE AUTHORS

Lisa J. Keenan-Lindsay graduated from the University of Toronto for both her BScN and MN degrees. Her clinical work has included pediatrics and perinatal nursing. She has worked as a staff nurse, head nurse, and clinical educator. Currently, Lisa is a professor of nursing at Seneca College teaching in both the baccalaureate and practical nursing programs. She has been involved in all aspects of nursing education, including curriculum development and incorporation of simulation into the curriculum.

Lisa has been an active board member of the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN) since its inception and before that was a Section Leader for AWHONN-Canada. She was President of CAPWHN in 2014. Lisa has previously been involved with the Society of Obstetricians and Gynaecologists of Canada (SOGC) as an RN member for the Maternal-Fetal Medicine Committee for many years and has co-authored many SOGC Clinical Practice Guidelines. She maintains her Perinatal Certification through the Canadian Nurses Association and is a member of the Perinatal Exam Committee. Lisa was also a Lamaze-certified childbirth educator for many years.

Lisa is also the editor of *Leifer's Introduction to Maternity and Pediatric Nursing in Canada and* is passionate about providing a Canadian focus to nursing education and textbooks.

Cheryl A. Sams is a graduate of Ryerson University (BScN) and D'Youville College (MSN). She has worked at the Hospital for Sick Children (SickKids®) in Toronto since she graduated from nursing school. She has held many positions there, including staff nurse, clinical educator, manager, director, and clinical nurse specialist. Cheryl has held many teaching positions at Ryerson University in the Post RN Program and the Nurse Practitioner Program. She has also taught at the University of Toronto in the BScN program. Cheryl taught at Seneca College in the York University Collaborative BScN program until her recent retirement.

As an author, Cheryl enjoys contributing to the nursing body of literature. She has contributed chapters to the Canadian publication of Lewis et al.'s *Medical-Surgical Nursing in Canada* and Potter and Perry's *Canadian Fundamentals of Nursing*. She was one of the editors for *Mosby's Comprehensive Review for the Canadian RN Exam*.

Constance (Connie) O'Connor, RN (EC), MN, is a nurse practitioner at the Hospital for Sick Children (SickKids®) who currently works in the Ehlers-Danlos Syndrome (EDS) and Connective Tissue Disorders Program. Connie obtained both her Bachelor of Science in Nursing and Master of Nursing degrees at the University of Toronto, where she is a clinical adjunct instructor in the Lawrence S. Bloomberg Faculty of Nursing. Connie has held various nursing roles in general pediatrics, respiratory medicine, and gastroenterology. Connie was Canada's first pediatric hepatology nurse practitioner specializing in chronic viral hepatitis and cholestatic liver disease. Connie has contributed to several committees for national and international organizations, including the Canadian Nurses' Association, Alpha-1 Antitrypsin Deficiency Canada, the Canadian Liver Foundation, and the International Consortium on the Ehlers-Danlos Syndromes. She has authored several peer-reviewed publications and has been invited to speak both locally and at national and international conferences.

US 6th Edition
Maternity:

Shannon E. Perry is Professor Emerita, School of Nursing, San Francisco State University, San Francisco, California. She received her diploma in nursing from St. Joseph Hospital School of Nursing, Bloomington, Illinois; a BSN from Marquette University; an MSN from the University of Colorado Medical Center; and a PhD in Educational Psychology from Arizona State University. She completed a 2-year postdoctoral fellowship in perinatal nursing at the University of California, San Francisco, as a Robert Wood Johnson Clinical Nurse Scholar.

Dr. Perry has had clinical experience in obstetrics, pediatrics, gynecology, and neonatal nursing. She has taught in schools of nursing in several states for over 30 years and was director of the School of Nursing at San Francisco State University. She is a Fellow in the American Academy of Nursing. Dr. Perry's experience in international nursing includes teaching in the United Kingdom, Ireland, Italy, Thailand, Ghana, and China, as well as participating in health missions in Ghana, Kenya, and Honduras.

Deitra Leonard Lowdermilk is Clinical Professor Emerita, School of Nursing, University of North Carolina at Chapel Hill. She received her BSN from East Carolina University and her MEd and PhD in Education from the University of North Carolina at Chapel Hill. She is certified in in-patient obstetrics by the National Certification Corporation. She is a Fellow in the American Academy of Nursing. In addition to being a nurse educator for more than 34 years, Dr. Lowdermilk has clinical experience in maternity and women's health care.

Dr. Lowdermilk has been recognized for her expertise in nursing education and women's health by state and national nursing organizations and by her alma mater, East Carolina University. A few examples include Educator of the Year by the Association of Women's Health, Obstetric and Neonatal Nurses and by the North Carolina Nurses Association. Dr. Lowdermilk also is co-author of *Maternity and Women's Health Care* (eleventh edition), *Maternity Nursing* (eighth edition), and *Maternal and Child Health* (fifth edition). In 2010, the East Carolina University College of Nursing named the Neonatal Intensive Care and Midwifery Laboratory in honour of Dr. Lowdermilk. In 2011, she was named as one of the first 40 nurses inducted into the College of Nursing Hall of Fame.

Mary Catherine (Kitty) Cashion is a clinical nurse specialist in the Maternal-Fetal Medicine Division, College of Medicine, Department of Obstetrics and Gynecology at The University of Tennessee Health Science Center in Memphis. She received her BSN from the University of Tennessee College of Nursing in Memphis and her MSN in parent-child nursing from the Vanderbilt University School of Nursing in Nashville, Tennessee. Ms. Cashion is certified as a high-risk perinatal nurse through the American Nurses Credentialing Center.

Ms. Cashion's job responsibilities at the University of Tennessee include providing education regarding low- and high-risk obstetrics to staff nurses in West Tennessee community hospitals. For over 20 years, Ms. Cashion has been an adjunct clinical instructor in maternal-child nursing at Northwest Mississippi Community College

in Senatobia, Mississippi, and Union University in Germantown, Tennessee. Ms. Cashion has contributed many chapters to maternity nursing textbooks over the years and also co-authored several major maternity nursing textbooks.

Kathryn Rhodes Alden is Associate Professor at the University of North Carolina at Chapel Hill School of Nursing, where she has taught clinical and didactic in maternal/newborn nursing for 29 years. She has received numerous awards for excellence in nursing education at the University of North Carolina, being recognized for clinical and classroom teaching expertise as well as for academic counselling. Dr. Alden was instrumental in the adoption of simulation-based learning for nursing education as well as for interprofessional education.

Dr. Alden earned a BSN from University of North Carolina at Charlotte, an MSN from the University of North Carolina at Chapel Hill, and a doctorate in adult education from North Carolina State University. She has clinical experience as a staff nurse in pediatrics, pediatric intensive care, and neonatal intensive care, as well as in postpartum home care of mothers, newborns, and families. She has served as a nursing administrator and coordinator of quality improvement. Dr. Alden has been an international board-certified lactation consultant for more than 20 years and has extensive experience working as an inpatient lactation consultant and a lactation educator.

Ellen F. Olshansky is Professor and Founding Chair of the Department of Nursing in the Suzanne Dworak-Peck School of Social Work at the University of Southern California. She earned a BA in social work from the University of California, Berkeley, and a BS, MS, and PhD from the University of California, San Francisco School of Nursing. She is a Fellow in the American Academy of Nursing and the Western Academy of Nursing through the Western Institute of Nursing.

Dr. Olshansky is a women's health nurse practitioner, certified through the National Certification Corporation, and her research focuses on women's health across the lifespan, with an emphasis on reproductive health. She is one of the founders of the Orange County Women's Health Project, which promotes women's health and wellness in Orange County, California. She recently completed a 10-year term as editor of the *Journal of Professional Nursing,* the official journal of the American Association of Colleges of Nursing. She has published extensively in numerous nursing and other health-related journals as well as authored many book chapters and editorials.

Pediatrics:

Marilyn J. Hockenberry is the Bessie Baker Distinguished Professor of Nursing and Professor of Pediatrics at Duke University. She is the Associate Dean of Research Affairs in the Duke School of Nursing. Her research focuses on symptom management and treatment-related side effects experienced by children who have cancer. Dr. Hockenberry's current National Institutes of Health–funded research studies are evaluating the treatment-related symptoms and neurocognitive deficits of leukemia treatment.

Cheryl C. Rodgers is an assistant professor at Duke University School of Nursing in Durham. Her research focuses on symptom assessment and symptom management among children undergoing cancer treatment or stem cell transplant. Dr. Rodgers is certified as a primary care pediatric nurse practitioner and a pediatric oncology nurse. She has over 25 years of clinical experience caring for children with hematological and oncological diseases.

PREFACE

This third edition of *Perry's Maternal Child Nursing Care in Canada* combines essential perinatal and pediatric nursing information into one text. The text focuses on the care of childbearing persons during their reproductive years and the care of children from birth through adolescence. The first section of the text focuses on important issues related to perinatal and pediatric nursing in Canada, including an overview of family and culture, as well as community nursing care. The second section discusses the promotion of wellness and the care of women experiencing common health concerns throughout the lifespan and care of the childbearing person. The health care of children and child development in the context of the family is the focus for the third section. The text provides a family-centred care approach that recognizes the importance of collaboration with families when providing care. This third edition of *Perry's Maternal Child Nursing Care in Canada* is designed to address the changing needs of Canadian persons during their childbearing years and those of children during their developing years.

Perry's Maternal Child Nursing Care in Canada was developed to provide students with the knowledge and skills they need to become competent critical thinkers and to attain the sensitivity needed to become caring nurses. This third edition reflects the Canadian health care system, the importance of family-centred care, the significance of Indigenous health, and the cultural diversity throughout the country. It includes the most accurate, current, and clinically relevant information available.

APPROACH

Professional nursing practice continues to evolve and adapt to society's changing health priorities. The rapidly changing health care delivery system offers new opportunities for nurses to alter the practice of perinatal and pediatric nursing and to improve the way in which care is given. Increasingly, nursing care must be artfully constructed using research to inform the care provided. It is incumbent on nurses to use the most up-to-date and scientifically supported information on which to base their care. To assist nurses in providing this type of care, Evidence-Informed Practice boxes are included throughout the text.

Consumers of perinatal and pediatric care vary in age, ethnicity, culture, language, social status, marital status, and sexual orientation. They seek care from a variety of health care providers in numerous health care settings, including the home. To meet the needs of these consumers, clinical education must offer students a variety of health care experiences in settings that include hospitals and birth centres, homes, clinics, health care providers' offices, shelters for the homeless or for adults and children who require protection, and other community-based settings.

The focus in the chapters is on nursing care, along with collaboration with other health care disciplines, as this combination provides the most comprehensive care possible to childbearing patients and children. Included on the Evolve site for this edition are the Nursing Process boxes and the Nursing Care Plans. The Nursing Process boxes include assessments, analysis, planning, implementation, and evaluation of nursing care, and the Nursing Care Plans reinforce the problem-solving approach to patient care. Throughout the discussion of assessment and care, warning signs and emergency situations are also highlighted, to alert the nurse to signs of potential problems.

Patient education is an essential component of nursing care of childbearing persons and children. Family-Centred Care boxes incorporate family considerations important to care to perinatal patients and children. Issues concerning grandparents, siblings, and various family constellations are also addressed. In the pediatric chapters (Part 3), these boxes focus on the special learning needs of families caring for their child. Legal Tips are integrated throughout the maternity section to emphasize these issues as they relate to the care of childbearing patients and infants.

This third edition features a contemporary layout with logical, easy-to-follow headings and an attractive four-colour design that highlights important content and increases visual appeal. Hundreds of colour photographs and drawings throughout the text illustrate important concepts and techniques to further enhance comprehension. To help students learn essential information quickly and efficiently, we have included numerous features that prioritize, condense, simplify, and emphasize important aspects of nursing care. In addition, students are encouraged to apply critical thinking in real-life scenarios presented in the Clinical Reasoning Case Studies.

NEW TO THIS EDITION

- A new chapter specifically focused on pediatric health promotion throughout childhood
- A new chapter focused on pediatric mental health
- A specific chapter that focuses on caring for the child with a complex chronic condition or at the end of life, with a focus on providing care in the home
- Expanded coverage with a focus on global health perspectives and health care in the LGBTQ2, Indigenous, immigrant, and other vulnerable populations.
- New and updated references, sources, and guidelines are provided, including the following:
  - Society of Obstetrician and Gynaecologists of Canada (SOGC) guidelines
  - Canadian Association of Perinatal and Women's Health Nurses (CAPWHN)
  - Public Health Agency of Canada, Sexually transmitted infection (STI) guidelines
  - Canadian Paediatric Society (CPS) standards
  - Canadian Association of Midwives (CAM)
  - Health Canada
  - Family-Centred Maternity and Newborn Care Guidelines from the Public Health Agency of Canada
  - Registered Nurses' Association of Ontario (RNAO)
  - Perinatal Services BC
  - American College of Obstetricians and Gynecologists (ACOG)
  - Centers for Disease Control and Prevention (CDC)
  - World Health Organization (WHO)
- There is increased emphasis on health promotion in the Perinatal and Pediatric sections of the text.

- Additional case studies and clinical reasoning/clinical judgement-focused practice questions in the printed text and on the Evolve companion website promote critical thinking and prepare students for exam licensure.
- New Evolve PN Case Studies for Clinical Judgement reflect current PN competencies including for Ontario and British Columbia on Evolve
- Next-Generation NCLEX™ (NGN)-Style Case Studies for Maternity and Pediatric on Evolve

SPECIAL FEATURES

- **Objectives** focus students' attention on the important content to be mastered.
- **Atraumatic Care** boxes emphasize the importance of providing competent care while minimizing undue physical and psychological distress for the child and family.
- **Community Focus** boxes emphasize community issues, provide resources and guidance, and illustrate nursing care in a variety of settings.
- **Clinical Reasoning Case Studies** present students with real-life situations and encourage students to make appropriate clinical judgements. Answer guidelines are provided on the book's Evolve site.
- **Cultural Awareness** boxes describe beliefs and practices about pregnancy, childbirth, parenting, women's health concerns, and caring for sick children.
- **Emergency** boxes alert students to the signs and symptoms of various emergency situations and provide interventions for immediate implementation.
- **Family-Centred Care** boxes highlight the needs of families that should be addressed when family-centred care is provided.
- **Guidelines** boxes provide students with examples of various approaches to implementing care.
- **Medication Guide** boxes include key information about medications used in maternity and newborn care, including their indications, adverse effects, and nursing considerations.
- **Patient Teaching** boxes assist students to help patients and families become involved in their own care with optimal outcomes.
- **Evidence-Informed Practice** boxes are incorporated throughout the book. Findings that confirm effective practices or that identify practices with unknown, ineffective, or harmful effects are located within the narrative.
- **Legal Tips** are integrated throughout Part 1 to provide students with relevant information to address important legal areas in the context of perinatal nursing.
- **Medication Alerts** provide important information regarding the safety of medications, including interactions with other medications and important nursing considerations.
- **Nursing Alerts** call the reader's attention to critical information that could lead to deteriorating or emergency situations.
- **Safety Alerts** call the reader's attention to potentially dangerous situations that should be addressed by the nurse.
- **Key Points**, located at the end of each chapter, help the reader summarize major points, make connections, and synthesize information. The Key Points are also available in a downloadable format and can be found on this book's Evolve site.
- **Additional Resources**, including websites and contact information for organizations and educational resources available for the topics discussed, are listed throughout.
- A highly detailed, cross-referenced **index** enables readers to quickly access needed information.

SUPPLEMENTAL RESOURCES

A comprehensive ancillary package is available to students and instructors using *Perry's Maternal Child Nursing Care in Canada*. The following supplemental resources have been thoroughly revised for this edition and can significantly assist in the teaching and learning of perinatal and pediatric nursing in classroom and clinical settings.

Study Guide – NEW!

This comprehensive and challenging study aid presents a variety of questions to enhance learning of key concepts and content from the text. Multiple-choice and matching questions and Critical Thinking Case Studies are included. Answers for all questions are included at the back of the study guide.

- *Thinking Critically* case-based activities require students to apply the concepts found in the chapters to solve problems, make clinical-judgement decisions concerning care management, and provide responses to patient questions and concerns.
- *Reviewing Key Concepts* questions in various formats give students ample opportunities to assess their knowledge and comprehension of information covered in the text. Activities, including matching, fill-in-the-blank, true/false, short-answer, and multiple-choice, help students identify the core content of the chapter and test their understanding after reading the chapter.
- *Learning Key Terms* matching and fill-in-the-blank questions let students test their ability to define all key terms highlighted in the corresponding textbook chapter.

Evolve Website

Located at http://evolve.elsevier.com/Canada/Perry/maternal, the Evolve website for this book includes the following elements.

For Students

- More than 500 Review Questions for Exam Preparation
- Answers to Clinical Reasoning Case Studies from the book
- Key Points
- **Nursing Care Plans** provide commonly encountered situations and disorders. Nursing diagnoses are included, as are rationales for nursing interventions that might not be immediately evident to students.
- **Nursing Processes** help students to easily identify information on some major diseases and conditions.
- **Nursing Skills** teach students how to implement concepts presented in the textbook and use them in real-life situations. This will enhance student knowledge and give students a better understanding of concepts they learn while reading the textbook.
- Audio Glossary
- PN Case Studies for Clinical Judgement reflect current PN competencies, including for Ontario and British Columbia

- Next-Generation NCLEX™ (NGN)-Style Case Studies for Maternity and Pediatrics

For Instructors

- Next-Generation NCLEX™ (NGN)-Style Case Studies for Maternity and Pediatric
- Case studies
- *TEACH for Nurses* Lesson Plans that focus on the most important content from each chapter and provide innovative strategies for student engagement and learning. These new Lesson Plans include strategies for integrating nursing curriculum standards, concept-based learning examples, relevant student and instructor resources, and an original instructor-only Case Study in most chapters.
- ExamView® Test Bank that features more than 1 500 examination-format test questions (including alternate-item questions), rationales, and answers. The robust ExamView® testing application, provided at no cost to faculty, allows instructors to create new tests; edit, add, and delete test questions; sort questions by category, cognitive level, and nursing process step; and administer and grade tests online, with automated scoring and gradebook functionality.
- PowerPoint® Lecture Slides consisting of more than 2 100 customizable text slides for instructors to use in lectures
- An Image Collection with over 500 full-colour images from the book for instructors to use in lectures
- Access to all student resources listed above

Simulation Learning System (SLS)

The Simulation Learning System (SLS) is an online toolkit that helps instructors and facilitators effectively incorporate medium- to high-fidelity simulation into their nursing curriculum. Detailed patient scenarios promote and enhance the clinical decision-making skills of students at all levels. The SLS provides detailed instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Each scenario in the SLS complements the textbook content and helps bridge the gap between lectures and clinical practice. The SLS provides the perfect environment for students to practice what they are learning in the text for a true-to-life, hands-on learning experience.

Sherpath

Sherpath's book-organized collections offer digital lessons, mapped chapter-by-chapter to the textbook, so the reader can conveniently find applicable digital assignment content. Sherpath features convenient teaching materials that are aligned to the textbook, and the lessons are organized by chapter for quick and easy access to invaluable class activities and resources.

Elsevier eBooks

This exciting program is available to faculty who adopt a number of Elsevier texts, including *Perry's Maternal Child Nursing Care in Canada*. Elsevier eBooks is an integrated electronic study centre consisting of a collection of textbooks made available online. It is carefully designed to "extend" the textbook for an easier and more efficient teaching and learning experience. It includes study aids such as highlighting, e-note taking, and cut-and-paste capabilities. Even more importantly, it allows students and instructors to do a comprehensive search within the specific text or across a number of titles. Please check with your Elsevier Canada sales representative for more information.

Next Generation NCLEX™ (NGN)

The National Council for the State Boards of Nursing (NCSBN) is a not-for-profit organization whose members include nursing regulatory bodies. In empowering and supporting nursing regulators in their mandate to protect the public, the NCSBN is involved in the development of nursing licensure examinations, such as the NCLEX-RN®. In Canada, the NCLEX-RN® was introduced in 2015 and is as of the writing of this text the recognized licensure exam required for practising RNs in Canada.

As of 2023, the NCLEX-RN® will be changing to ensure that its item types adequately measure clinical judgement, critical thinking, and problem-solving skills on a consistent basis. The NCSBN will also be incorporating into the examination the Clinical Judgement Measurement Model (CJMM), which is a framework the NCSBN has created to measure a novice nurse's ability to apply clinical judgement in practice.

These changes to the examination come as a result of findings indicating that novice nurses have a much higher than desirable error rate with patients (errors causing patient harm) and, upon NCSBN's investigation, discovering that the overwhelming majority of these errors were caused by failures of clinical judgement.

Clinical judgement has been a foundation underlying nursing education for decades, based on the work of a number of nursing theorists. The theory of clinical judgement that most closely aligns with what NCSBN is basing their CJMM on is the work by Christine A. Tanner.

The new version of the NCLEX-RN® is identified loosely as the "Next-Generation NCLEX" or "NGN" and will feature the following:

- Six key skills in the CJMM: recognizing cues, analyzing cues, prioritizing hypotheses, generating solutions, taking actions, and evaluating outcomes
- Approved item types as of March 2021: multiple response, extended drag and drop, cloze (drop-down), enhanced hot-spot (highlighting), matrix/grid, bowtie and trend. More question types may be added.
- All new item types are accompanied by mini-case studies with comprehensive patient information—some of it relevant to the question, and some of it not.
- Case information may present a single, unchanging moment in time (a "single episode" case study) or multiple moments in time as a patient's condition changes (an "unfolding" case study).
- Single-episode case studies may be accompanied by one to six questions; unfolding case studies are accompanied by six questions.

For more information (and details) regarding the NCLEX-RN® and changes coming to the exam, visit the NCSBNs website: https://www.ncsbn.org/11447.htm and https://ncsbn.org/Building_a_Method_for_Writing_Clinical_Judgment_It.pdf.

For further NCLEX-RN® examination preparation resources, see *Elsevier's Canadian Comprehensive Review for the NCLEX-RN Examination*, Second Edition, ISBN 9780323709385.

Prior to preparing for any nursing licensure examination, please refer to your provincial or territorial nursing regulatory body to determine which licensure examination is required in order for you to practice in your chosen jurisdiction.

ACKNOWLEDGEMENTS

The authors and contributors of the text recognize and acknowledge the diverse histories of the First Peoples of the lands now referred to as Canada. It is recognized that individual communities identify themselves in various ways; within this text, the term *Indigenous* will be used to refer to all First Nations, Inuit, and Métis people within Canada.

In the text, gender-neutral language is used, to be respectful of and consistent with the values of equality recognized in the Canadian Charter of Rights and Freedoms. Using gender-neutral language is professionally responsible and mandated by the Canadian Federal Plan for Gender Equality.

This text also recognizes that childbirth is experienced not only by women but also by others who do not identify as female or who find the term *woman* to not be representative of how they identify themselves. The terms *patient*, *person*, and *parent* are used when possible in the text. Woman/women is used when the research is specifically done with a population that identifies as a woman.

I would like to offer thanks to the many perinatal contributors who worked diligently to provide this text with an updated and uniquely Canadian perspective as well as to the perinatal nurses across the country who continue to provide high-quality, family-centred care to childbearing persons and their families. I thank my students, who always keep me on my toes and ensure that I provide the most current information in a way that is engaging. To my family, who always provide their support and encouragement, I thank you. Most importantly I would like to dedicate this text to the memory of both of my parents (Ross and Ruby Keenan), who encouraged me to always strive for the best.

Lisa Keenan-Lindsay

I would like to thank the many pediatric experts who have not only contributed to the "peds" part of this text but also made major contributions to the field of pediatric nursing in Canada. You make a difference every day to children and their families. I would also like to thank my husband, Stuart Sams, and my family for cheering me on.

Cheryl Sams

Thank you to my nursing colleagues who generously shared their knowledge and time in contributing to this text. I would also like to thank my family and friends for their support and encouragement.

Constance (Connie) O'Connor

A special thank you goes to Lenore Gray Spence, Jerri Hurlbutt, Abigail Bradberry, Roberta A. Spinosa-Millman, and the rest of the group at Elsevier for all of their exceptional support and encouragement throughout the development of this book. We also would like to thank all our chapter contributors and reviewers whose advice, expertise, insight, and dedication greatly assisted us in completing this edition. We appreciate all your time and guidance.

Lisa, Cheryl, and Connie

PART 1

Maternal Child Nursing

Unit 1. Introduction to Maternal Child Nursing, 2
Chapter 1. Contemporary Perinatal and Pediatric Nursing in Canada, 2
Chapter 2. The Family and Culture, 15
Chapter 3. Community Care, 27

1

Contemporary Perinatal and Pediatric Nursing in Canada

Erica Hurley

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the scope of perinatal and pediatric nursing in Canada today.
2. Examine the historical context of health care in Canada.
3. Identify social determinants of health and other factors that influence the health of childbearing persons, families and children, and explore approaches needed to address health inequities in Canada.
4. Explore trauma-informed care.
5. Describe the impact of colonialism on the health of Indigenous people.
6. Consider the role of research in perinatal and pediatric nursing.
7. Identify strategies to enhance interprofessional communication.
8. Describe how the Sustainable Development Goals (SDGs) are focused on improving the health of people worldwide.
9. Explore ethical issues in contemporary perinatal and pediatric nursing.

The focus of the first part of this book is to provide an overview of perinatal and pediatric nursing in Canada from a national and global perspective. The role of social, cultural, and family influences on health promotion will also be discussed, as will the role of nurses in the community. Chapters 4 through 29 focus on the care of childbearing patients and families, or *perinatal nursing*, as well as women's health promotion (Chapters 5 to 8). Chapters 30 to 55 address the issues and trends related to the health care of children.

PERINATAL AND PEDIATRIC NURSING

Nurses care for childbearing persons, for children, and for families in many settings, including the hospital, the home, and a variety of ambulatory and community settings. Nurses also work collaboratively with other health and social care providers, such as physicians, midwives, dietitians, doulas, and social workers, to name a few. *Perinatal nurses* are those nurses who work collaboratively with patients and families from the preconception period throughout the childbearing year. Pediatric nurses care for children from birth up to age 18 years. Nurses caring for children also provide care for the family. Nursing care is provided in many settings, including inner-city, urban, or rural communities. The setting where nursing care is provided may have implications for the services that are offered, as remote and rural communities may not have all services necessary to provide comprehensive care (see discussion below). Most nurses working in hospitals provide acute care, while nurses working in a community setting may provide care that focuses on health promotion, rehabilitation, and palliative care.

Nurses who provide care for childbearing persons as well as children can influence the health care system by drawing attention to the needs of the patients in their care. Through professional associations, nurses can have a voice in setting standards and influencing health policy by actively participating in the education of the public and that of local, provincial, and federal legislators. Nurses throughout history have developed strategies to improve the well-being of childbearing persons and their newborns and children, and they have led efforts to develop and implement clinical practice guidelines that draw on current evidence and research.

THE HISTORY AND CONTEXT OF HEALTH CARE IN CANADA

Canada's government-funded health insurance program (Medicare) provides universal medical and hospital services for all Canadians, although health services in Canada are organized provincially and territorially. Indigenous people within Canada may have different access to services funded through the federal government, although this funding is not at the same level as for provincial health services. Additionally, new immigrants to Canada may have to wait 90 days for

government health coverage, depending on which province or territory they live in. The Interim Federal Health Program provides temporary health coverage for certain groups of refugees before they are covered under provincial or territorial health insurance plans. The principles of the *Canada Health Act* include public administration, comprehensive "medically necessary" care, universality, portability, and accessibility. Home care, extended care, pharmaceuticals, and dental care are not currently covered under Medicare provisions, although different provinces do cover some of these items. For example, the province of Ontario covers the cost of over 4 400 medications for anyone age 24 years or younger who is not covered by a private plan, and Nova Scotia has a provincial drug insurance plan that is designed to help residents with the cost of their prescription medications if needed. Thus, to some extent, Canada's Medicare program shapes the health services offered to Canadians. In an effort to control health care costs, interest has grown in restructuring health services and developing community-based programs and preventive health services. For example, pharmacists in Nova Scotia are able to prescribe birth control, thus eliminating the need for a visit to another health care provider.

Since the Lalonde Report was released in 1974, Canada has been a global leader in health promotion. In 1986, Canada hosted the first international conference on health promotion, which resulted in the Ottawa Charter. Three challenges for Canadians were identified: reducing health inequities, increasing disease prevention, and enhancing people's capacities to live with chronic disease and disability. The Charter also acknowledged the need for intersectoral collaboration, or looking beyond health, to include other sectors (e.g., income security, employment, education, housing, and transportation) (Corbin, 2017). In the late 1990s, interest expanded to creating evidence-informed programs that address all factors that impact health. With the HIV/AIDS epidemic, increasing rates of tuberculosis and other infectious diseases, the threat of bioterrorism, the severe acute respiratory syndrome (SARS) epidemic, and Ebola outbreaks, Canadians were reminded of the importance of immunizations and public health measures. In 2004, the federal government created the Public Health Agency of Canada (PHAC). While the PHAC initially focused on population health and health promotion, the emergence of avian influenza shifted the focus toward planning for a pandemic, such as that with COVID-19, along with health promotion.

The delivery of health care within each community, province, and territory contains unique elements as each level of government tries to balance human resources, funding, and liability concerns with regulatory, educational, political, and demographic issues. Inequities in health care have developed and been identified as existing between rural, remote, inner-city, and Indigenous communities and other Canadian communities.

CONTEMPORARY ISSUES AND TRENDS

Social Determinants of Health

The emphasis in health care has shifted from treatment of illnesses to health promotion and disease prevention. In order to promote good health, the many complex influences on health need to be investigated and understood. To this end, the federal government has outlined the *social determinants of health* (Box 1.1). The social determinants of health are the social and economic factors that influence people's health, either positively or negatively. These determinants provide a blueprint for health care policies and help direct population health research with the goal of improving health for its citizens (PHAC, 2016). They relate to an individual's place in society, such as income, education, or employment. Experiences of discrimination, racism, and historical trauma are important social determinants of health for certain groups, such as Indigenous peoples, LGBTQ2 persons, and Black Canadians (Government of Canada, 2020b).

BOX 1.1 Social Determinants of Health

The main determinants of health include the following:

- Income and social status
- Employment and working conditions
- Education and literacy
- Childhood experiences
- Physical environments
- Social supports and coping skills
- Healthy behaviours
- Access to health services
- Biology and genetic endowment
- Gender
- Culture
- Race/Racism

Source: Adapted from Public Health Agency of Canada. (2020). *Social determinants of health and health inequalities.* https://www.canada.ca/en/public-health/services/health-promotion/population-health/what-determines-health.html

The Canadian Nurses Association (CNA) (2018) position statement regarding the social determinants of health states that nurses in all domains of practice can address social inequities by:

- Addressing policies related to income, employment, education, housing, transportation, and other factors; these should be evaluated in their planning stages for their impact on health
- Collaborating with others both within and outside the health sector, striving to reduce and, ultimately, eliminate health inequity
- Including the social determinants of health in their assessments and interventions with individuals, families and communities
- Incorporating the analysis of the social determinants of health, starting with a critical understanding of the political, economic and social factors that are the root causes of health inequities into nursing education.

Health inequity refers to health inequalities that are unfair or unjust, and modifiable. For example, Canadians who live in remote or northern regions do not have the same access to nutritious foods such as fruits and vegetables as other Canadians. *Health equity* is the absence of unfair systems and policies that cause health inequalities (Government of Canada, 2020b). Advocates of health equity seek to reduce inequalities and increase access to opportunities and conditions that are conducive to good health for all. Many health inequities also result from a lack of access to the social determinants of health that promote good health, creating conditions of vulnerability to experiencing poor health. For example, poverty has the most significant influence on the development of compromised maternal and child health (Abraha et al., 2019). Furthermore, continued examination is needed regarding how specific populations, alternate health care practices, and technology differ in terms of health determinants and overall health status.

Socioeconomic Status. There is strong and growing evidence that higher social and economic status is associated with better health. The term *poverty* implies both visible and invisible impoverishment. It is a condition in which families live without adequate resources (May & Standing Committee, 2017). *Visible poverty* refers to lack of money or material resources, which includes insufficient clothing, poor sanitation, and deteriorating housing. *Invisible poverty* refers to social and cultural deprivation, such as limited employment opportunities,

inferior educational opportunities, lack of or inferior medical services and health care facilities, and an absence of public services. The sum of all aspects of a low-income family's living situation can contribute to and compound health problems, such as crowded living conditions and poor sanitation, which facilitate transfer of disease (e.g., tuberculosis or COVID-19). Lack of funds or inaccessibility to health services can inhibit treatment for any but severe illness or injury. Sometimes health care is inadequate because of lack of information; individuals may not have information regarding causes, treatment, or outcomes of illness or preventive measures.

Although Canada has no official definition of poverty, it is typically measured using the low income cut-offs (LICO)—before and after taxes, the low income measures (LIM)—before and after taxes, and the market basket measures (MBM) (Statistics Canada, 2015a). The LICO is meant to express the income level at which a family faces constraints because it has to spend a higher percentage of its income on basic resources—for example, shelter, clothes, food—than the average similar-size family. In 2017, Statistics Canada, using the LIM, reported no significantly different rate from 2016 to 2017. However, the LIM for children was significantly lower in 2017 at 12.1%, down 1.9 percentage points from 2016 (Statistics Canada, 2019a). Low-income rates are more prevalent among certain subgroups of women. Poverty rates among Indigenous Canadians are 3.8 times higher than for nonracialized, non-Indigenous children (Beedie et al., 2019). Compared to lone male-parent families, lone mothers are more likely to have incomes that fall below the LICO (Statistics Canada, 2019b).

Health Inequity Within Certain Populations. In Canada, survival rates among childbearing patients and infants and children are among the best in the world. This is in part due to relatively high levels of education, economic and social well-being, and an effective universal health care system. However, it is important to recognize that Canada does have vulnerable populations who face significant health inequities. There are many families in this country who do not have ideal outcomes and face considerable challenges and health risks. Rates of adverse pregnancy outcomes, including preterm birth and intrauterine growth restriction, generally rise with greater socioeconomic disadvantage. For example, one contributing factor is that socioeconomically vulnerable patients are less likely to initiate early prenatal care, for a variety of reasons. All of these factors can translate into poor pregnancy outcomes. Poor fetal development is associated with many chronic diseases in later life (Baird et al., 2017). This means that the impact of being disadvantaged can last a lifetime. Vulnerable childbearing patients also face a higher risk of death after birth (Verstraeten et al., 2015). The high burden of illness responsible for premature loss of life arises in large part from the conditions in which people are born, grow, live, work, and age (National Academies of Sciences, Engineering & Medicine, 2017).

Overall, there are significant health inequalities among Indigenous peoples, sexual and racial minorities, immigrants, and people living with functional limitations, as well as inequalities based on socioeconomic status (income, education levels, employment, and occupation status) (PHAC, 2018). People affected include patients with mental health issues, those who work in the sex-trade industry, pregnant and parenting adolescents, and patients whose newborn has been taken into custody by child protection services. The offspring of persons belonging to these populations are also at increased risk for poor outcomes. Many of these poor outcomes are preventable through access to adequate nutrition, good prenatal care, and use of preventive health practices. Clearly, comprehensive, community-based care that is culturally relevant and accessible for all childbearing persons and for children and families is needed.

Health experiences differ within and between social groups. For example, immigrants; Indigenous women; women in remote and rural areas; women with disabilities; women living with mental illness; women living in low-income situations; and lesbian, bisexual, queer, and transgender people have differential access to health services and differing health care needs. Many persons belonging to these vulnerable population groups struggle to find health care practitioners who are knowledgeable and respectful of their specific needs and who provide care that is both culturally and socially sensitive and safe.

Indigenous people. Historical impacts of colonization have had a negative impact on the health of Indigenous people (Truth and Reconciliation Commission of Canada, 2015). Additionally, social determinants of health specific to Indigenous people have been identified that have had a unique impact on this population, such as a history of children being forced to reside at and attend residential schools, poverty, racism, and social exclusion (Figure 1.1). Indigenous families living in poverty consistently have poorer health outcomes and are at greater risk of adverse pregnancy and poor infant and child health outcomes. See further discussion of Indigenous people below.

Immigrants and refugees. While Canada has been home to immigrants and refugees since its creation, within the last decade there has been a steady increase in the number of immigrants moving to Canada. In 2011, 21% of all women living in Canada were born outside the country (Hudon, 2016). Among recent immigrant women, the largest share has come from the People's Republic of China, followed by the United Kingdom, India, the Philippines, and the United States (Hudon, 2016).

New immigrants often find themselves either underemployed or unemployed because of discrimination, complications around accreditation of foreign degrees, lack of available and affordable child care, and social isolation. Immigrant women's rate of participation in the labour force is considerably lower than that of immigrant men and Canadian-born women. For instance, newly arrived immigrant women, those who arrived up to 5 years prior to the 2006 Census, were more likely to be unemployed than those who had spent more time in Canada. However, among immigrant women aged 25 to 54, the challenge of finding work eased the longer they lived in Canada (Hudon, 2016).

Many of the conditions or illnesses that immigrants and refugees acquire contribute to the persistence of disparities in their health outcomes. Refugee status imposes a particular type of vulnerability on affected individuals and groups. Of primary significance are the precipitating factors by which people are displaced suddenly or forced to leave their country of origin: persecution, civil unrest, or war. Families are forced from their homes to seek residence and employment elsewhere. Often these groups are extremely impoverished and face extreme physical and emotional stress and trauma when they arrive in Canada. In general, refugees are more likely to live in poverty than are immigrants.

Immigrants typically arrive in Canada with better health than that of the Canadian-born population. This is because immigrants are screened on medical and other health-related criteria before they are admitted to the country. However, over time, this "healthy immigrant effect" tends to diminish as their health status converges with that of the host population. Some medical problems may arise as immigrants age, as well as when they integrate and adopt behaviours that have negative health impacts. Other health issues may arise from the stress of immigration itself, which involves finding suitable employment and establishing a new social support network. Some immigrants and refugees also have decreased access to social supports and may have a hard time navigating the health care system, often due to language difficulties, which can ultimately impact overall health.

Adolescents. Adolescent girls are considered vulnerable because of the increased probability of being involved in high-risk behaviours.

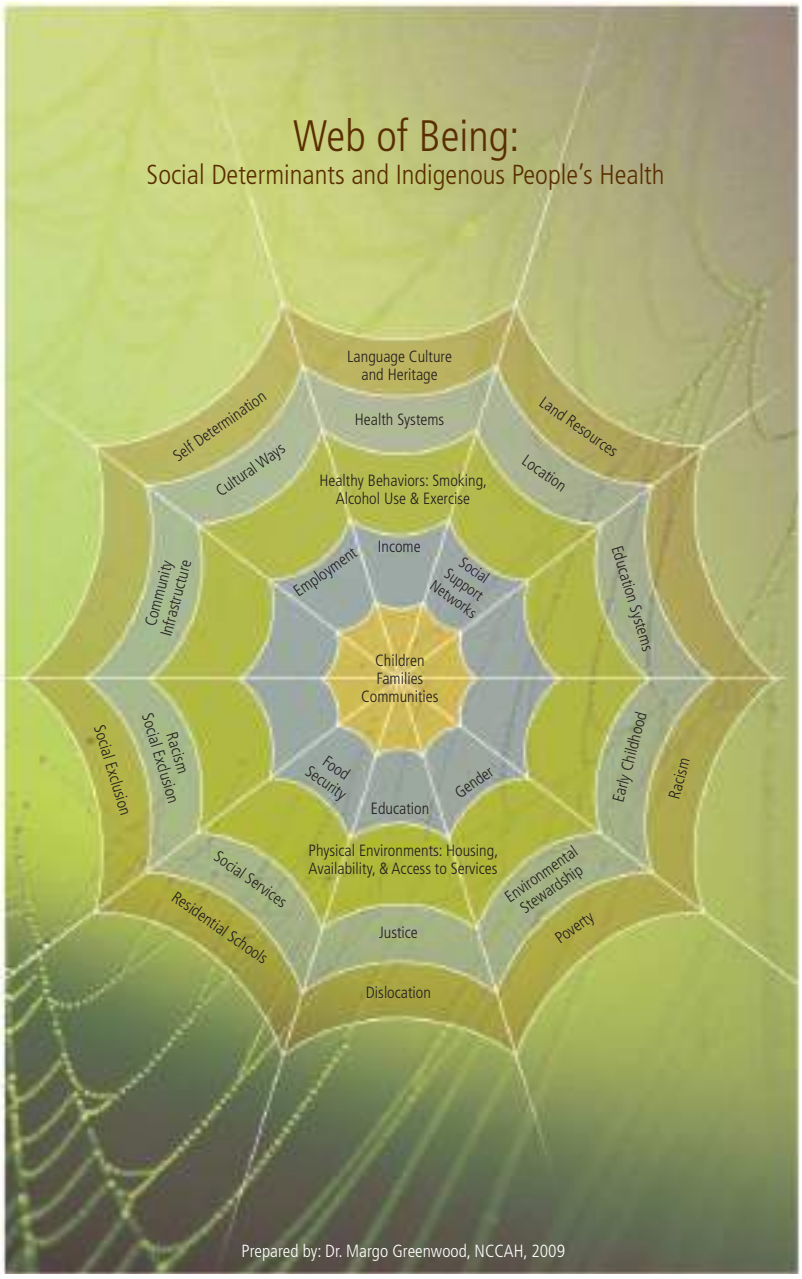

Fig. 1.1 Social determinants and Indigenous people's health. (From http://www.nccah-ccnsa.ca/docs/1791_NCCAH_web_being.pdf)

Girls from low-income or disrupted families are more likely to engage in early sexual activity and other high-risk behaviours, with both immediate and long-term health consequences (Ryan, 2015). In Canada, 2.9% of women aged 15 to 19 become pregnant each year (Dunn et al., 2019). Declining teen pregnancy rates for Canada in general are indicative of better sexual and reproductive health among young people. This decline in teen pregnancy can be attributed largely to more sexually active young people using reliable contraception such as condoms and birth control pills. However, the incidence of sexually transmitted infections (STIs), primarily chlamydia, syphilis, and gonorrhea, is on the rise in Canada, with the highest rates occurring in adolescents and young adult females (Government of Canada, 2017) (see Chapter 6).

Adolescent health is another broad target area for community health promotion efforts, including health education and policy initiatives. Because adolescents often fail to perceive their own vulnerability, they need help navigating a complex environment and dealing with risky behaviours through preventive strategies that enhance decision making and increase protective factors.

Older women. Women aged 65 and over constitute one of the fastest growing segments of the female population in Canada. In addition, women now predominate in the ranks of Canadian older persons, in large part because the life expectancy of women has risen more rapidly than that of men during most of the last century. The percentage of the female population accounted for by older women is expected to continue to rise during the next several decades. Over 6 million Canadians were aged 65 or older in 2014 (Government of Canada, 2014/2019). The average life expectancy for a 65-year-old is projected to increase by 1.8 years for women (to 88.8 years) between 2014 and 2036. While

this is higher than the life expectancy projected for men (86.5 years), women still tend to be the most vulnerable to serious health conditions and the most likely to experience socioeconomic difficulties.

While most older women report that their overall health is relatively good, almost all have a chronic health condition as diagnosed by a health care provider. Arthritis or rheumatism and high blood pressure are the most common chronic health issues reported by older women. However, there are preventive interventions that are effective in delaying or controlling age-related changes. Improving self-management activities such as diet and exercise are important health-promotion elements for this population.

Homelessness. Homelessness is an increasing social and health challenge in Canada. Women are at increased risk for hidden homelessness, living in overcrowded conditions or having insufficient money for shelter (Gaetz et al., 2013). Family violence is a major cause of homelessness, a significant reason attributing to the use of homeless shelters. Homeless people comprise a population that is at high risk for chronic and infectious diseases and premature death. While both homeless women and men experience similar health issues, homeless women have distinct characteristics, vulnerabilities, and treatment needs. Homeless women may also be pregnant or have young children in their custody. Some of the health issues of particular significance to this group include access to birth control, prenatal care, breast and cervical cancer screening, and STIs. Homeless people are also disproportionately represented among those with mental health challenges and substance use disorders. Poverty is the primary cause of homelessness.

While homeless people are a heterogeneous group, they do share a number of similar features that may contribute to their overall poor health status. These include low income, unemployment, low levels of education, insufficient material resources, fear and mistrust of the health care system and of health care providers, and limited social support. Canada urgently needs to find new and innovative strategies that will address the barriers to health care that homeless people face both in cities and in more remote rural areas.

Children. Research conducted over the past two decades has emphasized the significance of the early years in the growth and development of children. The World Health Organization (WHO) has identified early child development as a social determinant of health and as the most important period of overall development throughout a person's lifespan. The period from prenatal development to 8 years of age is critical for cognitive, social, emotional, and physical development (Lannen & Ziswiler, 2014). All facets of children's early development—those involving physical, social, emotional, and cognitive opportunities for growth—shape children's learning, school success, economic participation, social citizenry, and health. It is important to identify where children are most at risk for adversity and to intervene accordingly.

In terms of child well-being, Canada has room for improvement. UNICEF recently ranked Canada for children's health and well-being at 29 out of 41, of the world's richest nations (UNICEF Office of Research, 2017). In 2017, 622 000 children under 18 years of age, or 9%, lived below the poverty line (Statistics Canada, 2019a). Indigenous children stand out as being disproportionately burdened in Canada. In 2019, 47% of 254 100 First Nations children lived in poverty (Beedie et al., 2019). These children are growing up in deplorable conditions—some without running water, access to affordable nutritious food, housing, and a proper education, all of which are the responsibility of the federal government according to the *Indian Act*.

Clearly, Canadian children are not doing as well as they could be. Of great concern is the high rate of obesity (twenty-ninth of 30 countries) and the high rate of bullying (twenty-seventh of 31 countries). Canada's children also self-report that they have low life satisfaction; in fact, they are among the unhappiest children in the industrialized world (UNICEF Office of Research, 2017).

Trauma- and Violence-Informed Care

Trauma- and violence-informed care involves an approach that embraces an understanding of trauma and violence at every step in the health care system. This approach recognizes the connections between violence, trauma, negative health outcomes, and behaviours (Government of Canada, 2018b). Many people are at risk of experiencing violence and trauma, making it important for health care providers to gain the knowledge and skills required to assist patients in receiving the best care possible. Box 1.2 outlines the principles of how to integrate trauma-informed care. The goal of trauma- and violence-informed approaches is to minimize harm to all people, whether or not there is a known experience of violence; therefore, a universal trauma-informed approach is key for all people (Government of Canada,

BOX 1.2 Four Principles of Trauma-Informed Care

Understand trauma and violence and their impacts on people's lives and behaviours:

- Acknowledge the root causes of trauma without probing.
- Listen, believe, and validate victims' experiences.
- Recognize their strengths.
- Express concern.

Create emotionally and physically safe environments:

- Communicate in nonjudgemental ways so that people feel deserving, understood, recognized, and accepted.
- Foster an authentic sense of connection to build trust.
- Provide clear information and consistent expectations about services and programs.
- Encourage patients to bring a supportive person with them to meetings or appointments.

Foster opportunities for choice, collaboration, and connection:

- Provide choices for treatment and services, and consider the choices together.
- Communicate openly and without judgement.
- Provide the space for patients to express their feelings freely.
- Listen carefully to the patient's words and check in to make sure that you have understood correctly.

Provide a strengths-based and capacity-building approach to support patient coping and resilience:

- Help patients identify their strengths, through techniques such as motivational interviewing, a communication technique that improves engagement and empowerment.
- Acknowledge the effects of historical and structural conditions on peoples' lives.
- Help people understand that their responses are normal.
- Teach and model skills for recognizing triggers, such as calming, centring, and staying present.

Source: Adapted from Government of Canada. (2018). *Trauma and violence-informed approaches to policy and practice*. https://www.canada.ca/en/public-health/services/publications/health-risks-safety/trauma-violence-informed-approaches-policy-practice.html

2018b). Trauma- and violence-informed approaches are not about "treating" trauma, for example, through counselling. Instead, the focus is on minimizing the potential for harm and re-traumatization and to enhance safety, control, and resilience for all patients (Government of Canada, 2018b). Not all patients will disclose trauma or violence in their lives, but they do require respectful and safe care.

! NURSING ALERT

Universal trauma precautions are important for all patients in order to provide safe care. Embedding trauma- and violence-informed approaches into all aspects of policy and practice creates universal trauma precautions that can reduce harm and provide positive supports for **all** people (Government of Canada, 2018b).

Adverse Childhood Experiences

It is important for nurses to be aware of adverse childhood experiences (ACEs) in their patients. These ACE's are negative, stressful, traumatizing events that occur before the age of 18, and of the effects these can have on health risk across the lifespan (Alberta Family Wellness Initiative, 2021). These experiences can include adversities that children face in their home environment, such as various forms of physical and emotional abuse, neglect, and household dysfunction. Exposure to these experiences cause excessive activation of the stress response system. The more ACEs a child experiences, the more likely they will develop conditions like heart disease and diabetes, will have poor academic achievement, and may develop substance use disorders later in life (Center on the Developing Child at Harvard University, 2020). These experiences can occur across all socioeconomic groups. People who have experienced significant adversity (or many ACEs) are not irreparably damaged; through the implementation of three approaches—reducing stress, building responsive relationships, and strengthening life skills—the long-term effects of ACEs can be prevented or minimized (Center on the Developing Child at Harvard University, 2020). See Chapter 30 for further discussion of ACEs.

Indigenous People

In 2016, the number of Indigenous people in Canada, which includes First Nations, Métis, and Inuit, was 1 673 785, accounting for 4.9% of the total population (Statistics Canada, 2017a). The average age of Indigenous people was 32.1 years in 2016—almost a decade younger than that of the non-Indigenous population (40.9 years) (Statistics Canada, 2017a). In 2016, around one-third of First Nations people (29.2%) were 14 years of age or younger. For Métis, 22.3% of the population were 14 years of age or younger, and among Inuit, one-third (33.0%) were 14 years of age or younger (Statistics Canada, 2017a).

The history of Indigenous peoples is important to acknowledge, as it is the original history of the country—they are the first peoples of Canada and continue to play important roles in the country's development and its future. They have a vibrant and strong culture, arts practice, and heritage. Indigenous people have their own systems of health knowledge within their own specific ways of knowing and being, thus it is important to acknowledge and utilize this information when providing care.

It is also important to acknowledge the negative impacts that influence the lives of Indigenous people. As stated earlier, colonization continues to have a negative and lasting effect on all aspects of Indigenous people's health, along with specific health determinants that have been identified for Indigenous people (see Figure 1.1). Living in remote locations and lack of access to some of the positive social determinants of health account for some of these health inequities. Improving access to nutritious food, clean water, and safe and secure housing could be fundamental to the improvement of Indigenous people's long-term health.

Beginning in Ontario in 1831 and continuing until the closure of the last school in 1996 in Saskatchewan, the Canadian government, in partnership with a number of Christian churches, operated a residential school system for Indigenous children. The government-funded, usually church-run schools and residences were set up to force Indigenous children to assimilate into the Canadian mainstream by eliminating parental and community involvement in the intellectual, cultural, and spiritual development of Indigenous children in their own communities. More than 150 000 Indigenous children were placed in these residential schools (Truth and Reconciliation Commission [TRC], n.d.). The TRC has worked to reveal the history and ongoing legacy of church-run residential schools in a manner that fully documents the harms perpetrated against Indigenous people and that can lead the way toward respect, through reconciliation (TRC, 2012). In the TRC report, survivors describe what happened after they left the schools: They no longer felt connected to their parents or their families; some said they felt ashamed of themselves, their parents, and their culture; some children found it difficult to forgive their parents for sending them to residential school. Parents also reported the difficulties of having their children away from home and the issues that resulted when they returned home (TRC, 2012).

In these schools, children were often forbidden to speak their Indigenous language or engage in their cultural and spiritual practices. Most children were abused—mentally, spiritually, physically, and/or sexually. Generations of children were severely traumatized by the experience, resulting in an ongoing legacy of intergenerational trauma. *Intergenerational trauma* is defined as untreated trauma that carries through generations and continues to have an impact on subsequent generations. One example of the trauma that was incurred by these children is the abuse they suffered. This abuse by their caregivers was their role model for parenting, one which the victims often repeated when they became parents. Also, when these children got older, they often coped with the post-traumatic stress they suffered by drinking or using other substances. This vicious cycle has continued as individuals, families, and communities cope with intergenerational trauma, leaving its impact on generations of families through parenting difficulties and other stresses.

The TRC highlighted that Indigenous people need specialized health supports available near where they live. Many Indigenous people have to navigate services from the federal and provincial government, specifically those living on reservations. The need for health supports is especially acute in the northern and more isolated regions of Canada. It is imperative that health care providers become knowledgeable of Indigenous health and their view of health and illness, as well as of Indigenous healing practices in order to provide care that is culturally safe. The TRC (2015) final report calls on health care providers to acknowledge the necessity of Indigenous-led health and healing practices and to support these practices when requested. Such recognition is crucial to reconciliation.

Lesbian/Gay/Bisexual/Transsexual/Queer/2-Spirited (LGBTQ2) Health

LGBTQ2 people have higher rates of illness due to discrimination, minority stress, avoidance of health care providers, and irregular access to health care services (Gahagan & Subirana-Malaret, 2018). This situation may be due in part to negative past experiences. Many LGBTQ2 people may delay or avoid seeking health care or choose to withhold personal information from health care providers.

In general, LGBTQ2 people end up receiving less good-quality health care than the population as a whole (Rainbow Health Ontario [RHO], 2014). People who identify as LGBTQ2 also have some unique health concerns and may be at increased risk for certain health issues,

including mental health challenges; substance use; intimate partner violence; higher rates of smoking and cancer; and diet, weight, and body image concerns (RHO, 2014). Many health care providers are not trained in these LGBTQ2 health needs and may not have the knowledge required in how to care for individuals in this population and are thus unable to provide the safest care possible.

Nurses and other health care providers must provide care that is not seen as heteronormative and that is inclusive of people of any gender or sexuality and of those who choose to not state either. In providing care, questions need to be asked in a manner that does not make assumptions about sexuality or gender. Nurses should also be aware of their use of language and be careful not to genderize patients through the language that is used. They also need to be aware of how to be gender inclusive. Nurses caring for pediatric patients must also be conscious of LGBTQ2 concerns. Children and adolescents may have questions about their sexuality and gender, and if the nurse develops a therapeutic relationship with the child, the child may feel comfortable enough to ask questions and seek appropriate resources.

Throughout this text, an attempt has been made to integrate LGBTQ2 issues into the respective sections. Although a comprehensive discussion is beyond the scope of this text, additional resources are also included, when available.

Culture

Another factor that affects the delivery and quality of health care is the fact that the Canadian population is diverse in terms of **culture**, **ethnicity**, race, and age. According to the 2016 census, more than one fifth of Canadians were born in another country (Statistics Canada, 2019b). Statistics Canada predicts that by 2031, between 29 and 32% of Canadians will identify as belonging to a visible minority, and as many as three out of five people living in Toronto and Vancouver will identify as visible minorities (Statistics Canada, 2015b).

Significant disparity exists in health outcomes among people of various racial and ethnic groups in Canada. People also have different health needs, practices, and health service preferences related to their ethnic or cultural backgrounds. They may have dietary preferences and health practices that are not understood by their caregivers. To meet the health care needs of a culturally diverse society, nurses must provide culturally safe and responsive care (see Chapter 2).

Integrative Healing and Alternate Health Practices

Integrative healing encompasses complementary and alternative health modalities (CAM) that are sometimes used in combination with conventional biomedical modalities of treatment. Many popular healing modalities offer human-centred care based on philosophies that honour the individual's beliefs, values, and desires. The focus of these modalities is on the whole person, not just on a disease complex. Many patients often find that integrative modalities are more consistent with their own belief systems and allow for more autonomy in health care decisions. It is important that nurses understand the beliefs of patients to ensure that their health care needs are met.

Individuals may also have health practices based on their spirituality, culture, or race. Health care providers who practise cultural humility and acknowledge that they do not need to know all of these various alternatives but be open and receptive to gaining such knowledge are in a good position to assist in the patient's care.

High-Technology Care

Advances in scientific knowledge have contributed to a health care system that emphasizes high-technology care. For example, maternity care has extended to preconception counselling, more scientific techniques to monitor the childbearing person and fetus, more definitive tests for hypoxia and acidosis, and neonatal intensive care units, which have often saved the lives of premature children. Enhanced technology has also increased the life expectancy of many children with chronic illnesses. Internet-based information is available to the public that can promote interactions among health care providers, families, and community providers. Point-of-care testing is also available. Personal data assistants are used to enhance comprehensive care; the medical record is increasingly in electronic form.

Health information technology is also having a profound impact on the ways in which health services are delivered. **Telehealth** is an umbrella term for the use of communication technologies and electronic information to provide or support health care when participants are separated by distance. It enables specialists, including nurses, to provide health care and consultation to those needing care. While this technology can increase access to health services for people living in geographically isolated communities, nurses must use caution and evaluate the effects of such emerging technologies. Another Web-based resource is Healthlink, which provides people in several provinces with medically approved information on many health topics, medications, and tips for promoting healthy lifestyles (see Additional Resources).

Social Media

Social media is a form of Internet-based technologies that allow users to create their own content and participate in dialogue. Common social media platforms are Facebook, Instagram, Snapchat, Twitter, and LinkedIn (Tandoc et al., 2019). In addition to their own personal use of these technologies, nurses can connect with nurses with similar interests, share and exchange information about patient care, obtain training, and provide a space for collaboration (Hao & Gao, 2017). However, there are pitfalls for nurses using this technology. Patient privacy and confidentiality can be violated, and institutions and colleagues can be cast in an unfavourable light, with negative consequences for those posting the information. Nursing students have been expelled from school and nurses have been fired or reprimanded by their provincial regulatory body for injudicious posts. To help make nurses aware of their responsibilities when using social media, the International Nurse Regulator Collaborative (INRC) published the six P's for social media use (Box 1.3). Their report details issues of confidentiality and privacy, possible consequences of inappropriate use of social media, common myths and misunderstandings of social media, and tips on how to avoid related problems. The Canadian Nurses Protective Society (2012) states that before nurses communicate on a social media website, it is important to consider what is said, who might read it, and the impact it might have if viewed by an employer, a patient, or licensing body.

BOX 1.3 Six P's of Social Media Use

Professional—Act professionally at all times.
Positive—Keep posts positive.
Patient/Person-free—Keep posts patient or person free.
Protect yourself—Protect your professionalism, your reputation, and yourself.
Privacy—Keep your personal and professional life separate; respect privacy of others.
Pause before you post—Consider implications; avoid posting in haste or anger.

Source: Adapted from International Nurse Regulator Collaborative. (2016). *Position statement: Social media use: Common expectations for nurses*. http://www.cno.org/globalassets/docs/prac/incr-social-media-use-common-expectations-for-nurses.pdf

While patients may identify social media as having positive benefits, many also know that they are at risk of negative health impacts from social media. Harmful behaviours displayed on social media platforms such as the Tide Pod Challenge and showing condom snorting have resulted in children being harmed. The most documented negative consequences have been cyberbullying, depression, social anxiety, and exposure to developmentally inappropriate content (Subrahmanyam & Smahel, 2011). Health care providers must be aware of social media impacts both positive and negative.

Health Literacy

Health literacy involves the simultaneous use of a more complex and interconnected set of abilities: to read and act on written health information, to communicate needs to health providers, and to understand health instructions. Without adequate health literacy skills, ill-informed decisions may be taken, health conditions may go unchecked or worsen, questions may go unasked or remain unanswered, accidents may happen, and people may get lost in the health care system (Canadian Council on Learning, 2008). Recent findings show that 60% of adults and 88% of older persons in Canada are not health literate (ABC Life Literacy Canada, 2018). People who are not health literate have difficulty using the everyday health information that is routinely available in health care facilities, grocery stores, retail outlets, and schools; through the media; and in their communities. They may also have difficulty reading appointment slips and determining the proper way to take medication.

As a result of the increasingly multicultural nature of the Canadian population, there is an urgent need to address health literacy as a component of culturally and linguistically competent care. Canadians with low health-literacy skills were found to be more likely to be in poorer health (Berkman et al., 2011). Individuals and groups for whom English is a second language often lack the skills necessary to seek medical care and navigate the health care system. Health care providers can contribute to health literacy by speaking slowly and using simple, common words; avoiding jargon; using pictures and diagrams to illustrate key points; and assessing whether the patient understands the discussion. The skillful use of an interpreter or telephone interpretation service can promote understanding and **informed consent** (see Chapter 2).

SPECIALIZATION AND EVIDENCE-INFORMED NURSING PRACTICE

The increasing complexity of care required by childbearing persons and their newborns, as well as children who are sick, has contributed to the growth of specialized knowledge and skills needed by nurses working in the areas of perinatal and pediatric nursing. This specialized knowledge is gained through experience, advanced degrees, and certification programs.

Advanced practice nurses, such as clinical nurse specialists, provide care for adults as well as children with complex health challenges. Nurse practitioners may provide primary care throughout the life of many patients. Lactation consultants, many of whom are nurses, provide services in the hospital, on an outpatient basis, or in the patient's home. Maternal child nurses work collaboratively with public health nurses and an increasing array of health care providers. An example is working with registered midwives who may provide primary care during pregnancy and the early postpartum period. Public health nurses may also work with teachers in schools to provide quality education experiences for children with a chronic illness that affects their ability to attend school.

Evidence-Informed or Research-Based Practice

Evidence-informed practice (EIP) is the collection, interpretation, and integration of valid, important, and applicable patient-reported, nurse-observed, and research-derived information. Evidence-informed nursing practice combines knowledge with clinical experience and intuition. It provides a rational approach to decision making that facilitates best practice. Although not all practice can be evidence-informed, nurses must use the best available information to guide their interactions and interventions.

Practising nurses should contribute to research because they are the individuals observing human responses to health and illness. The current emphasis on measurable outcomes to determine the efficacy of interventions (often in relation to the cost) demands that nurses know whether clinical interventions result in positive outcomes for their patients. This demand has influenced the current trend toward EIP, which involves questioning why something is effective and whether a better approach exists. The concept of EIP also involves analyzing published clinical research and translating it into the everyday practice of nursing. When nurses base their clinical practice on science and research and document their clinical outcomes, they are better able to validate their contributions to health, wellness, and cure—not only to their patients and institutions but also to the nursing profession. Evaluation is essential to the nursing process, and research is one of the best ways to accomplish this.

Research plays a vital role in establishing perinatal, women's health, and child health science. It can validate that nursing care makes a difference. For example, although prenatal care is associated with healthier infants, no one knows exactly which interventions produce this outcome. In the past, medical researchers rarely included women in their studies; thus more research in this area is crucial. Many possible areas of research exist in maternity and women and children's health care. The clinician can identify problems in the health and health care of childbearing persons and of children. Through research, nurses can make a difference for these patients. Nurses should promote research funding and conduct research on perinatal, pediatric, and women's health, especially concerning the effectiveness of nursing strategies for these patients (see Evidence-Informed Practice box: Searching for and Evaluating the Evidence).

EVIDENCE-INFORMED PRACTICE

Searching for and Evaluating the Evidence

Throughout this text you will see Evidence-Informed Practice boxes. These boxes provide examples of how a nurse might conduct an inquiry into an identified practice question. Curiosity, access to a virtual or real library, and research critique skills are needed for nurses to be confident that their practice is informed by a sound foundation of evidence.

Nurses construct their practice informed by research from many different sources. Categorizing evidence by "levels" is being replaced with embracing multiple ways of knowing that include personal knowledge. Experienced nurses have practice knowledge that they need to share with other nurses through publication. Indigenous ways of knowing are increasingly being recognized within Westernized health care, and patients are being acknowledged as experts in their own health care experiences (Hyett et al., 2018). Quantitative and qualitative research has added to our understanding of a patient's experience with the health care system, whether during illness or wellness care.

Provided the professional organization is well respected and the process is rigorous, clinical practice guidelines and consensus statements reflect the current state of knowledge. Nurses need to also develop an inquiring mind and questioning attitude toward all forms of current evidence. In this way, the knowledge base required for perinatal and pediatric nursing will continue to grow and develop.

Standards of Practice and Legal Issues in Delivery of Care

Nursing standards of practice reflect current knowledge, represent levels of practice agreed on by leaders in the specialty and can be used for clinical benchmarking. In perinatal and women's health nursing, there are several organizations that publish standards of practice and education. These include the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN) and the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN), which publish standards of practice and education for perinatal nurses; and the National Association of Neonatal Nurses (NANN), which publishes standards of practice for neonatal nurses. The Canadian Association of Paediatric Nurses is the voice of pediatric nurses in Canada and has developed national standards.

The Canadian Nurses Association (CNA) Certification Program also has competencies developed for perinatal, community, general pediatric, pediatric critical care nurses, and neonatal nurses that guide certification exams for each of these specialties. Certification with the CNA demonstrates specialized knowledge and enhances a nurse's professional credibility, which is valued by employers.

In addition to these more formalized standards, agencies have their own policy and procedure books that outline standards to be followed in that setting. In legal terms, the **standard of care** is that level of practice that a reasonably prudent nurse would provide in the same or similar circumstances.

LEGAL TIP: Standard of Care

When there is uncertainty about how to perform a procedure, the nurse should consult the agency procedure book and follow the guidelines printed therein. These guidelines are the standard of care for that agency.

Patient Safety and Risk Management

Medical errors are a leading cause of death in the hospital or at home. According to the Canadian Adverse Events Study (Baker Study), the most quoted study in Canada regarding medical errors, 7.5% of hospitalized patients had an adverse event and of these, 16% died as a result (Baker et al., 2004). The cost of adverse events is staggering; the economic burden of adverse events is $1.1 billion, including $397 million for preventable adverse events (Etchells et al., 2012).

The actual numbers of adverse events are difficult to determine, as there is a culture of silence surrounding patient errors. The Canadian Patient Safety Institute (CPSI) was developed as an integrated strategy for improving patient safety in Canadian health care (Box 1.4). The CPSI facilitates collaboration among governments and care providers to enhance patient safety and provides a number of useful resources, including the Canadian disclosure guidelines, an incident analysis framework, and the safety competencies framework. Achieving a culture of patient safety requires open, honest, and effective communication between health care providers and their patients. Patients are entitled to information about themselves and about their medical condition or illness, including the risks inherent in health care delivery (CPSI, 2011).

Interprofessional Education

Interprofessional education (IPE) consists of faculty and students from two or more health professions who create and foster a collaborative learning environment. The underlying premise of interprofessional collaboration is that patient-centred care will improve when health professionals work together (WHO, 2010). Six competency domains highlight the knowledge, skills, attitudes, and values that shape the judgements essential for interprofessional collaborative practice (Canadian Interprofessional Health Collaborative, 2010). See Box 1.5 for a description of the practice competencies related to IPE.

GLOBAL HEALTH

As the world becomes a smaller place because of travel and communication technologies, nurses and other health care providers are gaining a global perspective and participating in activities to improve the health and health care of people worldwide. Nurses participate in medical outreach; provide obstetrical, surgical, ophthalmological, orthopedic, or other services; attend international meetings; conduct research; and provide international consultation. International student and faculty exchanges occur. More articles about health and health care in various countries are appearing in nursing journals. The WHO (2020) has stated that nurses and midwives make up about 50% of the global health care workforce. Increasingly, Canadian nurses are working internationally in global health settings (Figure 1.2). This role is supported by the CNA (2012), which believes that nurses have the right and the responsibility to contribute to the advancement of global health and equity.

Sustainable Development Goals

In the year 2000, the member nations of the United Nations (UN) developed the Millennium Development Goals (MDGs), which were eight international goals that focus on improving the health and education of the global community. The original plan was to reach these by the year 2015. The MDGs were drawn from the actions and targets contained in the Millennium Declaration that was adopted by 189 nations and signed by 147 heads of state and governments during the United

BOX 1.4 Goals of the Canadian Patient Safety Institute (CPSI)

The CPSI's four goals to improve patient safety:

- The CPSI will provide leadership on the establishment of a National Integrated Patient Safety Strategy.
- The CPSI will inspire and sustain patient safety knowledge within the system and, through innovation, enable transformational change.
- The CPSI will build and influence patient safety capability (knowledge and skills) at organizational and system levels.
- The CPSI will engage all audiences across the health system in the national patient safety agenda.

BOX 1.5 Competency Domains for Interprofessional Education (IPE)

The six competency domains are as follows:

- Interprofessional communication
- Patient/client/family/community-centred care
- Role clarification
- Team functioning
- Collaborative leadership
- Interprofessional conflict resolution

Nations Millennium Summit, in September 2000 (http://www.un.org/millenniumgoals/). These goals were an ambitious pledge to uphold the principles of human dignity, equality, and equity and free the world from extreme poverty. Much work had been done on the MDGs, and they have made a profound difference in the lives of many people across the world (UN, 2015). According to the UN (2015), global poverty has been halved; 90% of children in developing regions now enjoy primary education, and disparities between boys and girls in enrollment have narrowed. There are decreased rates of malaria and tuberculosis, and the likelihood of a child dying before age 5 has been nearly cut in half over the last two decades. The number of people who do not have access to good water sources has also been halved. Despite the significant gains that have been made for many of the MDG targets worldwide, the progress has been uneven across regions and countries, leaving significant gaps (UN, 2015).

In 2015 the UN endorsed the Sustainable Development Goals (SDGs) (Figure 1.3), which are a blueprint to achieve a better and more sustainable future for all. They address current global challenges, including those related to poverty, inequality, climate, environmental degradation, prosperity, and peace and justice, with a target of 2030 for achieving these (Government of Canada, 2018a). SDG #3 focuses on good health and well-being, and many of the goals related to this are focused on improving maternal and child health. Therefore, in the countdown to 2030 the aim is to support the monitoring and measurement of women's, children's, and adolescents' health in 81 countries (Boerma et al., 2018). While acknowledging success in the countdown to 2015, it is clear that there is still much work to be done to improve intervention coverage, equity, and reproductive, maternal, newborn, and child health.

Fig. 1.3 Sustainable Development Goals. The United Nations has developed 17 goals to improve the health and well-being of the global community. (From United Nations. [2015]. *Sustainable Development Goals kick off with start of new year.* https://www.un.org/sustainabledevelopment/blog/2015/12/sustainable-development-goals-kick-off-with-start-of-new-year/)

In 2010, with the signature of the Muskoka Declaration, the Canadian government promised to assist developing countries in addressing health inequities that affect mothers and infants (Government of Canada, 2014). With its additional $1.1 billion commitment to maternal, newborn, and child health, Canada's total commitment to reducing child mortality and improving maternal health was $3.25 billion from 2015 to 2020 (Government of Canada, 2020a).

ETHICAL ISSUES IN MATERNAL CHILD NURSING

Ethical concerns and debates have multiplied with the increased use of technology and scientific advances. For example, with reproductive technology, pregnancy is now possible in childbearing persons who thought they would never bear children, including some who are menopausal or postmenopausal. Should scarce resources be devoted to achieving pregnancies in older patients? Is giving birth to a child at an older age worth the risks involved? Should older parents be encouraged to conceive a baby when they may not live to see the child reach adulthood? Should a childbearing person who is HIV positive have access to assisted reproduction services? Who should pay for reproductive technologies, such as the use of induced ovulation and in vitro fertilization? Other examples of ethical dilemmas within nursing include the use of life-saving measures for very low birth weight (VLBW) newborns, the terminally ill child's right to refuse treatment, access to abortion, substance use of patients, informed consent, barriers to services, and confidentiality. Nurses may struggle with questions involving truthfulness, balancing their rights and responsibilities in caring for children with AIDS, whistle-blowing, or allocating resources.

Questions about informed consent and allocation of resources must be addressed with innovations such as intrauterine fetal surgery, fetoscopy, therapeutic insemination, genetic engineering, stem cell research, surrogate childbearing, surgery for **infertility**, "test-tube" babies, fetal research, and treatment of VLBW babies. For example, discussion is required when a 23-week gestation baby is born alive, and decisions need to be made regarding what treatment will be provided, based on the wants of the parents and the knowledge of health care providers. The introduction of long-acting contraceptives has created moral choices and policy dilemmas for health care providers and legislators (e.g., whether some patients [substance users or patients who are HIV positive] should be required to take the contraceptives). With the potential for great good that can come from fetal tissue transplantation, what research is ethical? What are the rights of the embryo? Should cloning of humans be permitted? Discussion and debate about these issues will continue for many years. Nurses and patients, as well as scientists, physicians, lawyers, lawmakers, ethicists, and clergy, must be involved in the discussions.

Nurses must prepare themselves systematically for collaborative ethical decision making. This can be accomplished through taking formal coursework and continuing education, reading contemporary literature, and working to establish an environment conducive to ethical discourse. Moreover, nurses need to be educated in the mechanisms for dispute resolution, case review by ethics committees, procedural safeguards, Canadian legislation, and case law.

The nurse can also use the professional code of ethics for guidance and as a means for professional self-regulation. The *Code of Ethics for Registered Nurses*, by the CNA, provides the framework and core responsibilities for nursing practice. The *Code of Ethics* focuses on the nurse's accountability and responsibility to the patient (CNA, 2017) and emphasizes the nursing role as an independent professional, one that upholds its own legal liability (see Additional Resources).

Ethical Guidelines for Nursing Research

Research with women and children may create ethical dilemmas for the nurse. For example, participating in research may cause additional stress for a person concerned about outcomes of genetic testing or for one who is waiting for an invasive procedure. Obtaining amniotic fluid samples or performing cordocentesis poses risks to the fetus (see Chapter 13). Research on children must be conducted in ways that ensure informed consent of parents and for children, when possible (see Chapter 44, Consent for Health Research in Children). Nurses must protect the rights of human participants in all research; women and children are already vulnerable, so they need to be reassured that their rights are being protected. For example, nurses may need to collect data on or care for patients who are participating in clinical trials. The nurse should ensure that the participants are fully informed and aware of their rights as participants. The nurse may be involved in determining whether the benefits of research outweigh the risks to the parent and the fetus or to children and needs to ensure that all research conducted has been approved by the appropriate research ethics board. Research involving Indigenous people involves specific ethical guidelines because of their history. The Canadian Institute of Health Research (CIHR) is an example of an organization that outlines ethical guidelines of health research involving Indigenous people in Canada (CIHR, 2013).

KEY POINTS

- Perinatal nursing focuses on caring for patients and their families throughout the childbearing years, and pediatric nurses care for children from birth to 18 years of age.
- Nurses can play an active role in shaping health policy and health systems to be responsive to the needs of Canadian women and children.
- The social determinants of health have an impact on the health of all people.
- Of the determinants of health, poverty remains the most important factor resulting in conditions of vulnerability such as homelessness.
- Families and children living in rural, remote, and Indigenous communities and in poverty in inner cities experience significant health challenges.
- Universal trauma precautions can assist in providing safe care to all patients.
- Indigenous patients have unique health care issues that require health care providers to understand the historical context and impact of the social determinants of health affecting these patients.
- LGBTQ2 patients require health care providers who understand their specific health care needs.
- Nurses must provide comprehensive, respectful care to all people, and knowledge about different cultural and diversity issues will assist in providing this care.
- Integrative healing combines modern technology with ancient healing practices and encompasses the whole body, mind, and spirit.
- Technology has had a tremendous influence on health care through use of high-technology care modalities as well as access to other health care providers and to patients through social media.
- Perinatal and pediatric nursing practice is increasingly informed by research.
- Nurses must ensure that safe care is provided to childbearing patients and children by communicating with other members of the health care team in a manner that ensures clear understanding.
- While the Millennium Development Goals have improved the health of many people worldwide, much work still needs to be done to reduce poverty, promote gender equality, and improve perinatal

and child health. The Sustainable Development Goals are focused on achieving a better and more sustainable future for all.
- Ethical concerns have multiplied with the increasing use of technology and scientific advances.

The Family and Culture

Karen MacKinnon
Originating US Chapter by *Shannon E. Perry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the variety of family forms encountered by nurses in Canada today.
2. Identify the principles that underpin interprofessional family-centred care.
3. Explore and describe theories and models developed as guides to family nursing in Canada.
4. Describe how different lenses or perspectives contribute to our understanding of family health promotion and relational nursing practice.
5. Explore and discuss how spirituality influences the health of individuals and their families.
6. Define culture, ethnocentrism, cultural safety, and cultural humility.
7. Describe what is meant by cultural competence and culturally safe care and reflect on how this will influence nursing practice.
8. Explore ways to provide culturally responsive family nursing care.

THE FAMILY IN CULTURAL AND COMMUNITY CONTEXT

Perinatal and pediatric nurses have important professional responsibilities to families. Despite modern stresses and strains, the family still forms a social network that acts as a potent support system for its members. Family health practices and relationships with providers are influenced by culturally related health beliefs and values. Ultimately, all of these factors have the power to affect perinatal and child health outcomes. Nurses work collaboratively with families to achieve their goals related to wellness and family development. Because the Canadian population has become increasingly diverse in terms of culture, ethnicity, and socioeconomic status, it is essential that nurses become culturally competent in order to provide appropriate nursing care.

The Family in Society

The social context for the family can be viewed in relation to social and demographic trends that reflect the population as a whole. Each family sets up boundaries between itself and society. People are conscious of the difference between "family members" and "outsiders," or people without kinship status. Some families isolate themselves from the outside community; others have a wide community network that they can turn to in times of stress. Although boundaries exist for every family, family members set up channels through which they interact with society.

Defining Family

The family has traditionally been viewed as the primary unit of socialization—the basic structural unit within a community. The family plays a pivotal role in health care and is often the central focus for nursing care. As one of society's most important institutions, the family represents a primary social group that influences and is influenced by other people and institutions. A variety of family configurations exist.

The term **family** has been defined in many different ways according to the individual's own frame of reference, value judgement, or discipline. There is no universal definition of family; a family is what an individual considers it to be. Biologists describe the family as fulfilling the biological function of perpetuation of the species. Psychologists emphasize interpersonal aspects of family and its responsibility for personality development. Economists view the family as a productive unit providing for material needs. In sociology, the family is depicted as a social unit interacting with the larger society, creating contexts within which cultural values and identity are formed. Others define family in terms of the relationships of the persons who make up the family units. Some of the common types of family relationships are *consanguineous* (blood relationships), *affinal* (marital relationships), and *family of origin* (family unit a person is born into).

Earlier definitions of family emphasized that family members were related by legal ties or genetic relationships and lived in the same household with specific roles. Later definitions have been broadened to reflect structural and functional changes. A *family* can be defined as an

institution in which individuals, related through biology or enduring commitments and representing similar or different generations and genders, participate in roles involving mutual socialization, nurturance, and emotional commitment.

Family Organization and Structure. Individuals define their own family and support system by choosing who is included and who is excluded. The definition of family may include two or more different people such as parents, siblings, grandparents, partners, aunts and uncles, or friends (Table 2.1).

The **nuclear family** consists of male and female partners and their children living as an independent unit sharing roles, responsibilities, and economic resources (Figure 2.1). In 2016, 73.3% of children under the age of 15 were living with two biological or adoptive parents in a nuclear family structure (Statistics Canada, 2019a).

Multigenerational or extended families, consisting of grandparents, children, and grandchildren living in the same household, are becoming increasingly common (Figure 2.2). Caring for aging parents can create stress for parents who are also caring for their own children. In other situations, the grandparents support the children and grandchildren or are sole caregivers for the grandchildren. For some groups, such as Indigenous peoples, the family network is an important resource for promoting health and healing.

TABLE 2.1 Definitions of Family

Type of Family	Description
Nuclear	Male and female parents with children May be biological or adoptive parents May be married or common-law
Multigenerational or extended family	Grandparents, children, and grandchildren living in same household
Blended families	Unrelated family members join to make a new household as result of death or divorce and remarriage
Lone-parent families	One biological or adoptive parent living with their child or children. They may or may not be living with other adults.
Same-sex parent families	May be married or common-law

Fig. 2.1 Nuclear family. (Courtesy Makeba Felton, Wake Forest, NC.)

Fig. 2.2 Extended (multigenerational) family. (Courtesy Makeba Felton, Wake Forest, NC.)

Blended families, those formed as a result of divorce and remarriage, consist of unrelated family members (step-parents, stepchildren, and stepsiblings) who join to create a new household. These family groups frequently involve a biological or adoptive parent whose spouse may or may not have adopted the child. In 2016, almost 10% of Canadian children under 15 were living in blended families (Statistics Canada, 2019a).

Lone-parent families comprise an unmarried biological or adoptive parent who may or may not be living with other adults. The lone-parent family may result from the loss of a spouse by death, divorce, separation, or desertion; from either an unplanned or planned pregnancy; or from the adoption of a child by an unmarried person. This family structure has become common, with Statistics Canada (2019a) reporting that 19.2% of all children under the age of 15 were living in a lone-parent family. More than 80% of lone-parent families were female-headed lone-parent families, while 18.7% were headed by males (Statistics Canada, 2019a). This gender difference is significant because female-headed lone-parent families are more likely to have lower incomes and to experience poverty than male lone-parent families, which in turn can affect the health status of family members.

Same-sex couple families may live together with or without children. Children in lesbian and gay families may be the offspring of previous heterosexual unions, conceived by one member of a lesbian couple through therapeutic insemination, or adopted. Overall, same-sex couples accounted for 0.9% of all couples in Canada in 2016; this number has increased significantly since 2006. In 2016, 12% of same-sex couples in Canada had children under 15 living with them, compared to about half of heterosexual couples (Statistics Canada, 2019b).

Transgendered couples also form families and often become parents, either through the use of fertility drugs, adoption, or transmen discontinuing the hormones they are taking so they can become pregnant themselves.

Family Dynamics

Ideally, the family uses its resources to provide a safe, intimate, and nurturing environment that supports the biopsychosocial development of family members. The family provides for the nurturing and socialization of children. Children form their earliest and closest relationships with their parents or parenting persons; these affiliations continue throughout a lifetime. Parent–child relationships may influence self-worth and the child's ability to form later relationships. The family also influences the child's perceptions of the outside world. The family provides the growing child with an identity that has both a past and a sense of the future. Cultural and religious beliefs, values, and rituals are passed from one generation to the next through the family.

Over time, the family develops protocols for problem-solving, particularly those regarding important decisions such as having a baby or buying a house. The criteria used in making decisions are based on family values and attitudes about the appropriateness of the behaviour and influenced by social, moral, political, and economic messages. The power to make critical decisions is given to a family member through tradition or negotiation. All families have strengths and the potential for growth. It is important for the nurse to identify those strengths and potential in order to facilitate the growth of the family (Gottlieb, 2013).

FAMILY NURSING

Families play a pivotal role in health care, representing the primary focus of health care delivery for perinatal and pediatric nurses. In treating the family with respect and dignity, nurses listen to and honour perspectives and choices of the family. They share information with families in ways that are positive, useful, timely, complete, and accurate. The family is supported to participate in their care and decision making at the level of their choice.

Because so many variables affect ways of relating, the nurse must be aware that family members may interact and communicate with each other in ways that are distinct from those of the nurse's own family of origin. Families may hold some beliefs about health that are different from those of the nurse. Their beliefs can conflict with principles of health care management predominant in the Western health care system. Nurses must learn to incorporate these family beliefs into the care that is provided.

In most perinatal and pediatric contexts family nursing could be understood as nursing *with* childbearing and child-rearing families. Family-focused nursing practice foregrounds the family in relation to the individual person within a holistic orientation to health that recognizes the importance of environmental and community contexts. From this perspective the nurse works *with* families by relating to them as people in a way that is meaningful to them, draws on a relational inquiry stance of learning *with* people, identifies patterns of experience that influence health and well-being, enacts professional responsibilities and social commitments, and addresses social determinants that influence health and result in health inequities.

In summary, family nursing practice is collaborative and directed by the family's needs and goals; growth oriented, building on family and community strengths (capacities and resources); respectful of family knowledge and expertise; and congruent with the principles of multidisciplinary family-centred care (Box 2.1) (Public Health Agency of Canada [PHAC], 2017; Registered Nurses' Association of Ontario [RNAO], 2015). An informed advocacy framework may also be helpful for perinatal and pediatric nurses in advancing the practice of family-centred nursing care (Marcellus & MacKinnon, 2016).

BOX 2.1 Principles of Family-Centred Interprofessional Health Care

Family-centred care (FCC) is a collaborative, complex, and dynamic process of providing safe, skilled, and individualized care. Such care responds to the physical, emotional, psychosocial, and spiritual needs of the person and family. FCC is health oriented and recognizes the importance of family participation and informed choice.

1. FCC is important in all health care contexts.
2. FCC is informed by research evidence.
3. FCC requires a holistic approach.
4. FCC requires collaboration among care providers.
5. Culturally appropriate care is important in a multicultural society.
6. Indigenous people and communities have distinctive knowledge, health needs, and experiences.
7. Providing care to families as close to home as possible is ideal.
8. The attitudes and language of health care providers affect the family's experiences with health care.
9. FCC functions within a health care system that requires ongoing evaluation.
10. Learning about FCC practices globally may offer valuable options for consideration in Canada.

(2017). *Chapter 1: Family-centred maternity and newborn care in Canada: Underlying philosophy and principles*. https://www.canada.ca/content/dam/phac-aspc/documents/services/publications/healthy-living/maternity-newborn-care/maternity-newborn-care-guidelines-chapter-1-eng.pdf

Theories as Guides to Understanding and Working With Families

A **family theory** can be used to describe families and how the family unit responds to events both within and outside the family. Each family theory makes certain assumptions about the family and has inherent strengths and limitations. Most nurses use a combination of theories in their work with families. A brief synopsis of several theories useful for working with families is given in Table 2.2. Application of these concepts can guide assessment and interventions for the family and can be used when providing care in many perinatal and pediatric situations.

TABLE 2.2 Theories and Models Relevant to Family Nursing Practice

Theory	Synopsis of Theory
Family Systems Theory (Wright & Leahy, 2013)	The family is viewed as a unit, and interactions among family members are studied, rather than individuals. A family system is part of a larger supra-system and is composed of many subsystems. The family as a whole is greater than the sum of its individual members. A change in one family member affects all family members. The family is able to create a balance between change and stability. Family members' behaviours are best understood from a view of circular rather than linear causality.
Family Life Cycle (Developmental) Theory (Carter & McGoldrick, 1999)	Families move through stages. The family life cycle is the context in which to examine the identity and development of the individual. Relationships among family members go through transitions. Although families have roles and functions, a family's main value is in relationships that are irreplaceable. The family involves different structures and cultures organized in various ways. Developmental stresses may disrupt the life cycle process.
Family Stress Theory (Boss, 2002)	This theory is concerned with ways that families react to stressful events. Family stress can be studied within the internal and external contexts in which the family is living. The internal context involves elements that a family can change or control, such as family structure, psychological defences, and philosophical values and beliefs. The external context consists of the time and place in which a particular family finds itself and over which the family

TABLE 2.2 Theories and Models Relevant to Family Nursing Practice—cont'd

Theory	Synopsis of Theory
	has no control, such as the culture of the larger society, the time in history, the economic state of society, the maturity of the individuals involved, the success of the family in coping with stressors, and genetic inheritance.
McGill Model of Nursing (Allen, 1997)	This model of situation-responsive nursing has a strength-based focus in clinical practice with families rather than a deficit approach. Identification of family strengths and resources, provision of feedback about strengths, and assistance given to the family to develop and elicit strengths and use resources are key interventions. The McGill model is particularly relevant for working with childbearing families, as pregnancy can be considered a "teachable moment" for promoting the health of the entire family.
The Collaborative Partnership Approach (Gottlieb & Feeley, 2006)	This model builds on the McGill model of nursing and more fully develops a collaborative partnership approach to family nursing. A *collaborative partnership* is defined as "the pursuit of person-centred goals through a dynamic process that requires the active participation and agreement of all partners." Features of a collaborative partnership include mutual identification of an agreement on goals; sharing expertise and power; being respectful, accepting, and nonjudgemental; being open to learning together and learning to live with ambiguity; and being reflective and self-aware.

Another source for information about family nursing practice models is the International Family Nursing Association: https://internationalfamilynursing.org/resources-for-family-nursing/practice/practice-models/

Family Assessment

When selecting a family assessment framework, it is important to consider the focus of nursing care. An appropriate model for a perinatal nurse is one that is health promoting rather than an illness-care model. The family can be assisted in fostering a healthy pregnancy, childbirth, and integration of the newborn into the family. Patients experiencing perinatal health challenges or conditions of vulnerability (e.g., poverty) or families with ill children have additional needs that the nurse may need to address while also promoting the health of the family.

The Calgary Family Assessment Model. A family assessment tool such as the Calgary Family Assessment Model (CFAM) (Box 2.2) can be used as a guide for assessing aspects of the family. Such an assessment is based on "the nurse's personal and professional life experiences, beliefs, and relationships with those being interviewed" (Wright & Leahy, 2013) and is not "the truth" about the family but, rather, one perspective at one point in time.

The CFAM consists of three major categories: structural, developmental, and functional. There are several subcategories within each category. The three assessment categories and the many subcategories can be conceptualized as a branching diagram (Figure 2.3). These categories and subcategories can be used to guide the assessment that will provide data to help the nurse better understand the family and formulate a plan of care. The nurse asks questions of family members about themselves to gain understanding of the structure, development, and function of the family at that point in time. Not all questions within the subcategories should be asked at the first interview, and some questions may not be appropriate for all families. Although individuals are the ones interviewed, the focus of the assessment is on interaction of individuals within the family.

Graphic Representations of Families. A *family genogram*, which is a family-tree format depicting relationships of family members over at least three generations (Figure 2.4), provides valuable information about a family and can be placed in the nursing care plan for easy access by care providers. An *ecomap*, a graphic portrayal of social relationships of the individual and family, may also help the nurse understand the social environment of the family and identify support systems available to them (Figure 2.5).

BOX 2.2 Calgary Family Assessment Model

There are three major categories of the Calgary Family Assessment Model (CFAM): structural, developmental, and functional. Each category has several subcategories. In this box, only the major categories are included. A few sample questions are included.

Structural Assessment

- Determine the members of the family, relationship among family members, and context of family.
- Genograms and ecomaps (see Figures 2.4, 2.5) are useful in outlining the internal and external structures of a family.

Sample Questions

- Who are the members of your family?
- Has anyone moved in or out lately?
- Are there any family members who do not live with you?

Developmental Assessment

- Describe the developmental life cycle—that is, the typical trajectory most families experience.

Sample Questions

- When you think back, what do you most enjoy about your life?
- What do you regret about your life?
- Have you made plans for your care as your health declines?

Functional Assessment

- Evaluate the way in which individuals behave in relation to each other in instrumental and expressive aspects. (Instrumental aspects are activities of daily living; expressive aspects include communication, problem-solving, roles, among others.)

Sample Questions

- Which one of the family is best at ensuring that your grandmother takes her medicine?
- Whose turn is it to make dinner for Grandma?
- How can we get Martin to help with Grandma's care?

Family Nursing as Relational Inquiry

Relational nursing challenges nursing practices based on structured assessment frameworks and proposes that nurses need to be "in relation" with patients and family members, taking cues from the family and collaboratively identifying capacity and adversity patterns and building knowledge together for health promotion (Doane & Varcoe, 2015). Recognizing that families are socially located in historical, cultural, and environmental contexts helps nurses to understand the factors that have a significant impact on family members' experiences of health and childbearing. Relational nursing moves beyond a health service provision approach toward one that is more congruent with holistic health promotion (Box 2.3). This approach is understood as a process of inquiry, and this process forms the framework for thoughtful, interpretive, critical, and spiritual inquiry. Nurses learn together *with* the family members about what matters most to them, about family strengths and health challenges, and about how to work toward better health for the family.

A relational inquiry approach also considers the family from four lenses or perspectives: (1) a phenomenological lens, (2) a sociopolitical lens, (3) a spiritual lens, and (4) a socioecological health promotion perspective. The phenomenological lens cues the nurse to learn more about the family members' experiences of health and illness. How does the family view illness? What do they do to enhance wellness? What is meaningful and significant to the family? The sociopolitical lens attends to power and gender, class, ethnic, racial, and professional relationships. The spiritual lens reminds us that health (e.g., childbearing or child-rearing) has particular personal, cultural, and religious meanings and significance. A socioecological perspective of health promotion is an understanding of health and health promotion that focuses on the family in their environmental context. It reminds nurses that nursing

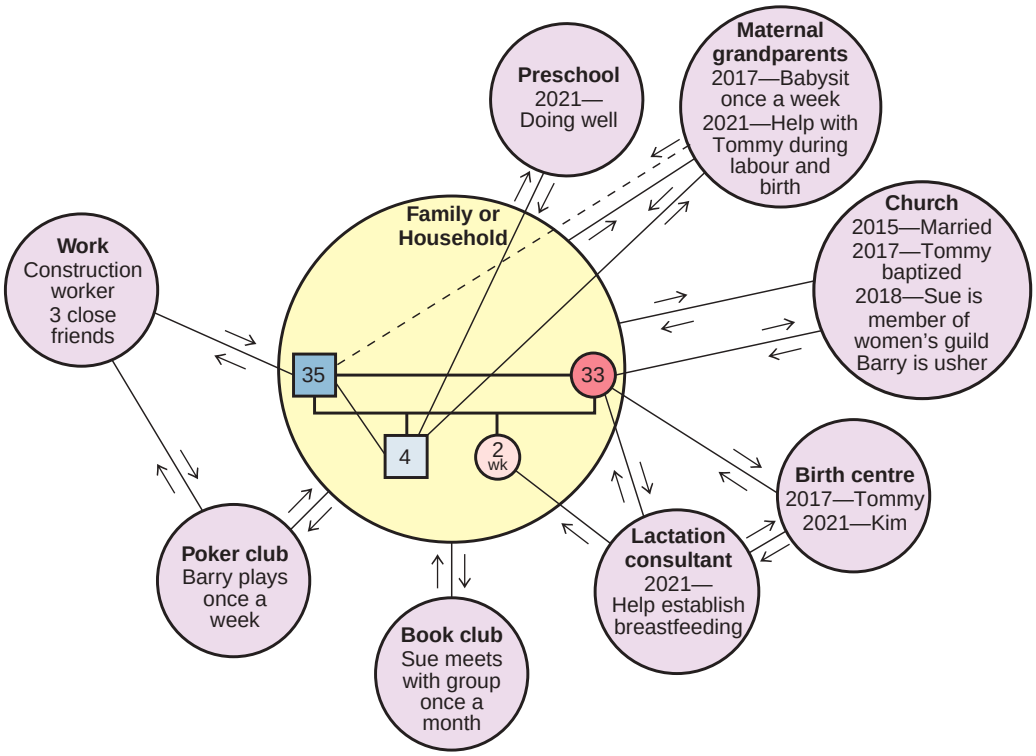

Fig. 2.5 Example of an ecomap. An ecomap describes social relationships and depicts available supports.

BOX 2.3 Relational Nursing Practice

Principles Underlying a Relational Inquiry Approach

Relational inquiry acknowledges that:

- Each person and family has a unique social location that shapes their identity and experiences.
- People are influenced by their context through a relational web (a socio-ecological perspective).
- All knowledge is limited, and knowing is considered to be relational action.
- Knowledge is useful when it allows nurses to be more responsive to the people and the situation at hand.

A relational inquiry approach to nursing practice:

- Involves attending to relational experiences of family, community, and culture.
- Calls on nurses to be compassionate, curious, committed to health equity, competent, and responsive in particular practice situations.
- Requires humility and reflection on oneself and how one enacts nursing practice.
- Involves theorizing which becomes a practical activity that is central to every nursing moment.
- Is guided by an ethic of social justice in addition to being health promoting.
- Involves habits of mind that support relational inquiry, including an inquiry stance of knowing and not knowing, and looking with fresh eyes.

Adapted from Doane, G., & Varcoe, C. (2015). *How to nurse: Relational inquiry with individuals and families in changing health and health care contexts*. Wolters Kluwer/Lippincott Williams & Wilkins.

assessment and intervention are primarily about supporting individuals' and family choices and enhancing their capacity to live healthy, meaningful lives within their particular personal, physical or material, and social context.

CULTURAL FACTORS RELATED TO HEALTH

The concept of "culture" has been defined in diverse ways. Historically, the word *culture* evolved from anthropology and referred to the beliefs, values, and traditions of the exotic and essentialized "other" (someone not like me). Culture is now understood as constructed historically by the person's life experiences, and by their gender and social position. Culture also can be thought of as a complex relational process or network of meanings and identities. Since the identity of a person or family is complex and not limited to race, ethnicity, or religion, it is now recognized that people express their cultural identity in many different ways that go beyond population groupings. Furthermore, culture is dynamic and changing throughout one's life. One way to think about culture is to explore the multiple "identities" that make up our own cultural backgrounds. A relational view of culture requires attention to the dynamic interplay of intrapersonal and interpersonal beliefs, values, and practices of *all* the people involved in the practice setting.

Multiculturalism in Canada

In 1971, Canada adopted multiculturalism as an official policy that affirmed the following:

- The value and dignity of all Canadians, regardless of their racial or ethnic origins, their language, or their religious affiliations
- The rights of Indigenous peoples
- The status of Canada's two official languages: French and English

The Canadian government's multiculturalism policy promotes multiculturalism by encouraging Canadians to participate in all aspects of life, including social, cultural, economic, and political affairs. Everyone is equal and has a right to be heard. However, government intentions have not been sufficient to achieve equity and integration. Racism

and cultural oppression have been realities for many minority groups living in Canada, especially for Indigenous people, who have experienced the long-standing impacts of poverty, poor health, loss of identity, and marginalization (Canadian Nursing Students Association [CNSA], 2015; RNAO, 2007). See Chapter 1 for further discussion on Canada's history and its impact on Indigenous people.

Cultural Context of the Family

The culture of an individual and family is influenced by their religion, environment, and historical events and plays a powerful role in the individual's health practices and patterns of human interaction. Culture is not static; it is an ongoing process that influences people throughout their entire lives, from birth to death. It is also important to remember that the social determinants of health (Box 1.1) will shape people's health experiences, as well as nursing practice. These determinants must include multiple dynamic interacting historical, economic, sociopolitical, physical, and linguistic structures and processes (Doane & Varcoe, 2015).

Cultural knowledge includes beliefs and values about each facet of life and is passed from one generation to the next. Cultural beliefs and traditions relate to food, language, religion, art, health and healing practices, kinship relationships, and all other aspects of community, family, and individual life. Culture also has been shown to have a direct effect on health practices. Values, attitudes, and beliefs that are culturally acquired may influence perceptions of illness as well as health care–seeking behaviour and responses to treatment. Learning about the person's cultural background can provide insight into how a person might react to illness, pain, and invasive medical procedures, as well as patterns of human interaction and expressions of emotion. The impact of these influences must be assessed by health care providers when giving health care.

A more complex relational or socioecological understanding of the family's environment and contexts for care is also required for responsive, culturally appropriate, family nursing practice. For example, nurses working with childbearing and child-rearing families also need to be aware of the impact that highly technological health care environments (such as those commonly seen in birthing and critical care units) may have on the ways that family members experience health care and nursing practices. Simply acknowledging the person before attending to the machine alarm or creating special moments for the parent with the child or infant within this foreign space can be incredibly meaningful for families.

Acculturation. In a multicultural society, many groups can influence traditions and practices. As cultural groups come in contact with each other, varying degrees of **acculturation** may occur. *Acculturation* refers to changes that occur within one group or among several groups when people from different cultures come in contact with one another (Figure 2.6). This familiarization among cultural groups can result in some overt similarities in dress, lifestyle, and mannerisms. Language patterns, food choices, and health practices in particular manifest differently among cultural groups. While acculturation can occur in Canada, the diversity and multiculturalism of people are highly valued.

Ethnocentrism is the view that one's own way of doing things is best while all other ways are unnatural or inferior. *Ethnic stereotyping* or *labelling* stems from ethnocentric views of people. Ethnocentrism is a common attitude among a dominant ethnic group and strongly influences the ability of one person to evaluate the beliefs and behaviours of others. This viewpoint tends to bias the individual's interpretation and understanding of the behaviour of others. The culturally competent nurse should be empathetic and aware of their own views and how they may differ from another person's, based on culture or social location. The nurse should be willing to ask questions that will provide a better understanding of the individual's or family's experiences and needs. Nurses are obligated to respect the cultural and spiritual beliefs and values of the person and family (Canadian Nurses Association [CNA], 2018).

Fig. 2.6 Teenagers from different cultural backgrounds interact within the larger culture. (iStock.com/izusek)

Frequently, nurses and other health care workers are not aware of their own cultural values and how those values influence their thoughts and actions. Understanding one's own worldview and that of the "other" can help to avoid stereotyping and the misapplication of scientific knowledge (RNAO, 2007). Self-awareness is the first step in achieving cultural competence. Evidence has shown that attitudes, whether one is conscious of them or not, have a direct and significant impact on the people around them. Through self- reflection, nurses are better able to acknowledge their own cultural beliefs and values, which will aid them in achieving cultural competence in practice (CNA, 2018).

Providing Culturally Competent Nursing Care

As our society becomes more culturally diverse, nurses have a professional and ethical responsibility to respect and be mindful of the culture of each person during every encounter (CNA, 2018). Nurses must examine their own beliefs so that they have a better appreciation and understanding of the beliefs of their patients. Values that underpin the provision of culturally competent care include respect, valuing difference, inclusivity, equity, and a commitment to providing culturally safe nursing care (CNA, 2018). To provide culturally competent care, the nurse must assess the beliefs, values, and practices of individuals and their families. Individuals and their families can be asked about their expectations so that nurses can learn collaboratively *with* the particular person and family (Box 2.4). It is also important for nurses to understand and value diversity and avoid stereotyping the individuals and families they care for.

The concept of cultural competence refers to the practices of health professionals, including nurses. Cultural competence is an ongoing, interactive process that has been described as a set of congruent behaviours, attitudes, and policies that come together to enable a system, organization, or professionals to work effectively in cross-cultural situations. Recent collaborative work with Indigenous people and communities has highlighted the limits of traditional understandings of cultural competence. This concept has been critiqued for a tendency to

BOX 2.4 Nursing Actions Important to Providing Culturally Safe Care

- Reflect and recognize the influence of your own ethnicity and culture and their effects on your life.
- Recognize the diversity of needs and experiences of the persons you serve.
- Obtain details based on personal information actually given by the patient or family members rather than making assumptions.
- Use simple language when discussing procedures, if necessary.
- Explore what is acceptable and suited to the patient or family for their care.
- Involve family members with the consent of the patient.
- Work out a mutually acceptable schedule of caring for the patient.

Adapted from Best Start Resource Centre. (2009). *Giving birth in a new land: Strategies for service providers working with newcomers.* https://resources.beststart.org/wp-content/uploads/2018/12/E26-E.pdf

instill a false sense of confidence by fitting all Indigenous people into one stereotypical mould and for failing to consider diversity within the Indigenous population.

In a joint document with Canadian Association of Schools of Nursing (CASN) and the Canadian Nurses Association (CNA), the Aboriginal Nurses Association of Canada (2009) identified two foundations of culturally appropriate nursing care: a constructivist understanding of culture—that culture is a complex shifting relational process—and cultural safety, which requires understanding power differentials in the health care system and addressing these inequities. Cultural competence can also be understood as a lifelong process of relational inquiry (CNA, 2018; Doane & Varcoe, 2015).

Work is just beginning in efforts to improve Indigenous perinatal and children's health care, by working with Indigenous communities across Canada. Promising practices for working with Indigenous people and communities have been identified and include the Aboriginal Prenatal Wellness Program, in Wetaskiwin, Alberta; the Inuulitsivik Health Centre Midwifery Initiative, in Northern Quebec; and the Strengthening Families Maternal Child Health Program, in Manitoba (Yeung, 2016).

The Health Council of Canada (2011) has also described a number of processes for culturally competent care that involve a constructivist understanding of culture and cultural safety. In this context, *cultural competence* is defined as the ability of nurses to self-reflect on their own cultural values and how these impact the way nursing care is provided (CNA, 2018). Recognizing the importance of culture and the presence of cultural differences and unique needs is required for the provision of promising practices for community-based programs and health services. Common features of such practices for improving Indigenous maternal and child health in Canada include the following:

- A holistic approach, which is vital to Indigenous maternal and child health. The physical, mental, social, spiritual, and emotional components of health are inseparable. Indigenous mothers and children cannot be considered in isolation; they are part of a larger family unit and a network of relationships in their community. The entire community—a healthy community—must be involved in connecting and supporting mothers and children (Health Council of Canada, 2011, p. 23).
- Embodying mutual respect, addressing what matters most to the person and family, and integrating traditional healing practices. These are essential nursing practices.

Cultural safety is the goal and outcome of practising in a culturally competent environment (CNA, 2018). Originally developed by Irihapeti Ramsden, a Maori nurse from New Zealand, the concept of cultural safety extends beyond the cultural understanding of the health care provider by highlighting the power imbalance that is present within the provider–patient or nurse–patient relationship. The term shifts the authority to determine if the care provided is culturally safe to the person receiving care (CNA, 2018). Nurses are studying ways to embed cultural safety within a relational practice approach to nursing care situations (Doane & Varcoe, 2015). Cultural safety results in an environment free of discrimination and racism, where people feel safe when receiving health care. It is an outcome based on respectful engagement that recognizes and strives to address power imbalances built into the health care system (First Nations Health Authority, 2016).

Cultural humility involves humbly acknowledging oneself as a learner when it comes to understanding another's experience. It is the process of self-reflection in order to raise awareness of personal and systemic biases and to maintain respectful relationships that are based in mutual trust (First Nations Health Authority, 2016). The need for cultural humility arose within the broader multicultural community. This concept highlights how difficult it can be for a health care provider to truly understand the person's or family's cultural identity. It begins with acknowledging that our own cultural practices are not always the "best" and should not always be used as the standard for judging health practices. One example that is salient for nurses who work with childbearing families is that many families around the world have cultural practices that provide extra support for new mothers during the first month following childbirth, sometimes referred to as "doing the month," when extended family members care for the new parent. The absence of this support has been articulated by many new Canadian women, exposing the limitations of our highly individualistic understanding of nuclear families within consumer-oriented North American cultures.

! NURSING ALERT

Cultural knowledge helps nurses better understand the behaviour of individuals and families. This knowledge helps to ensure that nurses are not making assumptions about patients' behaviour in a clinical context. By performing a cultural assessment, the nurse can elicit the patient's and family's understanding of their illness and individualize the patient's care plan.

To begin to understand and work effectively with families in a multicultural community, nurses need to recognize the barriers to transcultural communication and work toward removing those barriers. Nurses, too, are a product of their own cultural background. They need to recognize that they are part of the "nursing culture." Nurses function within the framework of a professional culture with its own values and traditions and, as such, become socialized into their professional culture in their educational program and later in their work environments and professional associations. Developing cultural competence means that the nurse becomes aware of their own cultural attributes and biases, and their impact on others.

Cultural beliefs and values, family structure and function, and experience with health care may influence a family's feelings and attitudes toward health, their children, and health care delivery systems. It is often difficult for nurses to be nonjudgemental when working with families whose behaviours and attitudes differ from or conflict with their own. Nurses need to understand *how* their own cultural background influences the way in which they deliver care, and they need to be responsible and accountable for incorporating culturally appropriate and culturally safe care into their nursing practice.

A holistic view of nursing practice also includes respect for and responsiveness to the spiritual beliefs and values of the person and family. Nurses should consider all aspects of culture, including spirituality, communication, space, time orientation, and family roles, when working with families.

Spirituality

Spirituality may be defined as "whatever or whoever gives ultimate meaning and purpose in one's life, that invites particular ways of being in the world in relation to others, oneself and the universe" (Wright, 2005). Spirituality is important in all phases of life; it relates to deep and important issues and will affect how patients face health issues (Giske & Cone, 2015). While religion is a more organized or rule-driven form of spirituality, one can be spiritual without being a member of an organized religion.

Spirituality is a component of holistic nursing and thus a professional responsibility. The CNA states that spirituality is an integral dimension of an individual's health and that being attentive to an individual's spirituality is a component of a holistic nursing assessment and nursing practice. When planning for and providing care, nurses have an ethical responsibility to be aware of and adjust for an individual's spiritual beliefs (CNA, 2010).

Openness to a range of spiritual perspectives (or lack thereof) is part of ethical nursing practice. Nurses do not need to be knowledgeable in particular spiritual traditions, but they do need to be open to inviting or allowing reflection by the individual on the spiritual dimension of their experience of illness and suffering (CNA, 2010). Nurses should also reflect on their own spiritual beliefs in order to provide beneficial nursing care.

Religious preference is usually included with demographic information on initial contact with health care organizations. Hospital chaplains and other clergy use the information to arrange visits with parishioners or others who desire their services. Nurses can use the information to pose questions about preferences or requests for prayers, blessings, counselling, or visits from clergy. Baptisms, b'nai mitzvah, salat, anointings, blessings, communion services, sacrament of the sick, and other religious observances and practices may occur. Memorial services may be held in the hospital chapel or prayer room. Occasionally, weddings are performed within a hospital. Nurses may be requested to provide the space and opportunity for such events to occur. At times, they may be invited or requested to participate. Depending on preferences, the nurse may choose to remain for the service or decline respectfully. The nurse need not be of the same religion, or any religion, to provide support through their presence.

Spirituality also plays an important role in providing meaning to nursing work (Pesut, 2013). For example, the Pause, which originated in an emergency room after the death of a patient, involves taking a minute or two, to acknowledge a lost human life, and is an example of recognizing the individual in this sad time. The Pause also lends support to those health care providers who worked to save the life (Bartels, 2014). After a death, the staff are asked to remain and bear witness, to be together and present in this time of grief and loss. The staff are able to be together and achieve some type of closure or resolution surrounding the unsuccessful efforts to resuscitate the individual. Use of the Pause is growing and is gaining advocates.

Spiritual Care. *Spiritual care* can be defined as a form of relational practice with the aim of increasing the spiritual well-being of the person and family. Brussat and Brussat (1996) described characteristics of the spiritually literate person as being present, having compassion, being connected, having hope, being kind, listening, having meaning and openness, and using silence. Relational inquiry and therapeutic communication skills are what make nurses ideal for attending to the spiritual dimensions of an individual's health. Spirituality is of relevance for all of nursing, not just for those in palliative care or for dying patients (Giske & Cone, 2015). As part of patient assessments, questions related to spirituality and religion should be included. Questions can be directed to patients as well as the family. Examples of such questions are in Box 2.5.

To provide spiritual care, the nurse must understand the meaning of spirituality to the person for whom care is being provided (Gordon et al., 2011). The nurse must listen attentively to learn what is important to the patient, what gives meaning to their life, what gives hope and strength, and what are their fears and concerns (Burkhardt & Nagai-Jacobson, 2015). Only then can the nurse respond appropriately and provide spiritual care that is healing.

Communication

Communication sometimes creates a challenging obstacle for nurses working with individuals from diverse cultural groups. Communication is not merely the exchange of words. Instead, it involves (1) understanding the individual's language, including subtle variations in meaning and distinctive dialects; (2) appreciation of individual differences in interpersonal style; and (3) accurate interpretation of the volume of speech, as well as the meanings of touch and gestures.

For example, members of some cultural groups tend to speak more loudly, with great emotion, and with vigorous and animated gestures when they are excited; this is true whether their excitement is related to positive or negative events or emotions. Therefore, it is important for the nurse to avoid rushing to judgement regarding an individual's intent when the individual is speaking, especially in a language not understood by the nurse. In these situations, it is critical that the nurse avoid instantaneous responses that may be based on an incorrect interpretation of the person's gestures and meaning. Instead, the nurse should withhold an interpretation of what has been communicated until it is possible to clarify the person's intent. The nurse needs to enlist the assistance of a person who can help verify with the person the true intent and meaning of their communication (see Clinical Reasoning Case Study).

BOX 2.5 Spiritual Assessment Questions

- Who or what provides the patient with strength and hope?
- Does the patient use prayer in their life?
- How does the patient express their spirituality?
- How would the patient describe their philosophy of life?
- What type of spiritual or religious support does the patient desire?
- What is the name of the patient's clergy, minister, chaplain, pastor, or rabbi?
- What does suffering mean to the patient?
- What does dying mean to the patient?
- What are the patient's spiritual goals?
- Is there a role of church or synagogue in the patient's life?
- How does faith help the patient cope with illness?
- How does the patient keep going day after day?
- What helps the patient get through this health care experience?
- How has illness affected the patient and their family?

Source: The Joint Commission. *Standards FAQ details, medical record—Spiritual assessment*. Excerpted from https://www.jointcommission.org/standards/standard-faqs/critical-access-hospital/provision-of-care-treatment-and-services-pc/000001669/

CLINICAL REASONING CASE STUDY

Culturally Competent Care in the Emergency Department

Arisha, a 37-year-old woman, accompanied by her 16-year-old son, Mahesh, is admitted to the emergency department (ED) with profuse vaginal bleeding. Arisha's primary language is Hindi, and she speaks very little English; Mahesh is fluent in Hindi and English. No health care providers present in the ED speak Hindi. The nurse assigned to care for Arisha must obtain a health history and perform an assessment. The nurse wants to provide culturally competent care for Arisha.

Questions

1. Evidence—Is there sufficient evidence to determine what culturally competent nursing care consists of?
2. Assumptions—What assumptions can be made about culturally competent care and the role language plays in providing that care?
   a. How the nurse, who speaks no Hindi, might effectively communicate with Arisha
   b. How the nurse can obtain a health history with questions about vaginal bleeding, sexual activity, and pregnancy if Mahesh is the only person available who speaks Hindi
   c. How the nurse can provide culturally competent teaching
   d. What teaching materials and resources are appropriate; what questions are appropriate to gain information about sexual activity and the possibility of pregnancy
3. What implications and priorities for nursing care are most important at this time?
4. What evidence supports your plan for culturally responsive nursing care?

Use of Interpreters. Inconsistencies between the language of family members and that of providers presents a significant barrier to effective health care. Because of the diversity of cultures and languages within the Canadian population, health care agencies are increasingly seeking the services of interpreters (of oral communication from one language to another) or translators (of written words from one language to another) to bridge these gaps and fulfill their obligation to provide linguistically appropriate health care.

Finding the best possible interpreter in these circumstances is critically important. A number of personal attributes and qualifications contribute to an interpreter's potential to be effective. Ideally, interpreters should have the same native language and be of the same religion or have the same country of origin as the patient. Interpreters should have specific health-related language skills and experience and help bridge the language and cultural barriers between the individual and the health care provider. The person interpreting should be mature enough to be trusted with private information. It is not appropriate to use a child or another family member to interpret health care information. However, because the nature of nursing care is not always predictable and because nursing care provided in a home or community setting does not always allow expert, experienced, or mature adult interpreters, ideal interpretive services are sometimes impossible to find when they are needed. In crisis or emergency situations or when family members are experiencing extreme stress or emotional upset, it may be necessary to use family members as interpreters. If this situation occurs, the nurse must ensure that the person is in agreement and comfortable with using the available interpreter to assist. Another alternative that has become more available in many settings is to access professional interpreters over the telephone when someone is not available in person. Most health care institutions have lists of staff members who may be available to interpret when required, although professional interpreters are the ideal.

When using an interpreter, the nurse needs to respect the family by creating an atmosphere of respect and privacy (Box 2.6). Questions should be addressed to the person and not to the interpreter. Even though an interpreter will of necessity be exposed to sensitive and privileged information about the family, the nurse should take care to ensure that confidentiality is maintained. A quiet location free from interruptions is the ideal place for interpretive services to take place. In addition, culturally and linguistically appropriate educational materials that are easy to read, with appropriate text and graphics, should be available to assist the individual and family in understanding health care information. When using interpretive services, the nurse demonstrates respect for the person and helps maintain a sense of dignity by taking care to do all of the following:

- Respect the person's wishes.
- Involve the person in the decisions about who will be the most appropriate person to interpret under the circumstances.
- Provide as much privacy as possible.

Personal Space

Cultural traditions define the appropriate personal space for various social interactions. Although the need for personal space varies from person to person and with the situation, the actual physical dimensions of comfort zones differ from culture to culture. Actions such as touching, placing the person in proximity to others, taking away personal possessions, and making decisions for the individual can decrease personal security and heighten anxiety. Conversely, respecting the need for distance allows the person to maintain control over personal space and support personal autonomy, thereby increasing a sense of security. Nurses must touch patients, but they frequently do so without any awareness of the emotional distress they may be causing individuals. It is important to ask permission before touching any person.

Time Orientation

Time orientation is a fundamental way in which culture affects health behaviours. People in various cultural groups may be relatively more oriented to past, present, or future. Those who focus on the past strive to maintain tradition or the status quo and may have little motivation for formulating future goals. In contrast, individuals who focus primarily on the present neither plan for the future nor consider the experiences of the past. These individuals do not necessarily adhere to strict schedules and are often described as "living for the moment" or "marching to the beat of their own drummer." Individuals oriented toward the future maintain a focus on achieving long-term goals.

The time orientation of the family may affect nursing care. For example, talking to a family about bringing the infant to the clinic for follow-up examinations (events in the future) may be difficult for the family that is focused on the present concerns of day-to-day survival. Because a family with a future-oriented sense of time plans far in advance and thinks about the long-term consequences of present actions, they may be more likely to return as scheduled for follow-up visits. Despite the differences in time orientation, each family may be equally concerned for the well-being of its newborn.

Family Roles

Family roles involve the expectations and behaviours associated with a member's position in the family (e.g., mother, father, grandparent). Social class and cultural norms also affect these roles, with distinct

BOX 2.6 Working With an Interpreter

Step 1: Before the Interview

A. Outline your statements and questions. List the key pieces of information you want or need to know.

Step 2: Meeting With the Interpreter

A. Introduce yourself to the interpreter and converse informally. This is the time to find out how well they speak English. No matter how proficient or what age the interpreter is, be respectful. Some ways to show respect are to acknowledge that you can learn from the interpreter or learn one word or phrase from the interpreter.
B. Emphasize that you would like to encourage the person to ask questions if they have any concerns and to feel comfortable doing so, as some cultures consider asking questions to be inappropriate.
C. Make sure that the interpreter is comfortable with the technical terms you need to use. If not, take some time to explain them.

Step 3: During the Interview

A. Ask your questions and explain your statements (see Step 1) directly to the person and maintain eye contact.
B. Make sure that the interpreter understands which parts of the interview are most important. You usually have limited time with the interpreter, and you want to have adequate time at the end for patient questions.
C. Try to get a "feel" for how much is "getting through." No matter what the language is, if in relating information to the person the interpreter uses far fewer or far more words than you do, "something else" is going on.
D. Stop every now and then and ask the interpreter, "How is it going?" You may not get a totally accurate answer, but you will have emphasized to the interpreter your strong desire to focus on the task at hand. If there are language problems, (1) speak slowly, (2) use gestures (e.g., fingers to count or point to body parts), and (3) use pictures.
E. Ask the interpreter to elicit questions. This may be difficult, but it is worth the effort.
F. Identify cultural issues that may conflict with your requests or instructions.
G. Use the interpreter to give insight into possibilities for solutions.

Step 4: After the Interview

A. Speak to the interpreter and try to get an idea of what went well and what could be improved related to the interpretation service. This will help you to be more effective with this or another interpreter.
B. Make notes on what you learned for your future reference or to help a colleague.

Remember:

Your interview is a *collaboration* between you and the interpreter. Listen as well as speak.

Notes

1. Be sensitive to cultural and situational differences (e.g., an interview with someone from an urban city will likely be different from an interview with someone from a transitional refugee camp).
2. Younger females telling older males what to do may be a problem for both a female nurse and a female interpreter. This is not the time to pioneer new gender relations. Be aware that in some cultures it is difficult for a woman to talk about some topics with a husband or a father present.

Courtesy Elizabeth Whalley, PhD, San Francisco State University.

expectations for men and women clearly determined by social norms. For example, culture may influence whether a man actively participates in pregnancy and childbirth, yet maternity care practitioners working in the Western health care system expect fathers to be involved. This can create a significant conflict between the nurse and the role expectations of some very traditional families, who usually view the birthing experience as a female affair. Family roles may also dictate who in the family makes the major decisions regarding health care, for example which family member decides treatment options for a sick child. It is important to know this information, as it may dictate who is given information first. The way that health care practitioners facilitate such a family's care may influence the family's experience and perception of the Western health care system.

KEY POINTS

- A family is two or more people who are related through enduring commitments.
- Contemporary Canadian society recognizes, accepts, and values diverse family forms.
- The family is a social network that acts as an important support system for its members.
- Family theories and practice models provide nurses with useful guidelines for working with childbearing and child-rearing families.
- Poverty and environmental factors, family resources and support systems, health challenges and responses to stress, and cultural and religious beliefs and practices are important factors influencing the health of the whole family.
- The beliefs and values of a culture are embedded in its economic, religious, kinship, and political structures and are reproduced through health and social practices.
- To provide quality care to perinatal and pediatric patients, nurses should be aware of the cultural beliefs, values, and practices important to particular families.
- No cultural group is homogenous; social identities are complex and reflect great diversity.
- Nurses need to listen to the stories that individuals and family members tell them about their culture, their health care experiences, their resources, and their needs.
- Cultural competence is a complex relational process of mutual learning that is a professional responsibility of nurses. Nurses can facilitate this process by recognizing cultural differences, integrating cultural knowledge, being aware of their own beliefs and practices, and acting in a respectful manner.
- Cultural safety results in an environment free of discrimination and racism, where people feel safe when receiving health care.
- Cultural humility involves humbly acknowledging oneself as a learner when it comes to understanding another's experience.
- Attention to and respect for the spiritual beliefs and values of the person and family is an important component of culturally responsive nursing.
- Because verbal and nonverbal forms of communication are important cultural considerations, nurses need to acknowledge and respect their patients' practices for productive interaction to occur.

Community Care

Judy Buchan

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Compare community-based home visiting programs and community health (population or aggregate-focused) care.
2. List indicators of community health status and their relevance to perinatal and children's health.
3. Identify the various roles and functions that nurses have in the community.
4. Describe three levels of preventive care and the differences between them.
5. Discuss selected aspects of the epidemiological process.
6. Explain the purpose of an economic evaluation.
7. Discuss the components of the community nursing process.
8. Describe data sources and methods for obtaining information about community health status.
9. Identify key components of the community assessment process.
10. Explore telephone contact centres and use of social media applications for nursing care options in perinatal and pediatric nursing in Canada.
11. Describe the nurse's role in perinatal and pediatric home visiting.
12. List the potential advantages and disadvantages of home visits.
13. Discuss safety and infection control principles as they apply to the care of patients in their homes.

Health care in Canada has evolved rapidly in recent years, with notable shifts in both the nature of health priorities and the ways in which health care is delivered to individuals, families, and populations. Today, greater emphasis is placed on health promotion and disease prevention than on the curative focus of past decades. This is in part a response to the skyrocketing costs of medical care and the realization that Canada's current health care system is unsustainable. Hospital stays are increasingly shorter, and patients are discharged home earlier with the expectation that they will receive care in the community. Knowing how health care is organized and governed within the community setting is of importance for perinatal and pediatric nurses.

At the national level, the Public Health Agency of Canada's (PHAC) mission is to promote and protect the health of Canadians through leadership, partnership, innovation, and action in public health (PHAC, 2021). This is done by promoting health; preventing and controlling chronic diseases, injuries, and infectious diseases; and preparing and responding to public health emergencies. The PHAC acts as a central hub through which Canada's expertise is shared with the rest of the world. The agency applies international research to Canada's public health programs and strengthens intergovernmental collaboration on public health, as well as facilitating national approaches to public health policy and planning (PHAC, 2021).

By focusing on the health of the population at both the individual and the community level, the Government of Canada works to improve the health of Canadians, reduce health disparities, and build the capacity to deliver on and support public health activities (PHAC, 2021). A population health approach considers the economic, social, and physical environmental factors that contribute to one's health—in essence it is the capacity of people to adapt to, respond to, or control life's changes (Frankish et al., 2001). Underpinning this are the determinants of health—the broad range of personal, social, economic, and environmental factors that determine individual and population health (Government of Canada, 2020). Determinants of health include income and social status; social support networks; education; employment and working conditions; social environments; physical environments; personal health practices and coping skills; healthy child development; gender; and culture (see Box 1.1). These are factors that contribute to a person's current state of health and well-being. By applying a health equity lens, public health policies and programs work to reduce health inequalities in the population by providing everyone the same opportunities and conditions to be healthy, no matter who they are or where they live (Government of Canada, 2020).

Nurses who work in the community promote, protect, and preserve the health and well-being of individuals, families, groups, communities, populations, and systems in settings where they work, live, and play (Community Health Nurses of Canada [CHNC], 2019). They practice in diverse urban, rural, and remote settings, which may include health centres, homes, clinics, schools, shelters, and other community-based

settings. By using a capacity-building and strengths-based approach, nurses provide, facilitate, and coordinate care and link people to community resources (CHNC, 2019).

There are many different roles that nurses have in the community, ranging from primary prevention, health promotion and protection, health education, surveillance, screening, and staffing immunization clinics to disaster management and emergency preparedness. Home health care nurses typically provide specific nursing care in the home or at a clinic; such care will be discussed later in this chapter. Public health and community health nurses have a broader role and bring a unique set of knowledge and skills needed to plan, implement, and evaluate both targeted and population-level public health interventions.

The terms *public health nurse* and *community health nurse* are used in many different ways across the various jurisdictions in Canada. In some places, the term *community health nurse* means the same as, or is used instead of, the term *public health nurse* (Canadian Public Health Association [CPHA], 2010). In other areas, community health nurse is an overarching term that refers to the complete range of nurses working in the community, of which public health nurses are one group (CPHA, 2010).

Throughout this chapter, *community health nurse* refers to nurses who provide public health nursing in the community. *Home health care nurse* refers to nurses who provide care in a patient's home.

ROLES AND FUNCTIONS OF COMMUNITY HEALTH NURSES

To understand the role of the nurse in public health, it is critical to examine the role of nurses who have the title of community health nurse and to look at the types of activities they engage in to promote the health of populations. Community nurses are equipped with knowledge of disease prevention and health promotion that is based on both their education and experience and includes an understanding of the clinical implications of public health interventions as well as the etiology and natural history of disease. Community health nursing practice is grounded in a holistic approach and considers the health of individuals, families, communities, and the population as a whole. The roles and functions of the community health nurse continue to evolve as more health care is delivered outside of the hospital system.

Community health nursing is a synthesis of nursing theory and public health science. The foundation for community health nursing includes a range of models and theories, such as population health promotion, illness and injury prevention, community participation, and community development (CPHA, 2010). Community health nurses work in the community to partner with people where they live, work, learn, meet, and play, in order to promote health and well-being. The goal for nurses who work with families and individuals in the community is to promote health, build individual and community capacity, connect with and care for patients, facilitate access, promote health equity, and demonstrate professional responsibility and accountability (CHNC, 2019).

In community-based health care settings, both the aggregate (group of people who have shared characteristics) and the population may become the focus of interventions. Health care providers are required to collaborate in order to determine health priorities for communities and develop successful plans of care to be delivered in a variety of settings, including health clinics, community health centres, patients' homes, or other settings. Community-based health care, including public health services, is often under-resourced and is challenged to meet the demands of growing populations. Thus, it is sometimes difficult to fully compensate for the gaps in health care service that currently exist.

Core Competencies

The PHAC has developed core competencies for all public health care providers, which outline 36 competencies deemed essential to all disciplines practising in public health (PHAC, 2008). To support the core competencies outlined by the PHAC, the Community Health Nurses of Canada (CHNC) has developed discipline-specific practice competencies for community health nursing. There are two sets of competencies set out by the CHNC: one set for community health nurses (CHNC, 2009) and one for home health nurses (CHNC, 2010). Together, these competencies identify the required knowledge, abilities, attributes, and judgement for community health nursing practice within Canada. In 2010, the Canadian Public Health Association (CPHA), in collaboration with the CHNC and PHAC, clarified and described the role and functions of community health nurses in Canada with the release of *Public Health/Community Health Nursing in Canada: Roles and Activities*, fourth edition (CPHA, 2010). Whereas previous editions had described public health/community health nursing roles as relating to communities, families, and individuals across the lifespan, the fourth edition has shifted its focus to populations and the broad determinants of health (CPHA, 2010).

Community health nurses can also become certified through the Canadian Nurses Association (CNA). This certification credential, part of a respected national certification program, is an important indicator to patients, employers, the public, and professional licensing bodies that the certified nurse is qualified, competent, and current in community health nursing practice.

! NURSING ALERT

Nurses are required to work interprofessionally, speaking a common language laid out in the PHAC and CHNC core competencies, as their work crosses many disciplines. This includes being able to understand terms used by demographers, epidemiologists, physicians, health promoters, social scientists, researchers, and economists.

Public Health Decision Making

The use of research evidence plays an important role in public health decision making. The process of evidence-informed decision making guides public health care decision making by using the best research evidence available. However, research evidence is only one part of a larger picture. Decision makers must interpret and apply the research evidence in the context of four other sources of evidence (Figure 3.1).

Public health expertise signifies that the public health practitioner contributes to the overall decision-making process. All the factors need to be weighed and balanced to make the most appropriate decision. When considering a policy or program change, it is important for the practitioner to understand the magnitude of the health issue in the local setting and how important this health issue is in comparison to other issues. This can help to ensure that those issues affecting the overall health status of the population receive priority over those which have a more limited impact on the public good (community health issues, local context). Community and political preferences and actions in Figure 3.1 refer to the need to understand the political climate at the municipal, provincial, and federal level; it is important to know the community's views on an issue. Public health resources include budget, staff, and technological infrastructure. Decision makers must determine whether or not there are sufficient resources, both in terms of personnel and technology and in terms of funding, to successfully implement a program or policy. Finally, research evidence empowers the public health practitioner with an understanding of what the best available research says about an issue. All these considerations help to bring evidence into practice, but they can only work as part of a comprehensive process and not independently of one another.

Fig. 3.1 A model for evidence-informed decision making in public health. (Source: NCCMT National Collaborating Centres of Methods and Tools. http://www.nccmt.ca/eiph/index-eng.html)

Community Health Promotion

Best practices in community-based health initiatives involve a thorough understanding of a community's health needs and priorities, the environmental context, power relationships, and available resources, as well as participation of community leaders. A community-based framework helps to bring together multiple perspectives and diverse community resources to address a specific health priority. The emphasis on community-based health promotion has grown in recent years, with the recognition that many health issues require the collaborative efforts of a diverse community network to achieve public health goals.

Economics. A basic understanding of the economics of health care enables the nurse to participate in decision making about the cost and benefits of health programs. Economists theorize that individuals and societies view health as a basic utility, that is, something that is perceived as valuable. Other basic utilities include food, shelter, and clothing. People may be willing to trade resources, such as money and time, for a program or intervention that will improve their health. Economists measure the amount of resources that individuals and communities are willing to pay for good health. Economic evaluation provides objective information to establish a program's value to the community.

Demography. *Demography* is the study of population characteristics. Demographic characteristics include age, gender, race and ethnicity, socioeconomic status, and education. Individuals, families, and communities may have demographic characteristics that affect their health risks (McFarlane & Gilroy, 2015). *Risk* is an increased probability of developing a disease, injury, or illness. Age is one of the most important risk factors for disease prevention and certain health conditions. For example, infants are more likely to die as a result of congenital malformations; children and adolescents, as a result of accidents; and middle-age adults, as a result of cancer (Statistics Canada, 2021). Gender also plays an important role. Males are at greater risk than females of having hemophilia A and B. Race and ethnicity have long been associated with increased risk for disease and disability, but it is now understood that, aside from genetic predisposition, there is a complicated relationship between minority status and socioeconomic status that increases the risk for disease and disability (PHAC, 2018).

Low socioeconomic status, an important determinant of health, predisposes adults and especially children to a variety of health challenges. Children represent one out of four low-income persons in Canada, which translates to approximately 1.2 million children living in a low-income household (Statistics Canada, 2017). This rate is even higher for Indigenous children, with more than one in three living in poverty, and even higher on reserves where over 60% of children live in poverty (O'Brien Institute for Public Health, 2018).

Brain development happens quickly in the early years of life, and a small child's brain development can be adversely affected by poverty, putting these children at increased risk of lifelong physical and mental health challenges (Center on the Developing Child at Harvard University, 2016). Poor children are more likely go hungry, to be overweight, and to have untreated dental problems. They are more likely to be treated in emergency departments because they do not have a regular health care provider, and they are more at risk for not reaching their developmental potential (Blair & Raver, 2016).

Epidemiology. *Epidemiology* is the science of population health applied to the detection of morbidity and mortality in a population. Through the epidemiological process, the distribution and causes of disease or injury across a population are identified (McFarlane & Gilroy, 2015). Epidemiology serves as an important component in developing health programs. For example, the Community Action Program for Children incorporated an epidemiological process to develop programs that promote the healthy development of young children from birth to 6 years (PHAC, 2020). Health care providers in community, provincial, and national organizations use the epidemiological process to guide the development of programs that will have the greatest impact on children's health.

Distribution of disease, injury, or illness. Morbidity rates are used to measure disease and injury and, along with birth and mortality rates, present an objective picture of a community's health status. There are two types of morbidity rates: incidence and prevalence. *Incidence* measures the occurrence of new events in a population during a period of time. *Prevalence* measures existing events in a population during a period of time. For example, the incidence of type 1 diabetes in a community is estimated by counting the new cases of type 1 diabetes in a population and dividing that figure by the size of the population at risk. The prevalence of type 1 diabetes is estimated by counting the existing cases of type 1 diabetes in a population and dividing that figure by the size of the population at risk. Both incidence and prevalence are usually given as rates per 1 000, 10 000, or 100 000 population, depending on their frequency. Box 3.1 presents frequently used mortality and morbidity rates.

Epidemiological triangle. Three factors form the epidemiological triangle, and their interrelationship alters the risk of acquiring a disease or condition. These factors are *agent*, *host*, and *environment* (Figure 3.2).

An agent is responsible for causing a disease. The agent may be an infectious agent, such as *Mycobacterium* tuberculosis; a chemical agent, such as lead in paint; or a physical agent, such as fire. Host factors are those that are specific to an individual or group. These may be genetic factors, which cannot be controlled, or they may be lifestyle factors, such as food selections or exercise patterns. Environmental factors provide a setting for the host and include the climatic conditions in which the host lives and factors related to the home, neighbourhood, and school.

Levels of Preventive Care. Population-based care may involve disease prevention activities focused on specific needs that are identified through the community assessment process. These levels of prevention provide a framework for nursing interventions.

Primary prevention. *Primary prevention* involves health promotion and disease prevention activities to decrease the occurrence of illness and enhance general health and quality of life. Primary prevention precedes disease or dysfunction and encourages individuals to achieve the

BOX 3.1 Frequently Used Mortality and Morbidity Rates

Crude Birth Rate

$$\frac{\text{Number of births in a population}}{\text{Total population}} \text{ within a time period} \times 1000$$

Crude Death Rate

$$\frac{\text{Number of deaths in a population}}{\text{Total population}} \text{ within a time period} \times 1000$$

Cause-Specific Death Rate

$$\frac{\text{Number of deaths in a population due to a certain disease}}{\text{Total population}} \text{ within a time period} \times 1000$$

Age-Specific Death Rate

$$\frac{\text{Number of deaths in a population in a certain age group}}{\text{Total population in that age group}} \text{ within a time period} \times 1000$$

Incidence of Disease

$$\frac{\text{Number of new events in a population}}{\text{Total at-risk population}} \text{ within a time period} \times 1000$$

Prevalence of Disease

$$\frac{\text{Number of existing events in a population}}{\text{Total at-risk population}} \text{ within a time period} \times 1000$$

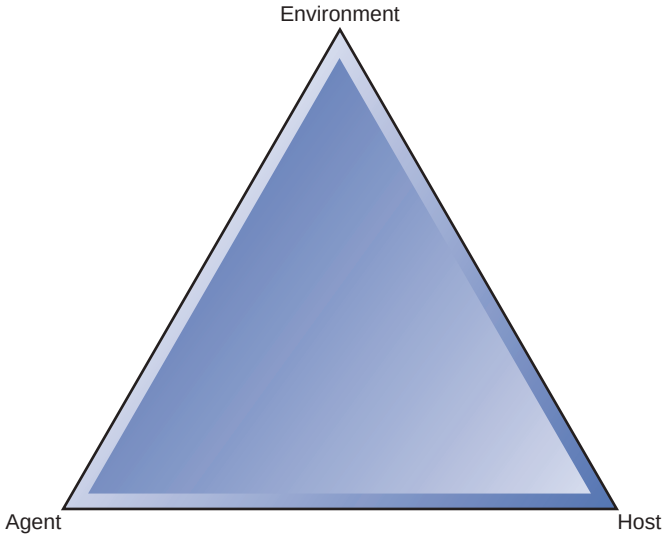

Fig. 3.2 The epidemiological triangle.

optimal level of health possible. Examples of primary prevention include health education and counselling about healthy lifestyle behaviours, including those related to nutrition and exercise. Other examples include well-child care clinics, immunization programs, water fluoridation, safety programs (use of bike helmets, car seats, seat belts, child-proof containers), nutrition programs, environmental efforts (clean air programs), sanitation measures (chlorinated water, garbage removal, sewage treatment), and community parenting classes. Educational programs that teach children and adolescents about healthy sexuality behaviours that reduce risk or convey the dangers of smoking, vaping, and drug use are also examples of primary prevention. Early childhood presents an ideal time for primary prevention strategies, as these programs and services can provide families with the support they need to build protective factors and prevent development of risk factors and vulnerabilities for their children. Childhood immunization programs are another excellent example of primary prevention. By supporting parents and caregivers, primary prevention programs help to ensure that children have stable and healthy living environments in which to grow, develop, and thrive.

Secondary prevention. *Secondary prevention* is aimed at early detection of a disease and prompts treatment to either cure the disease or slow its progression and prevent subsequent disability. Screening programs to detect disease while persons are asymptomatic are the most frequent forms of secondary prevention.

Examples of this level of prevention are newborn screening tests that are conducted after birth. Babies with one of the tested diseases may appear healthy at birth and, without newborn screening, might not be identified before irreversible damage has occurred. Another example of secondary prevention is a Pap (Papanicolaou) test, which is used to screen patients to detect premalignant and malignant cells on the cervix opening. If this condition is treated early, cervical cancer can be successfully prevented or cured.

The goal of secondary prevention is to shorten disease duration and severity, thus enabling an individual to return to normal function as quickly as possible. However, screening is not appropriate for every condition. Although screening may bring benefits, a certain amount of risk is associated with any intervention, and it is critical that the patient and/or caregiver make an informed decision. For example, during pregnancy, there are two diagnostic screening tests that are considered to be invasive. Both amniocentesis and chorionic villus sampling will provide expectant parents with definitive information about the health of their fetus; however, these procedures may also induce miscarriage.

It is essential to determine the evidence for a proposed screening program prior to initiating it. The benefits of screening should exceed the risks and costs. It is also important to ensure there are adequate resources available to support and treat persons with positive screening results.

Tertiary prevention. *Tertiary prevention* follows the occurrence of a disease or disability and is aimed at preventing disability through restoration of optimal functioning. Persons who have developed disease are provided treatment and rehabilitation to prevent complications and further deterioration.

Examples of tertiary prevention are early treatment and management of diabetes to reduce subsequent health problems. Pregnant patients may experience gestational diabetes mellitus (GDM) during their pregnancy, putting both their fetus and them at risk. In the long term, patients with GDM are seven times more likely to develop type 2

diabetes later in life, and exposure to GDM predisposes the child to increased fat accumulation over time, which is an important risk factor for obesity and diabetes development (Canadian Institutes for Health Information [CIHI], 2018). Other examples of tertiary interventions include rehabilitation and disease management programs for stroke, asthma, sickle cell disease, cancer, and anorexia as well as special education programs for children.

COMMUNITIES

There are many ways to define a community. A community can be a group of individuals with shared characteristics or interests who interact with each other. A community can also be a system that includes children and families, the physical environment, educational facilities, safety and transportation resources, political and governmental agencies, health and social services, communication resources, economic resources, and recreational facilities. The community itself is within the scope of practice of the community health nurse. The core of the community is the people, characterized by their age, sex, socioeconomic status, educational level, occupation, ethnicity, and religion. The community is often defined by geography or geopolitical boundaries, which can be used to determine the location of service delivery (Anderson & McFarlane, 2019).

Community health initiatives are directed at either the general health of the community as a whole or specific populations within the community that have unique needs. In this context, populations can be described as groups of people who live in a community, for example, pregnant women or school-age children. Priority populations or subpopulations are more narrowly defined groups (e.g., unimmunized preschoolers, or middle-school children who have obesity) which are the focus of activities to improve the health status of individuals in the group. Common values often guide behaviours of populations and subpopulations in relation to health promotion and disease prevention (Stanhope et al., 2017).

A wide variety of strategies have been used to engage families and groups in health-promoting activities or community health programs. Some are more successful than others. Engaging participants in the planning process and empowering them to create internal solutions are considered key factors in developing effective interventions. Many communities have organized coalitions to address specific health promotion agendas related to sharing information, educating community members, or advocating for health policies around perinatal and child health issues such as child and school safety zones. The benefits of partnership with faith-based organizations for community health improvement have been demonstrated in health promotion efforts aimed at lifestyle choices, health education, and perinatal and children's health outcomes.

Community Nursing Process

In community nursing, the nursing process shifts its focus from the individual patient and family to the community or target population (Box 3.2). The stages of the process (assessment, diagnosis, planning, implementation, and evaluation) are similar, whether the patient is one individual or a whole community.

Assessing the Community. A community health assessment is used to identify and measure the health status of the population of a given health authority or region. It is a complex but well-defined process through which the unique characteristics of the population, its assets, and needs are identified in order to facilitate collaborative action planning to improve community health status and quality of life. The purpose of this process is to identify direct service and advocacy needs of the prioritized aggregate or group and to improve the health of the community. Engaging the community and key stakeholders in the process increases buy-in and ultimately leads to better outcomes for the proposed services.

BOX 3.2 The Community Nursing Process

Assessment and diagnosis—The nurse collects subjective and objective information about a community and analyzes this information based on community needs and problems to develop priorities.

Planning—The nurse develops community-centred goals to address the identified needs and concerns.

Intervention—The nurse implements a program that enables community members to reach their goals.

Evaluation—The nurse conducts a systematic evaluation to determine that goals and program objectives were met by developing measurable outcomes.

During a community health assessment, data are collected, analyzed, and used to inform, educate, and mobilize communities; identify priorities; garner resources; and plan actions to improve the health of the public. Many models and frameworks of community assessment are available, but the actual process often depends on the extent and nature of the assessment to be performed, the time and resources available, and the way in which the information is intended to be used. For examples of community assessment tools, see the Additional Resources section at the end of the chapter.

The community asset mapping approach provides an overview of community attributes and strengths that may facilitate long-term change and improved quality of life for community residents. Understanding community capacity involves looking at a community's ability to address social and health issues or to develop knowledge, systems, and resources that contribute to a community's health status. These approaches help to direct the health promotion process by identifying community priorities and areas of needed change. The community health nurse may assist with community capacity building by working with the community to develop skills in accessing resources, developing social networks, and learning from the experience of others (CPHA, 2010).

Data collection and sources of community health data. Data collection is often the most time-consuming phase of the community assessment process, but it provides an important understanding and description of the community. Measures of community health include health status data, access to health care, access to healthy food, level of provider services available, and other social and economic factors. Consideration of individual, interpersonal, community, organizational, and policy-level data and the interaction of these factors are important in providing a comprehensive framework for community health promotion. A community assessment model (Figure 3.3) is often used to provide a comprehensive guide to data collection.

Some important community indicators of perinatal and children's health are as follows: maternal and infant mortality rates, low birth weight (LBW), number of stillbirths, level of first-trimester prenatal care, number of enhanced 18-month well-baby visits, immunization rates, the Early Developmental Instrument (EDI), and rates for other screening tests. Nurses may use these indicators as a reflection of access, quality, and continuity of health care in a community. Lower

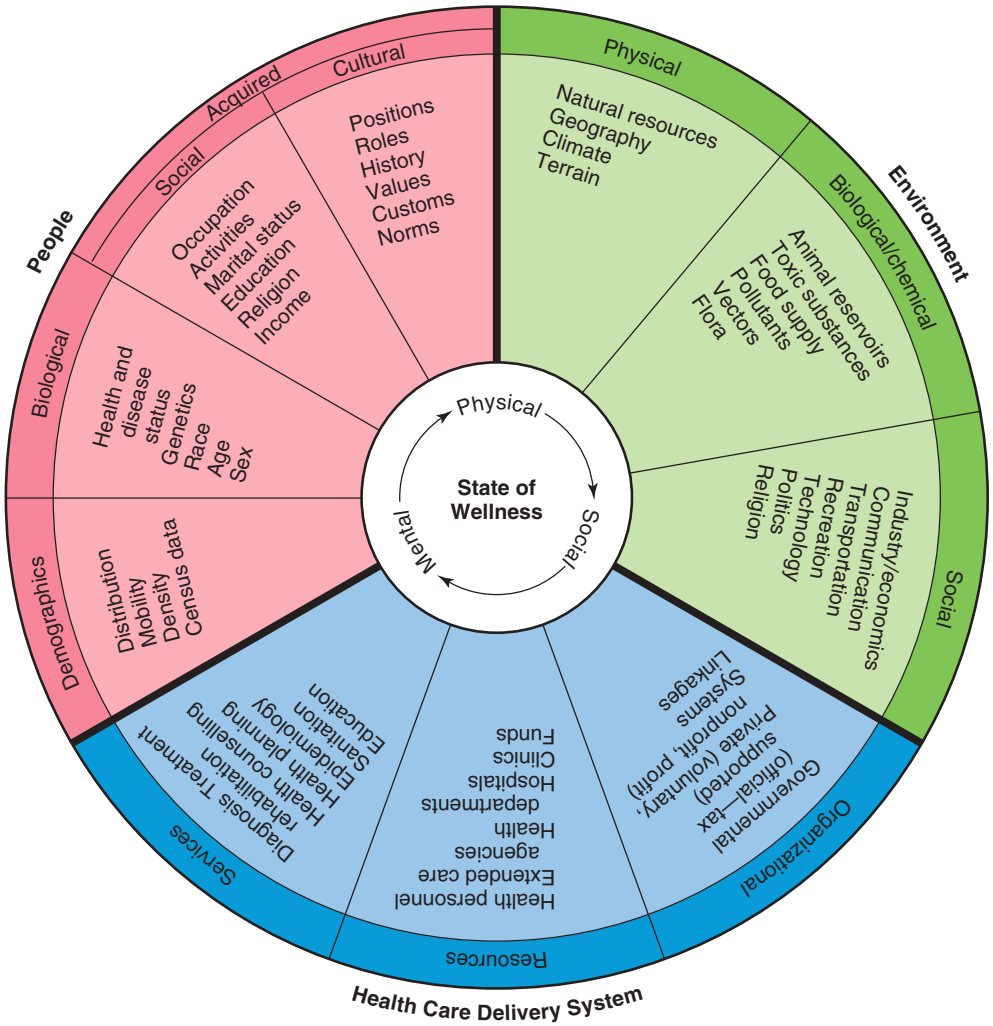

Fig. 3.3 Community health assessment wheel. (From Clemen-Stone, S. [2002]. Community assessment and diagnosis. In S. Clemen-Stone, S. McGuire, & D. Eigsti [Eds.], *Comprehensive community health nursing: Family, aggregate, and community practice* [6th ed.]. Mosby.)

neighbourhood income has been found to be associated with higher child vulnerability, as measured by EDI scores. Based on data collected across Canadian provinces between 2007 and 2012, 34.9% of children living in a low-income neighbourhood experienced higher health vulnerability, compared to 19.5% in high-income neighbourhoods (O'Brien Institute for Public Health, 2018). Vulnerability is an important determinant of child health as it has implications for lifelong health and well-being.

For all people, access to a consistent source of health care is critical. Not having a regular medical doctor or nurse practitioner is associated with fewer health care visits with general practitioners and specialists who can play a role in screening and treating medical conditions early (Glazier et al., 2008). Over the past decade, the percentage of Canadians who report having a primary care practitioner has declined slightly; remote areas in Canada report the lowest numbers of people with family doctors. In 2017, 15.3% of Canadians reported not having a primary care practitioner, with the highest rates reported in Quebec, Saskatchewan, and British Columbia (Statistics Canada, 2019). When people do not have access to a primary health care provider, they use walk-in clinics, hospital emergency departments, or community health centres. The growing numbers of nurse practitioners in Canada have helped to address the shortage of family physicians.

Access to health care is also an important measure of community health. This indicator relates to the availability of health department services, home health care services, hospitals, birth centres, walk-in clinics, community health centres, or other sources of care, as well as the accessibility of that care. In many areas where facilities and providers are available, geographic and transportation barriers render the care inaccessible for certain populations. This is particularly true in rural areas or other remote locations. Other barriers to care should also be evaluated, including cultural and language barriers and lack of providers for specialty care. Local health departments provide varied levels and types of services, which are mandated by their respective provincial/territorial ministries of health. Depending on the level of funding received, they may or may not meet the needs of the populations they serve. For example, primary care services are limited in many areas, although health education is offered by most health departments in Canada.

Health departments at the municipal, regional, and provincial/territorial level are a valuable resource for annual reports of births

and deaths and other important health status data. Maternal and infant death rates are particularly important as they reflect health outcomes that may be preventable. Local health departments also compile extensive statistics about birth complications, causes of death, and leading causes of morbidity and mortality for each age group. Local, provincial, and territorial health data are compiled and reported through various agencies, including Health Canada, Statistics Canada, the Canadian Institute for Health Information (CIHI), and the PHAC. However, national data are only as accurate and reliable as the local data on which they are based, thus caution is needed in interpreting the data and applying them to specific population groups.

The Canadian government census provides data on population size, age ranges, sex, racial and ethnic distribution, socioeconomic status, educational level, employment, and housing characteristics. Summary data are available for most large metropolitan areas, arranged by postal code and census tract, which usually correspond to a neighbourhood comprising approximately 2 000 to 8 000 people. Assessment of individual census tracts within a community can help in identifying subpopulations or aggregates whose needs may differ from those of the larger community. For example, women at high risk for inadequate prenatal care according to age, race, and ethnic or cultural group may be readily identified, and outreach activities may be provided as appropriate.

Other sources of useful data are hospitals and voluntary health agencies. Community health resources include health care providers or administrators, government officials, religious leaders, and representatives of voluntary health agencies. Community or regional health councils exist in many areas, with oversight of specific health initiatives or programs for that region. These key informants often provide a unique perspective that may not be accessible through other sources. Community gatekeepers who are at the forefront of addressing the social and health care needs of the population are also critical links to population-specific health information.

Data may also be retrieved from existing community health program reports, records of preventive health screenings, and other informal data. Established programs often provide reliable indicators of the health-promotion and disease-prevention characteristics of the population.

Data collection methods may be either qualitative or quantitative and may include visual surveys that can be completed by walking through a community, participant observation, interviews, focus groups, and analysis of existing data. Potential patients and health care consumers may be asked to participate in focus groups or community forums to present their views on needed community services and programs. Formal surveys conducted by mail, telephone, online, or face-to-face interviews can be a valuable source of information not available from national databases or other secondary sources. However, several drawbacks exist with this method. Surveys are generally expensive to develop and time-consuming to administer. In addition to the cost of such surveys, poor response rates often preclude a sufficiently representative response on which to base nursing interventions.

A local walking survey is generally conducted by making a walk-through observation of the community (see Community Focus box), taking note of specific characteristics of the population, economic and social environment, transportation, health care services, safety, and other resources. This method allows the nurse to collect subjective data and may facilitate other aspects of the assessment. Participant observation is another useful assessment method, in which the nurse actively participates in the community in order to understand the community more fully and to validate observations.

COMMUNITY FOCUS

Community Walk-Through

As you observe the community, take note of the following:

Physical environment—Older neighbourhood or newer subdivision? Sidewalks for safely walking with children and older persons, streets, and buildings in good or poor repair? Billboards and signs? What are they advertising? Are lawns kept up? Is there garbage in the streets? Parks or playgrounds? Parking lots? Empty lots? Industries? Air quality?

People in the area—Older persons, young people, homeless persons, children, predominant ethnicity, language? Is the population homogeneous? What signs do you see of different cultural groups? Are people out and about in the community? Are there natural gathering places for families?

Stores and services available—Restaurants: chain, local, ethnic? Grocery stores: neighbourhood or chain? Department stores, gas stations, real estate or insurance offices, travel agencies, pawn shops, liquor stores, discount or thrift stores, convenience stores? Can people walk to shopping or do they need a car? Are there services for families with young children, such as Early Years Centres?

Social—Libraries with programming for children, museums, community recreation centres, arenas, clubs, pubs, organizations (e.g., Lions Club, Canadian Legion)?

Religious—Churches, synagogues, mosques, temples? What denominations? Do you see evidence of their use other than on religious or holy days?

Health services—Drug stores, doctors' offices, clinics, dentists, mental health services, veterinarians, urgent care facilities, walk-in clinics, hospitals, shelters, long-term care facilities, home health agencies, public health services, well-baby clinics, local laboratory, traditional healers (e.g., herbalists, palmists)?

Transportation—Cars, bus, taxi, ride-sharing services, subway, light rail, sidewalks, bicycle paths, access for disabled persons?

Education—Schools, before-school and after-school programs, child care centres, libraries, bookstores? What is the reputation of the school or schools?

Government—What is the governance structure? Is there a mayor? City council? Are meetings open to the public? Are there signs of political activity (e.g., posters, campaign signs)? Is there a local neighbourhood business community organization?

Safety—How safe is the community? What is the crime rate? What types of crimes are committed? Are police visible? Is there a fire station? Are people comfortable walking in their neighbourhood after dark?

Parks and recreation facilities—Are there local parks for toddlers and children? Are there recreational facilities for adults and children to participate in sports and recreation activities?

Evaluation of the community, based on your observations—What is your impression of the community? Is the environment pleasing? Are services and transportation adequate? How difficult is it for residents to obtain needed services (i.e., how far do they have to travel)? Would you want to live in this community? Why or why not?

Finally, as part of the assessment process, nurses working in multiethnic and multicultural groups need an in-depth assessment of culturally based health behaviours. In some cultures it is common for mothers and their babies to remain at home for the first 30 to 40 days postpartum (postpartum confinement). It is important to consider how postpartum confinement might limit the use of services at well-baby clinics, infant feeding clinics, and other postnatal interventions in the community.

Analysis and synthesis of data obtained during the assessment process help in generating a comprehensive picture of the community's

health status, needs, and problem areas, as well as its strengths and resources for addressing these concerns. The goals of this process are to assign priorities to community health needs and to develop a plan of action for correcting them. A comparison of community health data with provincial and national statistics may be useful in the identification of appropriate target populations and interventions to improve health outcomes.

Community Planning. After the assessment is completed, the community nurse can collaborate with team members to analyze the results of surveys and questionnaires and determine whether the needs described by community members can be met by existing community agencies. During the analysis, the community's demographic characteristics, morbidity rates, and mortality rates are compared with a standard. In time comparisons, the nurse contrasts the rates in the current year with the rates during an earlier period. In comparisons of place, the nurse contrasts the rates in the community with those of a standard population. Standard rates may come from another community or from city, province/territory, or national data. For example, the rate of tuberculosis (TB) in a group of preschool children in a community in 2020 could be compared with the rate of TB in preschool children in the province in 2020. Some jurisdictions in Canada have a much higher rate of TB than others due to patterns of immigration and living conditions (Vachon et al., 2018). A community health diagnosis reflects health status, risk, or need. A community diagnosis is similar to that of an individual nursing diagnosis with a problem (need) and an etiology related to that problem (causative agent). An example of a community nursing diagnosis is increased rates of TB related to poor socioeconomic environment and overcrowded living conditions.

The nurse can collaborate with community members to develop a plan that addresses the target population's needs and problems utilizing a population health approach. To maximize the use of community resources, problems should first be prioritized on the basis of their severity, the community's identified needs, and the community nurse's ability to bring about change. The nurse or team works with community members to develop at least one goal for each problem. Goals are outcomes that give direction to interventions and provide a measure of the change the interventions produced. Community interventions frequently take the form of health programs for improving the target population's health status. Community health programs are based on the three levels of prevention: primary, secondary, and tertiary. For example, a goal for preventing bicycle injuries is "Within 1 year all students in the first grade will wear bicycle helmets." A nurse working within a group along with community members can then plan a program that includes health education about bicycle safety for students and their parents (primary prevention).

The planning group will consider the resources that are already available in the community and resources that will be needed for implementing a health program, including location, personnel, supplies, and equipment. Decisions are made about the program's timeline, the budget, and strategies to obtain funding. Program descriptions are found through professional contacts, online resources, and a review of the literature.

Community Intervention. During program implementation, the nurse or team and community members carry out the intervention. Whether the program is simple or complex, oversight is needed to ensure that everyone involved is communicating with one another, adhering to the plan's guidelines, keeping within the timeline, and documenting daily activities and expenses. The documentation will prove invaluable during the evaluation phase of the process.

Community Evaluation. Evaluation is used to identify whether the goals and program objectives were met. There are various models for measuring quality of health care. The most common framework used by health care organizations is the structure, process, and outcomes method described by Donabedian (1988). Donabedian conceptualized three quality-of-care dimensions: structure, process, and outcomes.

Structure—refers to attributes of the setting where the care is delivered. It is the context in which care is delivered that affects processes and outcomes—that is, the qualifications of personnel; the adequacy of buildings and offices, supplies, and equipment; and the target population's characteristics.

Process—whether or not good health care practices are followed.

Outcomes—the impact of the care on health status. Outcomes indicate the combined effects of structure and process—that is, whether program objectives and community goals were met.

To monitor outcomes is to monitor performances, which are conditional on structure and process. Only structure and process can be manipulated. Program evaluation should be ongoing so that an improvement in the way health care is delivered will affect the target population's health status.

Implications for Nursing

Working in the community or in the home with the full spectrum of family organizational styles, vulnerable populations, and cultural groups may present challenges for the nurse. Whether nursing care is focused on adults or children or on treatment and prevention of other health conditions in adults and children, such as communicable diseases and sexually transmitted infections, nurses must exhibit a high degree of professionalism and competence. Cultural sensitivity, compassion, and a critical awareness of family strengths, dynamics, and social stressors that affect health-related decision making are critical components in developing an effective plan of care. It is also important for nurses to have knowledge of health inequities related to the populations they provide care for.

Some examples of the importance of cultural sensitivity include working with immigrant families and the homeless population. Successful health promotion for new immigrants depends on the resources, benefits, and policies that ensure their healthy development and successful social adjustment. Culturally competent health care and involvement of the immigrant community in health care programs are recommended strategies for improving access to and effectiveness of health care for this population.

Nurses also work with homeless people and can be challenged to locate these patients on a regular basis and to establish a therapeutic relationship with them. Nurses and other health care providers may lack sufficient knowledge and sensitivity around the circumstances and special needs of this population and may inadvertently provide ineffective care. Many homeless people delay seeking health care or avoid it altogether because of having previous negative encounters with and lack of trust in health care providers. Case management is recommended for coordinating the services and disciplines that may be involved in meeting the complex needs of these families. Whenever possible, general screening and preventive services must be provided when the family member seeks treatment, as this may be the only opportunity to provide health information and intervention. Building on existing coping strategies and strengths, the health care provider can help the patient to reconnect with a social support system. Nurses also have an important role in advocating for funding to support homeless health services and to improve access to preventive care for all homeless populations.

HOME CARE IN THE COMMUNITY

Within the current health care system, home care is an important component of health care delivery, along the perinatal and child continuum of care. The growing demand for home care is based on several factors:

- Shortened hospital stays
- Increase use of outpatient procedures and surgeries
- New technologies that facilitate home-based assessments and treatments particularly for children with complex medical conditions
- Desire for the patient and family to be at home

Home care is the provision of technical, psychological, and other therapeutic support in the patient's home rather than in an institution. The scope of nursing care delivered in the home is necessarily limited to practices deemed safe and appropriate to be carried out in an environment that is physically separated from a health care institution and its resources. Nursing practice at home is consistent with provincial regulations that direct home care practice. The nurse demonstrates practice competence through formalized orientation and ongoing clinical education and performance evaluation in the respective home care agency.

Home health care can be viewed as an extension of in-hospital care. Essentially, the major difference between health care in a hospital and home care is the absence of the continuous presence of professional health care providers in a patient's home. Generally, but not always, home health care entails intermittent care by a professional who visits the patient's home for a health issue and/or provides care onsite for fewer than 4 hours at a time. For example, a new postpartum patient who requires dressing changes or other complex postpartum care may be eligible for home care.

The home health care agency maintains on-call professional staff to assist home care patients who have questions about their care and for emergencies, such as equipment failure. A wide range of professional health care services and products can be delivered or used in the home by means of technology and telecommunication. For example, telehealth and telemedicine make it possible for patients in the home to be interviewed and assessed by a specialist located hundreds of kilometres away.

Home care agencies are subject to regulation by governmental and professional organizations and provide interprofessional services including social work, nutrition, occupational therapy, and physiotherapy. Increasingly, their caseloads are made up of patients who require high-technology care, such as parenteral nutrition for pregnant patients with hyperemesis or children requiring care of central lines for chemotherapy. Although the home health nurse develops the care plan, all care must be ordered by a physician or a nurse practitioner.

Patient Selection and Referral

The office or hospital-based nurse is often the key person making referrals to home care. When considering a referral to home care, the following factors are evaluated:

- Health status of patient: Is the condition serious enough to warrant home care, and is it stable enough for intermittent observation to be sufficient?
- Availability of professionals to provide the needed services within the patient's community.
- Family resources, including psychosocial, social, and economic resources: Will the family be able to provide care between nursing visits? Are relationships supportive? Does the family have health benefits to support their care? Could a voluntary community agency provide needed care without payment?
- Cost-effectiveness: Is it more reasonable for the patient to receive these services at home or to go to a local outpatient facility to receive them?

Community referrals should not be limited to patients with physiological complications that require medical treatment. Patients at risk (e.g., patients with a perinatal mood disorder, young adolescents, families with a history of abuse, members of vulnerable population groups, developmentally disabled individuals) may need follow-up care at home. With the growing types of interprofessional health care now available, it is crucial that nurses communicate with social workers to tap into valuable community resources that patients can use in their own communities once discharged home.

High-technology home care requires additional information to be collected from the chart and consultation with the referring health care provider and other members of the health care team before a home care referral is made. These additional data include the medical diagnosis, medical prognosis, prescribed therapies, medication history, drug-dosing information, potential ancillary supplies, type of infusion and access device, and the available systems of social support for the patient and family. The nursing assessment and therapy data provide baseline information for the home care nurse and other health care providers involved in the care plan.

Nursing Care

Home Visiting. The community health or home health nurse will review the home visiting referral, including documents such as screening tool results, record of birth, available clinical data, demographic information, and any other relevant information, prior to setting up the visit with the patient. During the telephone call to arrange a mutually convenient visiting time, the nurse will determine the goals of the visit. During this contact, the nurse should identify themselves and begin to build rapport with the patient. The nurse should briefly explain what will occur during the visit and approximately how long the visit will last. The patient and family should be asked to restrain any pets that may be present during the visit. The nurse needs to review relevant policies and procedures, professional literature about any potential diagnosis, and community resources as part of the previsit preparation work (Box 3.3).

First home visit. Making the first home visit can be stressful for both the nurse and the family. The home visiting nurse is faced with an unknown environment controlled by the patient and the family. The patient and the family can also experience feelings about the unknown, such as anxiety about the way the nurse will treat them or what the nurse will do during the visit. The challenge for the community health or home health nurse is to establish a nurse–patient relationship and provide the prescribed services within the time provided for the initial home visit. One of the most important tasks of the home health nurse is modelling health-related behaviours for the patient and others who are in the home during the visit.

During the first visit, after introductions have been made, the nurse will complete an extensive assessment documentation with the patient. If the nurse needs to consult with the patient's physician, nurse practitioner, or other health care providers, a consent form will need to be signed by the patient. All patients have the right to participate actively in their plan of care. If the patient is a child, the parents or guardians will make decisions regarding the care of their child. Explanation of these patient rights and responsibilities should begin the discussion about the nurse and patient roles during this initial visit.

Assessment. The primary goals of the assessment phase are to develop a trusting relationship and collect data by various methods to obtain a comprehensive patient profile. The major areas of the assessment are demographics, medical history, general health history, medication history, psychosocial assessment (Box 3.4), home and community environment, and physical assessment. It may not be feasible or appropriate to collect in-depth information about all areas of

BOX 3.3 Protocol for Home Visits

Previsit Interventions

1. Contact the family to arrange details for a home visit.
   a. Identify self, credentials, and role of the community health or home health nurse.
   b. Review the purpose of the home visit.
   c. Schedule a convenient time for the visit.
   d. Confirm address and route to the family home.
2. Review and clarify appropriate data.
   a. Review all available assessment data for the patient or family (e.g., referral forms, hospital discharge summaries, family-identified learning needs).
   b. Review records of any previous nursing contacts.
   c. Contact other professional caregivers as necessary to clarify data (e.g., physician, midwife, nurse, referring source).
3. Identify community resources and teaching materials that are appropriate to meet needs already identified.
4. Plan the visit and prepare any resources required for the visit.

In-Home Interventions: Establishing a Relationship

1. Reintroduce self and establish the purpose of the visit for the parents, child, and family; offer the family an opportunity to clarify their expectations of contact.
2. Spend a brief time socially interacting with the family to become acquainted and establish a trusting relationship.

In-Home Interventions: Working With a Family

1. Conduct a systematic assessment of the patient to determine physiological adjustment and any existing complications.
2. Throughout the visit, collect data to assess the emotional adjustment of individual patient and family members to illness or lifestyle changes.
3. Determine adequacy of the support system if appropriate.
   a. To what extent does someone help with cooking, cleaning, and other home management tasks?
   b. To what extent is help being provided in caring for the patient or other family members?
   c. Are support persons encouraging the patient to care for themselves and get adequate rest?
4. Throughout the visit, observe the home environment for adequacy of resources (if appropriate):
   a. Space: privacy, safe play of children, sleeping
   b. Overall cleanliness and state of repair
   c. Number of steps the patient must climb
   d. Adequacy of cooking arrangements
   e. Adequacy of refrigeration and other food storage areas
   f. Adequacy of bathing, toilet, and laundry facilities
5. Throughout the visit, observe the home environment for overall state of repair and existence of safety hazards:
   a. Storage of medications, household cleaners, and other substances hazardous to children
   b. Presence of peeling paint on furniture, walls, or pipes
   c. Factors that contribute to falls, such as dim lighting, broken steps, scatter rugs
   d. Presence of vermin
   e. Use of crib or playpen that fails to meet safety guidelines
   f. Existence of emergency plan in case of fire; fire alarm or extinguisher
6. Provide care to the patient.
7. Provide teaching on the basis of previously identified needs.
8. Refer the family to appropriate community agencies or resources, such as telephone contact information lines and community support groups.
9. Ascertain that the patient and family know potential problems to watch for and whom to call if they occur.

In-Home Interventions: Ending the Visit

1. Summarize the activities and main points of the visit.
2. Clarify future expectations, including scheduling of the next visit.
3. Review the teaching plan and highlight important points.
4. Provide information about reaching the nurse or public health department if needed before the next scheduled visit.

Postvisit Interventions

1. Document the visit thoroughly, using the required agency forms.
2. Initiate the plan of care on which the next encounter with the patient or family will be based.
3. Communicate appropriately to other staff assigned to care for the family. This may include follow-up with other health care providers, if warranted.

BOX 3.4 Psychosocial Assessment

Language

Identify the primary language spoken in the home.
Assess whether there are any language barriers to receiving support.
Assess health literacy.

Community Resources and Access to Care

Identify primary and secondary means of transportation.
Identify community agencies that the family currently uses for health care and support.
Assess cultural and psychosocial barriers to receiving care.

Social Support

Determine the people living with the patient.
Identify who assists with household chores.
Identify who assists with child care and parenting activities.
Identify who the patient turns to with problems or during a crisis.
Determine social networks both formal and informal.

Interpersonal Relationship

Identify the way in which decisions are made in the family.
Identify the family's perception of the need for home visiting.
Identify roles of adults in caring for family members.

Caregiver

Identify the primary caregiver for the patient.
Identify other caregivers and their roles.
Assess the caregiver's knowledge of care required for the patient and the purpose of home visits.
Identify potential strain from the caregiver role.
Identify the level of satisfaction with the caregiver role.

Stress and Coping

Identify what the patient perceives as lifestyle changes and their impact on self and the family.
Identify the changes that the patient and family have made to adjust to the illness or life transition.

assessment during the first visit. However, in many instances the nurse may be limited to one visit and must obtain information pertinent to the current situation during that visit.

Establishing a trusting relationship begins with the previsit telephone call. An interview style that reflects sensitivity, conveys a nonjudgemental, accepting attitude, and shows respect for the patient's rights facilitates development of that trusting relationship. A skillful interviewer avoids barriers to communication, such as false reassurance, advice-giving, excessive talking, and showing approval or disapproval. This nurse–patient relationship will continue to develop over the course of each home visit.

The nurse is a guest in the patient's home and should show respect for the patient's belongings. Some adaptation of the home visit schedule may need to be made if numerous distractions interrupt a visit, such as caring for the needs of small children. The nurse may ask to have the volume of the television reduced or suggest moving to another room where it is quieter and more private.

Plan of care and implementation. The nursing plan of care is developed in collaboration with the patient, based on the health care and learning needs of the individual. Home visiting nurses work from a standard care plan and make adjustments to meet the needs of each individual patient. The frequency of the skilled nursing visit may vary with the individual plan of care, and a family visitor or lay home visitor may be recommended if additional support is suggested and available.

There are several areas of concern when caring for a patient in the home. In home care, the patient or family members may be responsible for administration of medications in the absence of the nurse. A careful medication history should be obtained to see if the patient is taking the medications correctly and understands their desired action and potential adverse effects. It is important that patients and caregivers have a clear understanding of medication regimens and are notified when medications change in any way. Even more important is ensuring that the patient and caregivers fully understand the information they are given by health care providers.

It is also important that nurses be aware of how to use and educate patients and families on the use of all home care equipment, such as infusion pumps and phototherapy lights. Although most newborn phototherapy is usually done in the hospital, sometimes jaundiced babies are treated at home. The nurse should be familiar with the types of phototherapy equipment (e.g., Bili Therapy Pad) they may encounter in the home setting. Nurses also must be skilled at performing various procedures, such as venipuncture and administration of intravenous medications or fluids. In addition to teaching about medications and equipment, nurses must be sure that patients and families know how to respond in emergency situations.

The provision of education during a home visit is a key component of the visit. Verbal explanations should be supplemented with clearly written instructions if the patient has difficulty remembering or if there is a language barrier. Many written resources are available in multiple languages to facilitate the transfer of information and knowledge.

Finally, as soon as home care has been provided, it is essential that the nurse document the assessment findings, care provided, recommendations for change, and any patient or family teaching done. Nursing documentation should reflect an objective description of the nursing assessment data collected at each visit and the associated outcomes. Once the home visiting outcomes are achieved or the patient is discharged from the program, documentation should include information about the patient's status at the time of discharge, progress toward attaining health care goals, and plans for any follow-up care. Appropriate care should be taken to complete the necessary home health care records accurately and in a timely manner and ensure appropriate privacy rules are maintained. Documentation guidelines are agency specific but may include writing or dictating notes or using eDocumentation shortly after the visit.

Safety issues for the home visiting nurse. Nurse safety and infection control are two important aspects specific to home care. The nurse should be fully aware of the home environment and the neighbourhood in which the home care will be provided. Unlike hospitals, where the environment is more predictable and controlled, the patient's neighbourhood and home have the potential for uncertainty. Home visiting nurses should take necessary safety precautions and avoid dangerous situations.

Personal strategies recommended for nurses visiting families with a history of violence or substance use include (1) self-awareness, (2) environmental assessment, (3) using listening and observation skills with patients to be aware of behavioural changes that indicate aggression or lack of impulse control, (4) planning for dealing with aggressive behaviour (i.e., allowing personal space and taking a nonaggressive stance), (5) making visits in pairs, and (6) having access to a cell phone at all times.

Personal safety. The home care nurse must be aware of personal safety behaviours before going on a home visit. Dress should be casual but professional in appearance, with a first-name-only identification tag. Limited jewellery should be worn. Carrying an extra set of car keys in the nursing home care bag saves time and frustration if the nurse becomes locked out of the automobile. Home visiting nurses should follow the same common-sense behaviours and precautions that guide behaviour when alone in any setting.

The community health nurse should ensure that their employer knows their itinerary by keeping their electronic calendar up to date as per protocol. Many nurses carry agency-provided cell phones that allow the department to contact the nurse throughout the day in order to give information about patient updates or schedule changes. A cell phone is also useful for notifying patients when the nurse is delayed.

Patient's home. Once inside the person's home, the nurse may encounter unsafe situations, such as the presence of weapons, abusive behaviour, or a health hazard. Each potentially hazardous situation must be dealt with according to agency policies and procedures. If abuse or neglect is reasonably suspected, the home care nurse should follow the department's and the province's regulations for reporting and documenting the situation. Nurses should maintain their own safety first and act accordingly throughout the visit.

Infection control. The importance of infection control does not diminish because nursing care is being provided in the patient's home. Patients are not likely to become infected because of their home environment, but the nurse may become exposed to an infectious disease.

Hand hygiene remains the single most important infection control procedure, and the caregiver is in a position to educate the family about the importance of this practice in preventing disease. Hands should be washed before and after each patient contact; wearing gloves does not eliminate the necessity for hand hygiene. If running water or clean facilities are unavailable, hands can be cleaned with hand sanitizer.

Phone and Online Health Support

Frequent and brief contacts with health care providers are required during the perinatal and early child development periods, making services that link patients to care important. There are several different ways in which these linkages can be made. Most public health departments in Canada offer telephone support lines or social media connections with families (Facebook, Twitter, text messaging) to provide parents with support and education about pregnancy, infant feeding, and parenting information and resources. Another Web-based resource are provincial websites that provide people with medically approved information on many health topics, medications, and tips

BOX 3.5 Telephone Triage Guidelines for Assessment

Date and time
Background
- Name, age, sex
- Chronic illness
- Allergies, current medications, treatments, or recent immunizations

Chief health concern
General symptoms
- Severity
- Duration
- Other symptoms
- Pain

- Advised to see practitioner
- Advice given for home care
- Call back if symptoms worsen or fail to improve

for promoting health lifestyles, for example, HealthlinkBC. More and more providers are using the Internet to communicate with their patients.

Telephonic nursing care through services such as nurse advice lines and telephonic nursing assessments is a valuable means of managing health care issues and bridging the gaps between acute, outpatient, and home care services. Nursing care via telephone is interactive and responsive to a patient's immediate health care questions about particular health care needs. Telehealth is another option in which nurses guide callers through urgent health care situations, suggest treatment options, and provide health education.

Telephone Triage and Counselling. Telephone triage care management has increased access to high-quality health care services and empowered parents to participate in their own health care. Consequently, patient satisfaction has significantly improved. Unnecessary emergency department and clinic visits have decreased, saving health care costs and time (with less absence from work) for families in need of health care.

Most often, health issues are assessed and prioritized according to urgency, and treatment is judiciously provided via telephone services. Telehealth nurses need to have communication skills training in telephone consultation and learn how to structure a call. A well-designed telephone triage program is essential for safe, prompt, and consistent-quality health care. Typically, guidelines for telephone triage include asking screening questions; determining when to immediately refer to emergency medical services (dial 911); and determining when to refer to same-day appointments, appointments in 24 to 72 hours, appointments in 4 days or more, or home care (Box 3.5).

KEY POINTS

- A community is defined as a locality-based entity composed of systems of societal institutions, informal groups, and aggregates that are interdependent and whose function is to meet a wide variety of collective needs.
- Caring for perinatal patients and children in their community requires nurses to utilize an interprofessional approach, as well as working with the families themselves.
- Community health nursing focuses on promoting and maintaining the health of individuals, families, and groups in the community setting.
- Economic evaluations provide objective information to establish a program's value to society.
- Individual families and communities may have demographic characteristics that affect their risk for disease or injury.
- Epidemiology is the science of population health applied to the detection of morbidity and mortality in a population.
- Community health programs are based on three levels of intervention: primary, secondary, and tertiary.
- A community needs assessment involves collection of subjective and objective information about the community.
- A community health diagnosis is a concern with a defined cause related to a community issue.
- Most changes aimed at improving community health involve partnerships between community residents, key stakeholders, and health care workers, among others. Community nurses are well positioned to facilitate partnership development.
- Evaluation of effective community programs includes consideration of the structure, process, and outcomes related to the program.
- Methods of collecting data useful to the nurse working in the community include walking surveys, analysis of existing data, informant interviews, and participant observation.
- Community health nurses must be aware of vulnerable populations within the community who may require additional care.
- Nurses play an important role in perinatal and children's health home visiting through the provision of evidence-informed care that includes consideration of community assets and resources and connecting families to the services and supports they require.
- Nurses who provide care in the community incorporate knowledge from community health nursing, acute care nursing, family therapy, health promotion, and patient education.
- Home visiting nurses should incorporate personal safety and infection control practices in the nursing plan of care.
- Telephone contact centres, credible websites, and social media platforms are low-cost health care services that facilitate continuous patient education, support, and health care decision making, even though health care is delivered in multiple sites.

Perinatal Nursing in Canada

Lisa Keenan-Lindsay

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the current scope of perinatal nursing in Canada.
2. Describe the history and context for perinatal care in Canada.
3. Discuss guiding principles for working with childbearing patients and their families.
4. Examine current trends in perinatal health and compare epidemiological data among groups and populations.
5. Explore current issues affecting perinatal nursing practice and envision creative alternatives.
6. Discuss the global health issues that impact the care that perinatal nurses provide.

This chapter presents a general overview of Canadian issues and trends related to the health and health care of patients, newborns, and families during the childbearing year.

Perinatal nursing is a recognized specialty in Canada. Perinatal nurses work collaboratively with childbearing persons and their families throughout the childbearing year, from preconception through pregnancy and childbirth, and over the postpartum transition period. This care is provided in many settings, including the hospital, the home, and a variety of ambulatory and community settings. Nurses also work collaboratively with other health and social care providers, such as physicians, midwives, dietitians, doulas, and social workers, to name a few. Perinatal nurses promote the physical, emotional, social, and spiritual well-being of the whole family and work to address health inequities that influence health outcomes.

In Canada, the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN) is the voice of women's health and perinatal nurses. CAPWHN has developed practice standards for perinatal nurses. The values and guiding principles for these standards are listed in Box 4.1. The Canadian Association of Schools of Nursing (CASN, 2017) has developed entry-to-practice competencies for nursing care of the childbearing family for baccalaureate programs in nursing (see Additional Resources at the end of this chapter). These represent the core competencies related to the nursing care of childbearing families that all baccalaureate nursing students in Canada should acquire over the course of their undergraduate education. The Canadian Nurses Association (CNA) offers a specialty certification for perinatal nurses. Nurses who obtain this certification are recognized nationally for their practice excellence and commitment to lifelong learning (CNA, 2019).

Perinatal nurses use evidence-informed practice to guide their interactions and interventions. The Society of Obstetricians and Gynaecologists of Canada (SOGC) consists of obstetricians, gynecologists, family physicians, nurses, midwives, and allied health professionals working in the field of women's sexual and reproductive health. The goals of the SOGC are to promote excellence in the practice of obstetrics and gynecology and to advance the health of women through leadership, advocacy, collaboration, and education. Many of the SOGC clinical practice guidelines are used by nurses to support their practice. Many regional health authorities have also developed guidelines for providing care—for example, Perinatal Services BC, and the Champlain Maternal Newborn Regional Program (see **Additional Resources**). Perinatal units often adapt these recommendations to their specific institutions, enabling nurses to become more informed about current evidence and provide more effective care for childbearing families.

PERINATAL SERVICES IN CANADA

In Canada, maternal and newborn services have changed from those of our colonial and Indigenous roots to the current system of regionalized perinatal and newborn care. Box 4.2 provides an overview of the history of perinatal services over the past two centuries and shows the progress that has been made, though there is still room for improvement in many areas.

The delivery of maternity care within each community, province, and territory contains unique elements as each level of government tries to balance human resources, funding, and liability concerns with regulatory, educational, political, and demographic issues. Inequities in access to good-quality maternity care have developed particularly in

BOX 4.1 Values and Guiding Principles for Perinatal Nursing in Canada

Caring: Perinatal nurses foster caring relationships with childbearing persons and families by providing safe, compassionate, competent, and ethical care; promoting family health and development; and assisting when childbearing challenges occur. Caring is demonstrated through authentic presence, which is achieved by addressing physical, emotional, spiritual, and psychosocial needs throughout the care trajectory.

Health and well-being: Perinatal nurses promote health and well-being by assisting childbearing persons and their families to strengthen their knowledge and skills to achieve their optimal level of well-being throughout the childbearing continuum.

Justice: Perinatal nurses uphold principles of justice by safeguarding human rights, equity and gender inclusivity, and fairness with childbearing persons, families, and newborns.

Informed decision making: Perinatal nurses recognize the rights of patients to make informed choices that are congruent with their own beliefs and values, and advocate for them to act on this right.

Dignity: Perinatal nurses share the intimacy of childbirth with childbearing persons and their families. Knowing that childbirth creates lasting memories of this important developmental transition, they strive to positively influence the childbearing experience by creating a healing environment that promotes and protects human dignity.

Confidentiality: Perinatal nurses recognize the importance of privacy, confidentiality, and maintaining the trust of childbearing persons and their families.

Accountability: Perinatal nurses act with integrity and in a manner consistent with their professional obligations, responsibilities, and standards of practice.

Adapted from Canadian Association of Perinatal and Women's Health Nurses (CAPWHN). (2018). *Perinatal nursing standards in Canada*. https://capwhn.ca/wp-content/uploads/2019/10/PERINATAL_NURSING_STANDARDS_IN_CANADA.pdf

BOX 4.2 Historic Milestones in the Care of Mothers and Infants

1847—Ether used in Scotland for an internal podalic version (first reported use of obstetric anaesthesia)

1848—Soeurs de Misericorde (Montreal) provide maternity care for unwed mothers

1861—Ignaz Semmelweis writes *The Etiology, Concept, and Prophylaxis of Childbed Fever*

1892—A law is passed making it illegal to sell or advertise contraceptives in Canada

1897—Victoria Order of Nurses (VON) established to improve maternal and infant health and to train nurses

1908—Childbirth classes started and prenatal care provided by outpost and public health nurses working in cities, small towns, and rural communities

1911—First milk bank in the United States, established in Boston

1912—Medical Council of Canada formed and makes midwifery illegal in most locations

1916—Margaret Sanger establishes the first American birth control clinic, in Brooklyn, New York

1920—Midwifery legalized in the colony of Newfoundland

1923—First US hospital centre for premature infant care, established in Chicago

1929—Modern tampon (with an applicator) invented and patented

1933—Sodium pentothal used as anaesthesia for childbirth; *Natural Childbirth* published by Grantly Dick-Read

1934—Dionne quintuplets born in Ontario and survive partly due to donated breast milk

1935—Sulfonamides introduced as cure for puerperal fever; Parents Information Bureau opened in Ontario to provide contraceptive information

1940—*Canadian Mother and Child* book first published and distributed free to Canadian mothers

1941—Penicillin used as treatment for infection; Papanicolaou (Pap) test introduced

1944—Society of Obstetricians and Gynaecologists of Canada (SOGC) formed

1953—Apgar scoring system of neonatal assessment published by Virginia Apgar

1956—Oxygen determined to cause retinopathy of prematurity

1957—*Hospital Insurance and Diagnostic Services Act* passed in Canada

1958—First fetal electrocardiogram from the maternal abdomen reported (first commercial electronic fetal monitor produced in the late 1960s); first clinical use of ultrasound to examine the fetus reported

1959—Agnes Higgins joins the Montreal Diet Dispensary and later develops an approach for improving nutrition for disadvantaged pregnant patients (Higgins method); cytological studies demonstrate that Down syndrome is associated with a particular form of nondisjunction (trisomy 21); *Thank You, Dr. Lamaze* published by Marjorie Karmel

1960—American Society for Psychoprophylaxis in Obstetrics (ASPO/Lamaze) and the International Childbirth Education Association (ICEA) formed; birth control pill introduced for "menstrual regulation" since contraceptives could not be legally prescribed in Canada

1962—Thalidomide found to cause birth defects

1963—Testing for phenylketonuria (PKU) begun

1967—Rho(D) immune globulin produced for treatment of Rh incompatibility; Reva Rubin publishes article on maternal role attainment

1968—The *Medical Care Act* passed and provinces begin to implement health insurance plans; rubella vaccine available

1969—Nurses Association of the American College of Obstetricians and Gynecologists (NAACOG) founded in the United States; some Canadian nurses join this organization; contraception decriminalized in Canada; mammogram becomes available

1970s—Total of 20 human milk banks across Canada receive donated breast milk

1974—LaLonde Report recommends more attention to health promotion and disease prevention

1975—The Pregnant Patient's Bill of Rights published by ICEA

1976—First home pregnancy kits approved

1978—First test-tube baby born in Britain; outpost nursing program at Memorial University, Newfoundland, includes a 10-month nurse-midwifery program

1980—Canadian Obstetrical Gynaecological and Neonatal Nurses (COGNN) formed as a special interest group within NAACOG

1986—Ottawa Charter for Health Promotion recommends more attention to health determinants; midwifery education program in Povungnituk, Quebec, begins preparing Inuit midwives

1987—Safe Motherhood Initiative launched by the World Health Organization and other international agencies

1988—Abortion decriminalized in Canada; SOGC launches International Women's Health Program

1991—Canadian Paediatric Society recommends that a minimum of one person skilled in neonatal resuscitation be present at every birth

1993—Midwifery education program launched in Ontario; human embryos cloned in the United States; first Canadian statement on reducing risk of sudden infant death syndrome (SIDS) released by Health Canada

Continued

BOX 4.2 Historic Milestones in the Care of Mothers and Infants—cont'd

1994—Midwifery legalized in Ontario; zidovudine guidelines published to reduce mother-to-fetus transmission of HIV; DNA sequences of BRCA1 and BRCA2 identified
1995—Canadian Perinatal Surveillance System (CPSS) launched
1998—Mandatory folic acid fortification of all breads and cereals sold in Canada
1998—COGNN becomes AWHONN Canada (Association of Women's Health, Obstetric and Neonatal Nurses Canada) and proposes to have perinatal nursing recognized as a specialty by the Canadian Nurses Association (CNA)
1999—First emergency contraceptive pill for pregnancy prevention (Plan B) approved; midwifery legalized in Quebec with midwives practising in birth centres
2000—*National Guidelines for Family-Centred Maternal and Newborn Care* published; first CNA Perinatal Nursing Certification exam; Canadian Association of Midwives (CAM) formed
2001—Joint statement on shaken baby syndrome released by Health Canada
2005—The Canadian Association of Neonatal Nurses (CANN) formed
2006—Human papillomavirus (HPV) vaccine first available
2008—Joint Policy Statement on Normal Birth released by SOGC; emergency contraception (Plan B) available over the counter in pharmacies; National Aboriginal Council of Midwives (NACM) officially established
2009—*What Mothers Say: The Maternity Experiences Survey,* published by the Public Health Agency of Canada, discusses Canadian patients' experience of childbearing
2010—Midwifery recognized as a legal and regulated profession in many Canadian provinces and territories; SOGC releases policy statement *Returning Birth to Aboriginal, Rural, and Remote Communities*
2011—AWHONN Canada becomes the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN)
2012—Breastfeeding Committee for Canada develops the Integrated Ten Steps Practice Outcome Indicators for Baby Friendly Initiative (BFI)
2013—Millennium Development Goals (MDGs)—Canada commits to reducing child mortality (MDG 4) and improving maternal health (MDG 5) through major monetary contributions and recommitment beyond 2015
2015—Four milk banks open in Canada with more under development; United Nations endorses the Sustainable Development Goals (SDGs) to improve global health
2016—Zika virus discovered, spread by mosquitos, and sexually transmitted by sperm if a male is infected, affects the fetus/newborn (microcephaly); Canadian Association of Schools of Nursing (CASN) publishes Entry-to-Practice Competencies for Nursing Care of the Childbearing Family for baccalaureate programs in nursing
2018—The first neonatal certification exam is offered by CNA; CAPWHN publishes perinatal nursing standards for Canadian nurses; Universal Pharmacare program is investigated by the federal government; revised family-centred maternity and newborn care guidelines published by the Public Health Agency of Canada

rural, remote, inner-city, and Indigenous communities, compared with access to such care in other Canadian communities. Many of these health inequities result from conditions of vulnerability and the social determinants of health (see Box 1.1; Social Determinants of Health). Childbearing patients and their families are affected by geography and the availability of social resources and programs in their communities. For instance, rural, remote, and Indigenous communities may have well-developed social networks but have less access to specialized health services. Maternity services, an important part of primary health care services, are often more difficult to provide in rural and remote locations. In many remote areas patients have access to a hospital, but often there are not care providers who are knowledgeable about pregnancy for birth available in the area.

Both the Canadian Perinatal Health Report (Canadian Perinatal Surveillance System [CPSS], 2008) and the Maternity Experiences Survey (Public Health Agency of Canada [PHAC], 2009) note that women living with poverty (those living below the low-income cut-off) and young women with less education consistently have the poorest perinatal outcomes. Indigenous women also have outcomes lower than the national averages, often related to government-imposed poverty and limited access to appropriate health care services. Limited maternal education, young maternal age, poverty, and the lack of prenatal care appear to be associated with higher **infant mortality rates**. Poor nutrition, smoking, alcohol use, and overall poor health or chronic conditions such as hypertension are also important contributors. To address the factors associated with infant mortality, there needs to be more focus on health promotion, improved access to appropriate care, strategies to decrease poverty, and preventive care for low-income families and childbearing patients experiencing conditions of vulnerability.

FAMILY-CENTRED MATERNITY AND NEWBORN CARE

The Public Health Agency of Canada (PHAC) (2017a) has published the *Family-Centred Maternal and Newborn Care: National Guidelines,* which is based on 17 guiding principles (Box 4.3). Perinatal nurses use these principles when providing care to childbearing persons, families, and newborns. Overall, family-centred maternity and newborn care (FCMNC) is about increasing the participation of patients and their families in the decision-making process concerning their pregnancy, birth, and early postpartum experiences in order to promote optimal health and well-being for the childbearing person, newborn, and family. This is sustained by an environment that values diversity and promotes collaboration, partnership, respect, and information-sharing between patients and families and their health care providers (PHAC, 2017a).

In order to provide family-centred care it is important to have a holistic, relationship-based model of care that is patient centred. Patient-centred care is grounded in the assumption that people know their own bodies and their health needs are defined by the person themselves, thus the person's choice must be respected. Health care providers are included in the patient's care according to the health needs, values, and preferences of the patient, taking into account their social and cultural context as they define it (PHAC, 2017a). Practitioners of patient-centred care also recognize that childbearing experiences vary, respect the many differences among people, and acknowledge that gender is an important determinant of health.

Promoting Healthy and Normal Birth

Family-centred maternity and newborn care is based on respect for pregnancy as a state of health and for childbirth as a normal physiological process. The central objective of care for childbearing persons, babies, and families is to maximize the probability of a healthy person giving birth to a healthy baby. Health care providers share this aim and recognize each patient as an individual. To promote the normal physiological process of childbirth, medical interventions should be judicious and appropriate and not routinely used. Many patients who labour in hospital settings are monitored electronically despite the lack of evidence that supports this practice.

Pregnancy and childbirth within a biomedical perspective are viewed as processes with inherent risks that are most appropriately

BOX 4.3 Guiding Principles of Family-Centred Maternal and Newborn Care

1. A family-centred approach to maternal and newborn care is optimal.
2. Pregnancy and birth are normal, healthy processes.
3. Early parent–infant attachment is critical for newborn and child development and the growth of healthy families.
4. Family-centred maternal and newborn care applies to all care environments.
5. Family-centred maternal and newborn care is informed by research evidence.
6. Family-centred maternal and newborn care requires a holistic approach.
7. Family-centred maternal and newborn care involves collaboration among care providers.
8. Culturally appropriate care is important in a multicultural society.
9. Indigenous people have distinctive needs during pregnancy and birth.
10. Care as close to home as possible is ideal.
11. Individualized maternal and newborn care is recommended.
12. Women and their families require knowledge about their care.
13. Women and their families play an integral role in decision making.
14. The attitudes and language of health care providers have an impact on a family's experience of maternal and newborn care.
15. Family-centred maternal and newborn care respects reproductive rights.
16. Family-centred maternal and newborn care occurs within a system that requires ongoing evaluation.
17. Family-centred maternal and newborn care best practices from global settings may offer valuable options for Canadian consideration.

Source: Public Health Agency of Canada. (2017). Chapter 1: Family-centred maternity and newborn care in Canada: Underlying philosophy and principles. In *Family-centered maternity and newborn care: National guidelines.* Author. https://www.canada.ca/content/dam/phac-aspc/documents/services/publications/healthy-living/maternity-newborn-care/maternity-newborn-care-guidelines-chapter-1-eng.pdf

managed by using scientific knowledge and advanced technology. This medical perspective toward childbirth stands in direct contrast to the belief systems of many cultures. Among many patients, birth is viewed as a completely normal process that can be managed with a minimum of involvement from health care practitioners. When encountering behaviour in patients unfamiliar with the biomedical model or those who reject it, the nurse may become frustrated and impatient and may label the patient's behaviour as inappropriate and believe that it conflicts with "good" health practices. If a Euro-centric health care system provides the nurse's only standard for judgement, the behaviour of the nurse will be ethnocentric (see Chapter 2, Providing Culturally Competent Nursing Care).

The language that health care providers use to describe patients and their concerns also needs to be reviewed (see Principle #14, Box 4.3). For example, practitioners may describe childbearing patients as having an "incompetent cervix," "failing to progress," or having an "arrest" of labour. They may describe a fetus as having intrauterine growth "retardation." They also may "allow" patient a "trial" of labour. The use of these phrases implies failure or inadequacy on the part of the patient or fetus, and there is now more emphasis being placed on incorporating more positive language into the practitioner's vocabulary.

Caring for Families

Use of the collaborative patient- and family-centred framework for perinatal nursing has brought greater understanding of how families need to be included in maternity care. Perinatal nurses' commitment to working in partnership with families can enhance the health and well-being of the whole family. Thus nurses must become competent in working collaboratively with families in a variety of contexts and settings. Relationships between childbearing patients, their families, and health care providers are based on mutual respect and trust. Such mutual respect and collaborative partnerships will help patients give birth safely, with power and dignity, in a way that promotes the health of the whole family. As well, it is crucial that the patient and family respect and trust nurses and other health care providers who will be providing care during times of vulnerability and change or transition.

The core concepts of patient- and family-centred care include the need for respect and cultural safety, involvement and participation, information sharing and collaboration, and active involvement in shared decision-making processes. When treating the patient and family with respect and dignity, health care providers listen to and honour their perspectives and choices. They share information with families in ways that are positive, useful, timely, complete, and accurate. The family is supported in participating in their care and decision making at the level of their choice. Collaboration with patients and their families in the development, implementation, and evaluation of policy and programs, facility design, professional education, and delivery of care by all involved is essential for providing family-centred care. This may be in contrast with the approach by some care providers who continue to focus on the medical nature of birth. Nurses need to advocate for change in caring for families to ensure that families are encouraged and allowed to make their own decisions about their birth.

Providing Care in a Culturally Safe Manner

The population of Canada is increasing in diversity, with one in five people identifying as coming from a visible minority (Statistics Canada, 2018); therefore, many patients giving birth may have cultural traditions and beliefs that are different from that of the perinatal nurse. Family-centred maternal and newborn care respects cultural differences between individuals, families, and communities (PHAC, 2017a). Perinatal nurses must integrate a cultural safety perspective into their practice which allows them to develop a critical understanding of culture and how this relates to maternal-child health (PHAC, 2017a). Cultural safety promotes partnership in a person's care and requires the practitioner to reflect on their own beliefs and also to be aware of the power disparities in health care delivery (see Box 2.4; Nursing Actions Important to Providing Culturally Safe Care). It is important to acknowledge that many childbearing patients may feel that health care providers are more knowledgeable and powerful than they are and will therefore sometimes feel coerced into decisions based on this power. These power differentials must be acknowledged with attempts to ensure this imbalance does not occur.

Providing care that meets the needs of the family can only occur when the individual's and family's cultural values, expressions, or patterns regarding care are known and used appropriately and in meaningful ways by health care providers. It is the childbearing patient who determines if the care provided is culturally appropriate. Nurses need to ask patients questions about their hopes and expectations regarding childbearing, about their capacities, and about their needs for nursing assistance.

In perinatal nursing, the nurse supports and nurtures beliefs that promote health, including those related to physical or emotional adaptation to childbearing. Table 4.1 provides examples of some cultural beliefs and practices surrounding childbearing. Rather than simply identifying particular cultural or ethnic groups, this table has been organized in a way that invites exploration of traditional beliefs and

TABLE 4.1 Cultural Practices and Successful Nursing Strategies During Childbearing and Parenting

Stage	Strategies
Pregnancy	
• In some cultures, the announcement of the pregnancy may be done in a specific manner (e.g., by a specific family member).	• Find out from the person what their wishes are around the announcement of the pregnancy and respect these wishes.
• Rituals may be performed to protect the pregnant person and child (e.g., reading from a sacred text, not going out at night, covering the person's head, wearing an amulet, giving to charity).	• Begin by asking each person about beliefs and practices around health and acknowledge these without judging them.
• Parents may not have the social support they would have had in their home country.	• Highlight the benefits of building social support prior to the birth to reduce the risk of postpartum mood disorders and to facilitate breastfeeding. Show the person specific ways of doing this through community, cultural, and religious groups, for example.
• In many cultures, pregnant patients learn what they will need for pregnancy and childbirth through their grandmothers, mothers, sisters, and aunts.	• With the person's permission, allow their partner, family, friends, and elders to accompany them to prenatal classes and appointments. • Respect the possibility that the partner may choose not to attend prenatal classes and that a family member will attend instead. • During the prenatal class, offer opportunities for participants to discuss their values and rituals related to pregnancy and birth as various topics come up. • Assist participants in developing a birth and breastfeeding plan in class. • Clarify when the labouring person should come to the hospital and what they should bring. • Ensure that a supportive environment is created in the prenatal classes to help pregnant persons build a social network.
• Language may be a barrier for some newcomers.	• If possible, use prenatal educators from linguistic communities similar to those of patients.
• Pregnancy information may be obtained from elders (e.g., grandmother, mother, mother-in-law).	• Collaborate with elders, friends, and relatives to provide consistent and appropriate education.
• Many prenatal tests and the concept of regular prenatal appointments may be unknown to the pregnant person.	• Explain the importance of prenatal care. • Explain the relevance of tests and make sure they are understood.
• Some people may have uncertainties about breastfeeding.	• Ask open-ended questions about the person's beliefs, knowledge, and concerns about breastfeeding and make sure this information is in their files if it might have an impact on breastfeeding after the baby is born. • Give the person information about where they can get help after the baby is born (breastfeeding clinic, lactation consultant, public health nurses, breastfeeding peer mentor, elders).
• The hospital may be a very unfamiliar setting to many newcomers. In many countries, home births are the norm.	• As with all expectant parents, a tour of the hospital is important to increase comfort levels. • Educate the person and family about the birthing process and Canadian practices (e.g., medications, interventions, newborn care) to enable patients to make informed decisions at the time of birth. • Inform the pregnant person about the possibility of using a midwife for a home birth or a doula as a birth assistant in the hospital.
• Some people may avoid certain foods in pregnancy or may eat certain foods or drink certain beverages during pregnancy.	• Discuss nutrition with the person, focusing on promoting a healthy pregnancy. • Ask what foods the patient is eating to maintain a healthy pregnancy.
Labour and Birth	
• Some people may birth in silence, and others may moan, groan, or scream.	• Respect cultural practices displayed by the person during the birthing process. Ask them what they feel like doing.
• Some labouring patients may squat or sit to assist in the birthing process.	• Encourage the labouring patient to use the most comfortable position for them during the birthing process.
• Some people might avoid pain-relieving medications such as epidurals and spinal medication.	• Explain the procedures with diagrams and models. • Suggest nonintrusive alternatives (e.g., warm towel on the back). • Ensure that the person provides informed consent.
• In some cultures, female genital cutting (FGC) is a routine practice, involving the stitching of the inner layers of the labia minor or majora, the removal of the clitoris or other parts of the genitalia, or both.	• Educate yourself about the practice of female genital cutting and the care required during childbirth.

Continued

TABLE 4.1 Cultural Practices and Successful Nursing Strategies During Childbearing and Parenting—cont'd

Stage	Strategies
• Some cultures may believe a Caesarean birth is not safe.	• During pregnancy, educate the person and their partner about the reasons for the procedure and the consequences of refusal. • Ensure informed consent at birth.
• Some patients may prefer same-gender health care providers.	• Incorporate patient preferences in health-related decisions where possible and appropriate. • During pregnancy, let the person know that it may not be possible to accommodate their preferences, depending on the staff on duty when they are admitted to the hospital.
Postpartum	
• There may be specific rituals performed to welcome the newborn.	• Accommodate the rituals, if possible, keeping in mind that these rituals may be particularly important for couples who are isolated from their extended families and removed from their culture.
• In many religions, the outcome of the birth (e.g., disability, Down syndrome, birth defect) is seen to be determined by God.	• These potential outcomes should be discussed during pregnancy. • Explain the short- and long-term consequences of the situation and the support options available. • Provide the family time to cope with the situation.
• Some postpartum patients may expect nurses to do everything related to newborn care.	• During the prenatal stage, educate the person about the roles and responsibilities of health care providers and other service providers in postpartum care. Encourage involvement of family members in caregiving after the birth.
• The baby may sleep with the postpartum patient in bed.	• Educate the parents about safe sleeping guidelines and co-sleeping and ensure that they make informed decisions regarding sleeping methods.
• Personal hygiene practices may vary widely depending on the culture. Some postpartum patients may not bathe or wash their hair or may bathe only once a week.	• Try to understand cultural hygiene practices and be understanding of a person's preferences. • Explain the signs and symptoms of infection and the importance of contacting a health care provider if this occurs.

health practices and offers some strategies for nurses. The aim of these strategies is to help nurses and other maternity care providers view these practices from a patient-centred perspective while taking into account Canadian practices and regulations.

In using Table 4.1 as a guide, nurses should exercise sensitivity in working with every family, being careful to assess the ways in which they adopt and adapt their cross-cultural nursing practice. Nurses are also reminded to reflect on the ways in which their own cultural practices (including the culture of nursing) may be interpreted by patients and family members. Nurses may not agree with all cultural practices of a patient, but it is important to respect the patient's decisions. Perinatal nurses need to listen to the stories that patients and family members tell them about their culture, their childbearing experiences, and their needs.

Care Environment

Family-centred maternity and newborn care applies to all care environments where childbearing patients and babies receive care, whether in a low-risk labour unit, the neonatal intensive care unit (NICU), or the home (PHAC, 2017a). Perinatal nurses must continue to work to promote normal birth within highly technological birth environments for patients and newborns who require this level of care. Family-centred care in the NICU may involve promoting skin-to-skin contact, breastfeeding, and rooming-in to help optimize outcomes for both families and babies.

Since childbirth is a normal life process, many people choose birthing centres or home birth as the location for giving birth. In support of this trend, the SOGC states that childbearing persons should have the choice of birthing location and that this right should be respected (SOGC, 2017). Patients who are low risk can safely give birth at home. There is evidence that patients who are low risk and who intend to give birth at home do not appear to have a different risk of fetal or newborn loss compared to a population of similarly low-risk patients intending to give birth in hospital (Hutton et al., 2019). In Canada, planning a home birth with a registered midwife or an appropriately trained physician is a reasonable choice for persons with a low degree of risk where the birth is anticipated to be uncomplicated and neither the childbearing person nor the newborn will require resources beyond the local capacity (Campbell et al., 2019).

For patients who live in rural and remote communities, registered nurses are essential to the provision of high-quality rural maternity care throughout pregnancy, birth, and the postpartum period. Maternity nursing skills should be recognized as a fundamental part of generalist rural nursing skills (Miller et al., 2017).

Most perinatal care in Canada is provided by physicians, with obstetricians providing the majority of perinatal care, although the number of midwifery-led births is increasing. In 2016/2017, midwives supported 10.8% of the births in Canada. Currently, British Columbia leads the country in highest percentage of midwifery-led births (22.4%)

(Canadian Association of Midwives, 2018). This number remains lower than in many other countries in the world but the number has been increasing. Most births in Canada take place in hospitals (98%), some occur in birth centres (1%), and home births account for approximately 1% of births (PHAC, 2018).

Midwifery. Midwives play a significant role in the delivery of maternity care. Although midwives have been in existence for years, it is only recently that midwives have been legislated in Canada and integrated into the health care system. Since the early 1990s, when midwifery legislation was first passed, most provinces and territories have gradually implemented midwifery-oriented health policy, including legalization of the profession, standardization of training, and the fees that are remunerated through their respective provincial insurance plans. In some provinces, for example, Ontario, childbearing patients who do not have provincial health care may be able to access free midwifery care. Midwifery care may be provided differently across jurisdictions. Whereas many midwives are fully funded and work in independent practice, some provinces have developed programs that enhance interdisciplinary care in order to provide midwifery care to patients who would not otherwise have access to it. An example is in Alberta, where the Rocky Mountain House midwives team up with the local primary care network, providing care to patients in three First Nations communities. In some jurisdictions where there are minimal numbers of midwives, a nurse will be the second care provider at the birth. See discussion below (Indigenous Women) regarding Indigenous midwifery.

The Canadian Association of Midwives (CAM) is the national voice for midwifery in Canada. Midwives in Canada have their own regulations and education separate from nursing education. Patients often choose midwifery care because of the philosophy behind midwifery practice that include supporting normal physiological birth, promoting informed choice, and optimizing the patient's childbirth experiences (Box 4.4).

BOX 4.4 Seven Core Principles of Canadian Midwifery Model of Care

- **Professional autonomy:** Canadian midwives are autonomous primary health care providers who provide comprehensive care during pregnancy, labour, postpartum, and the newborn period.
- **Partnership:** Midwives engage in a nonauthoritarian and supportive partnership with patients throughout their care.
- **Continuity of care provider:** Midwives provide continuity of care providers in order to build trust and partnership with women.
- **Informed choice:** Midwives recognize the right of each person to be the primary decision maker about their care.
- **Choice of birthplace:** Midwives recognize that everyone has the right to choose where they will give birth.
- **Evidence-informed practice:** Midwives support physiological birth and provide care that is informed by research, evidence-informed guidelines, clinical experience, and the unique values and needs of those in their care.
- **Collaborative care:** Midwives are autonomous health care providers, working independently and in collaboration with other health care providers as needed.

PERINATAL HEALTH INDICATORS: THE CANADIAN PERINATAL SURVEILLANCE SYSTEM

The Canadian Perinatal Surveillance System (CPSS) was developed in 1995 to monitor maternal and infant health across Canada. The CPSS collects data from a number of sources (e.g., vital statistics and the Canadian Institute for Health Information [CIHI]), analyzes and interprets the data, and provides studies and reports to be used as the basis for health policy and action. The CPSS has identified more than 50 perinatal health indicators and ranked many of these indicators for importance on the basis of current research evidence and knowledge about the determinants of health and impact of health outcomes.

The CPSS plays an important role in monitoring the quality of epidemiological (population) data available to assist with health and social service planning. Through data collection it has been determined that not every province or territory has the same birth registration practices. The CPSS has thus been working with some data collection agencies to improve the quality of the data collected so that provincial and international comparisons are more meaningful. Another organization that collects, interprets, and shares data regarding births in Ontario is Better Outcomes and Registry Network (BORN Ontario). The goal of BORN is to enhance the health of childbearing patients and newborns.

Nurses need to be aware that there are important differences in definitions for health indicators. An example is infant mortality rates, which have been identified as one of the best indicators of a nation's health status (CPSS, 2008). However, the infant mortality rate is a complex health indicator that is dependent on how "live births" are defined and registered and on how fetal and neonatal deaths are recorded. For example, Canada and the United States have adopted the World Health Organization (WHO) definition of live birth to include all products of conception that show signs of life at birth, without reference to birth weight or gestational age of the **fetus**. Many European countries have adopted different definitions; for example, in Sweden live births are considered to be at least 27 weeks' gestation and fetal deaths (stillbirths) are not recorded before 28 weeks' gestation. In Canada there has been a recent trend to include as "live births" more newborns born at less than 500 grams and 20 weeks' gestation, which may result in Canada and the United States comparing poorly with many European countries (Conference Board of Canada, 2019). Box 4.5 defines maternal and infant health indicators commonly used for reporting in Canada.

BOX 4.5 Common Perinatal Health Indicators

Birth rate—Number of live births in 1 year per 1 000 population

Fertility rate—Number of births per 1 000 women between the ages of 15 and 44 (inclusive), calculated on a yearly basis

Infant mortality rate—Number of deaths of infants under 1 year of age per 1 000 live births

Maternal mortality rate—Number of maternal deaths from births and complications of pregnancy, childbirth, and puerperium (the first 42 days after termination of the pregnancy) per 100 000 live births

Neonatal mortality rate—Number of deaths of infants under 28 days of age per 1 000 live births

Perinatal mortality rate—Number of stillbirths and number of neonatal deaths per 1 000 live births

Stillbirth—An infant who died in utero and at birth and demonstrates no signs of life, such as breathing, heartbeat, or voluntary muscle movements, with a birth weight of greater than 500 g or gestational age of 20 weeks or more

The CPSS releases a new report every 3 to 5 years and focuses on several perinatal health indicators that are deemed to be most important at the time. The 2017 edition of the CPSS report includes the top 16 perinatal health indicators for which there is currently sufficient national data available. Some of these indicators are discussed below.

Childbirth-Related Mortality Rate

Worldwide, approximately 830 childbearing patients die each day from complications related to pregnancy or childbirth (World Health Organization [WHO], 2019). In Canada in 2014–15, the annual **maternal mortality rate** (number of maternal deaths per 100 000 live births) was 7.4 (PHAC, 2017b). Although the overall number of maternal deaths is small, maternal mortality remains a significant problem because a high proportion of deaths are preventable, primarily through improving access to and use of prenatal care services.

The leading causes of maternal death attributable to pregnancy differ around the world. The following complications account for 75% of maternal deaths worldwide (WHO, 2019):

- Severe bleeding (mostly after childbirth)
- Infections (usually after childbirth)
- Hypertensive disorders during pregnancy (pre-eclampsia and eclampsia)
- Complications from the birth
- Unsafe abortion

Worldwide, strategies to reduce maternal mortality rates include improving access to skilled attendants at birth, providing post-abortion care, improving family planning services, and providing adolescents with better reproductive health services (WHO, 2019).

Currently, the leading causes of maternal mortality in Canada are diseases of the circulatory system, other indirect causes (e.g., disease of the digestive system), mental disorders and diseases of the nervous system, postpartum hemorrhage, hypertension, and obstetric embolism (PHAC, 2017b).

Maternal Morbidity

Although mortality is the traditional measure of maternal health and maternal health is often measured by newborn outcomes, pregnancy complications are important to consider. In 2014–15, the rate of severe maternal morbidity in Canada was 14.2 per 1 000 births, although this statistic does not include Québec. The most common severe maternal morbidities included blood transfusion with or without comorbidity (e.g. postpartum hemorrhage); cardiac arrest or failure, myocardial infarction or pulmonary edema; embolization or ligation of pelvic vessels or suturing of uterus and postpartum hemorrhage; and hysterectomy (PHAC, 2017b). Another factor that influences maternal morbidity is the impact of assisted reproductive technologies (ART). Patients who undergo infertility treatment, particularly in vitro fertilization, are at somewhat higher risk of severe maternal morbidity or death (Dayan et al., 2019).

Maternal morbidity results in a high-risk pregnancy. The diagnosis of high risk imposes a **situational crisis** on the family. The combined efforts of medical and nursing personnel are required to care for these patients, who often need the expertise of physicians and nurses trained in both critical care obstetrics and intensive care medicine or nursing.

Trends in Fertility and Birth Rate

Fertility trends and birth rates reflect childbearing patients' needs for health services. Canada's total fertility rate has been falling; in 2016 the rate was 1.54 children per woman, the lowest level observed since 2003 (Provencher et al., 2018). Indigenous fertility rates are different from these rates: 2.9 for First Nations women, 2.2 for Métis, and 3.4 for Inuit women (Smylie, 2011). These different rates may reflect cultural norms for certain populations. In recent years, more persons living in Canada have delayed childbearing until they are 35 years of age or older, and the rate of persons conceiving over age 35 has steadily increased since 2005 (PHAC, 2017b). In Canada, the average age of mothers at first birth was 28.7 years in 2012 and 29.2 years in 2016, although these ages are lower for Indigenous people, who often have their first child at a younger age (Provencher et al., 2018). The age of first birth is often culturally determined. Childbearing patients who conceive at older ages are more likely to experience chronic illnesses, placental issues, and multiple pregnancy, and their fetuses are more likely to have chromosomal abnormalities (e.g., Down syndrome). However, older patients also tend to be better educated, have higher income levels (less poverty), and seek early prenatal care.

The rate of live births to teenagers in Canada has been steadily decreasing since 2005, although there are significant geographic variations in adolescent fertility rates, with low rates in British Columbia to the highest in Nunavut, which may reflect significant cultural differences (PHAC, 2017b). The decline in teen pregnancy may be attributed to the accessibility and use of reliable contraception, such as condoms and birth control pills. Health issues associated with teen pregnancy include anemia and poor weight gain and twice the risk of giving birth to a preterm or low–birth weight baby (see Chapter 5). Teenage pregnancy can also influence the likelihood that the adolescent will not complete high school, which may result in underemployment and poverty.

Multiple Birth Rate

Multiple birth rates in Canada have fluctuated around 3% since 2005 and in 2014 were 3.3% of total births (PHAC, 2017b). Such pregnancies often occur in patients who are an older age at conception and are more likely to have used **assisted reproductive technologies** such as in vitro fertilization (IVF) (see Chapter 8). Multiple pregnancy can result in health issues for both the childbearing patient (anemia, pre-eclampsia, Caesarean birth) and their babies (preterm birth, low birth weight, perinatal death). There is growing evidence that decreasing the number of **embryos** may help decrease the poor health outcomes associated with higher-order (more than twins) multiple pregnancies.

Preterm Birth and Birth Weight

The proportion of preterm infants (born before 37 completed weeks' gestation) was 8.1 per 100 live births in 2014 (PHAC, 2017b). In industrialized nations, 60 to 80% of deaths of infants born without congenital anomalies are the result of preterm birth. Preterm birth is also associated with cerebral palsy and other long-term health issues. From 2010 to 2014, preterm birth rates ranged from 6.5 per 100 live births in the Northwest Territories to 11.9 per 100 live births in Nunavut (PHAC, 2017b).

Babies born both small (less than tenth percentile for sex-specific standardized birth weights) and large (greater than ninetieth percentile) for gestational age experience significant health challenges (see Chapter 28). Maternal cigarette smoking accounts for about 30 to 40% of small-for-gestational-age (SGA) babies born in industrialized countries, where malnutrition is not a predominant factor. Large-for-gestational-age (LGA) babies and their mothers are more likely to experience birth trauma (shoulder dystocia, nerve injuries, and **postpartum hemorrhage**). Maternal diabetes is another important risk factor (see Chapter 15).

Health Service Indicators

The CPSS also monitors a number of health service indicators, including, for example, rates of labour induction and Caesarean birth. The proportion of patients giving birth by Caesarean delivery has increased steadily, from 17.6% in 1995 to 28.4% in 2014–15 (PHAC, 2017b). Most of this increase is due to a higher rate of primary (first-time) Caesarean births, although the vaginal birth after Caesarean (VBAC) rate also decreased over the same time period. The overall trend is concerning, as evidence documents a higher risk of significant maternal morbidity (e.g., infection, thromboembolism, hysterectomy) for patients who have a Caesarean birth.

CURRENT ISSUES AFFECTING PERINATAL NURSING PRACTICE

Health Inequities Within Perinatal Populations

Patients must be viewed holistically and in the context in which they live; their physical, emotional, and social environment must be considered, because these interdependent factors influence health and illness. One of the primary factors compromising childbearing patients' health is lack of access to acceptable-quality health care. Therefore, recognition of the challenges experienced by both childbearing persons and maternity care providers who live and work in rural, remote, Indigenous, and inner-city communities must continue. The barriers to care may take many forms: living in a medically underserved area, or an inability to obtain needed services, particularly basic services such as prenatal care. For example, some rural and remote areas have few physicians and midwives; pregnant patients may have to travel hundreds of kilometres for this kind of care. Infant mortality is also higher for infants of mothers without a high school education than for those of mothers with such education.

Nurses must continue to address health inequities by working to create health policy and services that focus on the resources needed for health and access to health services. Some perinatal factors related to vulnerable populations are discussed below. Further discussion of vulnerable populations is provided in Chapter 1.

Indigenous Women. Canada's history has influenced the health and experience of pregnancy, childbirth, and parenting for Indigenous persons (see Chapter 1, Indigenous People). Having a healthy experience throughout pregnancy, childbirth, and parenting includes fostering positive mental and emotional health. Supporting individual resilience, creating supportive environments, and addressing the influence of the determinants of health are important considerations in promoting such an experience (British Columbia Reproductive Mental Health Program, 2011). Some Indigenous patients face unique challenges in having healthy pregnancies, birth, and parenting experiences, often because of culturally insensitive or unsafe care. Many of these patients live in an underserved area and with imposed poverty, which can reduce their ability to access healthy food and other supports. Thus supportive environments and relationships are especially important for Indigenous patients as they become pregnant, go through childbirth, and become parents (British Columbia Reproductive Mental Health Program, 2011). The people around pregnant patients can also help pass on important traditional practices.

Many Indigenous patients live in rural and remote communities and must often leave their communities in order to give birth. They must then experience labour and birth without the presence and support of family and community members, which can cause disruption and loss of cultural support, rather than strengthening families and communities (SOGC, 2017). The SOGC (2017) believes that childbearing persons should have the choice of birth place and supports and promotes the return of birth to rural and remote communities for patients at low risk of complications. While giving birth in a remote community may decrease access to immediate surgical backup available and to emergency air-evacuation, some patients are willing to take this risk in order to be closer to home when giving birth. Childbearing patients must be fully informed of the risks and benefits so they can make an informed choice about where to give birth.

The National Council of Aboriginal Midwives (NACM) is working to provide access to culturally safe sexual and reproductive health care for Indigenous families, the return of birth to Indigenous communities, and a reduction in the number of medical evacuations for births in remote areas (NACM, 2020). When care is provided in the community by an Indigenous midwife, families are kept together and important traditions and values about health are passed down to the next generation, which will ultimately improve early child development as well as the health and well-being of communities.

The NACM has developed core competencies for Indigenous midwives and is also working at enhancing education opportunities for Indigenous people who would like to become a midwife. Presently, there are two paths to becoming an Indigenous midwife: a 4-year university degree program or a community-based program. The community-based programs are in Six Nations in Ontario and in Northern Quebec. In these programs, students learn alongside the midwives in the community (for more information see Additional Resources at the end of this chapter). The core competencies for Indigenous midwives include the following (NACM, 2020):

- Provide culturally safe care
- Support rites of passage
- Communicate
- Develop the profession
- Support Indigenous health and well-being
- Manage prenatal care
- Manage labour and birth
- Manage postpartum care
- Provide newborn care

Homelessness and Pregnancy. Although little is known about pregnancy in this population, some homeless people do become pregnant. Pregnancy is linked to a whole host of health issues for homeless persons. Compared with women with housing, women who are homeless live with greater rates of depression and greater severity of mental health symptoms, and they are more prone to infection and to poorer maintenance of chronic conditions during pregnancy (Azarmehr et al., 2018). The homeless person is at risk for pregnancy complications because of many barriers to access in prenatal care, poor nutrition, stress, and exposure to violence. Homeless persons face multiple barriers to prenatal care, including lack of transportation, lack of knowledge of resources, negative perceptions of health care providers' communication styles and attitudes, inconvenient clinic hours, and psychosocial barriers, which include fear of having the child apprehended or fear of gynecological procedures due to previous history of trauma (Azarmehr et al., 2018). Nursing strategies for prenatal care of homeless pregnant persons are complex and include trauma-informed approaches, therapeutic communication, focused assessment, and upstream interdisciplinary approaches (Azarmehr et al., 2018).

Having access to supportive care during pregnancy and labour may improve outcomes for homeless patients. An example of this is a non-profit organization called Birthmark Support, a service available in Toronto and Hamilton, Ontario, which serves the needs of precariously housed people who are pregnant. This agency supplies the patient with a free doula who provides labour and pregnancy support, as well as

postpartum and breastfeeding support. Birthmark staff often attend appointments and assist in bridging the gap between these vulnerable people and the healthcare system. See Additional Resources for more information.

LGBTQ2 Concerns. Perinatal nurses may provide care to people who identify as LGBTQ2, and it is essential that their health care needs are appropriately met (see Chapter 1, Lesbian/Gay/Bisexual/Transsexual/Queer/2-Spirited (LGBTQ2) Health). Many lesbian, gay, and transsexual couples may become parents. They deserve respectful care during the childbearing experience as well as during health screening and wellness care. Their health care priorities are often similar to those of cisgender and heterosexual groups. While this text does not go into extensive detail regarding LGBTQ2 health care, whenever possible, LGBTQ2 concerns are integrated throughout the chapters.

LGBTQ2 people face challenges getting their reproductive health needs met, as health care providers may lack knowledge about LGBTQ2 health needs relevant to reproductive health priorities and treatment. LGBTQ2 patients may also experience discriminatory comments and treatment when receiving care (Wimbo et al., 2018). This discrimination and lack of appropriate quality care may affect health outcomes for these groups across the reproductive lifespan. Presently, perinatal care is based on that for nuclear cisgendered families, thus research and education must be done to ensure that the health care needs of persons not identifying as such are also met.

Interprofessional Care

A philosophy of respectful and collaborative work relationships between all different care providers underpins the framework for perinatal nursing in Canada (PHAC, 2017a). Nurses work with many different health care providers, including (but not limited to) obstetricians, family doctors, midwives, neonatologists, pediatricians, anaesthetists, childbirth and parenting educators, breastfeeding advisors, doulas, dietitians, social workers, and community support workers, to provide appropriate care for families undergoing the childbirth experience. It is important that perinatal nurses' knowledge and skills are recognized, and there must be mutual respect for all team members' scope of practice as well as respectful communication among all members. Interprofessional collaboration is key to ensuring good outcomes for perinatal patients, families, and newborns, as well as to ensuring successful practices for all member of the care team (Hutton et al., 2016). Important to this collaboration is undertaking interprofessional education (IPE) together as members of the health care team (see Chapter 1, Interprofessional Education). Teamwork and communication are key aspects of IPE; failure to communicate is a major cause of errors in health care.

Breastfeeding in Canada

Breastfeeding is recognized internationally as the optimal method of infant feeding; 6 months of exclusive breastfeeding with continuation for up to 2 years or longer with complementary foods is currently recommended (Critch, & Canadian Pediatric Society [CPS], Nutrition and Gastroenterology Committee, 2013/2018). The Breastfeeding Committee for Canada (BCC) has identified the WHO/UNICEF Baby Friendly Initiative (BFI) as a primary strategy for the protection, promotion, and support of breastfeeding. Many health care institutions and community centres have set the BFI strategy as the standard to achieve in Canada. The role of the perinatal nurse is to promote a culture of breastfeeding that also recognizes that breastfeeding may not be the right infant feeding option for all childbearing persons (see further discussion on breastfeeding and BFI in Chapter 27).

Community-Based Care

As health care costs continue to rise, Canada is faced with the challenge of providing safe and effective perinatal care that is innovative and cost-effective and meets the expectations of an increasingly educated public. Some childbearing patients who experience pregnancy complications are now cared for in the home by antepartum home care nurses. Portable fetal monitors and other forms of technology previously available only in the hospital are used. This change has affected the organizational structure of care, the costs of care, and the skills required to provide nursing care (Figure 4.1).

With the shorter length of hospital stay after birth, childbearing patients and their babies are often discharged home before they are successfully breastfeeding, before they have mastered basic baby care activities, and without sufficient supports at home. Public health departments and community agencies across the country must try to meet the needs of these new families. Changing demands on the community-based nurse have evolved out of these societal, economic, and health-related trends. Acuity of illness of home care patients is far

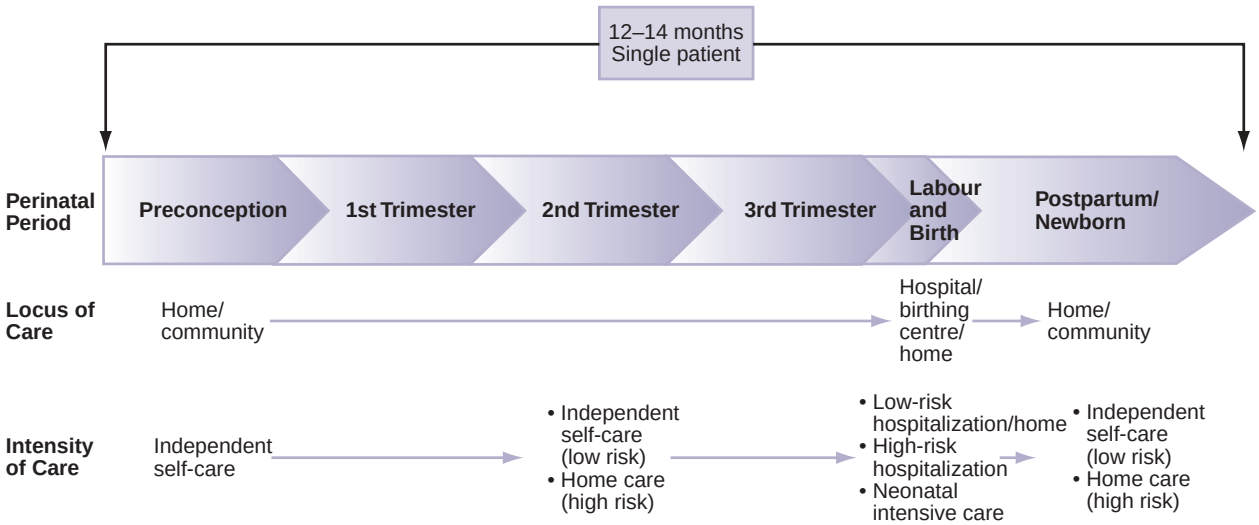

Fig. 4.1 Perinatal continuum of care.

greater than in the past, requiring the community nurse to become more adept at assessment, direct care, and health teaching (see Chapter 3 for further discussion of Community Health Nursing).

Perinatal nurses need to assess the resources that childbearing persons have to support them during the postpartum period at home. In many cultures, the childbearing person is cared for by extended family members so that the parent's primary responsibility is to breastfeed and recover from childbirth. In our independent North American culture, patients may need to be encouraged to ask for help. At times, perinatal nurses may need to advocate for a delay of hospital discharge until the needed supports are put in place. Nursing care has become more community based, with nurses providing care for childbearing patients and infants in homeless shelters and for adolescents in school-based clinics, and promoting health at community centres, churches, and shopping malls (see Community Focus box).

COMMUNITY FOCUS

Availability of Maternal Child Services in Your Community

To understand what services are available in your community, a good place to start is the Internet. Use the Internet to identify where the closest health department is located. Research what services are offered to childbearing families.

- How many other agencies provide services for childbearing families? Are they located in the area? What services do they offer?
- Are there registered nurses employed there? If not, what are the credentials of the people providing the services? Are there midwives and doulas also available?
- Is service provided in more than just English? If so, in what languages? Are interpreters available if needed?
- Do the agencies ever accept referrals for patients who cannot pay? Are there any bursaries or provisions made for families who cannot pay?
- Is there a maternal child home visiting program available in the community?

Based on the information you have gathered, are there adequate and appropriate services for pregnant patients and their families in your area? If not, is there a postpartum care clinic where new parents can access support for breastfeeding, hearing and dental screening, immunizations, well-baby care, and other related services?

Global Health

The United Nations has been working with countries around the world to improve maternal health. In 2015, the UN endorsed the Sustainable Development Goals (SDGs), which are a blueprint to achieve a better and more sustainable future for all (see Chapter 1, Figure 1.3). Two important targets of SDG #3 focused on perinatal nursing are to reduce the global maternal mortality ratio to less than 70 per 100,000 live births and to ensure universal access to sexual and reproductive health care services, including for family planning, information and education, by the year 2030 (Government of Canada, 2019).

Access to appropriate health care in the event of a complication can decrease the maternal and infant mortality rate. Some simple interventions to decrease the infant mortality rate include keeping the newborn warm, ensuring that the newborn is breathing, starting exclusive breastfeeding immediately, preventing malaria and tetanus, washing hands before touching the newborn, and enabling early recognition of illness and care seeking (WHO, 2020).

Two global health concerns that nurses in Canada might encounter are female genital cutting (FGC) and human trafficking. FGC includes procedures that intentionally alter or cause injury to the female external genitalia for nonmedical reasons and can negatively affect maternal health (WHO, 2018). More than 200 million girls and women alive today have been subjected to FGC, mainly in countries in Africa, the Middle East, and Asia. It is mainly done on young girls between infancy and age 15 years. With the growing number of Canadian immigrants from countries where FGC is practised, nurses will increasingly encounter women who have undergone the procedure. These women are significantly more likely to have adverse obstetric outcomes. The WHO, the International Council of Nurses, and other health professionals have spoken out against the procedures as harmful to women's health and a violation of the human rights of girls and women. It is nearly always carried out on minors and is a violation of the rights of children. The practice also violates a person's rights to health, security, and physical integrity; the right to be free from torture and cruel, inhuman, or degrading treatment; and the right to life when the procedure results in death (WHO, 2018) (see Chapter 5 and 17 for further discussion).

Human trafficking is a serious crime, an illegal business that exists in Canada and internationally, in which mostly women and children are "trafficked," or forced into hard labour, sex work, and even organ donation (Budiani-Saberi et al., 2014; United Nations Office on Drugs & Crime, 2019). Health care providers may interact with victims who are in captivity. If health care providers are appropriately trained, they may have the opportunity to identify victims, intervene to help them obtain necessary health services, and provide information about ways to escape from their situation. See Chapter 5 for further discussion of human trafficking.

KEY POINTS

- Perinatal nursing focuses on care for childbearing persons, their newborns, and families during the childbearing cycle.
- Childbirth practices have changed to become more person- and family-centred and include more alternatives in provider, birth place, and care.
- Collaborative family-centred maternal and newborn care is based on respect for pregnancy as a state of health and for childbirth as a normal physiological process.
- Perinatal nurses need to listen to the stories that childbearing patients and family members tell about their culture, their childbearing experiences, their resources, and their needs.
- Patients must be supported in the decisions they make regarding place of birth.
- Preterm birth and high Caesarean birth rates are current challenges in Canada.
- Childbearing persons living in rural, remote, and Indigenous communities and in poverty in inner cities experience significant health challenges and have increased difficulty accessing appropriate care.
- Nurses must continue to work toward decreasing health inequities among certain populations.
- The Baby Friendly Initiative (BFI) is a primary strategy to improve breastfeeding rates and support across the country.
- Perinatal nurses may encounter women who have undergone female genital cutting or who are victims of human trafficking and must ensure that appropriate care is provided.

Health Promotion

Kerry Lynn Durnford

Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify facilitators and barriers to accessing care in the health care system.
2. Analyze the determinants of health that may affect an individual's decision to seek and follow through with health care.
3. Describe the need for health promotion across the person's lifespan.
4. Discuss the importance of preconception counselling.
5. Analyze conditions and factors that increase health risks for patients across the lifespan, including life stage, substance use, eating disorders, medical and health conditions, pregnancy, and intimate partner violence.
6. Explain the cycle of violence and how an understanding of it can be used in assessment of and intervention for people who are victims of violence.
7. Identify community resources to prevent intimate partner violence.
8. Outline health-screening schedules for women.
9. Discuss how adult learning principles can be used in health-promotion education with patients and families.

REASONS FOR ENTERING THE HEALTH CARE SYSTEM

Many people initially enter the health care system because of some reproductive system–related situation, such as pregnancy, irregular menses, a desire for **contraception**, or an episodic illness, for example, a vaginal **infection**. It is important for health care providers to recognize the significance of health promotion and preventive health maintenance and to offer these services across the lifespan. This chapter presents an overview of the nurse's role in encouraging health promotion and illness prevention in women, although some of the information is also focused on people who may not identify as a woman but need specific care that focuses on their individual needs. Included is a schedule of screening tests recommended for women at different stages of their lives. Barriers to seeking health care as well as an overview of conditions and circumstances that increase health risks for patients across the lifespan are also included. Anticipatory guidance suggestions, such as nutrition and stress management, are included. Violence against women and against LGBTQ2 individuals, particularly intimate partner violence (IPV), is discussed because it is often in the health care setting that the person is able to acknowledge being in an abusive relationship.

Wellness Care Across the Lifespan

Maintaining optimal health is a goal for all people. Essential components of health maintenance are the identification of unrecognized health issues and potential risks, and the education and health promotion needed to reduce them.

A holistic approach to women's health care goes beyond simple reproductive needs; it includes a patient's health needs throughout their lifetime, with attention to physical, mental or emotional, social, and spiritual health. Patients' health is considered part of the primary health care delivery system, with assessment and screening focusing on a multisystem evaluation that emphasizes the maintenance and enhancement of wellness. Prevention of cardiovascular disease, promotion of mental health, and prevention of all forms of cancer, not just reproductive-related cancers, are all components of well-person care. It is important to consider all aspects of a patient's health, particularly in light of the fact that the leading causes of death in women in Canada include more than just reproductive health–related conditions (Box 5.1).

Even when focusing on reproductive health, it is critical to take a holistic approach to the health of patients. This is especially important for persons in their childbearing years because conditions that increase a patient's health risks are related not only to their well-being but also to

BOX 5.1 Top 10 Leading Causes of Death in Women in Canada

1. Malignant neoplasm (cancer)
2. Heart disease
3. Cerebrovascular disease (stroke)
4. Chronic lower respiratory disease
5. Accidents (unintentional injuries)
6. Influenza and pneumonia
7. Alzheimer's disease
8. Diabetes mellitus
9. Nephritis, nephrotic syndrome, nephrosis
10. Chronic liver disease and cirrhosis

Source: Statistics Canada. (2020). *Leading causes of death, total population, by age group, 2018.* https://www150.statcan.gc.ca/t1/tbl1/en/tv.action?pid=1310039401

the well-being of both mother and newborn in the event of a pregnancy. Prenatal care is an example of prevention that is practised after conception. However, prevention and health maintenance are also needed before conception because many of the patient's risks can be identified and modified then or perhaps even eliminated.

Health care needs vary with culture, religion, age, and personal differences. The changing responsibilities and roles of women, their socioeconomic status, and their personal lifestyles also contribute to differences in the health and behaviour of patients. Employment outside the home, physical disability, lone parenthood, and sexual orientation also can affect a patient's ability to seek and receive health care in clinical settings. As people age, well-women's health care should continue to include a complete history, physical examination, age-appropriate screening, and health promotion.

Adolescents. As females progress through developmental ages and stages, they are faced with conditions that are age related. All teens undergo progressive development of sex characteristics. They experience the developmental tasks of **adolescence**, such as establishing identity and sexual orientation, separating from family, and establishing career goals. Some of these processes can produce great stress for the adolescent. Female teenagers who enter the health care system usually do so for screening or because of a health concern, such as episodic illness or accidents, or gynecological issues associated with menses (either bleeding irregularities or dysmenorrhea), vaginitis or leukorrhea, sexually transmitted infections (STIs), contraception, or pregnancy. The adolescent may also be at risk for use of street drugs, for eating disorders, and for stress, depression, and anxiety.

Most young people begin having sex in their mid- to late teens, with the average age in Canada of first intercourse being 15.8 years (Bushnik, 2016). A sexually active teen who does not use contraception has a 90% chance of pregnancy within 1 year. Effective educational programs about sex and family life are imperative to help decrease the rate of teen pregnancy and STIs. Most Canadian public schools have a sexual health and education component in their curriculum.

Knowledge of and ability to apply growth and developmental concepts are critical for nurses in their work with adolescents. Involving adolescents in their care is important for establishing the nurse–patient relationship and for focusing on individual adolescents' strengths and resilience.

Teenage pregnancy. The rate of teenage pregnancy in Canada has decreased significantly; from 2001 to 2010, both teen birth and abortion rates decreased (McKay, 2013). The rate of adolescent pregnancies was 1.8% of all births in 2018 (Statistics Canada, 2021). When teenage pregnancy does occur, it often introduces additional stress into an already challenging developmental period, and there are greater risks than pregnancies for some other patients (see further discussion in Chapter 11). The emotional level of teens who are less than 16 years of age can be characterized by impulsiveness and self-centred behaviour, and they often place primary importance on the beliefs and actions of their peers. In attempts to establish a personal and independent identity, many teens do not realize the consequences of their behaviour; their thinking processes do not include planning for the future. From a public health perspective, the rate of teenage pregnancy is significant because teen pregnancy is more common among disadvantaged teenagers and may be a predictor of other social, educational, and employment barriers in later life (Bushnik, 2016). The incidence of violence may also be higher among adolescent mothers (see discussion later in chapter).

Teenagers often lack the financial and social resources to support a pregnancy and may not have the maturity to avoid teratogens or to have prenatal care and instruction or follow-up care. Pregnant teens have a greater risk of developing health concerns such as anemia, pre-eclampsia postpartum hemorrhage, chorioamnionitis, and depressive disorders, as well as of giving birth to newborns that are preterm or have low birth weight (Fleming et al., 2015; Kawakita et al., 2016). Children of teen mothers may be at risk for abuse or neglect because of the teen's inadequate knowledge of child growth and development and of parenting.

Implementation of specialized adolescent programs in schools, communities, and health care systems is demonstrating continued success in reducing the birth rate among teenagers.

Young and Middle Adulthood. Because people ages 20 to 40 years have a need for contraception, pelvic screening, and pregnancy care, they may prefer to use their gynecological or obstetrical provider as their primary care provider. During these years, the person may be "juggling" family, home, and career responsibilities, with resulting increases in stress-related conditions. Health maintenance includes not only pelvic screening but also promotion of a healthy lifestyle (i.e., good nutrition, regular exercise, no smoking, moderate or no alcohol consumption, sufficient rest, stress reduction, and referral for medical conditions and other specific issues). Common conditions requiring well-woman care include urinary tract infections, menstrual variations, sexual and relationship issues, and pregnancy.

Parenthood after age 35. The patient older than 35 years does not have a different physical response to a pregnancy per se but rather has had health status changes as a result of time and the aging process. These changes may be responsible for age-related pregnancy conditions. Other chronic or debilitating diseases or conditions increase in severity with time, and these in turn may predispose these patients to increased risks during pregnancy. Of significance to patients in this age group is the risk for certain genetic anomalies (e.g., Down syndrome). The opportunity for genetic counselling should be made available to all patients in this age group who are considering pregnancy (see Chapter 9).

Late Reproductive Age. Women of later reproductive age often experience change and a reordering of personal priorities. In general, the goals of education, career, marriage, and family have been achieved; now the person has more time and opportunity for new interests and activities. Divorce rates are high at this age, and children leaving home may produce an "empty nest syndrome," resulting in a potential increase in depression. Chronic illnesses also become more apparent. Many patients seek health care to discuss concerns with perimenopause (e.g., bleeding irregularities and vasomotor symptoms). Health maintenance screening continues to be of importance because some conditions such as breast disease or ovarian cancer occur more often during this stage.

APPROACHES TO CARE AT SPECIFIC STAGES DURING THE LIFESPAN

There are certain specific approaches to care of women at different stages of their lives. Several of these approaches are described in the next section.

Fertility Control and Infertility

Although information on unplanned pregnancies is not routinely collected, it is estimated that nearly 50% of all pregnancies in Canada are unplanned (Society of Obstetricians & Gynaecologists of Canada [SOGC], 2020). Education is key to encouraging people to make family planning choices based on preference and actual benefit-to-risk ratios. Health care providers can influence the patient's motivation and ability to use contraception correctly (see Chapter 8).

Individuals also enter the health care system because of their desire to become pregnant. The prevalence of infertility has increased, affecting approximately 16% of Canadian families (Public Health Agency of Canada [PHAC], 2019b). Many couples delay starting their families until they are in their 30s or 40s, which allows more time to be exposed to factors that affect fertility negatively (including age-related infertility for the person). In addition, rates of STIs, which can predispose to decreased fertility, are increasing significantly in Canada. From 2008 and 2017, chlamydia rates increased by 39%, gonorrhea increased 109%, and syphilis by 167% (Statistics Canada, 2020b). Many people are in workplaces and home settings where they may be exposed to reproductive environmental hazards.

Infertility can cause emotional pain for many couples. The inability to produce a child sometimes results in feelings of failure and places inordinate **stress** on the couple's relationship. Much time, money, and emotional investment may have been used for testing and treatment in efforts to build a family. A supportive health care team is important for the couple exploring fertility, struggling with fertility, or making choices for a life and career without children.

Steps toward prevention of infertility should be undertaken as part of ongoing routine health care. Such information is especially appropriate in preconception counselling. Primary care providers can undertake initial evaluation and provide counselling before couples are referred to specialists. For additional information about infertility, see Chapter 8.

Preconception Counselling and Care

Preconception health promotion provides patients and their partners with information needed to make decisions about their reproductive future. The health of parents prior to conception has an impact on the health of a child; therefore, appropriate preconception care will improve health outcomes for both parents and newborns. Preconception care involves identifying and modifying risk factors in individuals considering pregnancy in order to improve their health. Risk factors may include medical, behavioural, and social factors, many of which may be modifiable.

All patients should have an evaluation of their overall health and for opportunities to improve their health. They should also receive education about the effects of social, environmental, nutritional, occupational, behavioural, and genetic factors during pregnancy. Patients at high risk for an adverse pregnancy outcome should be identified. Such evaluation also involves identifying undiagnosed, untreated, or poorly controlled medical conditions. In order to make informed choices about childbearing, all individuals should be counselled regarding the increased risk of infertility, pregnancy complications, and adverse pregnancy outcomes when childbearing is delayed past the age of 35 (Liu & Case, 2017). The goals of the World Health Organization (WHO) for preconception care are to improve the health status of childbearing persons and their partners before conception, and to reduce those behaviours as well as individual and environmental factors that could contribute to poor maternal and child health outcomes (WHO, 2013). Some areas of focus for all health care providers who provide preconception health care are presented in Figure 5.1.

Activities that promote health in mothers and babies must be initiated before the period of critical fetal organ development, which is between 17 and 56 days after fertilization. By the end of the eighth week after conception and certainly by the end of the first trimester, any major structural anomalies in the fetus are already present. Because many patients do not realize that they are pregnant and do not seek prenatal care until well into the first trimester, the rapidly growing fetus may have already been exposed to many types of intrauterine environmental hazards during this most vulnerable developmental phase. These hazards include drugs, viruses, and chemicals. Thus, preconception health care should occur well in advance of an actual pregnancy.

The components of preconception care such as health promotion, risk assessment, and interventions are outlined in Box 5.2.

Pregnancy

A patient's entry into health care is often associated with pregnancy, for either confirmation of it or actual care. Early entry into prenatal care (i.e., within the first 12 weeks) enables identification of the patient at risk and initiation of measures to promote a healthy outcome. Early and consistent prenatal care improves outcomes for mothers and infants. More extensive discussion of pregnancy is found in Unit 4.

Menstrual Concerns

Irregularities or issues with the menstrual period are among the most common concerns of women and often cause them to seek help from a health care provider. Common menstrual disorders include amenorrhea, dysmenorrhea, premenstrual syndrome, endometriosis, and menorrhagia or metrorrhagia. Simple explanation and counselling may handle the concern; however, history and examination must be completed, as well as laboratory or diagnostic tests, if indicated. Questions should never be considered inconsequential, and age-specific reading materials are recommended, especially for teenagers. See Chapter 7 for an in-depth discussion of menstrual concerns.

Perimenopause and Menopause

Perimenopause is the interval between regular cycles of ovulation occurring and menopause (permanent infertility). The body responds to this natural transition in a number of ways, most of which are caused by the decrease in estrogen. Most patients seeking health care during the perimenopausal period do so because of irregular bleeding. Others are concerned about vasomotor symptoms (hot flashes and flushes). Although fertility is greatly reduced during this period, patients are urged to maintain some method of birth control because pregnancies still can occur. All patients need to receive factual information, have myths dispelled, and undergo a thorough examination. During menopause they should have appropriate periodic health screenings.

BARRIERS TO RECEIVING HEALTH CARE

The health of Canadians cannot be evaluated without consideration of the social determinants of health (see Box 1.1; Social Determinants of Health). These determinants of health include income and social status, social support networks, education and literacy, employment and working conditions, social environments, physical environments, personal health practices and coping skills, and healthy child development (Canadian Nurses Association, 2018; PHAC, 2016). Deficiencies in determinants of health and detrimental contextual factors may pose difficulties in accessing and receiving health care.

PRECONCEPTION HEALTH

The health of parents prior to conception establishes the foundation for their new child's health throughout his or her life. The goals for preconception care are to **improve the health status of women and men before conception** and to **reduce those behaviours and individual and environmental factors** that could contribute to poor maternal and child health outcomes.

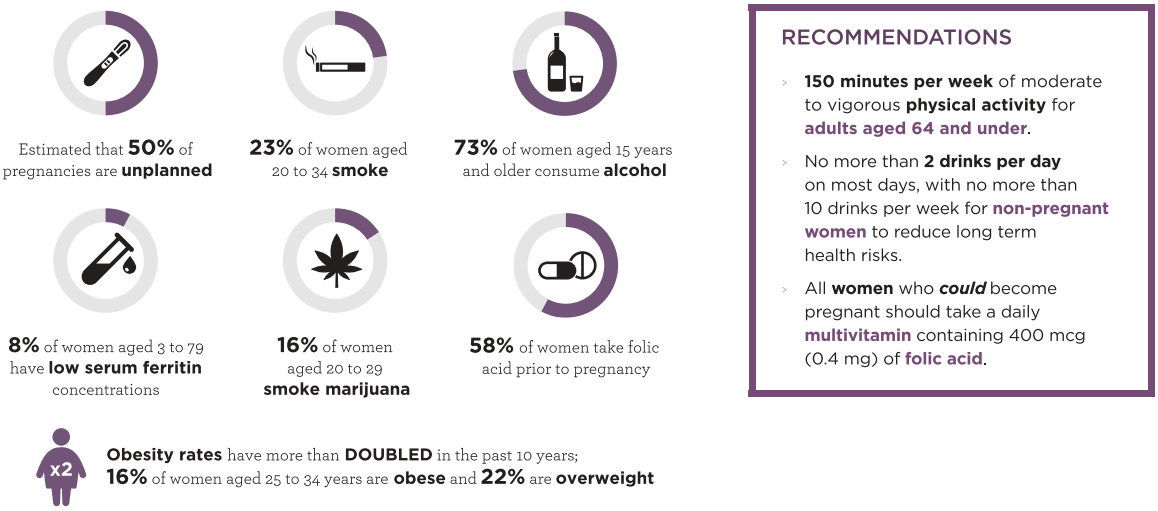

Fig. 5.1 Preconception care topics. From Public Health Agency of Canada. [2017]. *Preconception health*. https://www.canada.ca/content/dam/phac-aspc/documents/services/publications/healthy-living/maternity-newborn-care/preconception-health-infographic-eng.pdf)

BOX 5.2 Components of Preconception Care

Health Promotion: General Teaching

- Nutrition
- Healthy diet, including folic acid
- Optimal weight
- Exercise and rest
- Avoidance of use of substances (tobacco, alcohol, "recreational" drugs)
- Use of risk-reducing sex practices
- Attending to family and social needs

Risk Factor Assessment

- Chronic diseases
- Diabetes, heart disease, hypertension, asthma, thyroid disease, kidney disease, anemia, mental illness
- Infectious diseases
- HIV/AIDS, other sexually transmitted infections, vaccine-preventable diseases (e.g., rubella, hepatitis B, HPV)
- Reproductive history
- Contraception
- Pregnancies—unplanned pregnancy, pregnancy outcomes
- Infertility
- Genetic or inherited conditions (e.g., sickle cell anemia, Down syndrome, cystic fibrosis)
- Medications and medical treatment
- Prescription medications (especially those contraindicated in pregnancy), over-the-counter medication use, radiation exposure
- Personal behaviours and exposures
- Smoking, alcohol consumption, problematic drug use
- Overweight or underweight; eating disorders
- Spouse or partner and family situation, including intimate partner violence
- Availability of family or other support systems
- Readiness for pregnancy (e.g., age, life goals, stress)
- Environmental (home, workplace) conditions
- Safety hazards
- Toxic chemicals
- Radiation

Interventions

- Anticipatory guidance or teaching
- Treatment of medical conditions and results
- Medications
- Cessation or reduction in problematic substance use
- Immunizations (e.g., rubella, hepatitis, influenza)
- Nutrition, diet, weight management
- Exercise
- Referral for genetic counselling
- Referral to and use of:
  - Family planning services
  - Family and social services

AIDS, Acquired immunodeficiency syndrome; *HIV*, human immunodeficiency virus. *HPV*, human papillomavirus.

Financial Issues

Limited finances can be associated with lack of access to care, delay in seeking care, fewer illness prevention activities, and lack of accurate information about health and the health care system. Poverty is a significant health issue for many Canadian people. It is estimated that more than 4.9 million Canadians live in poverty, including 21% of lone mothers; 4.6% of Canadians were living in deep income poverty in 2018 (Canada Without Poverty, 2021; Statistics Canada, 2020a). In Canada, disparity among various ethnic groups and socioeconomic classes affects many facets of life, including health.

Indigenous people in Canada are twice as likely as non-Indigenous people to live in a home in need of major repair, are 90 times more likely to have no piped water, and are 5 times more likely to have no bathroom facilities (Smylie et al., 2010). Waterborne infections are more common in Indigenous communities, and 30% of their water systems are considered high risk for containing microbes that cause infection or toxins that are detrimental to health (Bradford et al., 2016). Infant mortality rates for Indigenous people in Canada have ranged from 1.7 to over 4 times national Canadian rates, and Indigenous children under the age of 6 are less likely to have access to health care than are non-Indigenous Canadian children (Smylie et al., 2010).

Socioeconomic status also affects birth outcomes. The rates of perinatal and maternal deaths, preterm births, and low–birth weight babies are considerably higher in disadvantaged populations (PHAC, 2019a). Lone mothers with little to no employment skills are caught in the bind of insufficient income for child care, restricting their ability to search for and obtain more secure employment, and increasing their risks for health concerns. Social isolation, especially among immigrant people, prevents them from accessing health care (Rezazadeh & Hoover, 2018). Multiple roles for women in general produce overload, conflict, and stress, resulting in higher risks for mental health issues.

Cultural Issues

As our nation becomes more racially, ethnically, and culturally diverse, the compromised health of minority groups has become a concern. A variety of reasons are given to explain some of the differences in accessing care when financial barriers are adjusted. Some patients experience racial discrimination or disrespectful, disillusioning, or discouraging encounters with community service providers such as social services and health care providers and may not access health care services because of lack of trust in the system. A lack of cross-cultural communication also presents challenges. Desired health outcomes are best achieved when the health care provider has knowledge of and understanding about the culture, language, values, priorities, and health beliefs of patients whose background is different from that of the provider. Conversely, patients need to understand the health goals to be achieved and the methods proposed to do so. Language differences can produce profound barriers between patients and providers.

Providers must consider culturally based differences that could affect treatment of diverse groups of patients, and the patients themselves must share practices and beliefs that could influence their responses or willingness to undertake treatment. For example, patients in some cultures value modesty to such an extent that they are reluctant to disrobe and as a result avoid physical examination unless it is absolutely necessary. Other patients rely on their partners to make major decisions, including those affecting their own health. Religious beliefs may dictate a plan of care, as with birth control measures or blood transfusions. Some cultural groups prefer traditional medicine, homeopathy, or prayer to Western medicine; others use a combination of some or all of these practices.

Recognition of factors that may affect Indigenous people's health is essential in the establishment of culturally safe policy and programs for Indigenous people. The Truth and Reconciliation Commission of Canada (2015) called for action by federal, provincial, and territorial governments to acknowledge and reduce disparities in the areas of education, child welfare, language, culture, health, and justice for Indigenous people in Canada (see Chapter 1 for further discussion). Despite some provincial and territorial innovations, the call for Indigenous-focused primary health care in Canada has yet to be fully realized (Henderson et al., 2018).

Community collaboration is needed to ensure that health programs and policies are created in a culturally safe manner and that services will meet the needs of and be used by patients and their families (see Chapter 2). It is not enough for health services to merely exist; they must be familiar and accessible to Canadians. This is especially important in the immigrant population, who may be struggling to navigate the Canadian health care system.

Gender Issues

Gender affects provider–patient communication and may influence access to health care in general. The most obvious gender consideration is that between men and women. Women tend to use primary care services more often than men and, some investigators believe, use them more effectively. The gender of the provider also plays a role. For instance, the concept of "gender concordance," in which the patient's gender matches the health care provider's gender, was found to be important for patients seeking Pap tests (McAlearney et al., 2011).

Sexual orientation may produce another barrier to adequate health care. Nurses need to understand the specific health care needs and issues related to sexual orientation (Brennan et al., 2012). Some LGBTQ2 clients may not disclose their sexual orientation to health care providers because they feel they may be at risk for hostility, inadequate health care, or breach of confidentiality. In many health care settings, heterosexuality is assumed, and the setting may be one in which the patient does not feel welcome (magazines, brochures, and the environment reflect heterosexual couples, or the health care provider shows discomfort interacting with the patient). This can result in lack of medical care, as well as in health care providers giving incorrect advice or not providing appropriate screening for patients. Not all gynecological cancers are related to sexual activity; patients who have never had children may be more at risk for breast, ovarian, and endometrial cancer. At the same time, lesbian and transgender patients' risk for heart disease, cancer of the lung, and colon cancer is not different from that of heterosexual patients. To offset stereotypes, it is necessary for providers to develop an approach that does not assume that all patients are heterosexual. More education and clinical skills in caring for this population are required (Knight et al., 2014).

RISK FACTORS THAT IMPACT HEALTH

In caring for patients at all stages of life, it is important to understand the various and complex risk factors that can affect a patient's health. This section describes these risk factors.

Substance Use

Use of illicit drugs and inappropriate use of prescription medications continue to increase and are found in all age groups, races, and ethnic groups and at all socioeconomic levels. **Addiction** to substances is seen as a biopsychosocial disease, with several factors leading to risk. These include biogenetic predisposition, lack of resilience to stressful life experiences, and poor social support. Although women are less likely than men to misuse drugs, the rate of women who misuse drugs has risen significantly. Pregnant patients who overuse substances have increased risk for development of their own health issues, and their offspring have increased risk for potential health challenges, including interference with optimal growth and development and for physical dependence on the drug. Patients who give birth to infants with neonatal abstinence syndrome (NAS) have a higher mortality rate in the years following birth, largely related to poverty, mental health issues, and addiction (Guttmann et al., 2019). See Chapter 15 for further discussion of substance use during pregnancy and Chapter 29 for care of

the newborn with NAS. Nurses must be aware of the potential impact of **substance use** and how to detect it, as many patients who have addiction issues may not readily access health care or disclose about their addictions.

Cigarette Smoking. Tobacco use is the leading cause of preventable death and illness. Smoking is linked to cardiovascular disease, various types of cancers (especially lung and cervical), chronic lung disease, and negative pregnancy outcomes. Tobacco contains nicotine, which is an addictive substance that creates physical and psychological dependence. Among both sexes, the number of current smokers has declined between 2015 and 2018 (from 20.4 to 18.6% for males and from 15.0 to 13.0% for females [Statistics Canada, 2019b]). A Canadian national youth survey found that approximately 32% of adolescents in grades 7 to 12 had smoked menthol cigarettes, which may be incorrectly perceived as less harmful, thus encouraging nicotine dependence and a possible predictor of marijuana use and binge drinking (Azagba & Sharaf, 2014; Manske et al., 2014).

Recently, alternatives to cigarettes have been used, including electronic cigarettes (e-cigarettes), smokeless tobacco, and water pipes. These alternative methods, however, may cause serious adverse effects due to the chemicals used in them and may have deleterious effects on health (Glauser, 2019). The full impact on health is not yet known, with more monitoring and research required.

Cigarette smoking impairs fertility in both women and men, may reduce the age for menopause, and increases the risk for osteoporosis after menopause. Passive, or secondhand, smoke (environmental tobacco smoke) contains similar hazards and presents additional health issues for the smoker and harm for the nonsmoker. Smoking during pregnancy may have adverse consequences for the infant, such as low birth weight. See the Family-Centred Care box, Smoking Cessation.

FAMILY-CENTRED CARE

Smoking Cessation

You are the nurse working in a family health team clinic; you observe that many of the young parents with newborns seen in the clinic smoke cigarettes. One new parent said, "I know it's bad for me but I can't quit. At least I don't smoke around the baby." What advice could you provide for the young parents about the effect of tobacco smoke on young infants, especially those under 6 months of age? Prepare a short presentation that can be shared with the young parents about the effects of tobacco on an infant's long-term health. Discuss options and resources for smoking cessation that are available from local community agencies.

Caffeine. Caffeine is found in society's most popular drinks: coffee, tea, soft drinks, and energy drinks. It is a stimulant that can affect mood and interrupt body functions by producing anxiety and sleep interruptions. Heart arrhythmias may be made worse by caffeine, and there can be interactions with certain medications, such as lithium. Birth defects have not been related to caffeine consumption; however, high intake has been potentially related to a slight decrease in birth weight and may also increase risk of miscarriage. Pregnant patients should limit their consumption of caffeine to less than 300 mg/day, or a little more than two cups (240 mL) per day (PHAC, 2020). It is important for the nurse to educate the patient on the various sources of caffeine, as it is found in a variety of food and drink products, such as tea, chocolate, and energy drinks.

Alcohol Consumption. The amount and frequency of alcohol consumption among young Canadian women is alarming: in 2012, 74% of Canadian women age 15 and older reported drinking alcohol; based on the amount of alcohol abused, 16% of those women are at risk for long-term complications and 10% at risk for acute illness (Canadian Centre on Substance Abuse, 2014). People who are problem drinkers are often depressed, have more motor vehicle injuries, and have a higher incidence of attempted suicide than do people in the general population. They are also at risk for alcohol-related liver damage. Early case finding and treatment are important for addressing **alcoholism**, for both the ill individual and family members.

Prenatal exposure to alcohol can have multiple, permanent cognitive and physical effects on the fetus (Jarmasz et al., 2017). Prenatal alcohol exposure has been found to increase the chance of birth defects significantly and poses a considerable personal, societal, and economic cost due to premature morbidity and mortality rates (Popova et al., 2016). Although fetal alcohol spectrum disorder (FASD) is a known consequence of prenatal alcohol intake, studies also indicate that other consequences include increased risk for miscarriage, stillbirth, preterm birth, and sudden infant death syndrome (SIDS). Clearly, alcohol consumption during pregnancy has wide-reaching effects.

Cannabis. Cannabis, or marijuana, is a substance derived from the cannabis plant. It is usually rolled into a cigarette and smoked, but it also may be mixed into food and eaten. Cannabis is considered more harmful if smoked because of the impact on the lungs (Centre for Addiction and Mental Health, 2018). Cannabis produces distorted perceptions, difficulty with problem solving and with thinking and memory, altered state of awareness, relaxation, mild euphoria, and reduced inhibition (National Institute on Drug Abuse, 2019).

In the pregnant patient, cannabis readily crosses the placenta and causes increased carbon monoxide levels in the mother's blood, which reduces the oxygen supply to the fetus. Cannabis use is higher among patients who also use alcohol and tobacco during pregnancy and is highest among patients aged 15–24 and persons of lower socioeconomic status (Corsi et al., 2019). Use of cannabis during pregnancy is associated with preterm birth and smaller-for-gestational-age babies (Leemaqz et al., 2016). The legalization of cannabis in 2018 in Canada calls for further research into rates of use among pregnant patients, as well as regarding newborn and long-term child development outcomes.

Prescription Medication Use. Women are more likely than men to report taking prescription medications (Rotermann et al., 2014). Such medications can bring relief from undesirable conditions such as insomnia, anxiety, depression, and pain. Because the medications have a mind-altering capacity, misuse can produce psychological and physical dependency in the same manner as illicit drugs. Risk-to-benefit ratios should be considered when such medications are used for more than a very short period of time.

Depression and anxiety are the most common mental health challenges in women (depression used to be considered the most common, but recently it has been noted that depression occurs comorbidly with anxiety). Many kinds of medications are used to treat depression and anxiety. All of these psychotherapeutic drugs can have some effect on the fetus and must be monitored very carefully in pregnant patients.

Illicit Drug Use

Cocaine. Cocaine is a powerful central nervous system stimulant that is addictive because of the tremendous sense of euphoria it creates. It can be snorted, smoked, or injected. Crack, or rock cocaine, is a form of the drug that is exceedingly potent and even more highly addictive. (Some say that an individual is "hooked" after the first use or at least after two or three "hits.") After ingestion of cocaine, an intensely

pleasurable high results that is followed by an uncomfortable low; this increases the urge to repeat using the drug.

Predisposing factors and problems associated with cocaine use are polydrug use; poor nutrition; poverty; STIs; hepatitis B infection; dysfunctional family systems; employment difficulties; stress; anger; poor self-esteem; and previous or present physical, emotional, and sexual abuse. The clinical manifestations of cocaine use include tachycardia, pupillary dilation, and hypertension.

Cocaine affects all of the major body systems. Among other complications, it produces cardiovascular stress (including tachycardia and hypertension) that can lead to heart attack or stroke, liver disease, central nervous system stimulation that can cause seizures, and even perforation of the nasal septum. Needle-borne diseases such as hepatitis B and acquired immunodeficiency syndrome (AIDS) are common among cocaine users.

Opioids. The opiates include opium, heroin, meperidine, morphine, codeine, and **methadone**. Heroin is one of the most commonly used drugs of this class. It is usually taken by intravenous injection but can be smoked or "snorted." The signs and symptoms of heroin use are euphoria, relaxation, relief from pain, "nodding out" (apathy, detachment from reality, impaired judgement, and drowsiness), constricted pupils, nausea, constipation, slurred speech, and respiratory depression.

The incidence of heroin use among pregnant patients is unknown because patients with a dependency on heroin often use multiple drugs. Patients who use opiates during pregnancy are at risk for many obstetrical complications (Stover & Davis, 2015). The recommended treatment is opioid agonist therapy with methadone or buprenorphine, ideally done by stabilizing the treatment before as well as during pregnancy. This treatment must be closely monitored because, methadone is metabolized more rapidly, leading to withdrawal symptoms in less than 24 hours in many patients. NAS is a serious concern for infants born to a parent who chronically uses opioids (see Chapter 29).

Methamphetamine. Methamphetamine is a relatively cheap and highly addictive stimulant. Methamphetamine makes many users feel hypersexual and uninhibited, and this may lead to more sex and less protection from pregnancy.

The active metabolite of methamphetamine is amphetamine, a central nervous system stimulant known as both "speed" and "meth." The crystalline form, which is smoked, is known as "ice." Methamphetamine causes a person to experience an elevated mood state and pleasure as well as increased energy and creates addiction within a short period. It can lead to cardiac concerns, including irregular heartbeat and hypertension and, over time, can create cognitive and mental as well as dental issues (Medline Plus, 2021). Most of the effects of amphetamines are similar to those of cocaine.

Other illicit drugs. A number of other street drugs pose risks to users. A few are derived from organic materials, but more and more are produced synthetically in laboratories. Sedatives such as "downers," "yellow jackets," or "red devils" are used to come off "highs." Hallucinogens alter perception and body function. PCP ("angel dust") and LSD produce vivid changes in sensation, often with agitation, euphoria, paranoia, and a tendency toward antisocial behaviour. Their use may lead to flashbacks, chronic psychosis, and violent behaviour.

Substance Use Cessation. Patients at all ages will receive substantial and immediate benefits from stopping or decreasing their use of substances. However, this is not easy, and most people will attempt to stop several times before they accomplish their goal. Many are never able to do so.

New approaches are needed to increase cessation among smokers and to discourage smoking among young patients, especially in adolescence and during pregnancy. Health care providers can have an impact on smoking behaviour and should attempt to motivate smokers to stop smoking. Raising questions about social consequences (e.g., stained teeth and foul-smelling breath and clothes) is sometimes effective with young people.

Those who wish to stop smoking can be referred to a smoking cessation program in which individualized methods can be implemented. Best practice guidelines regarding smoking cessation are also available from the Registered Nurses' Association of Ontario (RNAO) and the Canadian Smoking Cessation Clinical Practice Guideline, which offer recommendations and strategies for patients who would like to quit smoking (see Additional Resources at the end of this chapter). Box 5.3 includes guidelines for smoking cessation for the pregnant patient. There is good evidence that even brief advice from health providers has a significant effect on smoking cessation rates; advice from a health care provider has been shown to decrease the proportion of people smoking by about 2% per year (RNAO, 2015).

While the legal age for drinking alcohol and cannabis use varies among the provinces and territories (age 18 or 19), stronger regulation of advertising as well as health promotion and youth-designed programming, such as Students Against Drunk Driving (SADD), is having

BOX 5.3 Interventions for Smoking Cessation: The Five *A's*

Ask
- What was the person's age when they started smoking?
- How many cigarettes do they smoke a day? When was their last cigarette?
- Have they tried to quit?
- Do they want to quit?

Advise
- Give the patient information about the effects of smoking on pregnancy and the fetus, on their own future health, and on the members of their household.

Assess
- What were their reasons for not being able to quit before, or what made them start again?
- Does the patient have anyone who can help them?
- Does anyone else smoke at home?
- Does the patient have friends or family who have quit successfully?

Assist
- Provide support; give self-help materials.
- Encourage patient to set a quit date.
- Refer to a smoking-cessation program, or provide information about nicotine replacement products if they are interested.
- Teach and encourage the use of stress-reduction activities.
- Provide for follow-up with a phone call, letter, or clinic visit.

Arrange Follow-up
- Arrange to follow up with the patient to find out about smoking-cessation status.
- Make a phone call around the time of their quit date. Assess their status at every prenatal visit.
- Congratulate the patient on their success, or provide support for them if they relapse.
- Referral to intensive treatment may be necessary.

Adapted from Fiore, C. (2012). *Tobacco use and dependence: A 2011 update of treatments*. http://www.medscape.org/viewarticle/757167.

a positive impact. All primary care providers should screen for alcohol and other drug use, with an understanding of the obvious problem with relying on self-reporting of these behaviours. The use of over-the-counter medications by patients should also be explored.

Counselling for patients who appear to be drinking excessively or using drugs may include strategies to increase self-esteem and teaching of new coping skills to resist and maintain resistance to alcohol and substance use. Appropriate referrals should be made, with the health care provider arranging the contact and then following up to ensure that appointments are kept. General referral to sources of support should also be provided. Knowledge of harm reduction is important for the health care provider, to ensure that policies and programs exist that support reducing drug-related harm in the absence of abstention and are the first step in potential cessation of drug use.

Anticipatory guidance includes teaching about the health and safety risks of alcohol and mind-altering substances and discouraging drug experimentation among preteen and high school students. The use of drugs at an early age tends to predict greater involvement later.

Nutrition

Good nutrition is essential for optimal health. A well-balanced diet helps prevent illness and also is used to treat certain health conditions. Conversely, poor eating habits, eating disorders, and obesity are linked to disease and debility. *Canada's Food Guide* (see Appendix A) provides a variety of educational tools for patients and health care providers to promote health and reduce risks for chronic diseases through diet and physical activity. The Dietitians of Canada have a number of nutrition resources (see Additional Resources at the end of this chapter).

In addition to specific guidelines for healthy eating, environmental factors play an important role in nutrition. It is well known that social conditions and access to nutritious food are important contributors to patients' health. The availability of resources is a critical factor in nutrition and health. For example, patients who have access to healthy food have decreased levels of obesity (Dubowitz et al., 2012). *Food insecurity* is the inability to acquire or consume an adequate diet or the uncertainty that one will be able to do so. Household food insecurity is often linked with the household's limited financial ability to access adequate food (Health Canada, 2020). Early breastfeeding cessation is also a common factor among families struggling with food insecurity (Orr et al., 2018).

Nutritional Deficiencies. Overt disease caused by a lack of certain nutrients is rarely seen in Canada. However, insufficient amounts or imbalances of nutrients do pose health challenges for individuals and families. Overweight or underweight status, malabsorption, listlessness, fatigue, frequent colds and other minor infections, constipation, dull hair and nails, and dental caries are examples of conditions that could be related to poor nutrition and indicate the need for further nutritional assessment. Poor nutrition, especially that related to obesity and high fat and cholesterol intake, may lead to more serious conditions and contribute to heart disease, **malignant** neoplasms, cerebrovascular diseases, and diabetes—many of the leading causes of morbidity and mortality in Canada.

Other dietary extremes also produce risk. For example, insufficient amounts of calcium can lead to osteoporosis, too much sodium can aggravate hypertension, and megadoses of vitamins can cause adverse effects in several body systems. Fad weight-loss programs and yo-yo dieting (repeated and cyclical weight gain and weight loss) result in nutritional imbalances and, in some instances, medical concerns. Such diets and programs are not appropriate for weight maintenance. Adolescent pregnancy produces special nutritional requirements, because the metabolic needs of pregnancy are superimposed on the teen's own needs for growth and maturation at a time when eating habits are not ideal.

Obesity. The overall percentage of women in Canada who were overweight or obese in 2018 was 56.7% (Statistics Canada, 2019a). The likelihood of being overweight is greater among families living in low socioeconomic neighbourhoods, where the social environment is often less conducive to physical activity because of lack of safety and lack of available resources and opportunities.

There has been some debate over whether the body mass index (BMI) remains an effective diagnostic tool of assessing for obesity, or if waist circumference offers more clinically relevant information. Both BMI and waist circumference (Box 5.4) appear to have their value in assessing the patient for risk of obesity, central obesity, and cardiovascular disease. Waist circumference provides an indicator of abdominal fat. Excess fat around the waist and upper body (also described as an "apple" body shape) is associated with greater health risk than fat located more in the hip and thigh area (described as a "pear" body shape) (Health Canada, 2019). *BMI* is defined as a measure of an adult's weight in relation to their height, specifically the adult's weight in kilograms divided by the square of their height in metres (Table 5.1). Both BMI and waist circumference should be considered because even if BMI is "normal," a higher waist circumference poses some risks to health (Health Canada, 2019).

Overweight and obesity are known risk factors for premature death, diabetes, heart disease, stroke, hypertension, dyslipidemia, gallbladder disease, diverticular disease, constipation, osteoarthritis, gout, osteoporosis, respiratory dysfunction, sleep apnea, and some cancers (esophagus, uterine breast, colorectal, kidney, and endometrial) (Canadian Cancer Society, 2021). In addition, obesity is associated with high

BOX 5.4 Waist Circumference

Measure waist with clothing removed from abdomen. Place a measuring tape around waist, just above the hip bones.

Waist circumference (WC) = _____ centimetres.

Assess health risk.

High Risk

A WC measurement of 88 cm or more for women is associated with an increased risk of developing health issues such as type 2 diabetes, coronary heart disease, and high blood pressure. As the cut-off points are approximate, a WC just below this measurement should also be taken seriously. The risk of developing health issues increases as WC measurement increases above the cut-off points.

cholesterol, menstrual irregularities, hirsutism (excess body and facial hair), stress incontinence, depression, complications of pregnancy, increased surgical risk, and shortened lifespan. Pregnant women who are morbidly obese are at increased risk for hypertension, diabetes, gallbladder disease, post-term pregnancy, and musculoskeletal issues.

Eating Disorders. Anorexia nervosa and bulimia are two forms of eating disorders, although there are additional forms, such as binge eating disorders or other specified feeding or eating disorders. Some individuals, especially adolescents, do not have symptoms that lend themselves to a diagnosis of anorexia nervosa or bulimia, but they do fall under an unspecified category and require accurate diagnosis and prompt treatment (Sammarco, 2016). Eating disorders can affect not only the individual but also their family. Treatment must be personalized, including nutritional and behavioural/psychotherapeutic approaches.

It is important to assess for and treat people with eating disorders early because they are at increased risk for serious physical conditions as well as diminished quality of life (Sammarco, 2016). Eating disorders during pregnancy are also associated with increased risk to the pregnant woman and her fetus.

Anorexia nervosa. Some people have a distorted view of their bodies and, no matter what their weight, perceive themselves to be much too heavy. As a result, they undertake strict and severe diets and rigorous extreme exercise. This chronic eating disorder is known as **anorexia nervosa**. Patients can carry this condition to the point of starvation, with resulting endocrine and metabolic abnormalities. If it is not corrected, significant complications of arrhythmias, amenorrhea, cardiomyopathy, and heart failure occur and, in the extreme, can lead to death. The condition commonly begins during adolescence in young patients who have some degree of personality disorder. They gradually lose weight over several months, have amenorrhea (see Chapter 7), and are abnormally concerned with body image. A coexisting depression usually accompanies anorexia.

There are no specific tests to diagnose anorexia nervosa. A medical history, physical examination, and screening tests help identify patients at risk for eating disorders. Several tools are available to use in primary care settings. The SCOFF questionnaire, developed by Morgan, et al., (1999), is easy to administer and can help the nurse decide whether an eating disorder is likely and whether the patient needs further assessment and possibly psychiatric and medical intervention. See Box 5.5 for a description of the SCOFF assessment tool.

Bulimia nervosa. **Bulimia** refers to secret, uncontrolled binge eating alternating with methods to prevent weight gain: self-induced vomiting, laxatives or diuretics, strict diets, fasting, and rigorous exercise. During a binge episode, large numbers of calories are consumed, usually consisting of sweets and "junk foods." Binges occur at least twice per week. Bulimia usually begins in early adulthood (ages 18 to 25) and is found primarily in females. Complications can include dehydration and electrolyte imbalance, gastrointestinal abnormalities, and cardiac arrhythmias. Bulimia is somewhat similar to anorexia in that it is an eating disorder and usually involves some degree of depression. Unlike persons with anorexia, individuals with bulimia may feel shame or disgust about their disorder and tend to seek help earlier. The SCOFF screening assessment also can be used to assess patients with bulimia (see Box 5.5).

Lack of Exercise

Exercise contributes to good health by lowering risks for a variety of conditions that are influenced by obesity and a sedentary lifestyle. It is effective in the prevention of cardiovascular disease and in management of chronic conditions such as hypertension, arthritis, diabetes, respiratory disorders, and osteoporosis (Figure 5.2). Exercise also contributes to stress reduction and weight maintenance. Patients report that engaging in regular exercise improves their body image and self-esteem and acts as a mood enhancer. Aerobic exercise produces cardiovascular involvement because increasing amounts of oxygen are delivered to working muscles. Anaerobic exercise such as weight training improves individual muscle mass without stress on the cardiovascular system. Because patients are often concerned about both cardiovascular and bone health, weight-bearing aerobic exercises such as walking, running, racket sports, and dancing are preferred. However, excessive or strenuous exercise can lead to **hormone** imbalances, resulting in amenorrhea and its consequences. Physical injury is also a potential risk.

One particular exercise that is important for women is *Kegel exercise*, or pelvic muscle exercise. These exercises help patients prevent urinary incontinence that can occur after childbirth and a variety of other

BOX 5.5 Screening for Eating Disorders: SCOFF Questions

Each question scores 1 point. A score of 2 or more indicates that the person may have anorexia nervosa or bulimia.

1. Do you make yourself **S**ick (i.e., induce vomiting) because you feel too full?
2. Do you worry about loss of **C**ontrol over the amount you eat?
3. Have you recently lost more than 6 kg in a 3-month period?
4. Do you think you are too **F**at even if others think you are too thin?
5. Does **F**ood dominate your life?

Source: Morgan, J., Reid, F., & Lacey, J. (1999). The SCOFF questionnaire: Assessment of a new screening tool for eating disorders. *British Medical Journal, 319*(7223), 1467–1468.

Fig. 5.2 Exercise should be part of one's regular health routine. A cycle class is fun and provides moderate to vigorous exercise. (From wavebreakmedia/Shutterstock.com.)

conditions that may occur with age (Woodley, et al., 2017). This exercise is used to strengthen the muscles that support the pelvic floor and should be practised regularly. Instructions for this exercise are presented in the Family-Centred Care box: Kegel Exercise.

FAMILY-CENTRED CARE

Kegel Exercise

Description and Rationale

Kegel exercise, or pelvic muscle exercise, is a technique used to strengthen the muscles that support the pelvic floor. This exercise involves regularly tightening (contracting) and relaxing the muscles that support the bladder and urethra. By strengthening these pelvic muscles, a person can prevent or reduce accidental urine loss.

Technique

The person needs to learn how to target the muscles for training and how to contract them correctly. One suggestion for teaching is to have the patient pretend they are trying to stop the flow of urine in midstream or to have them think about how their vagina is able to contract around and move up the length of the penis during intercourse.

The patient should avoid straining or bearing-down motions while performing the exercise. They should be taught to avoid straining down by exhaling gently and keeping their mouth open each time they contract the pelvic muscles.

Specific Instructions

- Each contraction should be as intense as possible without contracting the abdomen, thighs, or buttocks.
- Contractions should be held for at least 10 seconds. The person may have to start with as little as 2 seconds per contraction until the muscles get stronger.
- They should rest for 10 seconds or more between contractions so that the muscles have time to recover and each contraction can be as strong as they can make it.
- They should feel the pulling up and over the three muscle layers so that the contraction reaches the highest level of the pelvis.
- Positive results can be achieved by performing the exercise for 15 minutes twice a day.

A qualitative study. *Physiotherapy Practice and Research, 40*, 135–143.

Physical activity and exercise counselling for persons of all ages should be available at schools, work sites, and primary care settings. Specific recommendations include at least 30 minutes of moderate activity at least 5 days of the week for adults, in intervals of 10 minutes or more (Heart and Stroke Foundation, 2020). Few Canadians exercise this often, and physical inactivity increases with age, especially during adolescence and early adulthood. Yet even small increases in activity can be beneficial.

Stress

Individuals are facing increasing levels of stress and, as a result, are prone to a variety of stress-induced illnesses. Stress often occurs because of conflict among multiple roles—for example, job and financial responsibilities can conflict with parenting and duties at home. To add to this burden, some people are socialized to be caregivers, which is emotionally draining, creating additional stress. They also may find themselves in positions of minimal power that do not allow them to have control over their everyday environments. Some stress is normal and contributes to positive outcomes. Many people thrive in busy surroundings. However, excessive or high levels of ongoing stress trigger physical reactions such as rapid heart rate, elevated blood pressure, slowed digestion, release of additional neurotransmitters and hormones, muscle tenseness, and a weakened immune system. Consequently, constant stress can contribute to clinical illnesses such as exacerbations of arthritis or asthma, frequent colds or infections, gastrointestinal upset, cardiovascular conditions, and infertility. Box 5.6 lists symptoms that may be related to chronic or extreme stress. Psychological symptoms such as anxiety, irritability, eating disorders, depression, insomnia, and substance use have also been associated with stress.

Because it is neither possible nor desirable to avoid all stress, people must learn how to manage it. The nurse should assess each patient for signs of stress, using therapeutic communication skills to determine risk factors and the patient's ability to function. Women are twice as likely as men to suffer from depression, anxiety, or panic attacks. Nurses must be alert to the symptoms of serious mental disorders such as depression and anxiety and make referrals to counselling or other mental health practitioners when necessary. People experiencing major life changes such as separation and divorce, bereavement, serious illness, and unemployment need special attention. A psychosocial assessment for stress and depression is recommended for pregnant patients in each trimester (Kingston et al., 2015). Thorough assessment allows for appropriate referrals and care planning.

Social support and good coping skills can improve a patient's self-esteem and give them a sense of mastery. Anticipatory guidance for developmental or expected situational crises can help people plan strategies for dealing with potentially stressful events. Role-playing, relaxation techniques, biofeedback, meditation, desensitization, healing touch, imagery, assertiveness training, yoga, diet, exercise, and weight control are all techniques that nurses can include in their repertoire of helping skills.

Depression, Anxiety, and Other Mental Health Conditions

Many patients experience depression or anxiety frequently. In addition, depression is sometimes described as a co-traveller because it exists comorbidly with other physical conditions. Depression or anxiety creates difficulties for quality of life and, at the extreme, create a risk for suicide. Recent research suggests that patients with comorbid anxiety and depression are at greater risk for developing cardiac disease (Cohen et al., 2014). In addition to depression and anxiety, patients may experience other mental health disorders, such as bipolar disease.

Sleep Disorders

Many people are at risk for sleep challenges, including poor sleep quality (Nugent & Black, 2016). During pregnancy and postpartum, many factors can negatively affect sleep, and Willis-Ekbom disease (restless legs syndrome) may result. Sleep disorders are correlated with physical and mental health challenges, including depression, pain, and fibromyalgia. Women tend to experience sleep and sleep issues at various stages across the lifespan (Shaver, 2015). It is important that the nurse talk with the patient about their sleep patterns and discuss ways to improve sleep, such as avoiding alcohol use before going to sleep and sleeping in a regular pattern.

BOX 5.6 Stress Symptoms

Physical
- Perspiration/sweaty hands
- Increased heart rate
- Trembling
- Nervous tics
- Dryness of throat and mouth
- Tiring easily
- Urinating frequently
- Sleeping problems
- Diarrhea, indigestion, vomiting
- Butterflies in stomach
- Headaches
- Premenstrual tension
- Pain in neck and lower back
- Loss of appetite or overeating
- Susceptibility to illness

Behavioural
- Stuttering and other speech difficulties
- Crying for no apparent reason
- Acting impulsively
- Startling easily
- Laughing in a high-pitched and nervous tone of voice
- Grinding teeth
- Increasing smoking
- Increasing use of drugs and alcohol
- Being accident prone

Psychological
- Feeling anxious
- Feeling scared
- Feeling irritable
- Feeling moody
- Having low self-esteem
- Being afraid of failure
- Being unable to concentrate
- Embarrassed easily
- Worrying about the future
- Being preoccupied with thoughts or tasks
- Forgetful

Adapted from State University of New York Counseling Center (2002). *Stress management*. University of Buffalo, State University of New York.

Environmental and Workplace Hazards

A safe environment is a key determinant of health. Environmental hazards in the home, the workplace, and the community can contribute to poor health at all ages. Categories and examples of health-damaging hazards include the following:

- Pathogenic agents (viruses, bacteria, fungi, parasites)
- Natural and synthetic chemicals (natural toxins from animals, insects, and plants; consumer and industrial products such as pesticides and hydrocarbon gases; medical and diagnostic devices; tobacco; fuels; and drug and alcohol use)
- Radiation (radon, heat waves, sound waves)
- Food substances (added ingredients that are not necessary for nutrition)
- Physical objects (moving vehicles, machinery, weapons, water, and building materials).

Environmental hazards can affect fertility, fetal development, live birth, and the child's future mental and physical development. Children are at special risk for poisoning from lead found in paint and soil. The Canadian government has called for strict guidelines regarding the amount of lead in children's toys, a regulation that is nonexistent in the rest of the world. Everyone is at risk from air pollutants such as tobacco smoke, carbon monoxide, smog, suspended particles (dust, ash, and asbestos), and cleaning solvents; noise pollution; pesticides; chemical additives; and poor preparation of food. Workers also face safety and health risks caused by ergonomically poor work stations and stress. It is important that risk assessments continue to be carried out to identify and understand environmental problems in public health.

Safe drinking water is a basic determinant of health. A significant number of communities are placed under a boil water advisory each year in Canada. While some advisories are preventative of a possible risk, others are based on actual risk. Working with communities to advocate for safe drinking water, lobby for proper sanitation and consistently high quality controls, and educate the public about how to maintain health in the face of a boil water advisory is a key role of the community nurse.

Sexual Practices

Potential risks related to sexual activity include undesired pregnancy and STIs. The risks are particularly high for adolescents and young adults. Adolescents report many reasons for wanting to be sexually active: peer pressure, desire to love and be loved, experimentation, to enhance self-esteem, and to have fun. However, many teens do not have the decision-making or values clarification skills needed to take this important step. They may also lack knowledge about contraception and STIs. Many do not believe that becoming pregnant or getting an STI will happen to them. An important role for the nurse is to ensure that youth have the correct information. Sex & U is an excellent resource for more information for youth and is listed in the Additional Resources.

Although some STIs can be cured with antibiotics, many cause significant health concerns. Possible sequelae include **infertility**, ectopic pregnancy, neonatal morbidity and mortality, genital cancers, AIDS, and even death. The incidence of some STIs is increasing rapidly and reaching epidemic proportions. Choice of contraception has an impact on the risk of contracting an STI; no method of contraception offers complete protection. (See Chapter 7 for a detailed discussion of STIs, and see Chapter 8 for a discussion of contraception.)

Prevention of STIs is predicated on the reduction of high-risk behaviours, through educating toward behavioural change. Behaviours that predispose to contracting an STI include having multiple sexual partners and carrying out unsafe sexual practices. Specific self-management measures to prevent STIs are listed in Box 5.7.

The overuse of alcohol and drugs is also a high-risk behaviour, as it results in impaired judgement and often thoughtless acts. Behavioural changes must come from within; therefore, the nurse must provide sufficient information for the individual or group to "buy into" the need for change. Education is a powerful tool in health promotion and prevention of STIs and pregnancy. However, it works best when delivered in a way that takes into account the language, culture, and lifestyle of the intended listener.

Medical Conditions

Most patients of reproductive age are relatively healthy. Heart disease; lung, breast, colon, and other nongynecological cancers; chronic lung disease; and diabetes are all concerns for patients because they are among the leading causes of death. Certain medical conditions present during pregnancy can have deleterious effects on both the patient and the fetus. Of particular concern are risks from all forms of diabetes,

BOX 5.7 STI and HIV Prevention

- Prevention of STIs and HIV is possible only if there is no oral, genital, or rectal exchange of body fluids or if a person is in a long-term, mutually monogamous relationship with an uninfected partner.
- Correct use of latex condoms, although greatly reducing risk, is not exclusively protective.
- Sexual partners should be selected with great care.
- Partners should be asked about history of STIs.
- Pre-exposure vaccination is one of the most effective methods for preventing transmission of some STIs (hepatitis A and hepatitis B, human papillomavirus).
- A new condom should be used for each act of sexual intercourse.
- Abstinence from sexual intercourse is encouraged for persons who are being treated for an STI or whose partners are being treated.
- Abstinence is also recommended if under the influence of drugs or alcohol.

Adapted from Sex & U: https://www.sexandu.ca/
HIV, Human immunodeficiency virus; *STI*, sexually transmitted infection.

urinary tract disorders, thyroid disease, hypertensive disorders of pregnancy, cardiac disease, and seizure disorders. Effects on the fetus vary and include intrauterine growth restriction, macrosomia, anemia, prematurity, immaturity, and stillbirth. Effects on the patient also can be severe. These conditions are discussed in Chapter 15.

Gynecological Conditions

Patients are at risk throughout their reproductive years for pelvic inflammatory disease, endometriosis, STIs and other vaginal infections, uterine fibroids, uterine deformities such as bicornuate uterus, ovarian cysts, interstitial cystitis, and urinary incontinence related to pelvic relaxation. These gynecological conditions may contribute negatively to pregnancy by causing infertility, miscarriage, preterm labour (see Chapter 7), and fetal and newborn health challenges. Gynecological cancers also affect patients' health, although risk factors depend on the type of cancer. The impact of developing a gynecological condition or cancer on patients and their families is shaped by a number of factors, including the specific type of condition or cancer, the implications of the diagnosis for the patient and their family, and the timing of the occurrence in the patient's and family's lives.

Female Genital Cutting

Female genital mutilation, infibulation (surgical closure of the labia majora), and *circumcision* are terms used to describe procedures in which part or all of the female external genitalia is removed for cultural or nontherapeutic reasons (WHO, 2020). The SOGC recommends using the term *female genital cutting* (FGC) for this procedure as it is less judgmental and stigmatizing and more culturally sensitive (Perron et al., 2020). These procedures are attempts to control women through controlling their sexuality. FGC is supposed to remove sexual desire so that the girl will not become sexually active until married.

FGC is practised in more than 45 countries, with most of these countries being in Africa. The increasing multicultural mosaic of Canada means that more practitioners are working with clients who have experienced FGC.

FGC occurs in women of many different ethnic, cultural, and religious backgrounds. Although FGC is usually performed on girls between the ages of 5 and 12 years, infants and adult women are sometimes subjected to the procedure. The procedure involves the removal of a portion of the clitoris but may extend to the removal of the entire clitoris and labia minora. In addition, the labia majora, which are often stitched together over the urethral and vaginal openings, may be affected.

The extent of the FGC site affects the seriousness of complications. Common complications include bleeding, pain, local scarring, keloid or cyst formation, and infection. Impaired drainage of urine and menstrual blood may lead to chronic pelvic infections, pelvic and back pain, and chronic urinary tract infections. Some women may require surgery before vaginal examination, intercourse, or childbirth if the vaginal opening is obstructed.

It is illegal in Canada to perform or assist with FGC. An obstetrical care provider may incise the closed labia to assist in the birth of a baby or remove cysts but may not sew the labia back to its previous state, reinfibulation. FGC is internationally recognized as a harmful practice and a violation of girls' and women's rights to life, physical integrity, and health (Perron et al., 2020). It reflects deep-rooted inequality between the sexes, and constitutes an extreme form of discrimination against women. FGC is nearly always carried out on minors and it is a violation of the rights of children.

Nurses in Canada are providing care to a growing number of women who have emigrated from the Middle East, Asia, and Africa, where FGC is more common, thus nurses need to increase their knowledge about FGC. Nurses must be sensitive to the unique needs of these patients, especially if these women have concerns about maintaining or restoring the intactness of the circumcision after childbirth. Health care providers must also be careful not to stigmatize women who have undergone FGC (Perron et al., 2020). As advocates for women's health, nurses are in a position to promote initiatives that promote the elimination of FGC and should use interactions with patients as opportunities to educate women and their families about FGC and other aspects of women's health and reproductive rights (Perron et al., 2020).

Human Trafficking

Human trafficking is actually a form of slavery in which people are forced into becoming part of the unpaid labour force, usually in sweatshops or in domestic work, or to serve as sex slaves (Green, 2016). The majority of these trafficking slaves are women and children, and many of these women have some interaction with health care providers. Thus, the implications for nursing are that it is imperative that signs of trafficking be recognized so that appropriate care can be delivered.

Similar to victims of IPV, these patients often have signs of physical abuse or neglect, such as scars, bruises, burns, unusual bald patches, or tattoos that may be a sign of branding. They may also demonstrate signs and symptoms of emotional distress and mental health issues. They are likely to be accompanied by someone who never leaves them alone and who speaks for them. They may not speak English and may lack identification documents or health care information. If the person is alone, they may have their cell phone on and in speaker mode so that the person on the other end can hear everything that is being said during the health care visit (Collins & Skarparis, 2020). The nurse needs to be creative in getting the patient alone for questioning. Strategies might include sending the accompanying person to the front desk to fill out paperwork, interviewing the patient in the restroom, or telling them they need to go for testing and cannot take their cell phone. With the consent of suspected or confirmed victims of human trafficking, intervention plans can be developed (Collins & Skarparis, 2020). Green (2016) recommended asking simple "yes" or "no" questions in order to screen for suspected trafficking (Box 5.8). Certain findings on history are also indicative of possible trafficking.

Intimate Partner Violence

Intimate partner violence (IPV), also called *gender-based violence*, is violence perpetrated by a spouse, partner, or someone with whom the person has had an ongoing intimate relationship, and is the most common form of violence experienced by women worldwide, with a

BOX 5.8 Screening for Victims of Human Trafficking

If human trafficking is suspected, the nurse should ask simple questions that are not threatening and that mostly require a "yes" or "no" response, as follows:

- Is the place where you sleep clean?
- Do you have enough food?
- Have you been threatened or harmed physically? Has your family been threatened?
- Are you free to talk to people outside of your home or job?
- Are you free to come and go as you please?
- Are you ever forced to have sex?
- Are you ever forced to work?
- Where are you from?
- How did you get here?
- Do you know where you are now?
- Do you have money? If you earn money, do you keep it? Or are you forced to give it to someone?
- Do you have identification papers?

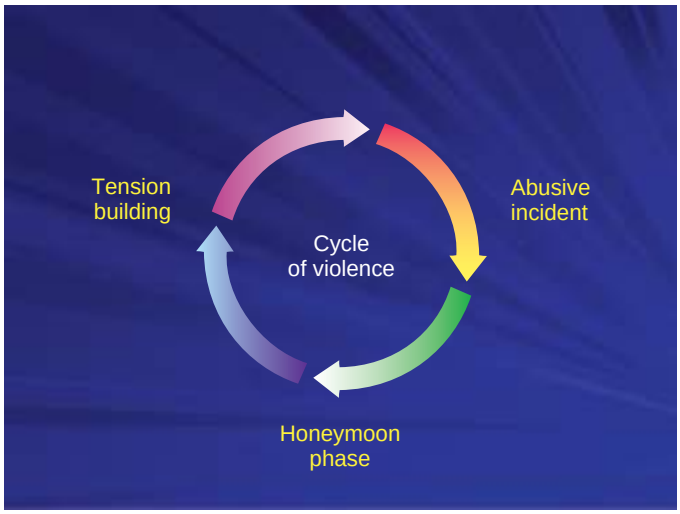

Fig. 5.3 Cycle of violence.

BOX 5.9 Signs of Intimate Partner Violence

- Overuse of health services
- Vague, nonspecific concerns
- Missed appointments
- Unexplainable injuries
- Untreated serious injuries
- Injuries not matching the description
- Intimate partner never leaving the patient's side
- Intimate partner insisting on telling the story of the injury

Source: Krieger, C. L. (2008). Intimate partner violence: A review for nurses. *Nursing & Women's Health, 12*(3), 224–234.

reported incidence of one out of every six women having been a victim of domestic violence. Common elements of IPV are physical abuse; psychological or emotional abuse; sexual assault; isolation; and controlling all aspects of the person's life, including money, shelter, time, and food. In some cases, people do not recognize that they are being abused; they may not realize that psychological aggression exhibited as public humiliation, coercive control, threats of harm, or damage to personal property are forms of IPV (Breiding et al., 2015). Estimates of IPV are low primarily because many people may be afraid to disclose the abuse for fear of retaliation and escalation of violence.

In Canada, IPV is a significant social concern that affects many individuals each year and costs millions of dollars in annual medical costs. In 2015, the rate at which women were killed by an intimate partner was five times that of men (Canadian Femicide Observatory for Justice and Accountability, 2020). Canadian Indigenous people are three times as likely to be victims of violence and at a significantly higher risk of being killed than non-Indigenous women (Canadian Femicide Observatory for Justice and Accountability, 2020; Scrim, 2017). Several factors present in Indigenous communities have been linked to this risk factor, including colonization, ongoing racism, and socioeconomic challenges (Varcoe et al., 2017).

Violence is neither random nor constant; rather, it occurs in repeated cycles. Health care providers often refer to the "cycle of violence" (Figure 5.3). A three-phase cycle includes a period of increasing tension leading to the battery. The battery consists of slaps, punches to the face and head, kicking, stomping, punching, choking, pushing, breaking of bones, burns from irons, and mutilations from knives and guns (see Box 5.9 for signs of IPV). The honeymoon phase is characterized by a period of calm and remorse in which the partner displays kind, loving behaviour and pleas for forgiveness. This honeymoon phase lasts until stress or other factors cause conflict and tension to mount again toward another episode of battering. Over time, the tension and battering phases last longer and the calm phase becomes shorter until there is no honeymoon phase. Dating violence is also a growing concern among adolescents. Knowledge of the potential for violence among youth in dating relationships is an important consideration for nurses when completing assessments with youth.

Because violence against women, as well as against LGBTQ2 persons, crosses all ethnic, educational, religious, and socioeconomic backgrounds and there are often misconceptions regarding who is at risk for being abused, it is important to differentiate myths from facts about this serious and often devastating condition (Table 5.2).

Violence is also known to increase during and after conflict (WHO, 2017), which has a particular impact for immigrant patients coming from countries with war and conflict. It is important that immigrants to Canada know that they will not be deported if they leave their partner because of violence, even if the partner is their sponsor. Reporting rates may not reflect the magnitude of the issue, as many patients do not disclose violence because of fear, embarrassment, or not having been asked by those from whom they seek help. Poor and uneducated patients tend to be disproportionately represented because they are seen in emergency departments, they are financially more dependent, and they have fewer resources and support systems. They also may have fewer problem-solving skills.

Although IPV is the preferred term, *domestic* or *family violence* are terms that may be applied to a pattern of assaultive and coercive behaviours inflicted by a partner in a marriage or other significant, intimate relationship. It is also important to note that not all violence is caused by an intimate partner; non-IPV also occurs. Violence in general has negative effects on people's health. Because IPV is not uncommon, with many patients being abused frequently, routine assessment of violence against patients should be included in primary care histories.

TABLE 5.2 Myths and Facts About Intimate Partner Violence (IPV)

Myths	Facts
Violence occurs in a small percentage of the population.	One third of all Canadian patients have experienced violence in their life.
Being pregnant protects the patient from abuse.	From 4 to 8% of all patients suffer IPV during pregnancy. IPV often begins or escalates in frequency and intensity during pregnancy. Pregnancy may be the result of forced sex or of the partner's control of contraception.
Violence occurs only in "problem" or lower-class families.	IPV can occur in any family. Although lower-income families have a higher reported incidence of violence, it also occurs in middle- and upper-income families. Incidence is not accurately known because of the tendency of middle- and upper-income families to hide the violence.
Individuals like to be beaten and deliberately provoke the attack. They are masochistic.	People are terrified of their assailants and go to great lengths to avoid a confrontation. In some cases, the person may provoke their partner to release tension that, if left unchecked, might lead to a more severe beating and possible death.
Only men or women with psychological problems are abusers.	Many offenders are successful professionals. Research indicates that only a small number of abusers have psychological problems.
Only people who come from abusive families end up in abusive relationships.	Most individuals report that their partners were the first person to subject them to violence.
Alcohol and drug use cause abuse.	Although alcohol may be involved in abusive incidents, it is not the cause. Many offenders use alcohol as an excuse for the violence and shift the blame to the alcohol.
Individuals would leave the relationship if the abuse were really that bad.	Individuals who stay in the relationship do so out of fear and financial dependence. Shelters have long waiting lists or may not be accessible in more remote communities.
Abusers and survivors of violence cannot change.	Counselling may effectively help both the offenders and victims of violence.
Some individuals stay in abusive relationships because it is part of their culture.	Many people stay because of social isolation, language barriers, and poverty or for a sense of family responsibility. Many immigrant patients may fear deportation.
Abuse does not happen in same-sex relationships.	Power dynamics can occur in any intimate relationship. Violence against a partner is a crime regardless of gender.

(2012). *Domestic violence in the LGBT community*. https://cwhn.ca/en/node/39623; Society of Obstetricians and Gynecologists of Canada. (2005). SOGC clinical practice guideline: Intimate partner violence consensus statement. *Journal of Obstetrics and Gynaecology Canada, 27*(4), 365–388.

All patients entering the health care system should be assessed for potential abuse. At least the following questions should be asked (Pellizzari et al., 2005):

- "Have you been hit, kicked, punched, or otherwise hurt by someone within the past year?"
- "Do you feel safe in your current relationship?"
- "Have you ever been forced to have sex or engage in sexual activities against your will?"

These questions give a patient permission to disclose sensitive information.

A therapeutic relationship and skillful interviewing can help patients disclose and describe their abuse (Box 5.10). Sensitive use of language is important when talking with patients. For example, the term *victim* connotes powerlessness and hopelessness; a more empowering term is *survivor*. Demonstrating concern for patients who are experiencing violence, showing respect, exercising confidentiality, and conveying a nonjudgemental attitude are important attributes of health care providers to facilitate disclosure of violence (Catallo et al., 2012). Many patients are concerned about health care providers discovering their IPV (Catallo et al., 2012).

If a patient discloses IPV, the first step is to assess for immediate danger and to take action to protect the person and their children, if needed. A complete physical examination is needed to assess for injuries and to observe the patient's behaviours and verbal responses when asked about the various injuries (Bianchi et al., 2016). The next step is to help the patient formulate a safety plan (Box 5.11). It is imperative that people are aware of resources available to them and have a plan of action if they stay with the violent partner. The nurse should provide telephone numbers of a hotline and a shelter or other safe haven. The patient can be offered a telephone to call the shelter if this is an option they choose. If they choose to go back to the abuser, a safety plan includes necessities for a quick escape: a bag packed with personal items for an overnight stay (can be hidden or left with a neighbour), money or a chequebook, an extra set of car keys, and any legal documents for identification. Legal options such as those for restraining orders or arrest of the perpetrator also are important aspects of the safety plan. A restraining order can be obtained 24 hours a day from the police department. Shelters also can be helpful with assistance in obtaining orders of protection. If the patient chooses not to act in the middle of a violent episode, they may use the hotline or shelter for some counselling when the threat of harm is no longer present.

Of critical importance to addressing IPV on a wider scale is a coordinated approach to maintain the safety of patients, good access to health care, and nonjudgemental treatment from health providers. Collaborative efforts to teach youth about healthy relationships are also essential to preventing IPV (Exner-Cortens et al., 2019). Community involvement in developing a response to IPV is important to sustaining safe, resilient communities.

Violence During Pregnancy. Violence against pregnant patients is a significant public health concern (Tailleu et al., 2016). The greatest predictor of violence during pregnancy is IPV prior to pregnancy; violence tends to worsen during pregnancy. Risk factors for IPV during pregnancy include younger age (especially adolescents), unintended pregnancy, lower income, and lower level of education (Martin-de-las-Heras et al., 2015). Abuse also may happen for the first time during pregnancy.

BOX 5.10 What Not to Say to a Person Who Has Been Subjected to Violence and What You Can Say and Do

What Not to Say

1. Do not ask "why." This question "re-victimizes" and blames the victim.
2. Do not talk negatively about the abuser to the victim. The person may become defensive and stop talking.
3. Do not talk directly to the abuser about your suspicions of abuse. The abuser will assume the victim told you, and the victim risks retaliation.

What to Say

1. "I'm afraid for your safety (and the safety of your children)."
2. "I believe you."
3. "It is progressive and will only get worse."
4. "You deserve better than this. You deserve to be treated with respect."
5. "You are not alone."
6. "It is a crime."
7. "I'm here for you."

What to Do

1. Empower the patient.
2. Sit down with them.
3. Assure the patient of total privacy and confidentiality (but only if you can).
4. Use your best listening and relational practice skills.
5. Call 911 or call local police and report any incident of imminent danger.
6. Give the patient the telephone number and/or email address of the nearest shelter or safe house.
7. For further assistance, refer to a victim services division in the city or province if available.

BOX 5.11 Safety Strategies

Survivors of intimate partner violence should try to maintain the following safety strategies:

- Always be aware of surroundings.
- Minimize time in kitchens, bathrooms, and closets when the abuser is near.
- Shop and bank at different places.
- Drive to work multiple ways.
- Get a protection order.
- Never lunch alone.
- Cancel joint credit cards and old bank accounts with the abuser.
- Provide a picture of the abuser to security at the workplace.
- Be escorted by workplace security to the car or transportation.
- When in danger, go to a place of safety and call 911 or local emergency response or police.
- Change locks on the house if the abuser has moved out.
- Get an unlisted telephone number.
- Block caller ID.

Source: Krieger, C. L. (2008). Intimate partner violence: A review for nurses. *Nursing & Women's Health, 12*(3), 224–234.

During pregnancy the nurse should assess for abuse at each prenatal visit and on admission to labour. Violent episodes initiate or increase in pregnancy for a variety of reasons: (1) the biopsychosocial stresses of pregnancy may strain the relationship beyond the couple's ability to cope, and frustration is followed by violence; (2) the partner may be jealous of the fetus, resenting intrusion into the couple's relationship and the pregnant person's displacement of attention; (3) the abuser may be angry at the unborn child or their partner; and (4) the violence may be the partner's conscious or subconscious attempt to end the pregnancy. A pregnant patient is often accompanied by their partner to the prenatal appointment, especially if the patient does not speak English and the partner does. Unless an interpreter is available, it is difficult to interview the patient alone. In addition, asking questions about abuse through an interpreter is more difficult unless the interpreter is patient and can communicate the nurse's sensitivity and concern accurately. See more discussion of IPV during pregnancy in Chapter 11.

Prevention. Nurses can make a difference in stopping IPV and preventing further injury. Educating patients that abuse is a violation of their rights and facilitating their access to protective and legal services is an important first step. Other helpful measures for nurses to take to discourage the risk of abusive relationships are promoting assertiveness and self-defence courses; suggesting support and self-help groups that encourage positive self-regard, confidence, and empowerment; and recommending educational and skills development classes that will enhance independence and the ability to take care of oneself. Classes for English-language learners may be particularly helpful to immigrant patients. Nurses can offer information on local classes.

HEALTH PROMOTION AND ILLNESS PREVENTION

Over the last several decades, women have made tremendous strides in education, careers, policy making, and overall participation in today's complex society. There have been costs for these advances, however; although women are living longer, they may not be living better. As a result, the health care system needs to include greater attention to the health consequences for women. Women also must be active participants in their own health promotion and illness prevention.

Nurses have a major opportunity and responsibility to help patients understand risk factors and motivate them to adopt healthy lifestyles that prevent disease. Lifestyle factors that affect health—and over which the patient has some control—include diet; use of tobacco, alcohol, and cannabis and substance use; exercise; sunlight exposure; stress management; and sexual practices. Other influences such as genetic and environmental factors may be beyond the patient's control, although some opportunities for prevention exist (e.g., through environmental legislative activism or genetic counselling services).

Knowledge alone is not enough to bring about healthy behaviours. The person must be convinced that they have some control over their life and that healthy life habits, including periodic health examinations, are a sound investment. They must believe in the efficacy of prevention, early detection, and therapy and in their ability to perform self-management practices. Many people believe that they have little control over their health, or they become so immobilized by fear and anxiety in the face of life-threatening illnesses such as cancer that they delay seeking treatment. The nurse must explore the reality of each person's perceptions about health behaviours and individualize teaching if it is to be effective.

Health Screening for Women Across the Lifespan

Periodic health screening includes history, physical examination, education, counselling, and selected diagnostic and laboratory tests. This regimen provides the basis for overall health promotion, prevention of illness, early diagnosis of health concerns, and referral for appropriate management. Such screening should be customized according to a patient's age and risk factors. In most instances it is completed in health care offices, clinics, or hospitals; however, portions of the screening are now being carried out at events such as community health fairs. An overview of health screening recommendations for women over 18 years of age is provided in Table 5.3. Consistent with information provided earlier in this chapter, it is important for the nurse to continually educate and counsel on diet, exercise, smoking cessation, alcohol moderation, help for substance use, and stress management.

TABLE 5.3 Health Screening Recommendations for Women Age 18 Years and Older

Intervention	Recommendation
Physical Examination	
Blood pressure	All primary care visits, but at least every 2 years
Height and weight and BMI*	At appropriate primary care visits, but at least every 2 years
Pelvic examination	Recommended to be done with Pap test unless symptomatic
Skin examination†	Yearly examinations or more frequently if risk factors; regular self-examinations recommended of moles, birthmarks, healing skin
Oral cavity examination	Annually if history of mouth lesion or exposure to tobacco or excessive alcohol at least annually
Breast Examination	
Clinical examination*	Not recommended in patients who have no risk factors Annually after age 18 if high risk with history of premenopausal breast cancer in first-degree relative
Laboratory and Diagnostic Tests	
Blood cholesterol (fasting lipoprotein analysis)‡	Screening at age 50 or postmenopausal Repeat yearly if have abnormal levels or risk factors for coronary artery disease; if low risk repeat every 3–5 years
Papanicolaou (Pap) test*	<25 years of age: screening is not routinely recommended Every 3 years from ages 25 to 69 Over age of 70: may stop screening if have had three negative screens
Mammography*	Ages 40 to 49: speak with health care provider about risk. Not routinely recommended Ages 50 to 69: every 2–3 years Ages 70 to 74: every 2–3 years Recommendations are different for patients at higher risk for breast cancer
Colon cancer screening*	Fecal occult blood test (FOBT) or fecal immunochemical test (FIT) every 2 years after age 50; more often if family history of colon cancer or polyps; screening colonoscopy at age 50 with schedule for this depending on what results show
Bone mineral density testing§	Over age 65 for everyone; earlier if risk factors (family history of osteoporosis, early menopause)
Risk Groups	
Fasting blood sugar or Hgb A_{1C}*	Screen every 3–5 years
Hearing screen	Annually with exposure to excessive noise or when hearing loss is suspected
Sexually transmitted infection screen (e.g., gonorrhea, syphilis, herpes)	As needed if sexually active with multiple partners and engaging in risky sexual behaviours
Tuberculin skin test	Annually with exposure to persons with tuberculosis or in risk categories for close contact with the disease
Vision¶	Age 19 to 40: at least every 10 years Age 41 to 55: at least every 5 years Age 56 to 65: at least every 3 years Over age 65: at least every 2 years If high risk (e.g., diabetes, thyroid, lupus) Over age 40: at least every 3 years Over age 50: at least every 2 years Over age 60: at least once a year
Immunizations**	
Diphtheria, tetanus, acellular pertussis, and inactivated polio virus vaccine (DTaP-IPV)	Tdap vaccine once and then booster every 10 years after primary series (given as infant). Also recommended to receive during every pregnancy
Measles, mumps, rubella	Given once if no evidence of immunity (initial series given as infant)
Human papillomavirus (HPV)	Primary series of injections for ages 9–26. Recommended schedule is 3 doses at 0, 2, and 6 months, with a minimum interval of 1 month between the first 2 doses. May be given to patients >26 if ongoing risk of exposure Male patients should also consider receiving vaccine
Hepatitis A	Primary series of two injections for all who are in risk categories
Hepatitis B††	Three doses: the second dose should be administered at least 1 month after the first dose, and the third at least 2 months after the second dose. Provinces and territories differ as to when the first dose is given.

Continued

TABLE 5.3 Health Screening Recommendations for Women Age 18 Years and Older—cont'd

Intervention	Recommendation
Influenza	Annually
Pneumococcal	One dose after age 65; earlier if risk factors
Varicella (chickenpox)	Susceptible adults up to and including 49 years of age: 2 doses; if previously received 1 dose should receive a second dose Known seronegative adults 50 years of age and older: 2 doses; routine testing is not advised
Herpes zoster (shingles)	One dose at age 60 (can be given between 50 and 59 years of age)

**Immunization schedules vary among provinces and territories. See local public health agency for specific schedules.
††Some provinces and territories start the first hepatitis B injection after the newborn is 24 hours old, some at 2 months, and some not until age 13. Check individual provincial and territorial immunization schedules.

HEALTH TEACHING

Health education is the process of providing information, encouraging a learner to use the resources they have, and teaching health promotion strategies or how to manage an existing condition. Nurses must have the knowledge to provide effective teaching to different groups of people. There are many factors to consider when planning teaching, including the domains of learning, factors that can enhance or inhibit learning, adult learning principles, and effective teaching strategies that can be used.

Domains of Learning

Learning often occurs through one or a combination of the three domains of learning: cognitive (understanding), affective (attitudes), and psychomotor (motor skills). When teaching patients, it is important to understand which domain is involved in order to plan the appropriate teaching strategy. See Box 5.12 for a discussion of teaching methods based on the domains of learning.

Cognitive Learning. Cognitive learning involves the acquiring of knowledge and development of intellectual skills, including the recall of specific facts. Bloom's taxonomy (knowledge, comprehension, application, analysis, synthesis, and evaluation) is frequently used to describe the increasing complexity of cognitive skills as learners move from beginner to more advanced in their knowledge of content. When considering which teaching strategies are appropriate to use for cognitive learning to occur, consult Box 5.12. An example of cognitive learning is when teaching a patient about the different types of birth control methods that are available.

Affective Learning. Affective learning involves feelings, emotions, and values. Changing attitudes and values clarification are part of affective learning. This domain deals with attitudes, motivation, willingness to participate, valuing what is being learned, and ultimately incorporating values into one's way of life. Discussing attitudes regarding the use of birth control is an example of incorporating affective learning in teaching.

Psychomotor Learning. The acquisition of a new motor skill involves psychomotor learning. This type of learning involves using physical movement. An example of this would be learning how to insert a diaphragm or how to put on a condom. Psychomotor skills are often taught using demonstrations and return demonstrations (see Box 5.12).

Adult Learning

Malcolm Knowles (1970) identified adult learning as an approach to learning that is problem based and collaborative. He focused on the equality between the learner and teacher. Knowles also identified six principles of adult learning:

1. Adults are internally motivated and self-directed—It is important to foster their internal motivation to learn and to facilitate learners' attitude toward being self-directed and responsible for their own learning. Adults resist learning when they feel it is being imposed on them.
2. Adults bring life experiences and knowledge to learning experiences—It is important to consider and build on learners' previous knowledge and experience; the ability to do this will enhance learning. Nurses should ask learners about their past experience and build on this information.
3. Adults are goal oriented—Learners will learn best when it is felt the information is important to them.
4. Adults are relevancy oriented—Adult learners like to know the relevance of what they are trying to achieve.
5. Adults are practical—It is important to ensure the learning applies to the specific situation.
6. Adult learners like to be respected—Nurses must convey respect and need to acknowledge the expertise and experience of the learner.

Learning Styles

Everyone processes information differently, therefore, learners have different learning styles and preferences. Processing information involves seeing and hearing, reflecting and acting, reasoning logically and intuitively, and analyzing and visualizing (Edgecombe, 2019). Visual learners learn best by seeing what they are learning. Auditory learners want to hear the information, often in a lecture or through discussion. Kinesthetic learners want to be involved with the learning by doing hands-on practice. Nurses must first assess the learning style of the patient to ensure that the appropriate learning strategy is used. Assessing the type of environment the patient prefers to learn in is also necessary before providing teaching. Some people like to learn on their own and are very self-directed, whereas others like to learn in groups. Nurses also need to assess the preferred learning style of the learner and adapt strategies to meet the needs of the learner. When providing teaching in a group setting, it is often necessary to use several

BOX 5.12 Appropriate Teaching Methods Based on Domains of Learning

Cognitive

Discussion (One-on-One or Group)
May involve nurse and one patient or nurse with several patients
Promotes active participation and focuses on topics of interest to patient
Facilitates peer support
Enhances application and analysis of new information

Storytelling
Can involve individual or group
Facilitates cultural relevance and safety
Enhances application of new information to a familiar context

Lecture
Is a more formal method of instruction because it is teacher controlled
Helps learner acquire new knowledge and gain comprehension

Question-and-Answer Session
Is designed specifically to address patient's concerns
Assists patient in applying knowledge

Role Play and Discovery
Encourages patient to actively apply knowledge in a controlled situation
Promotes synthesis of information and problem solving

Independent Projects (e.g., Computer-Assisted Instruction) and Field Experience
Assists patient to assume responsibility for learning at own pace
Promotes analysis, synthesis, and evaluation of new information and skills

Affective

Role Play
Encourages expression of values, feelings, and attitudes

Discussion (Group)
Enables patient to acquire support from other people in group
Encourages patient to learn from other people's experiences
Promotes responding, valuing, and organizing

Discussion (One-on-One)
Facilitates discussion of personal, sensitive topics of interest or concern

Psychomotor

Demonstration
Provides presentation of procedures or skills by nurse
Encourages patient to model nurse's behaviour
Allows nurse to control questioning during demonstration

Practice
Enables patient to perform skills by using equipment in a controlled setting
Allows repetition

Return Demonstrations
Enables patient to perform skill as nurse observes
Provides excellent source of feedback and reinforcement

Independent Projects and Games
Require teaching method that promotes adaptation and initiation of psychomotor learning
Enable learner to use new skills

Source: Potter, P., Perry, A., Stockert, P., et al. (Eds.). (2019). *Canadian fundamentals of nursing* (6th ed.). Elsevier.

different teaching methods in order to ensure the needs of all the learners are met.

Teaching Methods

Nurses need to consider the content being taught as well as how the patient learns best when deciding which method to use to provide the teaching. The nurse should assess the patient for their learning style and be prepared to modify the approach depending on how the patient responds. The most important factor when providing teaching is to provide an active learning environment; this is where the nurse and patient work together toward a common goal. See the Family-Centred Care box on teaching strategies for a guide to use when providing patient teaching.

One-on-One Discussion. Many times, nurses provide teaching in an individual session with a patient. Teaching one-on-one allows the learner to ask questions, and this should be encouraged. During the teaching session, the nurse can use pictures, written material, audiovisual aids, or models. The teaching aids that are used will depend on the learner's needs and how the person learns best.

Role Playing. Role playing is used to help a learner acquire new ideas and attitudes. The learner often takes the role of themselves or someone else in an unfamiliar situation and may practise a desired behaviour. An effective use for role playing is when a patient wants to feel more comfortable asking questions of a health care provider in an unfamiliar situation. The ability to practise the skill allows the learner to learn new skills and to feel more confident in situations when they are required.

Group Teaching. Teaching groups is often done through the use of lectures, although lecturing is not always the most effective method to enhance learning. Lectures can be very structured and limit interaction. A better way to provide teaching to groups is through discussion and practice (Edgecombe, 2019). People can learn well within group settings, especially if they are able to learn from other people's experiences. Nurses require practice and experience to feel comfortable facilitating group discussions rather than just lecturing.

Demonstration. Demonstration is an effective method to provide teaching about acquisition of a psychomotor skill. Showing the learner how to do something can be effective, although a more effective method is to have the learner return the demonstration to ensure that learning is acquired. Teaching new parents how to do a baby bath or a teenager how to apply a condom are examples of skills that are effectively taught using demonstration.

Factors That Influence Learning

Environment. An environment that is quiet with few distractions will enhance learning. The room should be well lit, well ventilated, and comfortable, as it is more difficult to learn in uncomfortable surroundings. It is important to determine whether the patient has pain or any other distractions, as these can affect learning. A new mother with a hungry, crying baby will find it difficult to concentrate on any teaching. The time of day may also have an impact on learning. People often learn better at different times of day. Nurses need to determine what is best for the patient when providing teaching.

FAMILY-CENTRED CARE

Teaching Strategies

- Establish trust with the patient before beginning the teaching–learning session.
- Limit teaching objectives.
- Use simple terminology to enhance the patient's understanding.
- Schedule short teaching sessions at frequent intervals; minimize distractions during teaching sessions.
- Begin and end each teaching session with the most important information.
- Present information slowly, pacing to provide ample time for the patient to understand the material.
- Repeat important information.
- Provide many examples that have meaning to the patient; for example, relate new material to a previous life experience.
- Build on existing knowledge.
- Use visual cues and simple analogies when appropriate.
- Ask the patient for frequent feedback to determine whether the patient comprehends information.
- Demonstrate procedures such as measuring dosages; ask for return demonstrations (which provide opportunities to clarify instructions and time to review procedures).
- Provide teaching materials that reflect the reading level of the patient; use material written with short words and sentences, large type, and simple format (in general, information written on a Grade 5 reading level is recommended for adult learners).
- Provide teaching materials that reflect health literacy of the patient; use material that avoids jargon, acronyms, and unnecessary medical terminology and defines medical terms that are necessary.
- Model appropriate behaviour and use role playing to help the patient learn how to ask questions and ask for help effectively.
- Pace the delivery of material so that patients can progress at their own speed.
- Include family members or other caregivers in the education process.

Data from Bastable, S. (2008). *Nurse as educator: Principles of teaching and learning for nursing practice*. Jones & Bartlett; Lowenstein, A. J., Foord-May, L., & Romano, J. C. (Eds.). (2009). *Teaching strategies for health education and health promotion: Working with patients, families and communities*. Jones & Bartlett.

Ability to Learn. The ability to learn depends on emotional, intellectual, and physical capabilities. If a patient's learning ability is impaired, the teaching may need to be postponed. For example, a patient who needs to learn to use a walker following hip surgery will not be able to learn this if their pain level is too high and they have not been out of bed postoperatively. It is important not to assume that everyone has the same intellectual ability to learn. Furthermore, it is important not to make the assumption that all people are literate.

Health Literacy. In Canada, 48% of adult Canadians have literacy skills that fall below a high school level, which negatively affects their ability to function at work and in their personal lives, and 60% of working-age adults in Canada are estimated to have less than adequate health literacy skills (ABC Life Literacy Canada, 2021). Health literacy is closely related to literacy, but focuses specifically on health information demands. Health literacy requires the ability to solve problems, evaluate information, and know when to take action. Individuals and groups for whom English is an additional language often lack the skills necessary to seek medical care and function adequately in the health care setting. Health literacy involves a spectrum of abilities, ranging from reading an appointment slip to interpreting medication instructions. Low health literacy may be an independent contributor to a disproportionate disease burden among disadvantaged populations. Nurses need to determine the level of reading ability before providing teaching and to ensure that written material is provided that meets the needs of the patient.

Motivation to Learn. The motivation to learn can be influenced by many factors, including a learner's culture as well as the health beliefs of the learner. If a person does not have access to some of the determinants of health, it can be more difficult to teach preventive health strategies or ways to manage an existing illness. If someone does not see the value in quitting smoking, teaching on this topic is less likely to be effective. Health teaching must be provided in a culturally competent manner and in a way that meets the needs of the patient.

Developmental level. The age and stage of development of a patient also can affect the ability to learn, as well as how the person learns best.

KEY POINTS

- Many determinants of health, including culture and socioeconomic status, as well as personal circumstances, the uniqueness of the individual, and the stage of development, influence a person's recognition of need for care, the degree to which they will or will not access care, and the response to the health care system and therapy.
- People have many reasons for accessing the health care system: well-person care, fertility prevention, infertility, and pregnancy.
- Preconception counselling is important to improve the health of all people and to ensure healthy pregnancy outcomes.
- There are many risk factors related to patients' health that must be considered when providing care, including nutrition, lack of exercise, stress, and substance use.
- IPV is a major social and health care issue in Canada and includes physical, sexual, emotional, psychological, and economic abuse. It affects all races and all socioeconomic, educational, and religious groups.
- Periodic health screening provides the basis for overall health promotion, prevention of illness, early diagnosis of health conditions, and referral for management.
- Health promotion and prevention of illness can help patients actualize their health potential by increasing motivation, providing information, and suggesting how to access specific resources.
- Teaching should be timed to work with the patient's readiness and ability to learn.
- Teaching is most effective when it meets the needs of the learner.
- The use of different types of teaching methods can improve the learner's attentiveness and overall learning.

Health Assessment

Lisa Keenan-Lindsay

Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe how to provide culturally competent care while completing a health assessment.
2. Describe components of taking a patient's history and performing a physical examination.
3. Identify how the history and physical examination can be adapted for people with special needs.
4. Identify how to screen for intimate partner violence.
5. Identify the correct procedure for assisting with and collecting Papanicolaou test specimens.

The purpose of this chapter is to review gynecological health assessment. Although some people may have been female-assigned at birth but no longer identify as a woman, it is important to recognize that some of these assessments would be appropriate for these individuals as well.

HEALTH ASSESSMENT

Trends in women's health have expanded its scope beyond a reproductive focus to include a holistic approach to health care across the lifespan and place women's health within primary care. Women's health assessment and screening focus on a systems evaluation that begins with a careful history and physical examination. Table 6.1 compares the variations in physical assessment related to age difference in women. During assessment and evaluation, the patient's responsibility for shared decision-making, health promotion, and enhancement of wellness is emphasized.

Often it is a nurse who takes the history, interprets test results, makes referrals, coordinates care, and directs attention to health issues requiring medical intervention. Advanced practice nurses who specialize in women's health, such as nurse practitioners and clinical nurse specialists, order diagnostic tests and perform complete physical examinations, including gynecological examinations. On completion of the assessment, the nurse will discuss goals with the patient and how to achieve them, and plan for follow up and future steps.

History

Contact with the patient usually begins with an interview, which is an integral part of the history. This interview should be conducted in a private, comfortable, and relaxed setting (Figure 6.1). The nurse should be seated and make sure that the person is comfortable. The person should be addressed by their title and name (e.g., Mrs. Khan) and asked how they prefer to be addressed. Then the nurse can introduce themselves using name and title. It is important to phrase questions in a sensitive and nonjudgemental manner. Body language should match oral communication. The nurse needs to be aware of a patient's vulnerability and assure them of strict confidentiality. For many patients fear, anxiety, and modesty make the examination a dreaded and stressful experience. Patients may feel that they do not have all the information a health provider has, may be misguided by myths, or be afraid that they will appear ignorant by asking questions about sexual or reproductive functioning. The person needs to be assured that no question is irrelevant.

The history begins with an open-ended question, such as "What brings you into the office (or clinic or hospital) today?" and is furthered by other prompts, such as "Anything else?" and "Tell me about it." Additional ways of encouraging patients to share information include the following:

Facilitation—Using a word or posture that communicates interest, such as leaning forward, making eye contact, or saying "Mm-hmmm" or "Go on"

Reflection—Repeating a word or phrase that the person has used

Clarification—Asking the person what is meant by a stated word or phrase

Empathic responses—Acknowledging the feelings of a person through statements such as "That must have been frightening"

TABLE 6.1 Female Reproductive Physical Assessment Across the Life Cycle

	Adolescent	Adult	Postmenopausal
Breasts	Tender when developing; buds appear; small, firm; one side may grow faster; areola diameter increases; nipples more erect	Grow to full shape in early adulthood; nipples and areola become darker	Become stringy, irregular, pendulous, and nodular; borders are less well delineated; may shrink and become flatter, elongated, and less elastic; ligaments weaken; nipples are positioned lower
Vagina	Vagina lengthens; epithelial layers thicken; secretions become acidic	Growth complete by age 20	Introitus constricts; vagina narrows, shortens, loses rugation; mucosa is pale, thin, and dry; walls may lose structural integrity
Uterus	Musculature and vasculature increase; lining thickens	Growth complete by age 20	Size decreases; endometrial lining thins
Ovaries	Increase in size and weight; menarche occurs between 8 and 16 years of age; ovulation occurs monthly	Growth complete by age 20	Size decreases to 1–2 cm; follicles disappear; surface convolutes; ovarian function ceases between 40 and 55 years of age
Labia majora	Become more prominent; hair develops	Growth complete by age 20	Labia become smaller and flatter; pubic hair becomes sparse and grey
Labia minora	Become more vascular	Growth complete by age 20	Become shinier and drier
Uterine tubes	Increase in size	Growth complete by age 20	Decrease in size

Fig. 6.1 The nurse interviews a patient as part of a routine history and physical examination. (© Can Stock Photo Inc./JackF.)

Confrontation—Identifying something about the person's behaviour or feelings not expressed verbally or apparently inconsistent with their history

Interpretation—Putting into words what the nurse infers about the person's feelings or about the meaning of their symptoms, events, or other matters

Nurses need to develop rapport and **trust** with their patients as they take a history; because communication within a caring context is core to nursing practice, nurses are well suited to taking a comprehensive history. Nurses should ask questions incrementally in order to build a comprehensive understanding, proceeding from the general to the specific. The nurse should also share insights with the patient by eliciting their concerns or thoughts as well as offering clarification to them.

At a patient's first visit, they are often expected to fill out a form with biographical and historical data before meeting with the examiner. This form aids the health care provider in completing the history during the interview. Box 6.1 describes the categories in a complete health history and assessment.

BOX 6.1 Health History and Review of Systems

Identifying data: Name, age, sex, marital status, occupation, and ethnicity

Reason for seeking care: A response to the question, "What concern or symptom brought you here today?" Is there more than one reason? Focus on the one they think is most important.

Present health: Current health status is described with attention to the following:

- *Use of safety measures:* Seat belts, bicycle helmets, designated driver
- *Exercise and leisure activities:* Regularity
- *Sleep patterns:* Length and quality
- *Sexuality:* Are they sexually active? With men, women, or both? Contraceptive use, risk-reducing sex practices?
- *Diet, including beverages:* 24-hour dietary recall
- *Nicotine, alcohol, illicit or recreational drug use:* Type, amount, frequency, duration, and reactions
- *Environmental and chemical hazards:* Home, school, work, and leisure setting; exposure to extreme heat or cold, noise, industrial toxins such as asbestos or lead, pesticides, radiation, cat feces, or cigarette smoke

History of present illness: A chronological narrative of the issue that includes a description of the following—location, quality or character, quantity or severity, timing (onset, duration, frequency), setting, factors that aggravate or relieve the issue, associated factors, and the patient's perception of the meaning of the symptom

Past health:

- *Infectious diseases:* e.g., measles, mumps, rubella, tuberculosis (TB), hepatitis, sexually transmitted infections (STIs)
- *Chronic disease and system disorders:* e.g., arthritis, cancer, diabetes, heart, lung, kidney, sickle cell anemia
- Adult injuries, accidents
- Hospitalizations, operations, blood transfusions
- Obstetrical history
- *Mental health concerns:* Previous history of depression, anxiety, bipolar disorder; has this been treated?

Continued

BOX 6.1 Health History and Review of Systems—cont'd

- *Allergies:* Medications, previous transfusion reactions, environmental allergies
- *Immunizations:* e.g., diphtheria, pertussis, tetanus, measles, mumps, rubella, influenza, hepatitis B, human papillomavirus (HPV), pneumococcal vaccine, COVID-19 vaccine
- *Last date of screening tests:* e.g., Pap test, mammogram, cholesterol test, colonoscopy
- *Current medications:* Name, dose, frequency, duration, reason for taking, and adherence to prescription regimen; home remedies, over-the-counter drugs, vitamin and mineral or herbal supplements used

Family history: Information about the ages and health of family members. Check for history of diabetes, heart disease, or other chronic disorders.

Screen for abuse: Has the person ever been hit, kicked, slapped, or forced to have sex against their wishes? Verbally or emotionally abused? History of childhood sexual abuse? If yes, have they received counselling or do they need a referral?

Review of systems: It is probable that all questions in each system will not be included every time a history is taken. The essential areas to be explored are listed in the following head-to-toe sequence. If a patient gives a positive response to a question about an essential area, more detailed questions should be asked and further assessment completed.

- *General:* Appearance, orientation, weight change, fatigue, weakness, fever, chills, or night sweats
- *Vital signs*: Temperature, pulse respiration, blood pressure
- *Skin:* Skin colour, integrity, texture, unusual odour; hair texture or nail changes; itching, bruising, bleeding, rashes, sores, lumps, or moles
- *Lymph nodes:* Enlargement, inflammation, pain, or drainage
- *Head:* Trauma, vertigo (dizziness), convulsive disorder, syncope (fainting); headache— location, frequency, pain type, nausea and vomiting, or visual symptoms present
- *Eyes:* Glasses, contact lenses, blurriness, tearing, itching, photophobia, diplopia, inflammation, trauma, cataracts, glaucoma, or acute visual impairment
- *Ears:* Hearing impairment, tinnitus (ringing), vertigo, discharge, pain, fullness, recurrent infections, or mastoiditis
- *Nose and sinuses:* Trauma, rhinitis, nasal discharge, epistaxis, obstruction, sneezing, itching, allergy, or smelling impairment
- *Mouth, throat, and neck:* Hoarseness, voice changes, soreness, ulcers, bleeding gums, goitre, swelling, or enlarged nodes
- *Breasts:* Masses, pain, lumps, dimpling, nipple discharge, fibrocystic changes, or implants
- *Respiratory:* Chest symmetry with respirations, shortness of breath, wheezing, cough, sputum, hemoptysis
- *Cardiovascular:* Rate, rhythm, murmurs, jugular vein distention, hypertension, rheumatic fever, murmurs, angina, palpitations, dyspnea, tachycardia, orthopnea, edema, chest pain, cough, cyanosis, cold extremities, ascites, phlebitis, or skin colour changes
- *Gastrointestinal:* Bowel sounds, appetite, nausea, vomiting, indigestion, dysphagia, abdominal pain, ulcers, bleeding with stools or black, tarry stools, diarrhea, constipation, bowel movement frequency, food intolerance, hemorrhoids, jaundice, or hepatitis
- *Genitourinary:* Frequency, hesitancy, urgency, polyuria, dysuria, hematuria, nocturia, incontinence, stones, infection, or urethral discharge; menstrual history, dyspareunia, discharge, sores, or itching
- *Peripheral vascular:* Coldness, numbness and tingling, leg edema, varicose veins, thromboses, or emboli
- *Endocrine:* Heat and cold intolerance, dry skin, excessive sweating, polyuria, polydipsia, polyphagia, thyroid conditions, diabetes, or secondary sex characteristic changes
- *Hematological:* Anemia, easy bruising, bleeding, petechiae, purpura, or transfusions
- *Musculoskeletal:* Muscle weakness, pain, joint stiffness, scoliosis, lordosis, kyphosis, range of motion, instability, redness, swelling, arthritis, or gout
- *Neurological:* Loss of sensation, numbness, tingling, tremors, weakness, vertigo, paralysis, fainting, twitching, blackouts, seizures, convulsions, loss of consciousness or memory
- *Mental status:* Moodiness, depression, anxiety, obsessions, delusions, illusions, or hallucinations
- *Functional assessment:* Ability to care for self

Physical Examination

In preparation for the physical examination, the patient should be asked to undress and given a gown to wear during the examination. They should be given the opportunity to undress privately. Objective data are recorded by system or location. A general statement of overall health status is a good way to start. Assessments are described in detail (see Box 6.1).

Cultural Considerations and Communication Variations in History and Physical

A person's recognizing signs and symptoms of disease and deciding to seek treatment may be influenced by cultural perceptions. *Cultural competence* is the ability of nurses to self-reflect on their own cultural values and how these impact the way they provide care (Canadian Nurses Association [CNA], 2018). Culture competence promotes cultural safety, and both are integral to providing high-quality, safe, and equitable nursing care (CNA, 2018) (see Chapter 2). Culture competence is more than simply acquiring knowledge about another ethnic group. It is essential that a nurse have respect for the rich and unique qualities that cultural diversity brings to individuals. In recognizing the value of these differences, the nurse can respond appropriately in planning, implementing, and evaluating a plan of care to meet the needs of each person. Nurses must also be aware of the power differentials that may occur in a health care interaction. The patient needs to be trusted that they are the expert on their life, culture, and experiences.

If the nurse asks with respect and a genuine desire to learn, the patient will tell the nurse how to care for them. Modifications may be necessary in conducting the physical examination. In many cultures, a female examiner is preferred. In some cultures, it may be considered inappropriate for the woman to disrobe completely for the physical examination.

Culturally safe care is particularly important for improving the health care experience of Indigenous patients. Positive experiences involving patient–provider interactions that are based on respect, free of judgement, and holistic and that demonstrate an understanding of the cultural context are important aspects of this relationship (Kolahdooz et al., 2016).

Communication may be hindered by different beliefs, even when the nurse and patient speak the same language. Examples of communication variations are listed in the Cultural Awareness box.

CULTURAL AWARENESS

Communication Variations

Conversational style and pacing—Silence may show respect or acknowledgement that the listener has heard. In cultures in which a direct "no" is considered rude, silence may mean no. Repetition or loudness may mean emphasis or anger.

Personal space—Cultural conceptions of personal space differ. For example, based on one's culture, someone may be perceived as being distant for backing off when approached or aggressive for standing too close.

Eye contact—Eye contact varies among cultures, from intense to fleeting. Consistent with the effort to refrain from invading personal space, avoiding direct eye contact may be a sign of respect.

Touch—The norms about how people should touch each other vary among cultures. In some cultures, physical contact with the same sex (embracing, walking hand in hand) is more appropriate than that with an unrelated person of the opposite sex.

Time orientation—In some cultures, involvement with people is more valued than being "on time." In other cultures, life is scheduled and paced according to clock time, which is valued over personal time.

Source: Srivastava, R. (2006). *The healthcare professional's guide to clinical cultural competence*. Mosby.

Adolescents (Ages 13 to 19)

As a young person matures, they should be asked the same questions that are included in any history. Particular attention should be paid to hints about risky behaviours, eating disorders, and depression. Sexual activity is addressed after rapport has been established. It is best to talk to a teen with the parent (or partner or friend) out of the room. The nurse should engage with the patient in a sensitive manner, using active listening and conveying a nonjudgemental manner.

Injury prevention should be a part of the counselling at routine health examinations, with special attention paid to use of seat belts and helmets, recreational hazards, and sports involvement. The use of drugs and alcohol and the non-use of seat belts increase the risk of motor vehicle injuries, which account for a great proportion of deaths in this age group. Information about contraceptives and sexually transmitted infection (STI) prevention may be needed for teens who are sexually active (see Chapter 7). Female athletes should have their weight assessed to ensure that they maintain an appropriate body mass index (BMI) (see Chapter 5).

To provide developmentally appropriate care, it is important to review the major tasks for patients in this stage of life. Major tasks for teens include values assessment; education and work goal setting; formation of peer relationships that focus on love, commitment, and becoming comfortable with sexuality; and separation from parents. The teen is egocentric as they progress rapidly through emotional and physical change. Their feelings of invulnerability may lead to misconceptions, such as the belief that unprotected sexual intercourse will not lead to pregnancy.

Women With Disabilities

Patients with emotional or physical disorders have special needs. Those with vision, hearing, emotional, or physical impairment or disabilities should be respected and involved in the assessment and physical examination to the full extent of their capabilities. The nurse should communicate openly, directly, and with sensitivity. It is often helpful to learn about the disability directly from the person, while maintaining eye contact. Family and significant others should be relied on only when absolutely necessary. The assessment and physical examination can be adapted to each person's individual needs.

Communication with a person who is hearing impaired can be accomplished without difficulty. Many people can read lips, write, or both. The interviewer who speaks and enunciates each word slowly and in full view may be easily understood. It is important that the interviewer not stand in front of a light source, as this can make it more difficult for the person to lip read. If a person is not comfortable with lip reading, they may use an interpreter. In this case, it is important to continue to address the person directly, avoiding the temptation to speak directly with the interpreter (see Chapter 2, Use of Interpreters).

The visually impaired person needs to be oriented toward the examination room and may have their guide dog with them. As with all patients, the visually impaired person needs a full explanation of what the examination entails before proceeding. Before touching them, the nurse should explain, "Now I am going to take your blood pressure. I am going to place the cuff on your right arm." The patient can be asked if they would like to touch each of the items that will be used in the examination, to reduce their anxiety.

Women at Risk for Abuse

Nurses should screen all patients for potential abuse who are entering the health care system. Abuse is a life-threatening public health concern that affects many patients and their children. Prior to asking about abuse, all patients should understand the reason for the questions being asked. A good way to present this is, "Because abuse happens to many people, we ask all patients if they have ever been in a situation that involved violence." The risk for intimate partner violence (IPV) increases during pregnancy and after separation or divorce. Most patients will not spontaneously provide information about family violence because of fear, guilt, and embarrassment; however, many patients will often disclose if asked. Help for the person may depend on the sensitivity with which the nurse screens for abuse, the discovery of abuse, and subsequent intervention. The nurse must be familiar with the laws governing abuse in the province or territory in which they practise.

Pocket cards listing emergency numbers (abuse counselling, legal protection, and emergency shelter) may be obtained from local police departments, women's shelters, or emergency departments. It is helpful to have these on hand in the setting where screening is done. An abuse assessment screen (Box 6.2) can be used as part of the interview or written history. If a partner is present, they should be encouraged to leave the room because the patient may not disclose experiences of abuse in their presence, or the partner may try to answer questions for the patient to protect themselves. The same procedure applies for adult children of older women.

Not all patients will disclose abuse, but clues in the history and evidence of injuries on physical examination should elicit a high index of suspicion. The areas most commonly injured are the head, neck, chest, abdomen, breasts, and upper extremities. Burns and bruises in patterns resembling hands, belts, cords, or other weapons may be seen, as well as multiple traumatic injuries. Attention should be given to patients who repeatedly seek treatment for somatic concerns such as headaches, insomnia, choking sensations, hyperventilation, gastrointestinal symptoms, and pain in the chest, back, or pelvis. During pregnancy, the nurse should assess for injuries to the breasts, abdomen, and genitalia. See Chapter 5 for further discussion of IPV.

Abusive relationships are often about power and control of the abuser over the person (see Figure 5.3). It is important to be aware of this when doing any physical examination, as any perception of power and control over the person by a health care provider may exacerbate an abused patient's anxiety, discomfort, or fear. All patients need to be shown respect and allowed control during the physical examination. **All people should always be addressed using eye contact first, and they should always be asked for permission prior to any physical contact.**

BOX 6.2 Screening for Intimate Partner Violence

Sample Screening Questions

While providing privacy, screen for intimate partner violence during new patient visits, annual examinations, initial prenatal visits, each trimester of pregnancy, and the postpartum checkup.

Framing Statement

"We've started talking to all of our patients about safe and healthy relationships because it can have such a large impact on your health."

Confidentiality

"Before we get started, I want you to know that everything here is confidential, meaning that I won't talk to anyone else about what is said unless you tell me that (insert the laws in your province or territory about what is necessary to disclose)."

Sample Questions

"Has your current partner ever threatened you or made you feel afraid?"

(Threatened to hurt you or your children if you did or did not do something, controlled who you talked to or where you went, or gone into rages)

"Has your partner ever hit, choked, or physically hurt you?"

("Hurt" includes being hit, slapped, kicked, bitten, pushed, or shoved.)

For patients of reproductive age:

"Has your partner ever forced you to do something sexually that you did not want to do, or refused your request to use condoms?"

"Does your partner support your decision about when or if you want to become pregnant?"

"Has your partner ever tampered with your birth control or tried to get you pregnant when you didn't want to be?"

For patients with disabilities:

"Has your partner prevented you from using a wheelchair, cane, respirator, or other assistive device?"

"Has your partner refused to help you with an important personal need, such as taking your medicine, getting to the bathroom, getting out of bed, bathing, getting dressed, or getting food or drink, or threatened not to help you with these personal needs?"

Source: American College of Obstetricians and Gynecologists. (2012). *Committee opinion: Intimate partner violence.* Reaffirmed 2019. https://www.acog.org/Clinical-Guidance-and-Publications/Committee-Opinions/Committee-on-Health-Care-for-Underserved-Women/Intimate-Partner-Violence

Transsexuality

There is an increasing number of individuals who transition from male to female or female to male. Health care providers need to provide respectful and sensitive care to transsexual men and women. A transsexual man who is in the process of transitioning may still have female reproductive organs and thus continues to need Pap tests, internal exams, and possibly mammograms.

Transgender men with a cervix should be screened with Pap smears following the guidelines for all women. This examination may be emotionally difficult or painful for trans men. Several strategies may be employed to minimize the discomfort or trauma associated with this examination for some men. Some strategies include asking the person what they call the body parts that are being examined, having a partner or support person with them, listening to music, or asking whether they want the procedure to be explained to them as it is happening.

Mammograms should be considered for trans women every 2 years if they are older than 50 years and on estrogen for more than 5 years. Initiation of screening may need to be considered at a younger age if additional risk factors are present (Canadian Cancer Society, 2020). See Additional Resources at the end of this chapter for further information on this topic.

Breast Assessment

Routine monthly breast self-examination (BSE), which is the systematic palpation of breasts to detect signs of breast cancer or other changes, is no longer recommended for women aged 40 to 74 years who do not have a high risk of developing breast cancer. Research has shown that BSE has not led to a decrease in mortality from breast cancer and has been linked to an increase in the number of unnecessary biopsies and other procedures (Klarenbach et al., 2018). Patients do need to know how their breasts feel and to look and watch for changes, but not on a regular schedule. There is no specific way to perform a BSE; it is just important to know what is normal for all the breast tissue so that changes can be noticed. Patients may hear conflicting information regarding BSE, and some patients may still choose to perform BSE.

Clinical breast examination (CBE) is also not effective in screening for breast cancer so is not recommended for patients with a low risk of developing breast cancer (Klarenbach et al., 2018). A routine mammogram every 2 to 3 years is the best screening tool; all provinces and territories have breast screening programs for patients aged 50 to 69 (see Chapter 7 for further discussion).

Pelvic Examination

Many people fear the gynecological portion of the physical examination. The nurse can be instrumental in allaying these fears by providing information and assisting the patient to express their feelings to the examiner.

The patient should be assisted into the lithotomy position for the pelvic examination. If the person is not comfortable in this position, alternative positions may be used (Figure 6.2). When the patient is in the lithotomy position, their hips and knees are flexed, with buttocks at the edge of the table, and their feet are supported by heel or knee stirrups.

Many patients, especially those with physical disabilities, cannot comfortably lie in the lithotomy position for the pelvic examination. Several alternative positions may be used, including a lateral (sidelying) position, a V-shaped position, a diamond-shaped position, or an M-shaped position (see Figure 6.2). The patient can be asked what has worked best for them previously. If they have never had a pelvic examination or have never had a comfortable pelvic examination, the nurse should proceed slowly by showing them a picture of various positions and asking them which one they would prefer. The nurse's support and reassurance can help the patient to relax, which will make the examination go more smoothly.

Some patients prefer to keep their shoes or socks on, especially if the stirrups are not padded. Patients may express feelings of vulnerability and strangeness when in the lithotomy position. During the procedure, the nurse can assist the patient with relaxation techniques. Breathing techniques can be particularly helpful for the adolescent and for the person whose introitus may be especially tight or for whom the experience is new or may provoke tension. Some patients relax when they are encouraged to become involved with the examination by having a

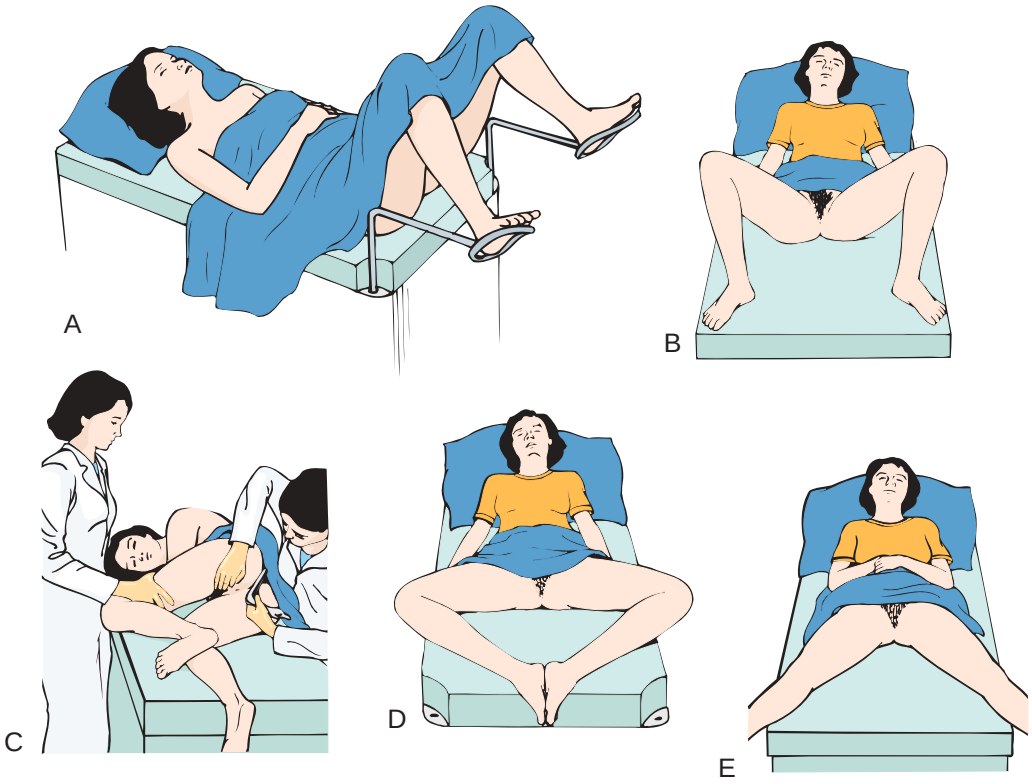

Fig. 6.2 Lithotomy, and variable positions for pelvic examination. **A:** Lithotomy position. **B:** M-shaped position. **C:** Side-lying position. **D:** Diamond-shaped position. **E:** V-shaped position.

BOX 6.3 Procedure: Assisting With Pelvic Examination

1. Perform hand hygiene. Assemble equipment (see illustration on right).
2. Ask patient to empty their bladder before the examination (obtain clean-catch urine specimen as needed).
3. Assist with relaxation techniques. Have patient place their hands on their chest at about the level of the diaphragm, breathe deeply and slowly (in through their nose and out through their O-shaped mouth), concentrate on the rhythm of breathing, and relax all body muscles with each exhalation.
4. Encourage patient to become involved with the examination if they show interest. For example, a mirror can be placed so that they can see the area being examined.
5. Assess for and treat signs of health concerns, such as supine hypotension.
6. Warm the speculum in warm water if a prewarmed one is not available.
7. Instruct patient to bear down when the speculum is being inserted.
8. Apply gloves and assist the examiner with collection of specimens for cytological examination, such as a Pap test. After handling specimens, remove gloves and wash hands.
9. Lubricate the examiner's fingers with water or water-soluble lubricant before bimanual examination.
10. Assist the patient to a sitting position upon completion of the examination.
11. Provide tissues to wipe lubricant from perineum.
12. Provide privacy for the patient while they are dressing.

Equipment used for pelvic examination. (Courtesy Michael S. Clement.)

mirror placed so that they can view the area being examined. This type of participation helps with health teaching as well. Distraction is another technique that can be used effectively (e.g., placing interesting pictures on the ceiling over the head of the table). Box 6.3 discusses the nurse's role in pelvic examinations.

Some patients find it distressing to attempt to converse in the lithotomy position. Most will appreciate an explanation of the procedure as it unfolds, as well as coaching for the type of sensations they may expect. Generally, however, patients prefer not to have to respond to questions until they are again upright and at eye level with the examiner. Being asked questions during the procedure, especially if they cannot see their questioner's eyes, may make some patients tense.

A teenager's first speculum examination is the most important one because they will develop perceptions that will remain with them for future examinations. What the examination entails should be discussed with the teen while they are dressed. Models or illustrations can be used

to show exactly what will happen. All of the necessary equipment should be assembled so that there are no interruptions. Pediatric specula that are 1 to 1.5 cm wide can be inserted with minimal discomfort. If the teen is sexually active, a small adult speculum may be used.

External Inspection. The examiner wears gloves and sits at the foot of the table for **inspection** of the external genitals and the speculum examination. In good lighting, external genitals are inspected for sexual maturity, including the clitoris, labia, and perineum, and for lesions indicative of STIs. After childbirth or other trauma there may be healed scars.

This is a good time to discuss with a patient the benefits of knowing their body and what is normal for them. If abnormalities are detected by the patient these should be discussed further with a health care provider. Many lesions, including malignancy, condyloma acuminatum (wartlike growth), and Bartholin cysts, can be seen or palpated and are easily treated if diagnosed early.

External Palpation. Before touching the patient, the examiner should explain what is going to be done and what the patient should expect to feel (e.g., pressure). The examiner may touch the patient in a less sensitive area such as the inner thigh to alert them that the genital examination is beginning. This gesture may put the patient more at ease. The labia are spread apart to expose the structures in the vestibule: urinary meatus, Skene glands, vaginal orifice, and Bartholin glands (Figure 6.3). To assess the Skene glands, the examiner inserts one finger into the vagina and "milks" the area of the urethra. Any exudate from the urethra or the Skene glands is cultured. Masses and erythema of either structure are assessed further. Ordinarily, the openings to the Skene glands are not visible; prominent openings may be seen if the glands are infected (e.g., with gonorrhea). During the examination, the examiner needs to keep in mind the data from the review of systems, such as history of burning on urination.

The vaginal orifice is then examined. Hymenal tags are normal findings. With one finger still in the vagina, the examiner repositions the index finger near the posterior part of the orifice. With the thumb outside the posterior part of the labia majora, the examiner compresses the area of Bartholin glands located at the 8 o'clock and 4 o'clock positions and looks for swelling, discharge, and pain.

The support of the anterior and posterior vaginal wall is also assessed. The examiner spreads the labia with the index and middle fingers and then asks the patient to strain down. Any bulge from the anterior wall (urethrocele or cystocele) or posterior wall (rectocele) should be noted and compared with the history, such as difficulty starting the stream of urine or with constipation.

Fig. 6.3 External examination. Separation of the labia. (From Wilson, S. F., & Giddens, J. F. [2013]. *Health assessment for nursing practice* [5th ed.]. Mosby.)

The perineum (area between the vagina and anus) is assessed for scars from old lacerations or **episiotomies**, thinning, fistulas, masses, lesions, and inflammation. The anus is assessed for hemorrhoids, hemorrhoidal tags, and integrity of the anal sphincter. The anal area is also assessed for lesions, masses, abscesses, and tumours. If there is a history of STI, the examiner may want to obtain a culture specimen from the anal canal at this time. Throughout the genital examination, the examiner should note any odour, which may indicate infection or poor hygiene.

Internal Examination. A vaginal speculum consists of two blades and a handle, and specula come in a variety of types and styles. A vaginal speculum is used to view the vaginal vault and cervix. The speculum is gently placed into the vagina and inserted to the back of the vaginal vault. The blades are opened to reveal the cervix and are locked into the open position. The cervix is inspected for position and appearance of the os: colour, lesions, bleeding, and discharge (Figure 6.4, A to D). Cervical findings that are not within normal limits include ulcerations, masses, inflammation, and excessive protrusion into the vaginal vault. Anomalies such as a cockscomb (a protrusion over the cervix that looks like a rooster's comb), a hooded or collared cervix (seen in diethylstilbestrol daughters), or polyps should be noted.

Collection of specimens. The collection of specimens for cytological examination is an important part of the gynecological examination. Infection can be diagnosed by examination of specimens collected during the pelvic examination. These infections include candidiasis, trichomoniasis, bacterial vaginosis, group B streptococcus, gonorrhea, chlamydia, and herpes simplex virus. Once the diagnoses have been made, treatment can be instituted (see discussion in Chapter 7).

Papanicolaou test. Carcinogenic conditions, whether potential or actual, can be determined by examination of cells from the cervix collected during the pelvic examination (i.e., a Pap test) (Box 6.4).

Vaginal wall examination. After the specimens are obtained, the vagina is viewed when the speculum is rotated. The speculum blades are unlocked and partially closed. As the speculum is withdrawn it is rotated; the vaginal walls are inspected for colour, lesions, rugae, fistulas, and bulging.

Bimanual Palpation. The examiner stands for this part of the examination. A small amount of lubricant is placed on the first and second fingers of the gloved hand for the internal examination. To avoid tissue trauma and contamination, the thumb is abducted, and the ring and little fingers are flexed into the palm (Figure 6.5). The vagina is palpated for distensibility, lesions, and tenderness. The cervix is examined for position, shape, consistency, motility, and lesions. The fornix around the cervix is palpated.

The other hand is placed on the abdomen halfway between the umbilicus and symphysis pubis and exerts pressure downward toward the pelvic hand. Upward pressure from the pelvic hand traps reproductive structures for assessment by palpation. The uterus is assessed for position, size, shape, consistency, regularity, motility, masses, and tenderness.

With the abdominal hand moving to the right lower quadrant and the fingers of the pelvic hand in the right lateral fornix, the adnexa is assessed for position, size, tenderness, and masses. The examination is repeated on the patient's left side.

Just before the intravaginal fingers are withdrawn, the patient is asked to tighten their vagina around the fingers as much as they can.

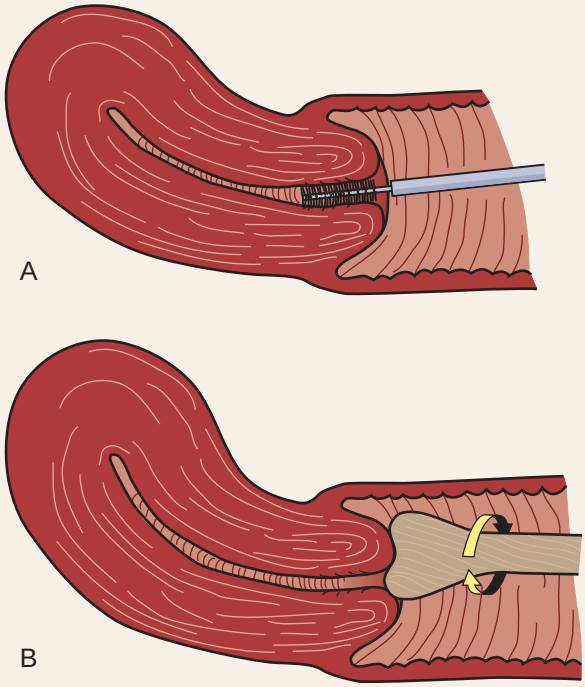

Fig. 6.4 Insertion of speculum for vaginal examination. **A:** Opening of the introitus. **B:** Oblique insertion of the speculum. **C:** Final insertion of the speculum. **D:** Opening of the speculum blades. (From Wilson, S. F., & Giddens, J. F. [2013]. *Health assessment for nursing practice* [5th ed.]. Mosby.)

BOX 6.4 Procedure: Papanicolaou Test

1. In preparation, make sure that the patient has not douched, used vaginal medications, or had sexual intercourse for at least 24 hours before the procedure. Reschedule the test if the patient is menstruating. Midcycle is the best time to test.
2. Explain to the patient the purpose of the test and what sensations they will feel as the specimen is obtained (e.g., for some patients this may feel uncomfortable, others may just feel pressure).
3. Assist the patient into a position that is most comfortable for them (usually lithotomy). A speculum is then inserted into the vagina.
4. The cytological specimen is obtained before any digital examination of the vagina is made or endocervical bacteriological specimens are taken. A cotton swab may be used to remove excess cervical discharge before the specimen is collected.
5. The specimen is obtained by using an endocervical sampling device (Cytobrush, Cervex-Brush, papette, or broom) (see Figures A and B). If the two-sample method of obtaining cells is used, the cytobrush is inserted into the canal and rotated 90 to 180 degrees, followed by a gentle smear of the entire transformation zone using a spatula. Broom devices are inserted and rotated 360 degrees five times. They are used to obtain endocervical and ectocervical samples at the same time. If the patient has had a hysterectomy, the vaginal cuff is sampled. Areas that appear abnormal on visualization require colposcopy and biopsy. If using a one-slide technique, the spatula sample is smeared first. This is followed by applying the Cytobrush sample (rolling the brush in the opposite direction from which it was obtained), which is less subject to drying artifact; the slide is then sprayed with preservative within 5 seconds. The ThinPrep Pap test is a liquid-based method

Continued

BOX 6.4 Procedure: Papanicolaou Test—cont'd

Pap test. **A:** Collecting cells from the endocervix using a cytobrush. **B:** Obtaining cells from the transformation zone using a wooden spatula. (From Lentz, G. M., et al. [2012]. *Comprehensive gynecology* [6th ed.]. Mosby.)

of preserving cells that reduces blood, mucus, and inflammation. The Pap specimen is obtained in the manner described above except that the cervix is not swabbed before collection of the sample. The collection device (brush, spatula, or broom) is rinsed in a vial of preserving solution that is provided by the laboratory. The sealed vial with solution is sent off to the appropriate laboratory. A special processing device filters the contents, and a thin layer of cervical cells is deposited on a slide, which is then examined microscopically. The Papnet test is similar to the ThinPrep test. If cytology is abnormal, liquid-based methods allow follow-up testing for human papillomavirus (HPV) DNA with the same sample.

6. Label the slides or vial with the patient's name and site. Include on the form to accompany the slides the patient's name, age, last menstrual period, and parity and the reason for taking the cytological specimens.
7. Send specimens to the pathology laboratory promptly for staining, evaluation, and a written report, with special reference to abnormal elements, including cancer cells.
8. Advise the patient that repeat tests may be necessary if the specimen is not adequate.
9. Instruct the patient about routine checkups for cervical and vaginal cancer. It is recommended that Pap tests be initiated by age 25 and done every 3 years for patients with no risk factors, although different provinces and territories may have different guidelines. Patients with abnormal Pap results need more frequent testing. Pap screening can be discontinued in a patient who is 70 years old and has had three negative smears in the past 10 years (Canadian Task Force on Preventative Health, 2013).
10. Record the examination date on the patient's record.

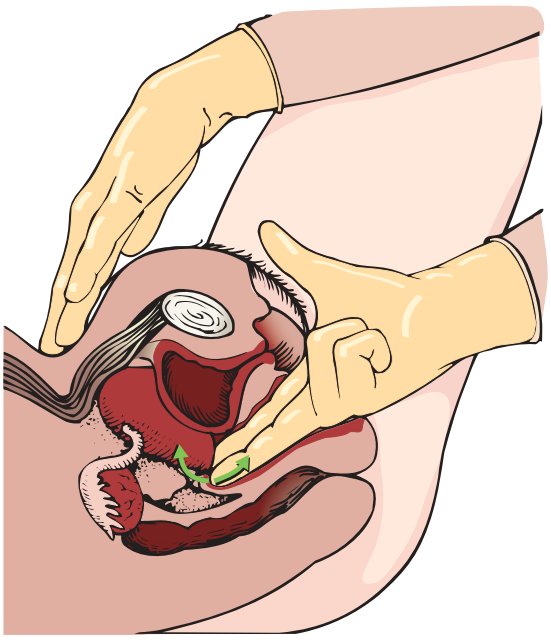

Fig. 6.5 Bimanual palpation of the uterus. (From Seidel, H. M., et al. [2011]. *Mosby's guide to physical examination* [7th ed., p. 566]. Mosby.)

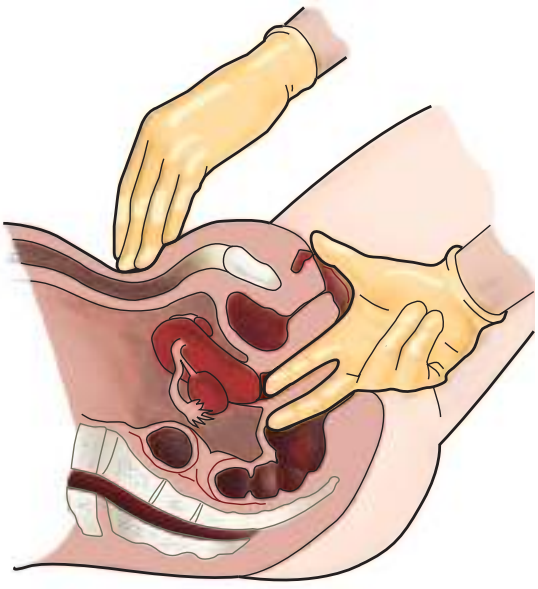

Fig. 6.6 Rectovaginal examination. (From Seidel, H. M., et al. [2011]. *Mosby's guide to physical examination* [7th ed., p. 568]. Mosby.)

If the muscle response is weak, the patient is assessed for their knowledge about **Kegel exercises**.

Rectovaginal Palpation. To prevent contamination of the rectum from organisms in the vagina, it is necessary to change gloves, add fresh lubricant, and then reinsert the index finger into the vagina and the middle finger into the rectum (Figure 6.6). Insertion is facilitated if the patient strains down. The manoeuvres of the abdominovaginal examination are repeated. The rectovaginal examination enables assessment of the rectovaginal septum, the posterior surface

of the uterus, and the region behind the cervix and the adnexa. The vaginal finger is removed and folded into the palm, leaving the middle finger free to rotate 360 degrees. The rectum is palpated for rectal tenderness and masses.

After the rectal examination is completed, the patient should be assisted into a sitting position, given tissues or wipes to cleanse themselves, and given privacy to dress. The examiner returns after the patient is dressed, to discuss findings and the plan of care.

Pelvic Examination During Pregnancy. The pelvic examination during pregnancy is done in the same way as during a routine examination on a nonpregnant person. Pelvic measurements are completed, and uterine size is estimated. A Pap test may be done initially and cytological specimens collected to test for gonorrhea, chlamydia, human papillomavirus, and herpes simplex virus.

While the pregnant patient is in lithotomy position, the nurse must watch for supine hypotension (decrease in blood pressure) caused by the weight of the uterus pressing on the vena cava and aorta. Symptoms of supine hypotension include pallor, dizziness, faintness, breathlessness, tachycardia, nausea, clammy skin, and sweating. The patient should be positioned on their side until symptoms resolve and vital signs stabilize. The vaginal examination can be done with the patient in lateral position.

Pelvic Examination After Hysterectomy. The pelvic examination after hysterectomy is done in much the same way as on a person with a uterus. Vaginal screening using the Pap test is not recommended in patients who have had a total hysterectomy with removal of the cervix for benign disease.

Laboratory and Diagnostic Procedures

The following laboratory and diagnostic procedures are ordered at the discretion of the clinician, considering the patient and family history: hemoglobin, glycated hemoglobin ($HgbA_{1C}$), fasting blood glucose, total blood cholesterol, lipid profile, urinalysis, syphilis serology (Venereal Disease Research Laboratories [VDRL] or rapid plasma reagent [RPR]) and other screening tests for STIs, mammogram, tuberculosis skin testing, hearing, visual acuity, electrocardiogram, chest radiograph, pulmonary function, fecal occult blood, flexible sigmoidoscopy, and bone mineral density (dual energy X-ray absorptiometry [DEXA] scan). Results of these tests may be reported in person, by phone call, through a secure online patient data system, or by letter. Tests for HIV, hepatitis B, and drug screening may be offered with informed consent in high-risk populations. These test results are usually reported in person.

KEY POINTS

- Periodic health screening, including history, physical examination, and diagnostic and laboratory tests, provides the basis for overall health promotion, prevention of illness, early diagnosis of health issues, and referral for management.
- Health screening needs to be performed in a culturally safe manner.
- Nurses have a role in screening patients for intimate partner violence.
- Routine screening mammography is recommended for early detection of breast cancer.
- The role of the nurse is to assist patients to feel more comfortable during pelvic examinations.

Reproductive Health

Lisa Keenan-Lindsay

Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the structures and functions of the female reproductive system.
2. Differentiate the menstrual cycle in relation to endometrial, hormonal, and ovarian responses.
3. Differentiate among the signs and symptoms of common menstrual disorders.
4. Develop a nursing care plan for the patient with primary dysmenorrhea.
5. Outline patient teaching about premenstrual syndrome.
6. Relate the pathophysiology of endometriosis to associated symptoms.
7. Describe the etiology, significance, and management of abnormal uterine bleeding.
8. Describe treatment for menopause symptoms.
9. Describe prevention and treatment of sexually transmitted infections in patients.
10. Summarize the care of patients with selected viral infections (i.e., human immunodeficiency virus and hepatitis B virus).
11. Differentiate the signs, symptoms, and management of selected vaginal infections.
12. Discuss the pathophysiology and emotional effects of selected benign breast conditions and malignant neoplasms of the breasts.

Health issues may occur at any point in a patient's life, especially during the reproductive years. Many factors, including anatomical abnormalities, physiological imbalances, and lifestyle, can affect the menstrual cycle. The average person may have some concerns related to their menstrual and gynecological health at some point in their life and may experience bleeding, pain, discharge, or infections associated with their reproductive organs or functions. This chapter provides information on the female reproductive system, menstrual cycle, common menstrual problems, sexually transmitted infections, and selected other infections that can affect reproductive functions. Benign breast conditions as well as breast cancer are also discussed.

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of external structures and internal structures located in the pelvic cavity as well as the breasts. The external and internal female reproductive structures develop and mature in response to estrogen and progesterone. This process starts in fetal life and continues through **puberty** and the childbearing years. Reproductive structures atrophy with age or in response to a decrease in ovarian hormone production. A complex nerve and blood supply supports the functions of these structures. The appearance of the external genitalia varies greatly among women. **Heredity**, age, race, and the number of children a patient has borne influence the size, shape, and colour of their external organs.

External Structures

The external genital organs, or *vulva*, include all **structures** visible externally from the pubis to the perineum. These include the mons pubis, labia majora, labia minora, clitoris, vestibular glands, vaginal vestibule, vaginal orifice, and urethral opening. The external genitalia are illustrated in Figure 7.1.

The *mons pubis* is a fatty pad that lies over the anterior surface of the symphysis pubis. In the postpubertal female the mons is covered with coarse, curly hair. The *labia majora* are two rounded folds of fatty tissue covered with skin that extend downward and backward from the mons pubis. The *labia* are highly vascular structures that develop hair on the outer surfaces after puberty. They protect the inner vulvar structures. The *labia minora* are two flat, reddish folds of tissue visible when the labia majora are separated. There are no hair follicles on the labia minora, but many sebaceous follicles and a few sweat glands are present. The interior of the labia minora is composed of connective tissue and smooth muscle and is supplied with extremely sensitive nerve endings. Anteriorly the labia minora fuse to form the **prepuce** (the hoodlike covering of the clitoris) and the frenulum (the fold of tissue under the

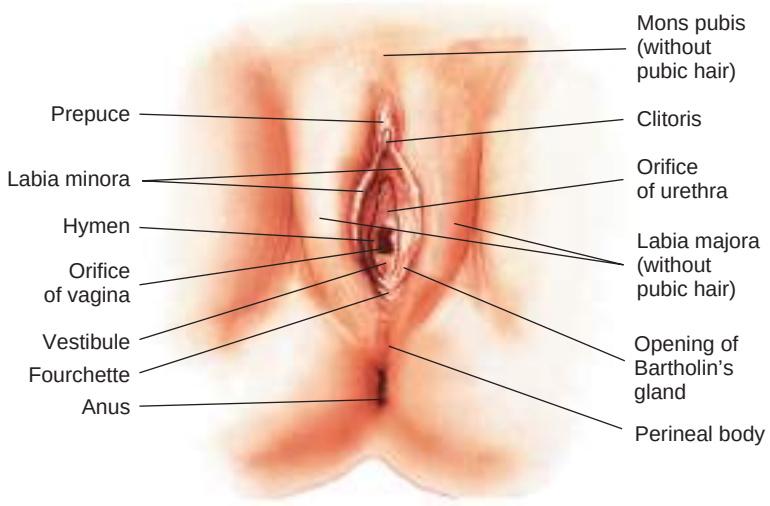

Fig. 7.1 External female genitalia.

clitoris). The labia minora join to form a thin, flat tissue, called the *fourchette,* underneath the vaginal opening at midline. The *clitoris,* located underneath the prepuce, is a small structure composed of erectile tissue with numerous sensory nerve endings. During sexual arousal the clitoris increases in size.

The *vaginal vestibule* is an almond-shaped area enclosed by the labia minora that contains openings to the urethra, Skene glands, vagina, and Bartholin glands. The urethra is not a reproductive organ but is discussed here because of its location. It usually is found about 2.5 cm below the clitoris. Skene glands are located on each side of the urethra and produce mucus, which aids in lubrication of the vagina. The vaginal opening is in the lower portion of the vestibule and varies in shape and size. The *hymen*, a connective tissue membrane that surrounds the vaginal opening, can be perforated during strenuous exercise, insertion of tampons, masturbation, and vaginal intercourse. Bartholin glands lie under the constrictor muscles of the vagina and are located posteriorly on the sides of the vaginal opening, although the ductal openings usually are not visible. During sexual arousal, the glands secrete clear mucus to lubricate the vaginal introitus.

The area between the fourchette and the anus is the *perineum*, a skin-covered muscular area that covers the pelvic structures. The perineum forms the base of the perineal body, a wedge-shaped mass that serves as an anchor for the muscles, fascia, and ligaments of the pelvis. The muscles and ligaments form a sling that supports the pelvic organs.

Internal Structures

The internal structures include the vagina, uterus, uterine tubes, and ovaries.

The *vagina* is a fibromuscular, collapsible, tubular structure that lies between the bladder and rectum and extends from the vulva to the uterus. During the reproductive years, the mucosal lining is arranged in transverse folds called **rugae**. These rugae allow the vagina to expand during childbirth. Estrogen deprivation that occurs after childbirth, during lactation, and at **menopause** causes dryness and thinning of the vaginal walls and smoothing of the rugae. The vagina, particularly the lower segment, has few sensory nerve endings. Vaginal secretions are slightly acidic (pH 4 to 5), so vaginal susceptibility to **infections** is limited. The vagina serves as a passageway for menstrual flow, as a female organ of copulation, and as a part of the birth canal for childbirth. The uterine cervix projects into a blind vault at the upper end of the vagina. There are anterior, posterior, and lateral pockets called **fornices** (singular: fornix) that surround the cervix. The internal pelvic organs can be palpated through the thin walls of these fornices.

The *uterus* is a muscular organ shaped like an upside-down pear that sits midline in the pelvic cavity between the bladder and rectum and above the vagina. Four pairs of ligaments support the uterus: cardinal, uterosacral, round, and broad. Single anterior and posterior ligaments also support the uterus. The *cul-de-sac of Douglas* is a deep pouch, or recess, posterior to the cervix formed by the posterior ligament.

The uterus is divided into two major parts, an upper triangular portion called the *corpus* and a lower cylindrical portion called the *cervix* (Figure 7.2). The **fundus** is the dome-shaped top of the uterus and is the site at which the uterine tubes (fallopian tubes) enter the uterus. The *isthmus*, or lower uterine segment, is a short, constricted portion that separates the corpus from the cervix.

The uterus serves for reception, implantation, retention, and nutrition of the fertilized ovum and later of the fetus during pregnancy and for expulsion of the fetus during childbirth. It is also responsible for cyclic menstruation.

The uterine wall is made up of three layers: the **endometrium**, the myometrium, and part of the peritoneum. The *endometrium* is a highly vascular lining made up of three layers, the outer two of which are shed during menstruation. The *myometrium* is made up of layers of smooth muscles that extend in three different directions (longitudinal, transverse, and oblique) (Figure 7.3). Longitudinal fibres of the outer myometrial layer are found mostly in the fundus, and this arrangement assists in the expelling of the fetus during the birth process. The middle layer contains fibres from all three directions, which form a figure-eight pattern encircling large blood vessels. These fibres assist in ligating blood vessels after childbirth and controlling blood loss. Most of the circular fibres of the inner myometrial layer are around the site where the uterine tubes enter the uterus and around the internal cervical os (opening). These fibres help keep the cervix closed during pregnancy and prevent menstrual blood from flowing back into the uterine tubes during menstruation.

The cervix is made up of mostly fibrous connective tissues and elastic tissue, making it possible for the cervix to stretch during vaginal childbirth. The opening between the uterine cavity and the canal that connects the uterine cavity to the vagina (endocervical canal) is the

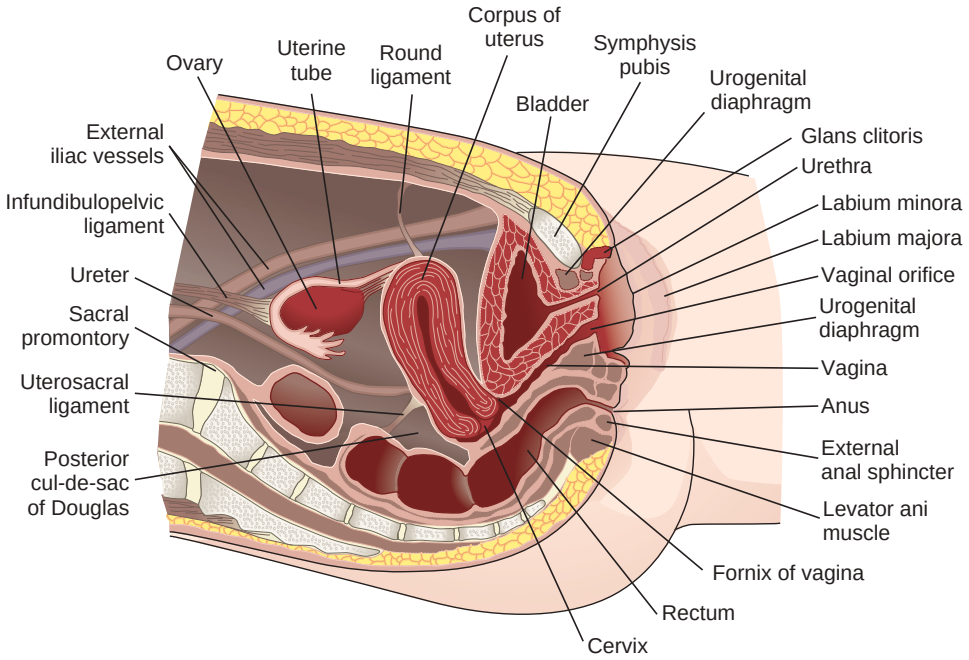

Fig. 7.2 Midsagittal view of female pelvic organs.

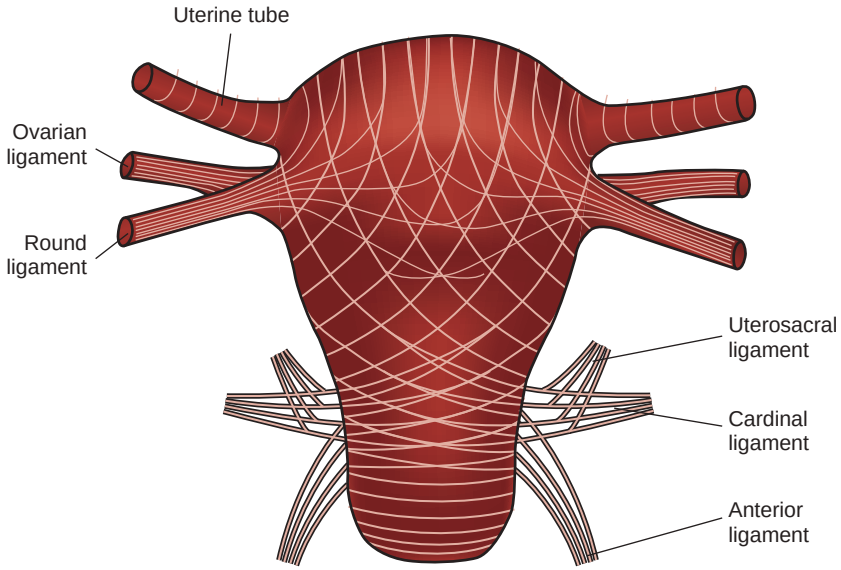

Fig. 7.3 Schematic arrangement of directions of muscle fibres. Note that uterine muscle fibres are continuous with supportive ligaments of the uterus.

internal os. The narrowed opening between the endocervix and the vagina is the *external os*, a small circular opening in patients who have never been pregnant. The cervix feels firm (like the end of a nose) with a dimple in the centre that marks the external os.

The outer portion of the cervix is covered with a layer of squamous epithelium. The mucosa of the cervical canal is covered with columnar epithelium and contains numerous glands that secrete mucus in response to ovarian hormones. The squamo-columnar junction, where the two types of cells meet, is usually located just inside the cervical os. This junction also is called the *transformation zone* and is the most common site for neoplastic changes. Cells from this site are scraped for the Papanicolaou (Pap) test.

The *uterine tubes* (fallopian tubes) attach to the uterine fundus. The tubes are supported by the broad ligaments and range from 8 to 14 cm in length. The tubes are divided into four sections: the interstitial portion is closest to the uterus; the isthmus and the ampulla are the middle portions; and the infundibulum is closest to the ovary (Figure 7.4). The uterine tubes provide a passage between the ovaries and the uterus for movement of the ovum. The infundibulum has fimbriated (fringed) ends, which pull the ovum into the tube. The ovum is pushed along the tubes to the uterus by rhythmic contractions of muscles of the tubes and by the current produced by the movement of the cilia that line the tubes. The ovum is usually fertilized by the sperm in the ampulla portion of one of the tubes.

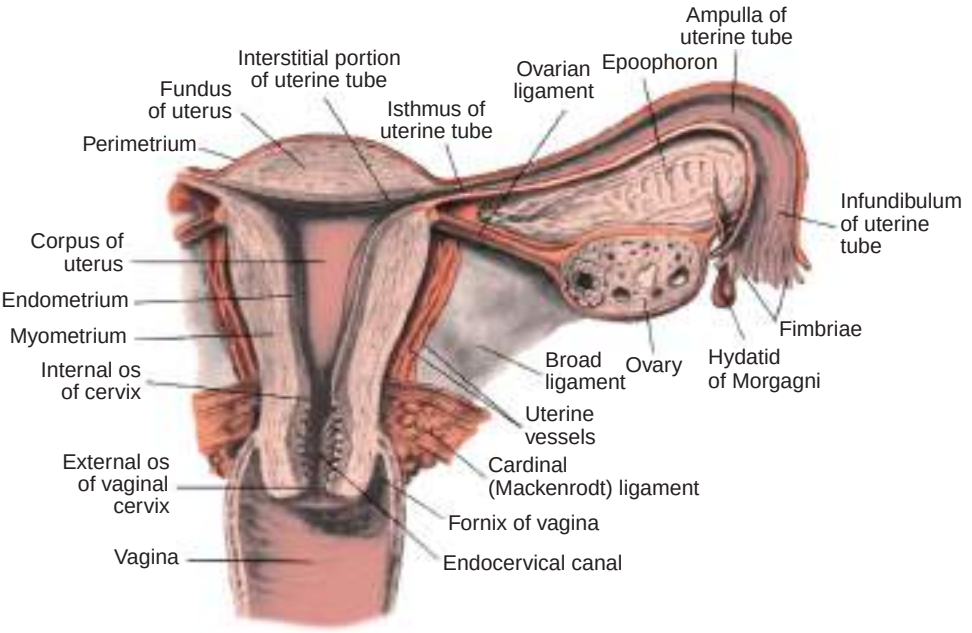

Fig. 7.4 Cross section of uterus, fallopian tubes, ovaries, and upper vagina.

The *ovaries* are almond-shaped organs located on each side of the uterus below and behind the uterine tubes. During the reproductive years, they are approximately 3 cm long, 2 cm wide, and 1 cm thick; they diminish in size after menopause. Before menarche each ovary has a smooth surface; after menarche they are nodular because of repeated ruptures of follicles at ovulation. The two functions of the ovaries are ovulation and hormone production. **Ovulation** is the release of a mature ovum from the ovary at intervals (usually monthly). Estrogen, progesterone, and androgen are the hormones produced by the ovaries.

The Bony Pelvis

The bony pelvis serves three primary purposes: protection of the pelvic structures, accommodation of the growing fetus during pregnancy, and anchorage of the pelvic support structures. The two innominate (hip) bones (consisting of ilium, ischium, and pubis), the sacrum, and the coccyx make up the four bones of the pelvis (Figure 7.5). Cartilage and ligaments form the symphysis pubis, sacrococcygeal joint, and two sacroiliac joints that separate the pelvic bones.

The pelvis is divided into two parts: the false pelvis and the true pelvis (Figure 7.6). The *false pelvis* is the upper portion above the pelvic brim or inlet. The *true pelvis* is the lower curved bony canal, which includes the inlet, the cavity, and the outlet through which the fetus passes during vaginal birth. The upper portion of the outlet is at the level of the ischial spines, and the lower portion is at the level of the ischial tuberosities and the pubic arch (see Figure 7.5). Variations that occur in the size and shape of the pelvis are usually related to age, race, and sex. Pelvic ossification is complete at about 20 years of age.

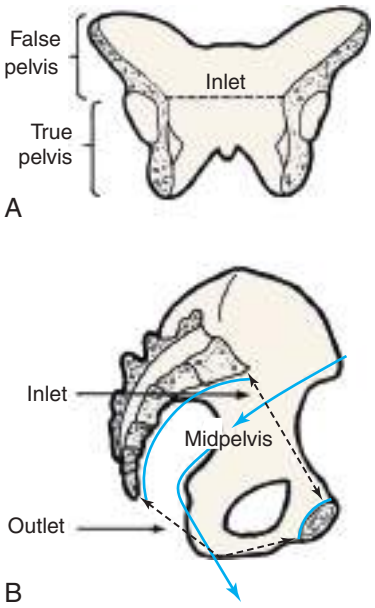

Fig. 7.6 Female pelvis. **A:** The cavity of false pelvis is shallow. **B:** The cavity of true pelvis is an irregularly curved canal *(arrows)*.

Breasts

The *breasts* are paired mammary glands located between the second and sixth ribs (Figure 7.7). About two-thirds of the breast overlies the pectoralis major muscle, between the sternum and midaxillary line, with an extension to the axilla referred to as the *tail of Spence*. The lower one-third of the breast overlies the serratus anterior muscle. The breasts are attached to the muscles by connective tissue or fascia. Besides their function of lactation, breasts function as organs for sexual arousal in the mature adult female.

The breasts of the healthy, mature patient are approximately equal in size and shape but often are not absolutely symmetrical. The size and shape vary with the patient's age, heredity, and nutrition. However, the contour should be smooth with no retractions, dimpling, or masses. Estrogen stimulates growth of the breast by inducing fat deposition in the breasts, development of stromal tissue (i.e., increase in its amount and elasticity), and growth of the extensive ductile system. Estrogen also increases the vascularity of breast tissue.

Once ovulation begins in puberty, progesterone levels increase. The increase in progesterone causes maturation of mammary gland tissue, specifically the lobules and acinar structures. During adolescence fat deposition and growth of fibrous tissue contribute to the increase in the size of the glands. Full development of the breasts is not achieved until after the end of the first pregnancy or in the early period of lactation.

Each mammary gland is made of a number of lobes that are divided into lobules. *Lobules* are clusters of acini. An *acinus* is a saclike terminal part of a compound gland emptying through a narrow lumen or duct. The acini are lined with epithelial cells that secrete colostrum and milk. Just below the epithelium is the *myoepithelium* (*myo*, or muscle), which contracts to expel milk from the acini.

The ducts from the clusters of acini that form the lobules merge to form larger ducts draining the lobes. Ducts from the lobes converge in a single nipple (mammary papilla) surrounded by an areola. The anatomy of the ducts is similar for each breast but varies among women. Protective fatty tissue surrounds the glandular structures and ducts. *Cooper's ligaments*, or fibrous suspensory ligaments, separate and support the glandular structures and ducts. Cooper's ligaments provide support to the mammary glands while permitting their mobility on the chest wall (see Figure 7.7). The round nipple is usually slightly elevated above the breast. On each breast the nipple projects slightly upward and laterally. It contains 4 to 20 openings from the milk ducts. The nipple is surrounded by fibromuscular tissue and covered by wrinkled skin (the *areola*). Except during pregnancy and lactation, there is usually no discharge from the nipple.

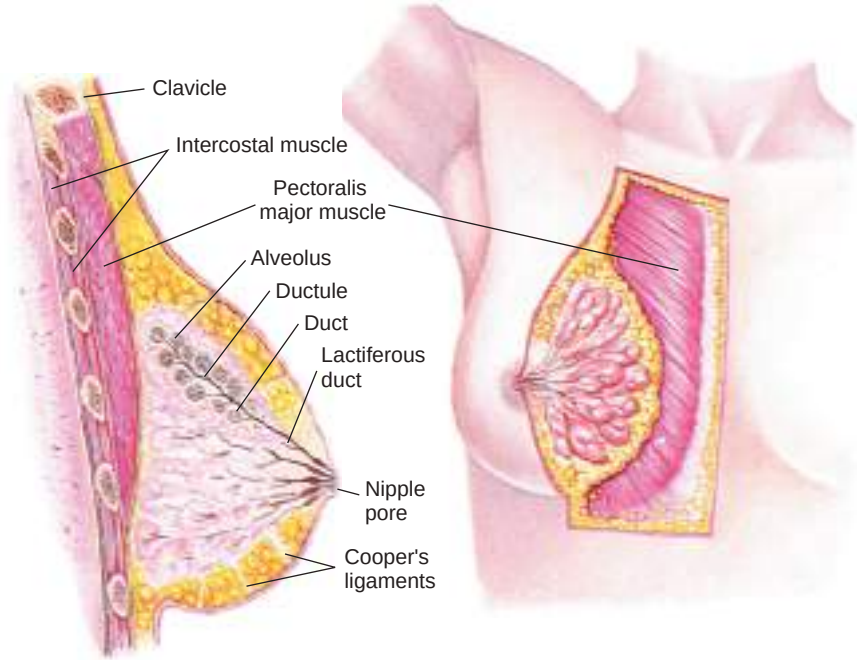

Fig. 7.7 Anatomy of the breast, showing position and major structures. (Adapted from Seidel, H. M., Stewart, R. W., Ball, J. W., et al. [2011]. *Mosby's guide to physical examination* [7th ed.]. Mosby.)

The nipple and surrounding areola are usually more deeply pigmented than the skin of the breast. The rough appearance of the areola is caused by sebaceous glands, Montgomery tubercles, directly beneath the skin. These glands secrete a fatty substance thought to lubricate the nipple. Smooth muscle fibres in the areola contract to cause the nipple to become erect, making it easier for the breastfeeding infant to grasp.

The vascular supply to the mammary gland is abundant. In the nonpregnant state, there is no obvious vascular pattern in the skin. The normal skin is smooth without tightness or shininess. The skin covering the breasts contains an extensive superficial lymphatic network that serves the entire chest wall and is continuous with the superficial lymphatic vessels of the neck and abdomen. The lymphatic vessels form a rich network in the deeper portions of the breasts. The primary deep lymphatic pathway drains laterally toward the axillae.

The breasts change in size and nodularity in response to cyclic ovarian changes throughout reproductive life. Increasing levels of both estrogen and progesterone in the 3 to 4 days before menstruation increase the vascularity of the breasts, induce growth of the ducts and acini, and promote water retention. The epithelial cells lining the ducts proliferate in number, the ducts dilate, and the lobules distend. The acini become enlarged and secretory, and lipid (fat) is deposited within their epithelial cell lining. As a result, breast swelling, tenderness, and discomfort are common symptoms just before the onset of menstruation. After menstruation, cellular proliferation begins to regress, acini begin to decrease in size, and retained water is lost. After breasts have undergone changes numerous times in response to the ovarian cycle, the proliferation and involution (**regression**) are not uniform throughout the breast. In time, after repeated hormonal stimulation, small persistent areas of nodulations may develop. This normal physiological change must be remembered when breast tissue is examined. Nodules may develop just before and during menstruation, when the breast is most active. The physiological alterations in breast size and activity reach their minimum level about 5 to 7 days after menstruation stops.

MENSTRUATION

Menarche and Puberty

Young girls secrete small, rather constant amounts of estrogen, but a marked increase in secretion occurs between 8 and 11 years of age. The term **menarche** denotes first menstruation. **Puberty** is a broader term that denotes the entire transitional stage between childhood and sexual maturity. Increasing amounts and variations in gonadotropin and estrogen secretion develop into a cyclic pattern at least a year before menarche. In North America this occurs in most females at about 13 years of age.

Initially, menstrual periods are irregular, unpredictable, painless, and anovulatory (no ovum is released from the ovary). After 1 or more years, a hypothalamic–**pituitary** rhythm develops, and the ovary produces adequate cyclic estrogen to make a mature ovum. Ovulatory (ovum released from the ovary) periods tend to be regular, with estrogen dominating the first half of the cycle and progesterone dominating the second half of the cycle.

Although pregnancy can occur in exceptional cases of true precocious puberty, most pregnancies in young patients occur after the normally timed menarche. It is important that young adolescents of both sexes are informed that pregnancy can occur at any time after the onset of menses.

Menstrual Cycle

Menstruation is the periodic uterine bleeding that begins approximately 14 days after **ovulation**. It is controlled by a feedback system of three cycles: endometrial, hypothalamic–pituitary, and ovarian. The average length of a menstrual cycle is 28 days, but variations are normal. The first day of bleeding is designated as day 1 of the menstrual cycle, or *menses* (Figure 7.8). The average duration of menstrual flow is 5 days (with a range of 3 to 6 days), and the average blood loss is 50 mL (with a range of 20 to 80 mL), but these vary greatly.

The menstrual blood clots within the uterus, but the clot usually liquefies before being discharged from the uterus. Uterine discharge includes mucus and epithelial cells in addition to blood.

The menstrual cycle is a complex interplay of events that occur simultaneously in the **endometrium**, the **hypothalamus**, the pituitary glands, and the ovaries. The menstrual cycle prepares the uterus for pregnancy. When pregnancy does not occur, menstruation follows. A patient's age, general health and emotional status, and environment influence the regularity of their menstrual cycles.

Endometrial Cycle. The four phases of the endometrial cycle are (1) the menstrual phase, (2) the proliferative phase, (3) the secretory phase, and (4) the ischemic phase (see Figure 7.8). During the *menstrual phase* shedding of the functional two-thirds of the endometrium (the compact and spongy layers) is initiated by periodic vasoconstriction in the upper layers of the endometrium. The basal layer is always retained, and regeneration begins near the end of the cycle from cells derived from the remaining glandular remnants or stromal cells in this layer.

The *proliferative phase* is a period of rapid growth lasting from about the fifth day to the time of ovulation. The endometrial surface is completely restored in approximately 4 days, or slightly before bleeding ceases. From this point on, an 8-fold to 10-fold thickening occurs, with a levelling off of growth at ovulation. The proliferative phase depends on estrogen stimulation derived from ovarian follicles.

The *secretory phase* extends from the day of ovulation to about 3 days before the next menstrual period. After ovulation, larger amounts of progesterone are produced. An edematous, vascular, functional endometrium is now apparent. At the end of the secretory phase, the fully matured secretory endometrium reaches the thickness of heavy, soft velvet. It becomes luxuriant with blood and glandular secretions, a suitable protective and nutritive bed for a fertilized ovum.

Implantation of the fertilized ovum generally occurs about 7 to 10 days after ovulation. If fertilization and implantation do not occur, the **corpus luteum**, which secretes estrogen and progesterone, regresses. With the rapid decrease in progesterone and estrogen levels, the spiral arteries go into spasm. During the *ischemic phase*, the blood supply to the functional endometrium is blocked and necrosis develops. The functional layer separates from the basal layer, and menstrual bleeding begins, marking day 1 of the next cycle (see Figure 7.8).

Hypothalamic–Pituitary Cycle. Toward the end of the normal menstrual cycle, blood levels of estrogen and progesterone decrease. Low blood levels of these ovarian **hormones** stimulate the hypothalamus to secrete gonadotropin-releasing hormone (GnRH). In turn, GnRH stimulates anterior pituitary secretion of follicle-stimulating hormone (FSH). FSH stimulates development of ovarian **graafian follicles** and their production of estrogen. Estrogen levels begin to decrease, and hypothalamic GnRH triggers the anterior pituitary to release luteinizing hormone (LH). A marked surge of LH and a smaller peak of estrogen (day 12) (see Figure 7.8) precede the expulsion of the ovum from the graafian follicle by about 24 to 36 hours. LH peaks at about day 13 or 14 of a 28-day cycle. If fertilization and implantation of the ovum have not occurred by this time, regression of the corpus luteum follows. Levels of progesterone and estrogen decline,

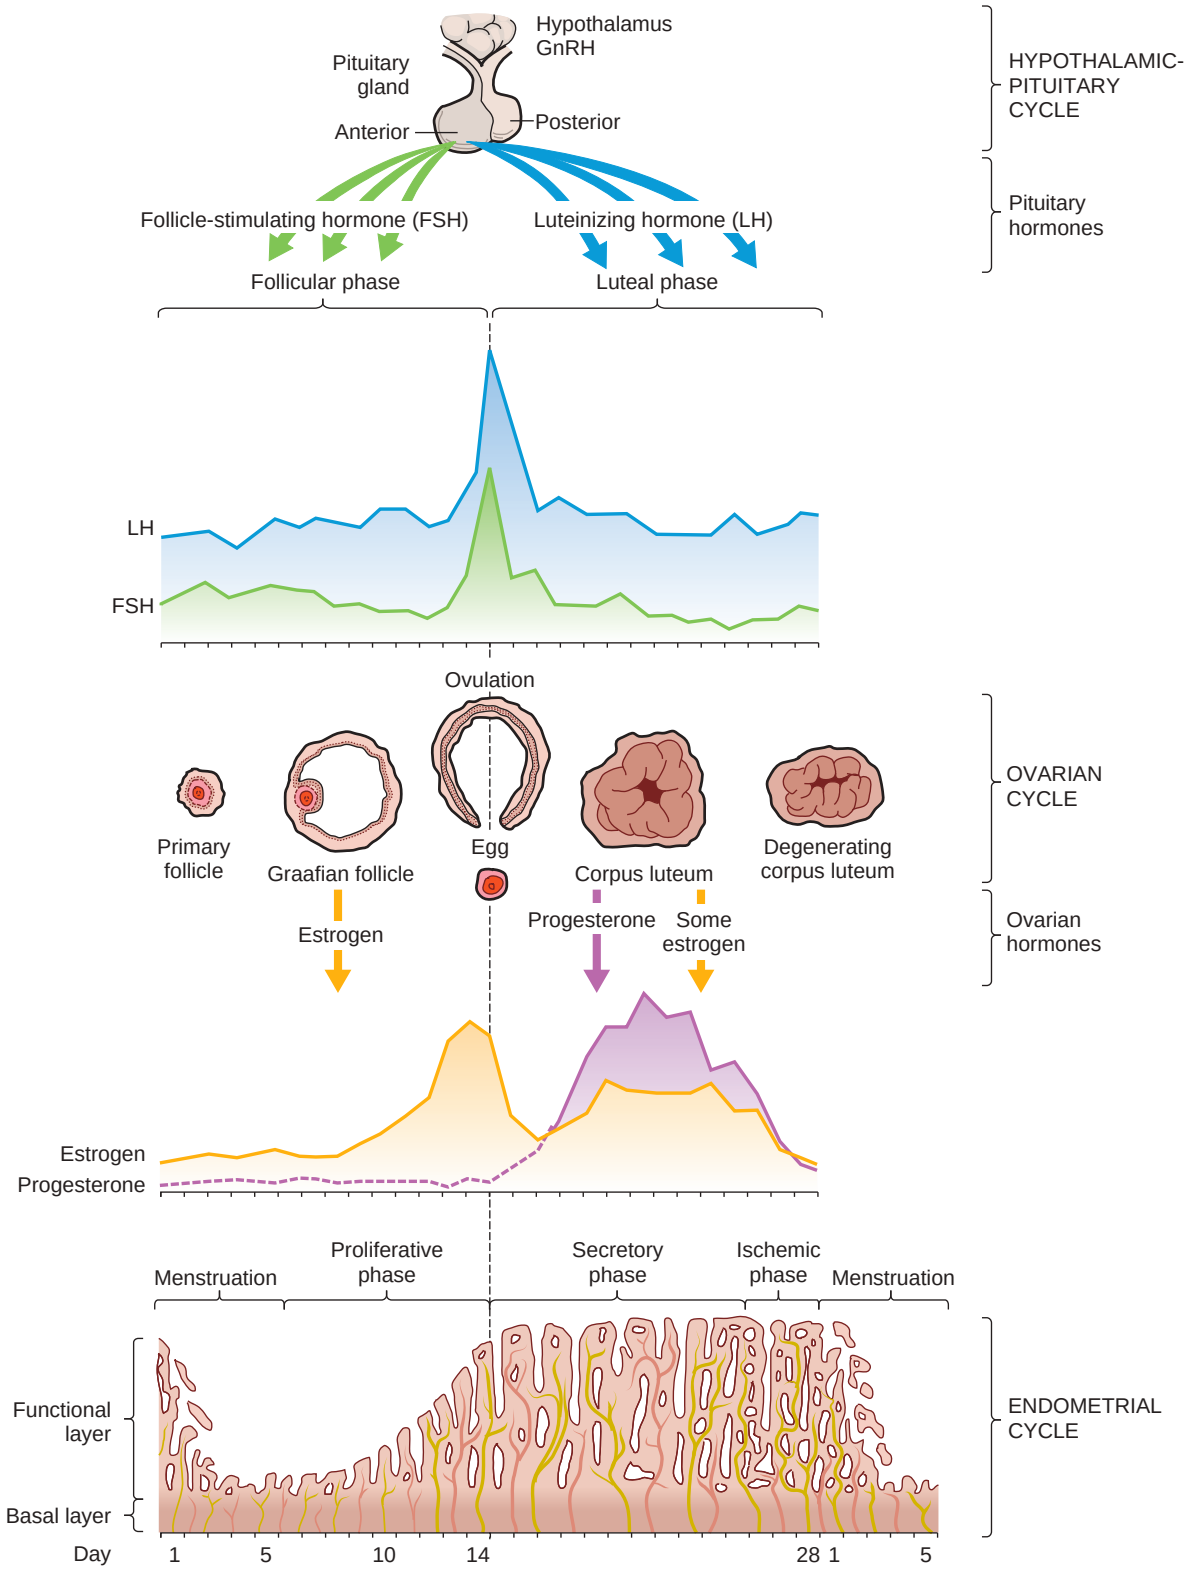

Fig. 7.8 Menstrual cycle: hypothalamic–pituitary, ovarian, and endometrial. *GnRH,* Gonadotropin-releasing hormone.

menstruation occurs, and the hypothalamus is once again stimulated to secrete GnRH. This process is called the *hypothalamic–pituitary cycle*.

Ovarian Cycle. The primitive graafian follicles contain immature oocytes (primordial ova). Before ovulation, from 1 to 30 follicles begin to mature in each ovary under the influence of FSH and estrogen. The preovulatory surge of LH affects a selected follicle. The oocyte matures, ovulation occurs, and the empty follicle begins its transformation into the corpus luteum. This *follicular phase* (preovulatory phase) (see Figure 7.8) of the ovarian cycle varies in length from person to person.

Almost all variations in ovarian cycle length are the result of variations in the length of the follicular phase. On rare occasions (i.e., 1 in 100 menstrual cycles) more than one follicle is selected, and more than one oocyte matures and undergoes ovulation.

After ovulation, estrogen levels drop. For 90% of people only a small amount of withdrawal bleeding occurs and it goes unnoticed. In 10% of people there is sufficient bleeding for it to be visible, resulting in what is termed *midcycle bleeding*.

The *luteal phase* begins immediately after ovulation and ends with the start of menstruation. This postovulatory phase of the ovarian cycle usually requires 14 days (range 13 to 15 days). The corpus luteum reaches its peak of functional activity 8 days after ovulation, secreting the steroids estrogen and progesterone. Coincident with this time of peak luteal functioning, the fertilized ovum is implanted in the endometrium. If no implantation occurs, the corpus luteum regresses, and steroid levels drop. Two weeks after ovulation, if fertilization and implantation do not occur, the functional layer of the uterine endometrium is shed through menstruation.

Other Cyclic Changes. When the hypothalamic–pituitary–ovarian axis functions properly, other tissues undergo predictable responses. Before ovulation, the woman's **basal body temperature** is often less than 37°C; after ovulation, with increasing progesterone levels, her basal body temperature rises. Changes in the cervix and cervical mucus follow a generally predictable pattern. Preovulatory and postovulatory mucus is viscous (thick) so that sperm penetration is discouraged. At the time of ovulation, cervical mucus is thin and clear. It looks, feels, and stretches like egg white. This stretchable quality is termed **spinnbarkeit**. Some women have localized lower abdominal pain, called **mittelschmerz**, that coincides with ovulation. Some spotting may occur.

Prostaglandins. *Prostaglandins* (PGs) are oxygenated fatty acids classified as hormones. The different kinds of prostaglandins are distinguished by letters (PGE and PGF), numbers (PGE_2), and letters of the Greek alphabet ($PGF_{2\alpha}$).

PGs are produced in most organs of the body, including the uterus. Menstrual blood is a potent PG source. PGs are metabolized quickly by most tissues. They are biologically active in minute amounts in the cardiovascular, gastrointestinal, respiratory, urogenital, and nervous systems. They also exert a marked effect on metabolism, particularly on glycolysis. PGs play an important role in many physiological, pathological, and pharmacological reactions.

PGs affect smooth muscle contractility and modulation of hormonal activity. Indirect evidence indicates that PGs have an effect on ovulation, fertility, changes in the cervix and cervical mucus that affect receptivity to sperm, tubal and uterine motility, sloughing of endometrium (menstruation), onset of miscarriage and induced abortion, and onset of labour (term and preterm).

After exerting their biological actions, newly synthesized PGs are rapidly metabolized by tissues in such organs as the lungs, kidneys, and liver.

PGs may play a key role in ovulation. If PG levels do not rise along with the surge of LH, the ovum remains trapped within the graafian follicle. After ovulation PGs may influence production of estrogen and progesterone by the corpus luteum.

The introduction of PGs into the vagina or the uterine cavity (from ejaculated semen) increases the motility of uterine musculature, which may assist the transport of sperm through the uterus and into the oviduct.

PGs produced by the patient cause regression of the corpus luteum and regression and sloughing of the endometrium, resulting in menstruation. PGs increase myometrial response to oxytocic stimulation, enhance uterine contractions, and cause cervical dilation. They may be a factor in the initiation of labour, the maintenance of labour, or both. They may also be involved in dysmenorrhea (see discussion later in chapter) and pre-eclampsia (see Chapter 14).

CONCERNS RELATED TO THE MENSTRUAL CYCLE

Generally, a person's menstrual frequency stabilizes at 28 days within 1 to 2 years after puberty, with a range of 26 to 34 days. Although no person's cycle is exactly the same length every month, the typical month-to-month variation in an individual's cycle is usually plus or minus 2 days. However, greater but still normal variations are commonly noted.

People typically have menstrual cycles for about 40 years. Once a cyclic, predictable pattern of monthly bleeding is established, patients may worry about any deviation from that pattern or from what they have been told is normal for all menstruating people. A patient may be concerned about their ability to conceive and bear children or believe that they are not really a woman without monthly menstruation. Amenorrhea or excess menstrual bleeding can be a source of severe distress and concern for a person.

Amenorrhea

Amenorrhea, the absence of menstrual flow, is a clinical sign of a variety of conditions. Generally, the following circumstances should be evaluated: (1) the absence of both menarche and secondary sexual characteristics by 13 years of age; (2) the absence of menses by 15 years of age, regardless of normal growth and development (**primary amenorrhea**); (3) the absence of menstruation within 5 years of breast development; or (4) a 6-month or more cessation of menses after a period of menstruation (**secondary amenorrhea**) (Lobo, 2017).

Someone who is moderately obese (20 to 30% above ideal weight) may have early-onset menstruation, whereas delay of onset is known to be related to malnutrition (starvation, such as that with anorexia). People who exercise strenuously before menarche can have delayed onset of menstruation, until about age 18 (Lobo, 2017).

Although amenorrhea is not a disease, it is often a sign of disease. It may occur from any defect or interruption in the hypothalamic–pituitary–ovarian–uterine axis (see Figure 7.8). It may also result from anatomical abnormalities such as outflow tract obstruction, anterior pituitary disorders, other endocrine disorders such as polycystic ovary syndrome (PCOS), hypothyroidism or hyperthyroidism, chronic diseases such as type 1 diabetes, medications such as phenytoin (Dilantin), substance use (opiates, marijuana, cocaine), eating disorders, strenuous exercise, emotional stress, or oral contraceptive use. Secondary amenorrhea is commonly the result of pregnancy.

Hypogonadotropic Amenorrhea. Hypogonadotropic amenorrhea reflects a problem in the central hypothalamic–pituitary axis. In rare instances a pituitary lesion or genetic inability to produce FSH and LH is at fault. However, Lobo (2017) has noted that patients without a lesion who had a low level of gonadotropins were believed to have primary pituitary failure, referred to as *hypogonadotropic hypogonadism*, but it has been noted that GnRH stimulation results in increased FSH and LH levels. This suggests a hypothalamic defect with lack of adequate GnRH synthesis or a defect in a central nervous system (CNS) neurotransmitter.

Hypogonadotropic amenorrhea often results from hypothalamic suppression as a result of stress (in the home, school, or workplace) or a sudden and severe weight loss, eating disorders, strenuous exercise, or mental illness. Research on the interaction between nervous system or neurotransmitter functions and hormone regulation throughout the

body has demonstrated a biological basis for the relation of stress to physiological processes. Patients who are more than 20% underweight for height or who have had rapid weight loss, and patients with eating disorders such as anorexia nervosa may report amenorrhea. Amenorrhea is one of the classic signs of anorexia nervosa. The interrelation of disordered eating, amenorrhea, and premature osteoporosis has been described as the female athlete triad (Mielke et al., 2015). A loss of calcium from the bone, comparable to that seen in postmenopausal patients, may occur with this type of amenorrhea.

Exercise-associated amenorrhea can occur in patients undergoing vigorous physical and athletic training and is thought to be associated with many factors, including body composition (height, weight, and percentage of body fat); type, intensity, and frequency of exercise; nutritional status; and presence of emotional or physical stressors. People who participate in sports emphasizing low body weight are at greatest risk. Such sports include the following (Lobo, 2017):

- Sports in which performance is subjectively scored (e.g., dance, gymnastics)
- Endurance sports favouring participants with low body weight (e.g., distance running, cycling)
- Sports in which body contour–revealing clothing is worn (e.g., swimming, diving, volleyball)
- Sports with weight categories for participation (e.g., rowing, martial arts)
- Sports in which prepubertal body shape favours success (e.g., gymnastics, figure skating)

Assessment of amenorrhea begins with a thorough history and physical examination. Specific components of the assessment process depend on the patient's age—adolescent, young adult, or perimenopausal—and whether they have menstruated previously.

An important initial step, often overlooked, is to be sure that the patient is not pregnant. Once pregnancy has been ruled out by a β-human chorionic gonadotropin (hCG) pregnancy test, diagnostic tests may include a complete blood count (CBC), urinalysis, and serum chemistries in order to rule out any systemic conditions. FSH level, thyroid-stimulating hormone (TSH) and prolactin levels, radiographic or computed tomography (CT) scan of the sellaturcica, a progestational challenge, and possible pelvic sonogram are performed (Lobo, 2017).

Collaborative care. For patients with amenorrhea caused by hypothalamic disturbances, the nurse is an ideal health professional to assist with this condition. Many of the causes are potentially reversible (e.g., stress, weight loss for nonorganic reasons). Counselling and education are primary interventions and appropriate nursing roles. When a stressor known to predispose a patient to hypothalamic amenorrhea is identified, initial management involves addressing the stressor. Together, the patient and nurse plan how the patient can decrease or discontinue medications known to affect menstruation, correct weight loss, deal more effectively with psychological stress, address emotional distress, and alter exercise routine.

The nurse can work with the patient to help them identify, cope with, and eliminate sources of stress in their life. Deep-breathing exercises and relaxation techniques are simple yet effective stress-reduction measures. Referral for biofeedback or massage therapy also may be useful. In some instances, referrals for psychotherapy may be indicated.

If a person's exercise program is thought to contribute to their amenorrhea, several options exist for management. They may decide to decrease the intensity or duration of their training or to modify their diet to include the appropriate nutrition for their age. Accepting the former alternative may be difficult for a person who is committed to a strenuous exercise regimen. The patient and nurse may have several sessions before the patient elects to try exercise reduction. Many young female athletes may not understand the consequences of low bone density or osteoporosis; nurses can point out the connection between low bone density and stress fractures. The nurse and patient should also investigate other factors that may be contributing to the amenorrhea and develop plans for altering lifestyle and decreasing stress.

Research on recommended dosages of calcium, vitamin D, and potassium is inconclusive for patients experiencing amenorrhea associated with the female athlete triad. Oral contraceptives may be helpful in amenorrheic patients but are usually not used in young patients with amenorrhea associated with the female athlete triad unless there are specific issues that warrant such treatment, which are best discussed with the patient's health care provider (Drakh, 2016).

Dysmenorrhea

Dysmenorrhea, or pain during or shortly before menstruation, is one of the most common gynecological concerns in patients of all ages. Symptoms usually begin with menstruation, although some patients have discomfort several hours before onset of flow. The range and severity of symptoms are different from person to person and from cycle to cycle in the same person. Symptoms of dysmenorrhea may last several hours or several days.

Many adolescents have dysmenorrhea in the first 3 years after menarche. Young adult patients ages 17 to 24 are most likely to report painful menses. Approximately 75% of patients report some level of discomfort associated with menses, and approximately 15% report severe dysmenorrhea (Mendiratta, 2017); however, the amount of disruption in patients' lives is difficult to determine. Menstrual issues, including dysmenorrhea, are relatively more common in patients who smoke and are obese. Severe dysmenorrhea is also associated with early menarche, nulliparity, and lack of physical exercise (Mendiratta, 2017). Traditionally, dysmenorrhea is differentiated as primary or secondary.

Primary Dysmenorrhea. **Primary dysmenorrhea** is a condition associated with ovulatory cycles. Research has shown that primary dysmenorrhea has a biochemical basis and arises from the release of prostaglandins with menses. During the luteal phase and subsequent menstrual flow, prostaglandin F_2-alpha ($PGF_{2\alpha}$) is secreted. Excessive release of $PGF_{2\alpha}$ increases the amplitude and frequency of uterine contractions and causes vasospasm of the uterine arterioles, resulting in ischemia and cyclic lower abdominal cramps. Systemic responses to $PGF_{2\alpha}$ include backache, weakness, sweats, gastrointestinal symptoms (anorexia, nausea, vomiting, and diarrhea), and CNS symptoms (dizziness, syncope, headache, and poor concentration). Pain usually begins at the onset of menstruation and lasts 12 to 72 hours (Mendiratta, 2017).

Primary dysmenorrhea is not caused by underlying pathology. Rather, it is the occurrence of a physiological alteration in some patients. Primary dysmenorrhea usually appears within 6 to 12 months after menarche when ovulation is established. Anovulatory bleeding, common in the first few months or years after menarche, is painless. Because both estrogen and progesterone are necessary for primary dysmenorrhea to occur, it is experienced only with ovulatory cycles. This is the most common menstrual symptom in patients in their late teens and early 20s; the incidence declines with age. Psychogenic factors may influence symptoms, but symptoms are definitely related to ovulation and do not occur when ovulation is suppressed.

Risk factors for dysmenorrhea include smoking or exposure to environmental tobacco smoke, frequent life changes, decreased social supports, stressful close relationships, and mood disorders, and there may be an increased prevalence of dysmenorrhea in lower socioeconomic groups (Burnett & Lemyre, 2017).

Collaborative care. Management of primary dysmenorrhea depends on the severity of the issue and an individual patient's response to various treatments. Patients with symptoms of primary dysmenorrhea may not seek medical assistance and frequently do not make use of the prescription therapies that are available, for a variety of reasons, including the belief that the pain is inevitable or lack of or limited accessibility to a health care provider. Education and support are important components of nursing care. Because menstruation is so closely linked to reproduction and sexuality, menstrual concerns such as dysmenorrhea can have a negative influence on a person's sense of sexuality and self-worth.

Nurses can correct myths and misinformation about menstruation and dysmenorrhea by providing facts about what is normal. Patients need support to foster their feelings of positive sexuality and self-worth.

Often, nurses can offer more than one alternative for alleviating menstrual discomfort and dysmenorrhea, giving patients options for deciding which works best for them. Several of these alternatives are discussed in the following paragraphs (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Management of Dysmenorrhea

Cheri, 16, has come to the adolescent health clinic for a checkup. She reports that she has "really bad cramps" for the first 2 days of her period. She has been taking Advil 200 mg every once in a while, but says that it does not help "a lot." She wants to know if anything else can be done to relieve her pain. How should the nurse respond?

Questions

1. Evidence—Is evidence sufficient to draw conclusions about what advice the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Causes and symptoms of primary dysmenorrhea
   b. Self-help strategies (e.g., comfort measures, medications)
3. What implications and priorities for nursing care can be drawn at this time?

Complementary and alternative health modalities (CAM) have become increasingly popular as a therapy for dysmenorrhea. The use of heat (heating pad or hot bath) minimizes cramping by increasing vasodilation and muscle relaxation and minimizing uterine ischemia. Massaging the lower back can reduce pain by relaxing paravertebral muscles and increasing the pelvic blood supply. Soft, rhythmic rubbing of the abdomen (effleurage) is useful because it provides a distraction and an alternative focal point. High-frequency transcutaneous electrical nerve stimulation (TENS) in combination with heat therapy has been shown to be helpful in alleviating pain (Burnett & Lemyre, 2017).

Behavioural interventions such as biofeedback, desensitization, breathing, hypnotherapy, and relaxation training can also be used to decrease menstrual discomfort, although evidence is inconclusive regarding their effectiveness (Barnett & Lemyre, 2017). Acupuncture and acupressure may also provide benefit, although research trials have not been well done. Behavioural therapies and acupuncture/acupressure are probably most useful as an adjunct to pharmacological therapy or in patients who prefer an alternative to medication (Burnett & Lemyre, 2017).

Aerobic exercise has also been found to help alleviate pain (Mendiratta, 2017). Exercise may help relieve menstrual discomfort through increased vasodilation and subsequent decreased ischemia. It also releases endogenous opiates (specifically beta-endorphins), suppresses prostaglandins, and shunts blood flow away from the viscera, resulting in reduced pelvic congestion. Research shows a reduction in dysmenorrhea with exercise, although the evidence is not strong. Assuming that exercise is unlikely to result in harm, it is reasonable to recommend it to patients, even without strong supportive evidence from randomized trials (Burnett & Lemyre, 2017).

In addition to maintaining good nutrition at all times, specific dietary changes may be helpful in decreasing some of the systemic symptoms associated with dysmenorrhea. Ginger supplementation taken during the first 3 to 4 days of menstruation may be comparable to the use of nonsteroidal anti-inflammatory drugs (NSAIDs). Although good-quality research is lacking, there is some evidence for the use of fenugreek, fish oil, fish oil plus vitamin B_1, valerian, vitamin B_1 alone, zataria, and zinc sulphate (Burnett & Lemyre, 2017). Herbal preparations, including Chinese herbal medicine, have long been used for management of menstrual issues, including dysmenorrhea (Table 7.1). However, it is essential that patients understand that these therapies are not without potential toxicity and may cause medication interactions.

! NURSING ALERT

Nurses must routinely ask patients about the use of herbal and other alternative therapies and document their use. Nurses need to be aware of the potential for medication interactions with some herbal therapies.

TABLE 7.1 Herbal Medicinals Taken Orally for Menstrual Disorders

Symptoms or Indications	Herbal Therapy*	Action
Menstrual cramping, dysmenorrhea	Black haw	Uterine antispasmodic
	Fennel	Uterotonic
	Catnip	Uterine antispasmodic
	Dong quai	Uterotonic; anti-inflammatory
	Ginger	Anti-inflammatory
	Motherwort	Uterotonic
	Wild yam	Uterine antispasmodic
	Valerian	Uterine antispasmodic
	Potentilla	Anti-inflammatory
Premenstrual discomfort, tension	Black cohosh root	Estrogen-like luteinizing hormone suppressant; binds to estrogen receptors
	Chamomile	Antispasmodic
Breast pain	Chaste tree fruit	Decreases prolactin levels
	Bugleweed	Antigonadotropic; decreases prolactin levels
Menorrhea, metrorrhagia	Lady's mantle	Uterotonic
	Raspberry	Uterotonic
	Shepherd's purse	Uterotonic

*Many women's herbs do not have rigorous scientific studies backing their use; most uses and properties of herbs have not been validated by Health Canada.

Data from Annie's Remedy. (2018). *Dysmenorrhea—Herbs for painful periods*. http://www.anniesremedy.com/chart_remedy_dysmenorrhea.php; National Center for Complementary and Alternative Medicine. (2019). *Herbs at a glance*. https://nccih.nih.gov/health/herbsataglance.htm

TABLE 7.2 Medications Used to Treat Dysmenorrhea

Medication	Recommended Dosage (Oral)	Common Adverse Effects	Comments
diclofenac (Voltaren)	50 mg tid or 100 mg initially, then 50 mg tid up to 150 mg/day	Nausea, diarrhea, constipation, abdominal distress, dyspepsia, heartburn, flatulence, dizziness, tinnitus, itching, rash	Enteric coated; immediate release
ibuprofen (Motrin, Advil)	400 mg q6–8h, 200 mg q4–6h up to max 1 200 mg/day	See diclofenac	If GI upset occurs, take with food, milk, or antacids; avoid alcoholic beverages; do not take with Aspirin; stop taking and call health care provider if rash occurs
naproxen	500 mg initially, then 250 mg q6–8 h or 500 mg q12h; not to exceed 1 250 mg/day on day 1; subsequent doses should not exceed 1 000 mg/day	See diclofenac	See ibuprofen
mefenamic acid	500 mg initially, then 150 mg q6h/day	See diclofenac	Very potent and effective prostaglandin-synthesis inhibitor; antagonizes already formed prostaglandins; increased incidence of adverse GI effects
acetaminophen	325–650 mg q4–6h; to maximum 4 g/day	Good GI tolerance Can cause liver damage with 3 or more alcoholic drinks/day	Does not have antiprostaglandin property of NSAIDs

Note: Risk with all NSAIDs is gastrointestinal ulceration, possible bleeding, and prolonged bleeding time. Incidence of adverse effects is dose related. Reported incidence, 1 to 10%. Do not give if patient has hemophilia or bleeding ulcers; do not give if patient has had an allergic or anaphylactic reaction to Aspirin or another NSAID; do not give if patient is taking anticoagulant medication.
GI, Gastrointestinal; *NSAID,* nonsteroidal anti-inflammatory drug; *tid,* three times daily.
Data from Calis, K. A. (2016). Dysmenorrhea medication. *Medscape*. http://emedicine.medscape.com/article/253812-medication#2; Mendiratta, V. (2017). Primary and secondary dysmenorrhea, premenstrual syndrome, and premenstrual dysphoric disorder: Etiology, diagnosis, and management. In R. A. Lobo, D. M. Gershenson, G. M. Lentz, et al. (Eds.), *Comprehensive gynecology* (7th ed.). Elsevier.

Medications used to treat primary dysmenorrhea in patients not desiring contraception include prostaglandin synthesis inhibitors, primarily NSAIDs (Table 7.2). NSAIDs are most effective if started with the onset of bleeding or associated symptoms and are usually not required for more than 2 or 3 days (Barnett & Lemyre, 2017). All NSAIDs have potential gastrointestinal adverse effects, including nausea, vomiting, and indigestion. All patients taking NSAIDs should be warned to report dark-coloured stools, which may be an indication of gastrointestinal bleeding. Approximately 80% of dysmenorrheic patients obtain relief with prostaglandin inhibitors.

Over-the-counter (OTC) preparations indicated for primary dysmenorrhea contain the same active ingredients (e.g., ibuprofen or naproxen sodium) as those in prescription preparations. However, the labelled recommended dose may be subtherapeutic. Acetaminophen may also be used, although it is probably less effective than NSAIDs because acetaminophen does not have the antiprostaglandin properties of NSAIDs. Acetaminophen causes fewer gastrointestinal symptoms.

! NURSING ALERT

If one NSAID is ineffective, often a different one may be effective. If the second medication is unsuccessful after a 6-month trial, combined oral contraceptive pills may be used. Patients with a history of Aspirin sensitivity or allergy should avoid using all NSAIDs.

Combined oral contraceptives (COCs), which contain both progesterone and estrogen, are a reasonable choice for patients who may want to use contraception. COCs are effective in relieving symptoms of primary and secondary dysmenorrhea. The benefit of a COC is that it suppresses ovulation and endometrial tissue growth, attributing to decreased prostaglandin synthesis and decreased menstrual blood flow and uterine cramping (Burnett & Lemyre, 2017). Extended-cycle or continuous hormonal contraception (CHC) has been found to be superior to cyclical regimens for pain relief in dysmenorrhea (Burnett & Lemyre, 2017). Since COCs have adverse effects, patients may not wish to use them for dysmenorrhea, and they may be contraindicated for some patients. (See Chapter 8 for a complete discussion of oral contraceptives.) Depot medroxyprogesterone acetate (DMPA) works by suppressing ovulation, which results in relief of dysmenorrhea symptoms. Continuous oral progestin may also be a useful alternative to CHC with comparable pain relief and fewer adverse effects (Burnett & Lemyre, 2017). Levonorgestrel intrauterine system (LNG-IUS) is an intrauterine system that releases progestin inside the uterine cavity, causing a local effect on the endometrium, and can be considered for use with primary or secondary dysmenorrhea.

If dysmenorrhea is not relieved by one of the NSAIDs or COCs, further investigation into the cause of the symptoms is necessary.

Secondary Dysmenorrhea. *Secondary dysmenorrhea* is menstrual pain that develops later in life than primary dysmenorrhea, typically after age 25. It is associated with an underlying pelvic pathology such as adenomyosis, endometriosis, pelvic inflammatory disease, endometrial polyps, or submucous or interstitial myomas (fibroids). Patients with secondary dysmenorrhea often have other symptoms that may suggest the underlying cause. For example, heavy menstrual flow with dysmenorrhea suggests a diagnosis of leiomyomata, adenomyosis, or endometrial polyps. Pain associated with endometriosis often begins a few days before menses but can be present at ovulation and continue

through the first days of menses or start after menstrual flow has begun. In contrast to primary dysmenorrhea, the pain of secondary dysmenorrhea is often characterized by dull, lower abdominal aching that radiates to the back or thighs. Often patients experience feelings of bloating or pelvic fullness. In addition to a physical examination with a careful pelvic examination, diagnosis may be assisted by ultrasound examination, **dilation and curettage (D&C)**, endometrial biopsy, or laparoscopy.

Treatment is directed toward removal of the underlying pathology. Many of the measures described for pain relief of primary dysmenorrhea are also helpful for patients with secondary dysmenorrhea. Surgical options may be used to decrease the pain when other medical alternatives have been refused or were unsuccessful, and hysterectomy can be considered when all other options have not worked and fertility is no longer a consideration (see the Nursing Process box on Evolve).

Premenstrual Syndrome

Approximately 75% of people experience premenstrual symptoms at some time in their reproductive lives (Mendiratta, 2017). Establishing a universal definition of **premenstrual syndrome (PMS)** is difficult, given that so many symptoms have been associated with the condition and at least two different syndromes have been recognized: PMS and **premenstrual dysphoric disorder (PMDD)**.

A diagnosis of PMS is made when a specific group of symptoms consistent with PMS occurs in the luteal phase, to such a degree that lifestyle or work is affected, and is followed by a symptom-free week leading up to ovulation at midcycle (Reid & Soares, 2018). PMS symptoms include fluid retention (abdominal bloating, pelvic fullness, edema of the lower extremities, breast tenderness, and weight gain); behavioural or emotional changes (depression, crying spells, irritability, panic attacks, and impaired ability to concentrate); premenstrual cravings (sweets, salt, increased appetite, and food binges); headache; fatigue; and backache.

All age groups are affected, with patients in their 20s and 30s most frequently reporting symptoms. Ovarian function is necessary for the condition to occur. PMS does not occur before puberty, after menopause, or during pregnancy. The condition is not dependent on the presence of monthly menses; patients who have had a hysterectomy without bilateral salpingo-oophorectomy (BSO) still can have cyclic symptoms.

PMDD is a more severe variant of PMS in which 3 to 8% of people have marked irritability, dysphoria, mood lability, anxiety, fatigue, appetite changes, and a sense of feeling overwhelmed (Mendiratta, 2017). The most common symptoms are those associated with mood disturbances. Box 7.1 lists the criteria that must be met for a diagnosis of PMDD.

While the etiology of PMS and PMDD is not clear, there is general agreement that they are distinct psychiatric and medical syndromes rather than an exacerbation of an underlying psychiatric disorder. They do not occur if there is no ovarian function. A number of biological and neuroendocrine etiologies have been suggested; however, none have been substantiated conclusively as the causative factor. Reproductive hormones, genetic predisposition, and psychological stress may all contribute to the expression of premenstrual symptoms (Reid & Soares, 2018).

Collaborative Care. There is little agreement on management of PMS. A careful, detailed history and daily log of symptoms and mood fluctuations spanning several cycles may give direction to a plan of management. When a single symptom is distressing, a symptom-based approach to therapy may be sufficient (Reid & Soares, 2018). Any changes that assist a patient with PMS to exert control over their life have a positive impact. For this reason, lifestyle changes may be effective in its treatment.

BOX 7.1 Diagnosis of Premenstrual Dysphoric Disorder (PMDD)

At least 5 of the following 11 symptoms should be experienced during most cycles over the previous 12 months. Of note, at least one of the symptoms listed in bold (numbers 1–4) should be present.

1. **Depressed mood**
2. **Anxiety, tension**
3. **Affective lability**
4. **Anger, irritability**
5. Decreased interest in usual activities
6. Difficulty in concentrating
7. Lack of energy, fatigue
8. Change in appetite, food cravings
9. Changes in sleep (hypersomnia, insomnia)
10. Feeling overwhelmed, "out of control"
11. Physical discomforts such as breast tenderness, joint pains, headaches, bloating, weight gain

Also:

PMDD interferes markedly with usual activities (work, school, social, relationships).

PMDD is NOT a mere exacerbation of an underlying condition (e.g., depression, anxiety).

PMDD should be confirmed by prospective daily ratings for two consecutive cycles.

Source: Reid, R., & Soares, C. (2018). Premenstrual dysphoric disorder: Contemporary diagnosis and management. *Journal of Obstetrics & Gynaecology Canada, 40*(2), 215–223.

Education is an important component of the management of PMS. Nurses can advise patients that self-help modalities often result in significant symptom improvement. Patients have found a number of complementary and alternative therapies to be useful in managing the symptoms of PMS. Diet and exercise changes are a useful way to begin and may provide symptom relief for some people. Nurses can suggest that patients not smoke and limit their consumption of refined sugar, salt, red meat, alcohol, and caffeinated beverages. Patients can be encouraged to include whole grains, legumes, seeds, nuts, vegetables, fruits, and vegetable oils in their diets; reduce the amount of salt, sugar, and caffeine in their diets; and incorporate 60 minutes or more of physical exercise daily (a monthly program that varies in intensity and type of exercise according to PMS symptoms is best). Patients who exercise regularly seem to have less premenstrual anxiety than do nonathletic patients. Researchers believe aerobic exercise increases beta-endorphin levels to offset symptoms of depression and to elevate mood.

The use of natural diuretics may help reduce fluid retention. Nutritional supplements may assist in symptom relief. Calcium and vitamin B_6 have been shown to be moderately effective in relieving symptoms, to have few adverse effects, and to be safe. Daily supplements of evening primrose oil are reportedly useful in relieving breast symptoms with minimal side effects, but research reports are conflicting. Chasteberry has been found to alleviate symptoms of PMS (Jafari & Orenstein, 2015). Other herbal therapies have long been used to treat PMS, although research on their effectiveness and safety is not conclusive; specific suggestions are found in Table 7.1.

Nurses can explain to patients the relation between cyclic estrogen fluctuation and changes in serotonin levels, which can lead to mood changes. Serotonin is one of the brain chemicals that assists in coping with normal life stresses, and there are different management strategies available to help maintain serotonin levels. Support groups or individual or couple counselling may also be helpful in managing PMS. Stress-reduction techniques may assist with symptom management.

If these and other nonpharmacological strategies do not provide significant symptom relief in 1 to 2 months, medication is often added. Many medications have been used in the treatment of PMS, but no single medication alleviates all PMS symptoms. Medications often used in the PMS treatment include diuretics, prostaglandin inhibitors (NSAIDs), and COCs. These have been used mainly for the physical symptoms. Studies of progesterone have not shown it to be an effective treatment (Mendiratta, 2017). Serotonergic-activating agents, including the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac), sertraline (Zoloft), and paroxetine (Paxil), are used as first-line pharmacological therapy. Use of these medications during the luteal phase of the menstrual cycle has been shown to result in a decrease in emotional premenstrual symptoms, especially depression (Mendiratta, 2017; Reid & Soares, 2018). Common adverse effects of these medications are headaches, sleep disturbances, dizziness, weight gain, dry mouth, and decreased libido.

Endometriosis

Endometriosis is characterized by the presence and growth of endometrial tissue outside of the uterus. The tissue may be implanted on the ovaries; anterior and posterior cul-de-sac; broad, uterosacral, and round ligaments; rectovaginal septum; sigmoid colon; appendix; pelvic peritoneum; cervix; and inguinal area (Figure 7.9). Endometrial lesions have been found in the vagina and in surgical scars, as well as on the vulva, perineum, and bladder. Lesions have also been found on sites far from the pelvic area, such as the thoracic cavity, gallbladder, and heart. A cystic lesion of endometriosis found in the ovary is sometimes described as a "chocolate cyst" because of the dark colouring of the contents of the cyst, caused by the presence of old blood.

Endometrial tissue responds to cyclic hormone stimulation in the same way that the uterine endometrium does, but often out of phase with it. The endometrial tissue grows during the proliferative and secretory phases of the cycle. During or immediately after menstruation, the tissue bleeds, resulting in an inflammatory response with subsequent fibrosis and adhesions to adjacent organs.

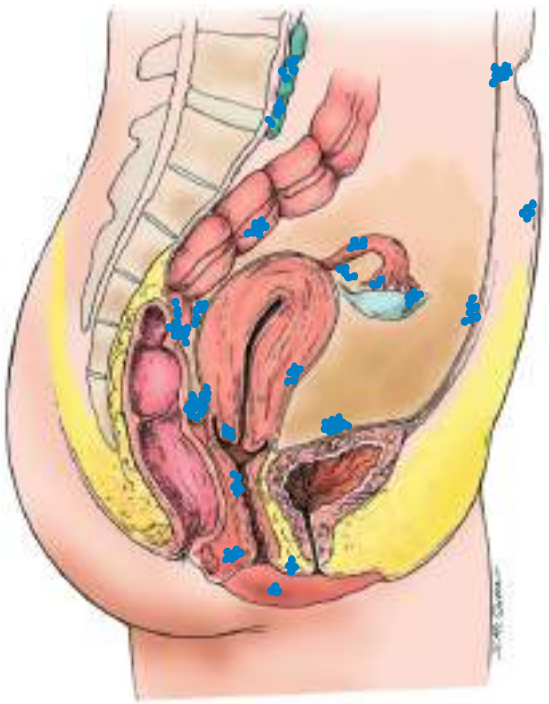

Fig. 7.9 Common sites of endometriosis *(identified in blue).* (From Lentz, G. M., Lobo, D. M., Gershenson, D. M., et al. [2017]. *Comprehensive gynecology* [7th ed.]. Elsevier.)

The overall incidence of endometriosis is 5 to 15% in reproductive-age patients, 30 to 45% in infertile patients, and 33% in patients with chronic pelvic pain (Advincula et al., 2017). Although the condition usually develops in the third or fourth decade of life, endometriosis has been found in adolescents, with disabling pelvic pain or abnormal vaginal bleeding. Currently it is estimated that approximately 50% of teens with pelvic pain have endometriosis (Advincula et al., 2017). Endometriosis may worsen with repeated cycles, or it may remain asymptomatic and undiagnosed, eventually disappearing after menopause. However, it has been reported to occur in about 5% of postmenopausal patients receiving menopausal hormone therapy.

Symptoms ranging from nonexistent to incapacitating vary among patients. The severity of symptoms can change over time and may not reflect the extent of the disease. The major symptoms of endometriosis are pelvic pain, dysmenorrhea, and dyspareunia (painful intercourse). Patients may also have chronic noncyclic pelvic pain, pelvic heaviness, or pain radiating into the thighs. Many people report bowel symptoms such as diarrhea, pain with defecation, and constipation caused by avoiding defecation because of the pain. Other symptoms include abnormal bleeding (hypermenorrhea, menorrhagia, or premenstrual staining) and pain during exercise as a result of adhesions (Advincula et al., 2017).

Impaired fertility may result from adhesions around the uterus that pull the uterus into a fixed, retroverted position. Adhesions around the uterine tubes may block the fimbriated ends or prevent the spontaneous movement that carries the ovum to the uterus.

Collaborative Care. Treatment is based on the severity of symptoms and the goals of the person or couple. Patients with endometriosis must be assessed for the level of pain they experience, their pain coping strategies, and the impact of the pain on their life. Patients without pain who do not want to become pregnant need no treatment. In patients with mild pain who may desire a future pregnancy, treatment may be limited to use of NSAIDs during menstruation (see earlier discussion of these medications).

Patients who have early symptomatic disease and who can postpone pregnancy may be treated with COCs that have a low estrogen-to-progestin ratio to shrink endometrial tissue. The CHCs are taken continuously for 6 to 12 months, without any withdrawal time of the CHC. This approach is believed to lead to a more complete suppression, thus decreasing the endometriosis (Advincula et al., 2017). Any low-dose CHCs can be used if taken for 15 weeks, followed by 1 week of withdrawal. This therapy is associated with minimal adverse effects and can be taken for extended periods. Limited data exist on the effectiveness of progestogen-only medications for treating pain related to endometriosis. CHCs, the estrogen/progestin patch, or estrogen/progestin vaginal ring for menstrual suppression and administration of NSAIDs are the usual treatment for adolescents under the age of 16 who have endometriosis.

Suppression of endogenous estrogen production and subsequent endometrial lesion growth is another method of disease management. Two main classes of medications are used to suppress endogenous estrogen levels: GnRH agonists and androgen derivatives. GnRH agonist therapy (leuprolide [Lupron, Eligard], nafarelin [Synarel], and goserelin acetate [Zoladex]) acts by suppressing pituitary gonadotropin secretion. FSH and LH stimulation of the ovary declines markedly, and ovarian function decreases significantly. A medically induced menopause develops, resulting in anovulation and amenorrhea. Shrinkage of already established endometrial tissue, significant pain relief, and interruption in further lesion development follow. The hypoestrogenism results in hot flashes in almost all patients. Trabecular

bone loss is common, although most loss is reversible within 12 to 24 months after the medication is stopped (Advincula et al., 2017).

Leuprolide (3.75 mg intramuscular injection given once a month), nafarelin (200 mg administered twice daily by nasal spray), and goserelin (3.6 mg every 28 days by subcutaneous implant) are effective and well tolerated. These medications reduce endometrial lesions and pelvic pain associated with endometriosis and have post-treatment pregnancy rates similar to those of danazol (Cyclomen) therapy (Jarrell et al., 2018). Common adverse effects of these medications are those of natural menopause—hot flashes and vaginal dryness. Occasionally, patients report headaches and muscle aches. Treatment is usually limited to 6 months, to minimize bone loss. Although unlikely, it is possible for a patient to become pregnant while taking a GnRH agonist. Because the potential teratogenicity of this medication is unclear, patients should use a barrier contraceptive during treatment. GnRH agonist therapy for severe symptoms may have possible adverse effects on bone mineralization in adolescents, thus bone mineral density should be carefully monitored.

Danazol, a mildly androgenic synthetic steroid, suppresses FSH and LH secretion, thus producing anovulation and hypogonadotropism. This results in decreased secretion of estrogen and progesterone and regression of endometrial tissue. Danazol can produce adverse effects severe enough to cause discontinuation of the medication. Adverse effects include masculinizing traits in the patient (weight gain, edema, decreased breast size, oily skin, hirsutism, and deepening of the voice), all of which often disappear when treatment is discontinued. Other adverse effects are amenorrhea, hot flashes, vaginal dryness, insomnia, and decreased libido. Danazol should never be prescribed when pregnancy is suspected, and barrier contraception should be used with it because ovulation may not be suppressed. Danazol can produce pseudohermaphroditism in female fetuses. The medication is contraindicated in patients with liver disease and should be used with caution in patients with cardiac and renal disease. Danazol should be given for a minimum of 3 months before other medical options are considered (Jarrell et al., 2018).

Surgical intervention is often needed for severe, acute, or incapacitating symptoms. Decisions regarding the extent and type of surgery are influenced by a patient's age, their desire for children, and location of the disease. For patients who do not want to preserve their ability to have children, the only definite cure is total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH with BSO). In patients who are in their childbearing years and want children, reproductive capacity should be retained through the use of laparoscopic surgery, which may help decrease pain and subfertility associated with mild to moderate endometriosis. Laparoscopic excision and ablation treats the causes of pain and subfertility by destroying or removing all visible endometriotic lesions and repairing damaged organs and other sites (Duffy et al., 2014).

Regardless of the type of treatment (short of TAH with BSO), endometriosis recurs in approximately 40% of patients. Thus, for many people, endometriosis is a chronic illness with conditions such as persistent pain or infertility. Counselling and education are critical components of nursing care for patients with endometriosis. Patients need an honest discussion of treatment options, with potential risks and benefits of each option reviewed. Because pelvic pain is a subjective, personal experience that can be frightening, support is important. Listening to patients, understanding their concerns, avoiding disease labelling, explaining plainly what is known and what is unknown, and giving constant reassurance and encouragement may be exceedingly important for the successful management of endometriosis and may change the patient's perception of the clinical condition. Providing empathy may help a person to successfully cope with the disease (Vercellini et al., 2017). Sexual dysfunction resulting from dyspareunia is common and may necessitate referral for counselling. Support groups for people with endometriosis may be found in some locations. The nursing care discussed in the previous section on dysmenorrhea is appropriate for managing persistent pelvic pain and dysmenorrhea experienced by patients with endometriosis (see Evolve resources for Nursing Care Plan for Patient With Endometriosis).

Alterations in Cyclic Bleeding

Some patients experience changes in amount, duration, interval, or regularity of menstrual cycle bleeding. Commonly, patients worry about menstruation that is infrequent **(oligomenorrhea)**, is scanty at normal intervals **(hypomenorrhea)**, is excessive **(menorrhagia)**, or occurs between periods **(metrorrhagia)**.

Treatment depends on the cause and may include education and reassurance. For example, nurses should explain to patients that oral contraceptive pills (OCPs) can cause scanty menstrual flow and midcycle spotting. Progestin intramuscular injections and implants can also cause midcycle bleeding. A single episode of heavy bleeding may signal an early pregnancy loss, such as a miscarriage or ectopic pregnancy. This type of bleeding is often thought to be a period that is heavier than usual, perhaps delayed, and is associated with abdominal pain or pelvic discomfort. When early pregnancy loss is suspected, hematocrit and pregnancy tests are indicated.

Uterine **leiomyomas** (fibroids or myomas) are a common cause of menorrhagia. Fibroids are benign tumours of the smooth muscle of the uterus with an unknown cause. Fibroids occur in approximately 70% of patients, with about 50% having symptoms (Ryntz & Lobo, 2017). Other uterine growths ranging from endometrial polyps to adenocarcinoma and endometrial cancer are common causes of heavy menstrual bleeding and intermenstrual bleeding.

! NURSING ALERT

If the person considers the amount or duration of bleeding to be excessive, the concern should be investigated.

Treatment for menorrhagia depends on the cause of the bleeding. If the bleeding is related to contraceptive method (e.g., an intrauterine device [IUD]), provide factual information and reassurance and discuss other contraceptive options. Tranexamic acid (an antifibrolytic agent) has also been shown to be effective in reducing menstrual blood loss between 40 and 59% from baseline (Singh et al., 2018).

If there is no known cause for the bleeding and anatomical causes have been ruled out, therapy is aimed at reducing the amount of heavy bleeding. Current options for treatment include OCPs, NSAIDs, and other therapies: the levonorgestrel-releasing IUD, danazol, and antifibrinolytic agents (e.g., tranexamic acid) (Ryntz & Lobo, 2017; Singh et al., 2018).

If bleeding is related to the presence of fibroids, the degree of disability and discomfort associated with the fibroids and the person's plans for childbearing influence treatment decisions. Treatment options include medical and surgical management. Most fibroids can be monitored by frequent examinations to judge growth, if any, and correction of anemia if present. Patients with metrorrhagia should be warned to avoid using Aspirin because of its tendency to increase bleeding. Medical treatment is directed toward temporarily reducing symptoms, shrinking the myoma, and reducing its blood supply (Ryntz & Lobo, 2017; Singh et al., 2018). This reduction is often accomplished with the use of a GnRH agonist. However, usually after cessation of this treatment, the myomas return to their pretreatment size (Singh et al., 2018). If the person wishes to retain childbearing potential, a

myomectomy may be performed. Myomectomy, or removal of the tumours only by laparoscopic or hysteroscopic resection or laser surgery, is particularly difficult if multiple myomas must be removed. One in four patients will have a hysterectomy performed within 20 years of having a myomectomy. If the person does not want to preserve their childbearing function or if they have severe symptoms (severe anemia, severe pain, considerable disruption of lifestyle), uterine artery embolization (UAE; a procedure that blocks blood supply to fibroid) or hysterectomy (removal of uterus) may be performed. After UAE, 20 to 30% of women will undergo a hysterectomy within 5 years (Ryntz & Lobo, 2017).

Nursing roles include informing patients of their options, counselling and education as indicated, and referring patients to the appropriate specialists and health care services.

Abnormal Uterine Bleeding

Abnormal uterine bleeding (AUB) may be defined as any variation from the normal menstrual cycle and includes changes in regularity and frequency of menses, in duration of flow, or in amount of blood loss, as well as bleeding **that is not related to menses**. AUB is a common condition affecting patients of reproductive age that has significant social and economic impact due to loss of work time and possible decreased social interactions (Singh et al., 2018). Box 7.2 lists possible causes of AUB. Inherited bleeding disorders may be an underlying cause of AUB, with von Willebrand's disease present in the majority of cases (Singh et al., 2018), and should be considered when other causes cannot be determined.

Collaborative Care. The selection of a treatment for AUB will depend on the impact of the bleeding on the patient's overall health (Singh et al., 2018).

Acute bleeding episode. The most effective medical treatment of acute bleeding episodes of AUB is administration of high-dose estrogen and tranexamic acid. Surgery would only be done as a last resort because of the high morbidity associated with operating on patients with acute anemia and the resulting impaired healing, further bleeding, and infection. Surgical options in the acute setting include uterine curettage and hysteroscopic ablation, hysterectomy, and uterine artery embolization (Singh et al., 2018).

Once the acute phase has passed, the patient is maintained on an oral conjugated estrogen and progestin regimen for at least 3 months. Such long-term treatment will help prevent recurrence of the pattern of AUB and hemorrhage. If the person wants contraception, they should continue to take OCPs. If the person has no need for contraception, the treatment may be stopped to assess their bleeding pattern. If their menses do not resume, a progestin regimen 10 days before the expected date of their menstrual period may be prescribed. This is done to prevent persistent anovulation with chronic unopposed endogenous estrogen hyperstimulation of the endometrium, which can result in eventual atypical tissue changes (Singh et al., 2018).

PERIMENOPAUSE AND MENOPAUSE

The **climacteric** is a transitional phase during which ovarian function and hormone production decline. This phase spans the years from the onset of premenopausal ovarian decline to the postmenopausal time

BOX 7.2 Possible Causes of Abnormal Uterine Bleeding

Pregnancy-Related Conditions
Threatened or spontaneous miscarriage
Retained products of conception after elective abortion
Ectopic pregnancy
Placenta previa/placental abruption
Trophoblastic disease

Lower Reproductive Tract Infections
Cervicitis
Endometritis
Myometritis
Salpingitis

Benign Anatomical Abnormalities
Adenomyosis
Ovarian cyst
Leiomyomata
Polyps of the cervix or endometrium

Neoplasms
Endometrial hyperplasia
Cancer of the cervix and endometrium
Hormonally active tumours (rare)
Vaginal tumours (rare)

Malignant Lesions
Cervical squamous cell carcinoma
Endometrial adenocarcinoma
Estrogen-producing ovarian tumours
Testosterone-producing ovarian tumours
Leiomyosarcoma

Trauma
Genital injury (accidental, coital trauma, sexual abuse)
Foreign body
Lacerations

Systemic Conditions
Adrenal hyperplasia and Cushing's disease
Blood dyscrasias
Coagulopathies (e.g., von Willebrand's disease)
Hypothalamic suppression (from stress, weight loss, excessive exercise)
Polycystic ovary disease
Thyroid disease
Pituitary adenoma or hyperprolactinemia
Severe organ disease (renal or liver failure)

Iatrogenic Causes
Medications with estrogenic activity
Anticoagulants
Exogenous hormone use (oral contraceptives, menopausal hormone therapy)
Selective serotonin reuptake inhibitors
Tamoxifen
Intrauterine devices
Herbal preparation (e.g., ginseng)

Modified from Ryntz, T., & Lobo, R. A. (2017). Abnormal uterine bleeding: Etiology and management of acute and chronic excessive bleeding. In R. A. Lobo, D. M. Gershenson, G. M. Lentz, et al. (Eds.), *Comprehensive gynecology* (7th ed.). Elsevier; Singh, S., Best, C., Dunn, S., et al. (2018). SOGC clinical practice guideline: Abnormal uterine bleeding in pre-menopausal women. *Journal of Obstetrics and Gynaecology Canada, 40*(5), e391–e415.

when symptoms stop. A natural part of aging, *menopause* is considered the point at which a person has not had a menstrual period for 12 months. The average age for menopause to occur is 51.4 years, with an age range of 35 to 60 years. *Perimenopause* is the period of time prior to this when a person experiences physical and emotional changes; this lasts an average of 5 years. During this time, ovarian function declines. Ova slowly diminish, and menstrual cycles may be anovulatory, resulting in irregular bleeding. The ovary stops producing estrogen, and eventually menses no longer occur. Any patient with postmenopausal bleeding always needs to be investigated for cancer.

Menopause symptoms may vary from mild to intense. The common symptoms that patients report include vasomotor instability (hot flashes, night sweats), depression, anxiety, irritability, vaginal dryness, atrophic vaginitis, decreased **libido**, fatigue, aches and pains, and insomnia.

Some patients will find that vasomotor symptoms decrease when they make lifestyle modifications, which include eating well, maintaining a healthy weight, regular exercise, reducing core body temperature (dressing in layers, use of a fan, and drinking cold fluids), smoking cessation, and limiting consumption of triggers (such as hot drinks and alcohol) (Reid et al., 2014). Stress management (relaxation, yoga, meditation) may also help with some psychological symptoms.

Hormonal therapy (HT) is used to decrease menopausal symptoms. Estrogen alone or combined with a progestin is the most effective therapy for the medical management of menopausal symptoms. There has been some increased risk of breast cancer, ovarian cancer, thromboembolism, and heart disease identified with estrogen/progesterone therapy, and estrogen-only therapy has been associated with an increased rate of stroke (Reid et al., 2014). Patients for whom HT is contraindicated or not desired may use nonhormonal therapies. These include certain antidepressant medications, gabapentin, clonidine, and bellergal, which may provide some relief from hot flashes. These medications have their own adverse effects (Reid et al., 2014).

The use of black cohosh and foods that contain phytoestrogens may improve mild menopausal symptoms, including hot flashes. Isoflavone (found in soy) and St. John's wort may also be used (Reid et al., 2014). Patients should be asked about the use of any complementary therapies in order to decrease the risk of interactions with any medications. At present, the use of these therapies may be useful for some people, although research on the use of CAM is limited, and patients should be advised that alternative measures should be used with caution (Reid et al., 2014).

Every person will go through the transition of menopause differently. Patients need an understanding health care provider who can explain what is considered normal and provide support. An excellent resource for information for patients is found at http://www.menopauseandu.ca.

INFECTIONS

Infections of the reproductive tract can occur throughout a person's life and are often the cause of significant reproductive morbidity, including ectopic pregnancy and tubal factor infertility. The direct economic costs of these infections can be substantial, and the indirect cost is equally overwhelming. Some consequences of infection, such as infertility, last a lifetime. The emotional costs may include damaged relationships and lowered self-esteem.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) comprise more than 25 infectious diseases that are transmitted through sexual activity and the dozens of clinical syndromes that they cause (Box 7.3). STIs continue to be a significant and increasing public health concern in Canada, with rates of the three nationally reportable bacterial STIs (chlamydia, gonorrhea, and syphilis) increasing, especially among persons aged 15 to 24. The World Health Organization (WHO) has developed a global strategy for the prevention and control of STIs, because of the health and economic burden of STIs (WHO, 2016) (see Community Focus box). The most common STIs in women are chlamydia, human papillomavirus (HPV), gonorrhea, herpes simplex virus (HSV) type 2, syphilis, and human **immunodeficiency** virus (HIV) infection. Neonatal effects of STIs are discussed in Chapter 28.

BOX 7.3 Sexually Transmitted Infections

Bacteria
Chlamydia (reportable to local health authority)
Gonorrhea (reportable to local health authority)
Syphilis (nationally reportable if infectious)
Chancroid
Lymphogranuloma venereum
Genital mycoplasmas

Viruses
Human immunodeficiency virus (reportable to local health authority)
Herpes simplex virus, types 1 and 2
Cytomegalovirus
Viral hepatitis A and B (hepatitis B is reportable to local health authority)
Human papillomavirus

Protozoa
Trichomoniasis

Parasites
Pediculosis (may or may not be sexually transmitted)
Scabies (may or may not be sexually transmitted)

COMMUNITY FOCUS

Sexually Transmitted Infections

While working in a clinic, interview a nurse about sexually transmitted infections commonly seen in the clinic.

- What are the most common infections seen in the clinic?
- Has the incidence of infections changed over the last 5 years? Which infections have increased and which have decreased in incidence during that time?
- Are adolescents seen in the clinic? Is there a special clinic for adolescents?
- How are patients diagnosed and treated for sexually transmitted infections?
- What patient teaching guidelines are available in the clinic? Are the guidelines available in languages other than English?

Prevention. Preventing infection (primary prevention) is the most effective way of reducing the adverse consequences of STIs for people and for society. Prompt diagnosis and treatment of current infections (secondary prevention) can prevent personal complications and transmission to others. Preventing the spread of STIs requires that people at risk for transmitting or acquiring infections change their behaviour related to sexual activity (Box 7.4). A critical first step is for the nurse to include questions about a person's sexual history, sexual risk behaviours, and drug-related risky behaviours as a part of the patient's assessment (Box 7.5). Effective techniques in providing prevention counselling include using open-ended questions, using understandable

BOX 7.4 Risk Factors for Sexually Transmitted Infections (STIs)

The following STI risk factors are associated with increased incidence of STIs:

- Sexual contact with person(s) with a known STI
- Sexually active youth under 25 years of age
- A new sexual partner or more than two sexual partners in the past year
- Serially monogamous individuals who have one partner at present but who have had a series of one-partner relationships over time
- No contraception or sole use of nonbarrier methods of contraception (i.e., oral contraceptives, Depo Provera, intrauterine device)
- Injection drug use
- Other substance use, such as alcohol or chemicals (marijuana, cocaine, ecstasy, crystal meth), especially if associated with having sex
- Any individual who is engaging in unsafe sexual practices (i.e., unprotected sex, oral, genital or anal; sex with blood exchange, including sadomasochism; sharing sex toys)
- Sex workers and their clients
- "Survival sex": exchanging sex for money, drugs, shelter or food
- Street involvement, homelessness
- Anonymous sexual partnering (i.e., Internet, bathhouse, rave party)
- Victims of sexual assault or abuse
- Previous STI

(2013). *Section 2: Canadian guidelines on sexually transmitted infections—Primary care and sexually transmitted infections*. https://www.canada.ca/en/public-health/services/infectious-diseases/sexual-health-sexually-transmitted-infections/canadian-guidelines/sexually-transmitted-infections/canadian-guidelines-sexually-transmitted-infections-17.html#a2

BOX 7.5 Focused Risk Assessment for Sexually Transmitted Infections

Information should be requested in a nonjudgemental manner, using language that is understandable.

Relationship

Do you have a regular sexual partner?
If yes, how long have you been with this person?
Do you have any concerns about your relationship?
If yes, what are they? (e.g., violence, abuse, coercion)

Sexual Risk Behaviour

When was your last sexual contact? Was that contact with your regular partner or with a different partner?
How many different sexual partners have you had in the past 2 months? In the past year? Are your partners men, women, or both?
Do you perform oral sex (i.e., Do you kiss your partner on the genitals or anus)?
Do you receive oral sex?
Do you have intercourse (i.e., Do you penetrate your partner in the vagina or anus [bum]? Or does your partner penetrate your vagina or anus [bum])?

Personal Risk Evaluation

Have any of your sexual encounters been with people from a country other than Canada? If yes, where and when?
How do you meet your sexual partners (when travelling, in a bathhouse, on the Internet)?
Do you use condoms? All the time, some of the time, never?
What influences your choice to use protection or not?
If you had to rate your risk for STI, would you say that you are no risk, low risk, medium risk, or high risk? Why?

STI History

Have you ever been tested for an STI or HIV? If yes, what was your last screening date?
Have you ever had an STI in the past? If yes, what and when?

Current Concern

When was your last sexual contact of concern?
If symptomatic, how long have you had the symptoms you are experiencing?

Reproductive Health History

Do you and/or your partner use contraception? If yes, what? Any problems? If no, is there a reason?
Have you ever had any reproductive health problems? If yes, when? What?
Have you ever had an abnormal Pap test? If yes, when? Result, if known?
Have you ever been pregnant? If yes, how many times? What was the outcome (number of live births, abortions, miscarriages)?

Substance Use

Do you use alcohol? Drugs? If yes, frequency and type?
If you use injection drugs, have you ever shared equipment? If yes, what was your last sharing date?
Have you ever had sex while intoxicated? If yes, how often?
Have you had sex while under the influence of alcohol or other substances? What were the consequences?
Do you feel that you need help because of your substance use?
Do you have tattoos or piercings? If yes, were they done using sterile equipment (i.e., professionally)?

Psychosocial History

Have you ever

- traded sex for money, drugs, or shelter?
- paid for sex? If yes, what is the frequency, duration, and last event?
- been forced to have sex? If yes, when and by whom?
- been sexually abused?
- been physically or mentally abused? If yes, when and by whom?

Do you have a home? If no, where do you sleep?
Do you live with anyone?

HIV, Human immunodeficiency virus; *STI,* sexually transmitted infection.

language, and reassuring the patient that treatment will be provided regardless of ability to pay, language spoken, or lifestyle (Public Health Agency of Canada [PHAC], 2013a).

Before considering any risk reduction strategy for preventing STIs, the person must first accept the fact that they are or might be sexually active. Nurses need to show understanding of a person's sexuality by initiating a nonjudgemental, two-way dialogue to help them examine the choices they make related to their sexuality. Examining these choices can be useful in helping patients to proactively plan risk reduction measures appropriate to their specific situation (PHAC, 2013a).

Prevention messages should include descriptions of specific actions to be taken to avoid acquiring or transmitting STIs (e.g., refraining from sexual activity if STI-related symptoms are present) and should be individualized for each person, giving attention to the specific risk factors. To be motivated to take preventive actions, a person must believe that acquiring a disease will be serious for them and that they are at risk for infection. Nurses have a responsibility to ensure that their patients have accurate, complete knowledge about transmission and symptoms of STIs and the behaviours that place people at risk for contracting an infection.

Primary preventive measures are individual activities aimed at avoiding infection. These practices include attaining knowledge of the partner, reducing the number of sexual partners, practising low-risk sex, avoiding the exchange of body fluids, and pre-exposure vaccinations. Nurses need to be aware that some patient do not have the ability or agency to take preventive action and may engage in high-risk behaviour because they have little choice or lack the confidence to take preventive measures. For these patients, nurses need to provide individualized and respectful care.

Patients should be helped to plan for prevention by openly discussing safer sex, using a continuum approach (i.e., masturbation/mutual masturbation, low risk; oral sex, moderate risk for STIs and low risk for HIV; unprotected vaginal or anal intercourse, high risk for STIs and HIV). This can be useful in helping patients understand the risks associated with various activities, make informed choices about the initiation and maintenance of STI preventive actions, and deal with possible partner resistance (PHAC, 2013a). Specific self-management measures to prevent contracting and transmitting STIs are listed in Box 7.6.

All patients need to be encouraged to think about the risk of STIs and to consider pre-sex testing before they become sexually active with a new partner so they can be proactive in preventing the risk of transmission. It is important to reinforce that it is not possible to assess the chances that a partner has an STI on the basis of knowing the partner's sexual history, being in a close relationship with a partner, or being monogamous with a partner who has a sexual history and who has not been tested (PHAC, 2013a). Individuals also need to be aware that it is not possible to test for all STIs (e.g., HPV, HSV), so even if they or their partner's tests are all negative, they may still have an asymptomatic STI. Nurses also need to discuss with patients the need to limit alcohol or drug intake prior to sexual activity, as these substances can impact decision-making and negotiation skills (PHAC, 2013a).

The physical barrier promoted for the prevention of sexual transmission of HIV and other STIs is the condom. The nurse should teach the patient the importance of using a condom with every sexual encounter; to use latex or plastic male condoms rather than natural skin condoms for STI protection; to use a condom with a current expiration date; to use each one only once; and to handle it carefully in order to avoid damaging it with fingernails, teeth, or other sharp objects. Condoms should be stored away from high heat. Although it is not ideal, people may choose to carry condoms in wallets, shoes, or inside a bra. Patients can be taught the differences among condoms: price ranges, sizes, and where they can be purchased. Explicit instructions for how to apply a male condom are provided in Box 8.8.

The female condom (a lubricated polyurethane sheath with a ring on each end that is inserted into the vagina) may be an effective mechanical barrier to viruses, including HIV. The consistent use of condoms for every act of sexual intimacy when there is the possibility of transmission of disease is ideal but not always possible in some situations. Patients should be encouraged to discuss concerns with their partner (Box 7.7).

Evidence has shown that vaginal spermicides do not protect against certain STIs (e.g., chlamydia, cervical gonorrhea) and that frequent use of spermicides containing nonoxynol-9 has been associated with genital lesions and may increase HIV transmission. Use of condoms lubricated with nonoxynol-9 is not recommended (PHAC, 2013a).

Vaccination is an effective method for the prevention of some STIs such as hepatitis B and HPV. Hepatitis B vaccine is recommended for all people at high risk for STIs. A vaccine is available for HPV types 6, 11, 16, and 18 for females aged 9 to 45 and for males aged 9 to 26 (Salvadori & Canadian Paediatric Society [CPS], Infectious Diseases and Immunization Committee, 2018) (see later discussion).

Patients should be counselled to watch out for situations that make it hard to talk about and practise risk reduction. These situations include romantic times when condoms are not available and when use of alcohol or drugs makes it difficult to make wise decisions.

BOX 7.6 STI and HIV Prevention

- Prevention of STIs and HIV is possible only if there is no oral, genital, or rectal exchange of body fluids or if a person is in a long-term, mutually monogamous relationship with an uninfected partner.
- Correct use of latex condoms, although greatly reducing risk, is not exclusively protective.
- Sexual partners should be selected with great care.
- Partners should be asked about history of STIs.
- Pre-exposure vaccination is one of the most effective methods for preventing transmission of some STIs (hepatitis A and hepatitis B, human papillomavirus).
- A new condom should be used for each act of sexual intercourse.
- Abstinence from sexual intercourse is encouraged for persons who are being treated for an STI or whose partners are being treated.
- Abstinence is also recommended if under the influence of drugs or alcohol.

BOX 7.7 Strategies to Enhance A Person's Negotiation and Communication Skills Regarding Condom Use

- Suggest that the patient talk with their partner about condom use at a time not during sexual activity.
- Role play possible partner reactions with the patient and their alternative responses.
- For a patient who appears particularly uncomfortable, ask them to rehearse how they might approach the topic of condom use with their partner.
- Patients may feel more comfortable and in control of the situation if they sort out their feelings and fears before talking with their partners. Reassure the patient that it is natural to be uncomfortable and that the hardest part is getting started.
- Suggest that the patient clarify for themselves what they will and will not do sexually.
- Suggest that the patient begin the conversation by saying, "I need to talk with you about something that is important to both of us. It's hard for me, and I feel embarrassed, but I think we need to talk about ways to reduce risk when we have sex."
- The partner may need time to think about what they have heard.
- If the partner resists risk-reducing sexual behaviours, the patient may wish to reconsider the relationship.

Sexually Transmitted Bacterial Infections

Chlamydia. *Chlamydia trachomatis* is a reportable STI in Canada. Rates of chlamydia in Canada and elsewhere have been steadily increasing; between 2005 and 2014 the rate of chlamydia in females increased by 49% (PHAC, 2017a). Among males, the rates increased by 64.6%. Persons aged 15 to 29 comprised nearly 80% of chlamydia cases reported in 2014 (PHAC, 2017a). It is important to note that chlamydia is often underdiagnosed because the majority of infected individuals are asymptomatic (PHAC, 2017b). Risk factors are those listed in Box 7.4. While these infections are often silent, they are highly destructive, and their sequelae and complications can be very serious. Chlamydial infections are difficult to diagnose; the symptoms, if present, are nonspecific.

Acute salpingitis, or pelvic inflammatory disease, is the most serious complication of chlamydial infections. Past chlamydial infections are associated with an increased risk of ectopic pregnancy and tubal factor infertility. Furthermore, chlamydial infection of the cervix causes inflammation, resulting in microscopic cervical ulcerations that may increase risk of acquiring HIV infection. More than half of infants born to a parent with chlamydia will develop conjunctivitis or pneumonia after perinatal exposure to the parent's infected cervix. *C. trachomatis* is the most common infectious cause of ophthalmia neonatorum.

Screening and diagnosis. In addition to obtaining information about the presence of risk factors (see Box 7.4), the nurse should inquire about the presence of any symptoms. All pregnant patients should have cervical cultures done for chlamydia at the first prenatal visit. Screening late in the third trimester (36 weeks) may be carried out if the patient was positive previously or is younger than 25 years, has a new sex partner, or has multiple sex partners.

Although chlamydia infections are usually asymptomatic, some women may experience spotting or postcoital bleeding, mucoid or purulent cervical discharge, or **dysuria**. Bleeding results from inflammation and erosion of the cervical columnar epithelium.

Diagnosis of chlamydia is best done using nucleic acid amplification testing (NAAT), which is more sensitive and specific than culture, enzyme immunoassay (EIA), and direct fluorescent antibody assay (DFA). NAAT should be used whenever possible for urine, urethral, or cervical specimens. Results are highly dependent on the type of test available, specimen collection and transport, and laboratory expertise. Not all local laboratories will have the ability to provide all types of testing, so it is important to know what is available in the particular region (PHAC, 2017b).

Collaborative care. The Public Health Agency of Canada (PHAC) (2017b) recommendations for the treatment of chlamydial infections include doxycycline or azithromycin (Table 7.3). Azithromycin is often prescribed when adherence may be an issue, because only one dose is needed. Because chlamydia is often asymptomatic, the patient should be cautioned to take all medication prescribed. Patients treated with recommended or alternative regimens do not need to be retested unless symptoms continue (PHAC, 2017b). All sexual partners who have had contact with the index case within 60 days before symptom onset must

TABLE 7.3 Sexually Transmitted Infections and Medication Therapies*

Disease	Nonpregnant Patient (>18 yr)	Pregnant/Lactating Patient
Chlamydia	doxycycline, 100 mg orally bid for 7 days *or* azithromycin, 1 g orally once (if poor adherence is suspected) For children <18 years of age: doxycycline, 5 mg/kg/day orally in divided doses (max 100 mg bid) for 7 days *or* azithromycin, 12–15 mg/kg (max 1 g) orally once (if poor adherence is suspected) Alternatives: erythromycin 40 mg/kg/day orally in divided doses (max 500 mg qid for 7 days or 250 mg qid for 14 days) *or* sulfamethoxazole 75 mg/kg/day orally in divided doses (max 1 g bid) for 10 days	amoxicillin, 500 mg orally tid for 7 days *or* erythromycin 2 g/day orally in divided doses for 7 days *or* erythromycin 1g/day orally in divided doses for 14 days *or* azithromycin 1 g orally in a single dose, if poor adherence is expected **Doxycycline should not be used in pregnancy or while breastfeeding.**
Gonorrhea	ceftriaxone, 250 mg IM once Plus azithromycin 1 g orally in a single dose *or* cefixime 800 mg orally in a single dose Plus azithromycin 1 g orally in a single dose	ceftriaxone, 250 mg IM once Plus azithromycin 1 g orally in a single dose
Syphilis	**Primary, secondary, early-latent disease:** benzathine penicillin G, 2.4 million units IM once **Late-latent or unknown-duration disease:** benzathine penicillin G, 2.4 million units weekly for 3 doses **Penicillin allergy:** doxycycline, 100 mg orally bid for 14 days	**Primary, secondary, early-latent disease:** benzathine penicillin G, 2.4 million units IM weekly for 1 to 2 doses **Late-latent or unknown-duration disease:** benzathine penicillin G, 2.4 million units weekly for 3 doses No proven alternatives to penicillin in pregnancy Pregnant women who have a history of allergy to penicillin should be desensitized and treated with penicillin.

Continued

TABLE 7.3 Sexually Transmitted Infections and Medication Therapies—cont'd

Disease	Nonpregnant Patient (>18 yr)	Pregnant/Lactating Patient
Human papillomavirus	*For external genital warts:* **Patient-applied:** podophyllotoxin/podofilox 0.5% solution to wart with a cotton swab q12h for 3 days (followed by 4 days without treatment) for up to 4 weeks *or* imiquimod 3.75% cream, daily at hs for 8 weeks *or* imiquimod, 5% cream, at hs 3 times a week for ≤16 weeks *or* sinecatechins 10% ointment tid for up to 16 weeks **Provider-applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* podophyllin resin, 25%, 1–2 mL weekly (wash off in 1–4 hr). Repeat weekly for up to 6 weeks as necessary *or* TCA 50–90% in 70% alcohol weekly for 6–8 weeks **Surgical treatment:** CO_2 laser vaporization; electrosurgical treatments; surgical excision	*For external genital warts:* **Provider applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* trichloracetic acid (TCA) 50–90% solution in 70% alcohol weekly for 6–8 weeks. Imiquimod, podophyllin, podofilox/podophyllotoxin, and sinecatechins should not be used in pregnancy or during lactation.
Genital herpes simplex virus (HSV-1 or HSV-2)	**Primary infection:** acyclovir, 200 mg orally 5 times a day for 5–10 days *or* famciclovir, 250 mg orally tid for 5 days *or* valacyclovir, 1 g orally bid for 10 days For severe primary disease, IV acyclovir 5 mg/per kg infused over 60 minutes q8h with conversion to oral therapy when substantial improvement has occurred **Recurrent infection:** valacyclovir, 500 mg orally bid or 1 g daily for 3 days *or* famciclovir, 125 mg orally bid for 5 days *or* ayclovir, 200 mg orally 5 times/day for 5 days **Suppression therapy:** *Take daily for up to 1 year:* acyclovir, 200 mg orally 3 to 5 times/day or 400 mg orally bid *or* famciclovir, 250 mg orally bid *or* valacyclovir, 500 mg orally once a day (for patients with ≤9 recurrences/year) *or* valacyclovir, 1 g orally once a day (if >9 recurrences/year)	No increase in birth defects beyond the general population has been found with acyclovir use in pregnancy or while breastfeeding. **Suppression therapy:** 4 weeks before birth for women with recurrent infections can reduce the need for a Caesarean birth. acyclovir 200 mg orally qid *or* acyclovir 400 mg orally tid *or* valacyclovir 500 mg orally bid

bid, Twice daily; *hs,* bedtime; *HSV,* herpes simplex virus; *IM*, intramuscularly; *IV,* intravenously; *qid*, four times daily; *tid*, three times daily.
*List is not inclusive of all medications that may be used as alternatives.
Data from Public Health Agency of Canada. (2019). *Canadian guidelines on sexually transmitted infections*. http://www.phac-aspc.gc.ca/std-mts/sti-its/cgsti-ldcits/index-eng.php#toc

be tested and treated (PHAC, 2017b). Chlamydia is a reportable disease to the local health authority in all provinces and territories. Local public health authorities are able to help notify contacts.

Gonorrhea. Gonorrhea is the second most common reported STI in Canada. The number of cases reported in 2016 was more than double the number reported in 2010 (rising from 33.5 to 65.4 per 100 000 population), corresponding to a 95% increase in rates. Males accounted for at least 56% of all cases diagnosed. The most commonly affected age group was 15- to 39-year-olds; they comprised 82% of reported cases of gonorrhea, although they represented only 33% of the total population (Bodie et al., 2019). The incidence of medication-resistant cases of gonorrhea, in particular penicillinase-producing *Neisseria gonorrhoeae*, is increasing dramatically in Canada and worldwide.

Gonorrhea is caused by the aerobic, Gram-negative diplococci *N. gonorrhoeae*. It is transmitted almost exclusively by sexual contact. The principal means of transmission is genital-to-genital contact during sexual activity; however, it is also spread by oral–genital and anal–genital contact. There is also evidence that infection may spread in females from vagina to rectum.

Patients are often asymptomatic; but when they are symptomatic, they may have a greenish-yellow purulent endocervical discharge or may experience menstrual irregularities. Patients may also have pain: chronic or acute severe pelvic or lower abdominal pain, or menses that last longer or are more painful than normal. Infrequently, dysuria, vague abdominal pain, or low backache prompts a person to seek care. Gonococcal rectal infection may occur in patients after anal intercourse. Individuals with rectal gonorrhea may be completely asymptomatic or, conversely, have severe symptoms with profuse purulent anal discharge, rectal pain, and blood in the stool. Rectal itching, fullness, pressure, and pain are also common symptoms, as is diarrhea. A diffuse vaginitis with vulvitis is the most common form of gonococcal infection in prepubertal females. Signs of infection may include vaginal discharge, dysuria, or swollen, reddened labia.

Gonococcal infections in pregnancy potentially affect both the pregnant parent and their fetus. Patients with cervical gonorrhea may develop salpingitis in the first trimester. Perinatal complications of gonococcal infection include postpartum endometritis or sepsis in the patient and ophthalmia neonatorum or systemic neonatal infection in the newborn (PHAC, 2017c).

Screening and diagnosis. Because gonococcal infections are often asymptomatic, all pregnant patients should be screened at the first prenatal visit, and infected patients and those identified with risky behaviours rescreened at 36 weeks of gestation (PHAC, 2017d). Gonococcal infection cannot be diagnosed reliably by clinical signs and symptoms alone. Individuals may have "classic" symptoms, vague symptoms that may be attributed to a number of conditions, or no symptoms at all. Cultures should be obtained from the endocervix, the rectum, and, when indicated, the pharynx. Cultures are critical for improved public health monitoring of antimicrobial resistance patterns and trends (PHAC, 2017c). Depending on the clinical situation, consideration should be given for collection of samples using both culture and NAAT, especially in symptomatic patients. Because coinfection is common, any person suspected of having gonorrhea should have a chlamydial culture and serological test for syphilis as well as HIV counselling and testing.

Collaborative care. Management of gonorrhea is becoming more challenging as medication-resistant strains are increasing. Treatment should optimally be combination gonorrhea infection therapy in response to increasing antimicrobial resistance (PHAC, 2017c). Combination therapy using medications with two different mechanisms of action is thought to improve treatment efficacy as well as to potentially delay the emergence of cephalosporin-resistant gonorrhea (PHAC, 2017c). Patients should also receive concomitant treatment for chlamydia because coinfection is common (PHAC, 2017c) (see Table 7.3).

Gonorrhea is highly communicable. Recent (past 60 days) sexual partners must be notified and should be examined, cultured, and treated with appropriate regimens. Most treatment failures result from reinfection. The patient needs to be informed of this, as well as of the consequences of reinfection in terms of chronicity, complications, and potential infertility. Patients should be counselled to use condoms. Repeat screening for individuals with a gonococcal infection is recommended 6 months post-treatment (PHAC, 2017c).

LEGAL TIP

Gonorrhea, chlamydia, infectious syphilis, and HIV are reportable communicable diseases in all provinces and territories. Health care providers are legally responsible for reporting all cases of these STIs to local public health authorities. All patients should be informed that the case will be reported, told why it will be reported, and informed of the possibility of being contacted by a health department epidemiologist.

Syphilis. Syphilis, one of the earliest described STIs, is caused by *Treponema pallidum*, a motile spirochete. Transmission is thought to occur by entry through microscopic abrasions in the subcutaneous tissue, which can happen during vaginal, anal, or oral sexual contact. Transplacental transmission may occur at any time during pregnancy; the degree of risk is related to the quantity of spirochetes in the maternal bloodstream. The risk of transmission to the fetus in untreated pregnant patients is 70 to 100% with primary or secondary syphilis, 40% with early latent syphilis, and 10% in late latent stages in pregnancy. About 40% of pregnancies in patients with infectious syphilis result in fetal demise (PHAC, 2020).

Infectious syphilis (primary, secondary and early latent stages) is the least common of the three nationally reportable bacterial STIs, although the rate of infectious syphilis in Canada has been increasing since 2001. From 2010 to 2015, the rate of infectious syphilis in Canada increased by 85.6%, from 5.0 to 9.3 cases per 100 000 population. In 2015, a total of 3 321 cases of infectious syphilis were reported, mainly in males (93.7%), and most of these increases were in men having sex with men (Choudhri et al., 2018).

Syphilis is a complex disease that can lead to serious systemic disease and even death when untreated. Infection occurs in distinct stages with different symptoms and clinical manifestations. Primary syphilis is characterized by a primary lesion, the chancre, which appears 3 to 90 days after infection. This lesion often begins as a painless papule at the site of inoculation and then erodes to form a nontender, shallow, indurated, clean ulcer several millimetres to centimetres in size (Figure 7.10, *A*). Secondary syphilis occurs 2 weeks to 6 months after the appearance of the chancre. It is characterized by a widespread, symmetrical, maculopapular rash on the palms and soles and generalized

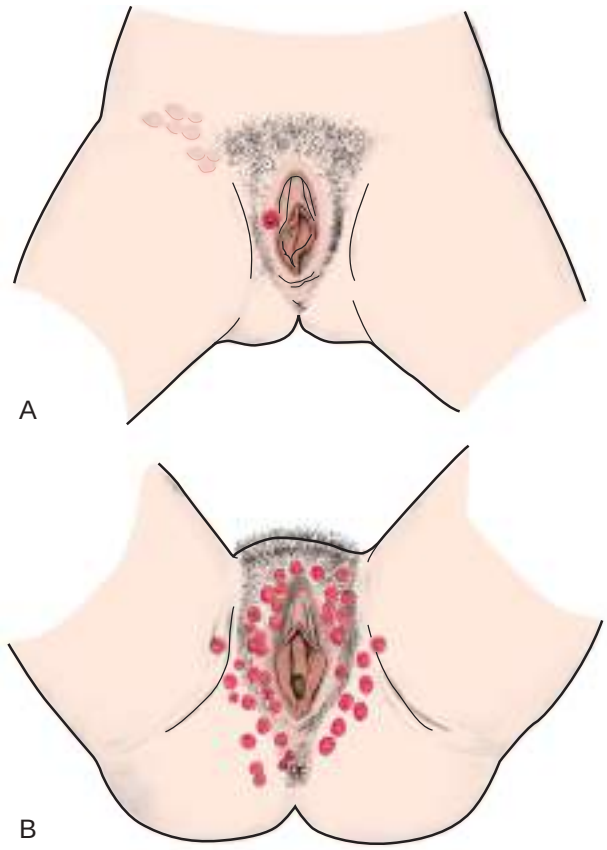

Fig. 7.10 Syphilis. **A:** Primary stage: chancre with inguinal adenopathy. **B:** Secondary stage: condylomata lata.

lymphadenopathy. The infected individual also may experience fever, headache, and malaise. Condylomata lata (broad, painless, pink-grey, wartlike infectious lesions) may develop on the vulva, perineum, or anus (see Figure 7.10, *B*). If the person remains untreated, they enter a latent phase that is asymptomatic for most individuals. Left untreated, about one third of these patients will develop tertiary syphilis. Neurological, cardiovascular, musculoskeletal, or multiorgan system complications can develop in the third stage.

Screening and diagnosis. All individuals who are diagnosed with another STI or with HIV should be screened for syphilis. Universal screening of all pregnant patients is important and remains the standard of care in most jurisdictions. The screening test should be repeated at 28 to 32 weeks and again during labour in patients at high risk of acquiring syphilis (PHAC, 2020). Diagnosis depends on microscopic examination of primary and secondary lesion tissue and serology during latency and late infection. A test for antibodies may not be reactive in the presence of active infection because it takes time for the body's immune system to develop antibodies to any antigens. Up to one third of people with early primary syphilis may have nonreactive serological tests. Two types of serological tests are used: nontreponemal and treponemal. Nontreponemal antibody tests such as VDRL (Venereal Disease Research Laboratories) and RPR (rapid plasma reagin) are used as screening tests. False-positive results are not unusual, particularly when conditions such as acute infection, autoimmune disorders, malignancy, pregnancy, and substance use disorder exist, and after immunization or vaccination. The treponemal tests, fluorescent treponemal antibody absorbed and microhemagglutination assays for antibody to *T. pallidum*, are used to confirm positive results. Test results in patients with early primary or incubating syphilis may be negative. Seroconversion usually takes place 6 to 8 weeks after exposure; thus testing should be repeated in 1 to 2 months when a suggestive genital lesion exists.

Screening for concomitant STIs (e.g., chlamydia and gonorrhea) as well as HIV should also be considered.

Collaborative care. Penicillin is the preferred medication for treating patients with all stages of syphilis, including pregnant patients (see Table 7.3). Although doxycycline, tetracycline, and erythromycin are alternative treatments for penicillin-allergic patients, both tetracycline and doxycycline are contraindicated in pregnancy, and erythromycin is unlikely to cure a fetal infection. Therefore, if necessary, pregnant patients should receive skin testing and be treated with penicillin or be desensitized (PHAC, 2020).

! NURSING ALERT

Patients treated for syphilis may experience a Jarisch–Herxheimer reaction. This is an acute febrile reaction often accompanied by headache, myalgias, and arthralgias that develop within the first 24 hours of treatment. The reaction may be treated symptomatically with analgesics and antipyretics. If treatment precipitates this reaction in the second half of pregnancy, patients are at risk for preterm labour and birth. They should be advised to contact their health care provider if they notice any change in fetal movement or have any contractions.

Monthly follow-up is important so that repeated treatment may be given, if needed. The nurse should emphasize the necessity of long-term serological testing even in the absence of symptoms. The patient should be advised to practise sexual abstinence until treatment is completed, all evidence of primary and secondary syphilis is gone, and serological evidence of a cure is demonstrated. Infectious syphilis is reportable in all provinces and territories to the PHAC. Noninfectious syphilis is reportable at the provincial/territorial level but not to the PHAC. All sexual or perinatal contacts must be notified and treated, and preventive measures should be discussed (PHAC, 2020).

Pelvic Inflammatory Disease. Pelvic inflammatory disease (PID) is an infectious process that most commonly involves the uterine tubes, causing salpingitis; the uterus, causing endometritis; and, more rarely, the ovaries and peritoneal surfaces. Multiple organisms have been found to cause PID; most cases are associated with more than one organism. The pathogenic organisms can be categorized as sexually transmitted or endogenous (PHAC, 2013b). In the past, the most common causative agent was thought to be *N. gonorrhoeae*; however, *C. trachomatis* is now estimated to cause one half of all cases of PID. In addition to gonorrhea and chlamydia, a wide variety of anaerobic and aerobic bacteria cause PID.

Most PID results from the ascending spread of microorganisms from the vagina and endocervix to the upper genital tract. This spread most commonly happens at the end of or just after menses following reception of an infectious agent. During the menstrual period, several factors facilitate development of an infection: the cervical os is slightly open, the cervical mucous barrier is absent, and menstrual blood is an excellent medium for growth. PID also may develop after a miscarriage or an induced **abortion**, pelvic surgery, or childbirth.

Risk factors for acquiring PID are those associated with the risk of contracting an STI, including young age, multiple partners, high rate of new partners, and a history of STIs. PID tends to recur and is a significant public health concern in Canada. There are approximately 100 000 cases of PID annually in Canada, although up to two thirds of cases go unrecognized, and underreporting is common (PHAC, 2013b).

Patients who have had PID are at increased risk for ectopic pregnancy, infertility, and chronic pelvic pain. The incidence of long-term sequelae of PID is directly related to the number of episodes of PID. Other conditions associated with PID include **dyspareunia**, *pyosalpinx* (pus in the uterine tubes), tubo-ovarian abscess, and pelvic adhesions.

The symptoms of PID vary, depending on whether the infection is acute, subacute, or chronic. However, pain is common to all clinical presentations. It may be dull, cramping, and intermittent (subacute) or severe, persistent, and incapacitating (acute). Patients may also report one or more of the following: fever, chills, nausea and vomiting, increased vaginal discharge, symptoms of a urinary tract infection, and irregular bleeding. Abdominal pain is usually present (PHAC, 2013b).

Screening and diagnosis. PID is difficult to diagnose because of the accompanying wide variety of symptoms. A complete abdominal and pelvic examination should be performed in any patient with lower abdominal pain. PID should be treated in all sexually active young individuals and others at risk for STIs if the following criteria are present and no other cause or causes of the illness are found: lower abdominal tenderness, bilateral adnexal tenderness, and cervical motion tenderness. Other criteria for diagnosing PID include an oral temperature of 38.3°C or above, abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein, and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis* (PHAC, 2013b).

Collaborative care. The most important nursing intervention is prevention counselling (see earlier discussion). Early diagnosis and treatment are crucial in order to maintain fertility, particularly the detection of asymptomatic gonorrheal or chlamydial infections. Primary prevention includes education in avoiding contracting STIs; secondary prevention involves preventing a lower genital tract infection from ascending to the upper genital tract. Instructing individuals in self-protective measures such as practices to avoid contracting STIs and using barrier methods is critical. Patients using hormonal

contraception or an IUD and those who have chosen tubal ligation must be reminded to use a condom with intercourse when indicated.

Although treatment regimens vary with the infecting organism, generally a broad-spectrum antibiotic is used (PHAC, 2013b). Treatment for PID may be intramuscular ceftriaxone plus oral doxycycline with or without metronidazole; or cefoxitin parenterally plus oral probenecid in a single dose concurrently once with doxycycline; or other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime) with doxycycline. Regimens can be administered in inpatient or outpatient settings. PID can be difficult to treat if due to an antibiotic-resistant organism (specifically gonorrhea), and this needs to be determined. Also, management of patients with PID is considered inadequate unless their sexual partners are also clinically evaluated (PHAC, 2013b). All outpatients treated for PID should undergo evaluation 2 to 3 days after the initiation of treatment (PHAC, 2013b). When and if patients with PID are hospitalized varies according to their particular circumstances. The PHAC recommends hospitalization for parenteral antibiotic treatment in the following situations (PHAC, 2013b):

- Surgical emergencies such as appendicitis cannot be excluded.
- The person has a tubo-ovarian abscess.
- The person is pregnant.
- The person does not respond clinically to oral antimicrobial therapy.
- The person is unable to follow or tolerate an outpatient oral regimen.
- The person has severe illness, nausea and vomiting, or high fever.

The patient with acute PID should be on bed rest in a semi-Fowler's position. Comfort measures include **analgesics** for pain and all other nursing measures applicable to a patient confined to bed. Few pelvic examinations should be done during the acute phase of the disease. During the recovery phase, the patient should restrict their activity and make every effort to get adequate rest and a nutritionally sound diet. Follow-up laboratory work after treatment should include endocervical cultures for a test of cure.

Health education is central to effective management of PID. Nurses should explain the nature of the disease to affected patients and encourage them to continue with all therapy and prevention recommendations, emphasizing the need to take all medication, even if symptoms disappear. Any potential issues (such as lack of money for prescriptions or lack of transportation to return for follow-up appointments) that would prevent a person from completing a course of treatment should be identified, referrals made for assistance as needed, and the importance of follow-up visits stressed. Patients should be counselled to refrain from sexual intercourse until their treatment is completed. Contraceptive counselling, including information on barrier methods such as condoms, the contraceptive sponge, and the diaphragm, should be provided.

The potential or actual loss of reproductive capabilities can be devastating and can adversely affect a person's self-concept. Part of the nurse's role is to help the person adjust their self-concept to fit reality and to accept alterations in a way that promotes health. Because PID is so closely tied to sexuality, **body image**, and self-concept, the patient diagnosed with it will need supportive care. The patient's feelings should be discussed and the partner(s) included in the discussion, when appropriate.

Sexually Transmitted Viral Infections

Human Papillomavirus. Human papillomavirus (HPV) infection, also known as *condylomatata acuminate*, or *genital warts*, is the most common viral STI seen in ambulatory health care settings. It is estimated that 70 to 80% of the adult population will have at least one genital HPV infection over their lifetime, and prevalence among females is usually highest in those aged less than 25 years (Zimmermann et al., 2018). HPV prevalence is highest in socially disadvantaged females, such as those living in low-income housing, inner-city settings, and Indigenous communities (PHAC, 2015).

HPV, a double-stranded DNA virus, has more than 40 serotypes that can be transmitted sexually, 5 of which are known to cause genital wart formation and 8 of which are currently thought to have oncogenic (tumour-causing) potential (PHAC, 2015). HPV is the primary cause of cervical neoplasia.

In patients, HPV lesions are most commonly seen in the posterior part of the introitus. Lesions also are found on the buttocks, vulva, vagina, anus, and cervix (Figure 7.11). Typically the lesions are small (2 to 3 mm in diameter and 10 to 15 mm in height), soft, papillary swellings occurring singly or in clusters on the genital and anal–rectal region. Infections of long duration may appear as a cauliflower-like mass. In moist areas such as the vaginal introitus, the lesions may appear to have multiple fine, fingerlike projections. Vaginal lesions are often multiple. Flat-topped papules, 1 to 4 mm in diameter, are seen most often on the cervix. Often these lesions are visualized only under magnification. Warts are usually flesh coloured or slightly darker on White people, black on Black people, and brownish on Asian people. The lesions are usually painless, but they may be uncomfortable, particularly when very large, inflamed, or ulcerated. Chronic vaginal discharge, pruritus, or dyspareunia can occur.

During pregnancy, pre-existing HPV lesions may enlarge, a proliferation presumably resulting from the relative state of immunosuppression present during this period. Lesions may become so large during pregnancy that they affect urination, defecation, mobility, and fetal descent, although birth by Caesarean is rarely necessary. **Caesarean birth** should be reserved for patients with obstructions that do not allow the fetus to pass through. Initial observation of large growths can be misleading, suggesting that the entire vagina is involved. However, all of the growth may derive from one stalk; and in such cases it may be possible to push the large mass to the side, allowing the fetus to pass through.

Screening and diagnosis. A person with HPV lesions may have symptoms such as profuse, irritating vaginal discharge, itching, dyspareunia, or postcoital bleeding. The person also may report "bumps" on the vulva or labia. History of a known exposure is important; however, because of the potentially long latency period and the possibility of subclinical infections in men, the lack of a history of known exposure cannot be used to exclude a diagnosis of HPV infection.

Fig. 7.11 Human papillomavirus (HPV) infection. Genital warts or condylomata acuminata.

Physical inspection of the vulva, perineum, anus, vagina, and cervix is essential whenever HPV lesions are suspected or seen in one area. Because speculum examination of the vagina may block some lesions, it is important to rotate the speculum blades until all areas are visualized. When lesions are visible, the characteristic appearance previously described is considered diagnostic. However, in many instances cervical lesions are not visible, and some vaginal or vulvar lesions also may be unobservable to the naked eye. Because of the potential spread of vulvar or vaginal lesions to the anus, gloves should be changed between vaginal and rectal examinations.

Viral screening and typing for HPV is available but not standard practice. History, evaluation of signs and symptoms, Pap test, and physical examination are used in making a diagnosis. Some research shows that combining an HPV test with a Pap test may extend the time between cervical cancer screenings. HPV testing is most useful in screening for cervical cancer in individuals 30 years of age or older (Canadian Cancer Society [CCS], 2021a).

Collaborative care. Untreated warts may resolve on their own in young patients since their immune systems may be strong enough to fight the HPV infection. Treatment of genital warts, if needed, is often difficult. No therapy has been shown to eradicate HPV. Therefore, the goal of treatment is removal of warts and symptom relief (PHAC, 2015). The patient often must make multiple office visits; frequently many different treatment modalities will be used.

Treatment of genital warts may be patient- (self) or clinician-applied and should be guided by preference of the patient; availability of resources; cost, size, shape, number, and site of lesions; convenience; potential adverse effects; and experience of the health care provider (PHAC, 2015). No one of the treatments is superior to all other treatments, and no one treatment is ideal for all warts (PHAC, 2015) (see Table 7.3). Imiquimod, polophyllin, and podofilox are common treatments but should not be used during pregnancy. Because the lesions can proliferate and become friable during pregnancy, many experts recommend their removal using cryotherapy or various surgical techniques (PHAC, 2015).

Individuals who have discomfort associated with genital warts may find that bathing with an oatmeal solution and drying the area with cool air from a hair dryer provides some relief. Keeping the area clean and dry also decreases growth of the warts. Cotton underwear and loose-fitting clothes that decrease friction and irritation may lessen discomfort. Individuals should be advised to maintain a healthy lifestyle to aid the immune system and be counselled regarding diet, rest, stress reduction, and exercise.

Patient education is essential. Patients must understand the virus, how it is transmitted, that no immunity is conferred with infection, and that reinfection is likely with repeated contact (PHAC, 2015). All sexually active people with multiple partners or a history of HPV should be encouraged to use latex condoms for intercourse to decrease acquisition or transmission of the infection.

Semiannual or annual health examinations are recommended to assess disease recurrence and to screen for cervical cancer. The provinces and territories have different cervical cancer screening guidelines for follow-up for patients who have been treated for HPV infections and these should be referred to.

People with HPV infection may radically alter their sexual practices both from fear of transmission to and from a partner and from genital discomfort associated with treatment, which may have a negative impact on their sexual relationships. Unless the partner accepts and understands the necessary precautions, it may be difficult for the patient to follow the treatment regimen. The nurse can offer to discuss feelings that the person may have. When indicated, joint counselling can be suggested.

Prevention. The two most important preventive strategies are the use of condoms and prophylactic vaccination (PHAC, 2015). A vaccine against HPV was approved by Health Canada in 2006 and is recommended for females ages 9 to 45 and males aged 9 to 26. There are three approved HPV vaccines in Canada. The vaccine approved most recently is Gardasil 9 (HPV-9), the nonavalent vaccine against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58. The quadrivalent vaccine (Gardasil or HPV-4) targets HPV 6, 11, 16, and 18. The bivalent (HPV-2) vaccine (Cervarix) targets HPV 16 and 18. HPV-4 and HPV-9 are approved for use in females aged 9 to 45 and males aged 9 to 26; Carvarix is only approved for use in females (Salvadori & CPS, Infectious Diseases and Immunization Committee, 2018). The HPV vaccine is highly effective and is given in two or three doses depending on the vaccine used over a 6-month period. All provinces and territories in Canada have implemented publicly funded HPV vaccine programs for females and eight provinces fund vaccine administration to males, with the goal of reducing the risk of cervical cancer (Salvadori & CPS, Infectious Diseases and Immunization Committee, 2018). For provincial/territorial guidelines for immunizations see Additional Resources at the end of this chapter.

Herpes Simplex Virus. Unknown until the middle of the twentieth century, herpes simplex virus (HSV) infection is now widespread in Canada, especially in females. HSV infection results in painful, recurrent ulcers. It is caused by two different antigen subtypes of HSV: HSV type 1 (HSV-1) and HSV type 2 (HSV-2). HSV-2 is usually transmitted sexually and HSV-1, nonsexually. Although HSV-1 is more commonly associated with gingivostomatitis and oral labial ulcers (fever blisters) and HSV-2 with genital lesions, neither type is exclusively associated with the respective sites.

HSV infection is not a reportable disease in Canada, therefore the number of cases is unknown, although it is known that the incidence and prevalence of HSV-1 genital infection is increasing globally (PHAC, 2013d). Recurrent HSV infections are much more common. Most persons infected with HSV-2 have not been diagnosed, and most infections are transmitted by persons unaware that they are infected. Genital herpes increases the risk of acquisition of HIV twofold (PHAC, 2013d).

An initial HSV genital infection is characterized by multiple painful lesions, fever, chills, malaise, and severe dysuria and may last 2 to 3 weeks. Women generally have a more severe clinical course than men do. Women with primary genital herpes have many lesions that progress from macules to papules; they then progress to form vesicles, pustules, and ulcers that crust and heal without scarring (Figure 7.12). These ulcers are extremely tender, and primary infections may be bilateral. Patients also may have itching, inguinal tenderness, and

Fig. 7.12 Herpes genitalis.

lymphadenopathy. Severe vulvar edema may develop, and individuals may have difficulty sitting. HSV cervicitis is common with initial HSV-2 infections. The cervix may appear normal or be friable, reddened, ulcerated, or necrotic. A heavy, watery-to-purulent vaginal discharge is common. Extragenital lesions may be present because of autoinoculation. Urinary retention and dysuria may occur secondary to autonomic involvement of the sacral nerve root.

People with recurrent episodes of HSV infections commonly have only local symptoms that are usually less severe than those associated with the initial infection. Systemic symptoms are usually absent, although the characteristic prodromal genital tingling is common. Recurrent lesions are unilateral, are less severe, and usually last 9 to 11 days. Lesions begin as vesicles and progress rapidly to ulcers. Few patients with recurrent disease have cervicitis.

During pregnancy infection with HSV-2 can have adverse effects on both the pregnant patient and fetus. Viremia occurs during the primary infection, and congenital infection is possible, although rare. The risk for newborn infection is greatest when the primary infection occurs in the third trimester in the pregnant patient. Primary infections during the first trimester have been associated with increased miscarriage rates (Money et al., 2017).

Screening and diagnosis. Although a diagnosis of herpes infection may be suspected from the history and physical examination, it is confirmed by laboratory studies. A viral culture is obtained by swabbing exudate during the vesicular stage of the disease. A primary infection can be confirmed by demonstrating an absence of HSV antibody in an acute-phase blood sample and the presence of antibody in the convalescent sample (i.e., seroconversion). Most individuals seroconvert within 3 to 6 weeks; by 12 weeks, more than 70% will have seroconverted (PHAC, 2013d).

Collaborative care. Genital herpes is a chronic and recurring disease for which there is no known cure. Management is directed toward specific treatment during primary and recurrent infections, prevention, self-help measures, and psychological support.

Oral medications used for treating the first clinical HSV infection include acyclovir, famciclovir, and valacyclovir. These medications are considered for episodic or suppressive therapy for recurrent HSV. Intravenous acyclovir may be used for patients with severe disease (PHAC, 2013d) (see Table 7.3). Acyclovir and valacyclovir may be used during pregnancy to reduce the symptoms of HSV and to suppress HSV close to the time of birth.

Cleaning lesions twice a day with saline helps prevent secondary infection. Bacterial infection must be treated with appropriate antibiotics. Measures that may increase comfort for individuals when lesions are active include warm sitz baths with baking soda; keeping lesions dry by using cool air from a hair dryer or by patting dry with a soft towel; wearing cotton underwear and loose clothing; using drying aids such as hydrogen peroxide, Burow solution, or oatmeal baths; and applying cool, wet, black tea bags to lesions. Patients can also apply compresses with an infusion of cloves or peppermint oil and clove oil to lesions.

Oral analgesics such as Aspirin or ibuprofen may be used to relieve pain and systemic symptoms associated with initial infections. Because the mucous membranes affected by herpes are extremely sensitive, any topical agents should be used with caution. Nonantiviral ointments, especially those containing cortisone, should be avoided. A thin layer of lidocaine ointment or an antiseptic spray may be applied to decrease discomfort, especially if walking is difficult.

Counselling and education are critical components of the nursing care of patients with herpes infections. Information regarding the etiology, signs and symptoms, transmission, and treatment should be provided. The nurse should explain that each patient is unique in their response to herpes and emphasize the variability of symptoms. Patients should be helped to understand when viral shedding and thus transmission to a partner are most likely. They should be counselled to refrain from sexual contact from the onset of prodrome until the complete healing of lesions.

Some authorities recommend consistent use of condoms for all persons with genital herpes. Condoms may not prevent transmission, particularly male-to-female transmission; however, this does not mean that the partners should avoid all intimacy. Individuals can be encouraged to maintain close contact with their partners while avoiding contact with lesions. Patients should be taught how to look for herpetic lesions using a mirror and good light source and a wet cloth or finger covered with a finger cot to rub lightly over the labia. The nurse should ensure that individuals understand that when lesions are active, they should not share intimate articles (e.g., washcloths or wet towels) that come into contact with the lesions. Only plain soap and water are needed to clean hands that have come in contact with herpetic lesions; isolation is neither necessary nor appropriate.

Stress, menstruation, trauma, febrile illnesses, chronic illness, and ultraviolet light have all been found to trigger genital herpes. Individuals may wish to keep a diary to identify stressors that seem to be associated with recurrent herpes attacks so that they can then avoid these stressors when possible. The role of exercise in reducing stress can be discussed. Referral for stress-reduction therapy, yoga, or meditation classes may be indicated. Avoiding excessive heat, sun, and hot baths and using a lubricant during sexual intercourse to reduce friction may also be helpful. Individuals in their childbearing years should be counselled about the risk of herpes infection during pregnancy. They should be instructed to use condoms if there is any risk of contracting an STI from a sexual partner. If they become pregnant while taking acyclovir, the risk of birth defects does not appear to be higher than that for the general population; however, continued use should be based on whether the benefits for the patient outweigh the possible risks to the fetus. Acyclovir does enter breast milk, but the amount of medication ingested during breastfeeding is very low and is usually not a health concern (Centers for Disease Control and Prevention [CDC], 2015).

Because newborn HSV infection is such a devastating disease, prevention is critical. Patients with a history of HSV are often placed on acyclovir for suppression during the last few weeks of pregnancy to try to prevent an outbreak at the time of labour and birth. This could prevent the need for Caesarean birth and also decrease the risk of newborn infection (PHAC, 2013d). Patients should be questioned regarding the presence of HSV at the onset of labour. If visible lesions are not present when labour begins, vaginal birth is acceptable. Caesarean birth within 4 hours after labour begins or membranes rupture is recommended if visible lesions are present. Infants who are born through an infected vagina should be observed carefully and cultured.

The emotional impact of contracting an incurable STI such as herpes can be considerable. The most common psychological patient concerns include the following:

- Fear of transmission
- Fear of being judged or rejected by a partner
- Loneliness, depression, and low self-esteem
- Anxiety concerning potential effect on childbearing

Patients need the opportunity to discuss their feelings and may need help in learning to live with the disease. A patient can be encouraged to think of themselves as someone who is healthy and merely inconvenienced from time to time. Herpes can affect a person's sexuality, their sexual practices, and their current and future relationships. They may need help in discussing their HSV status with their partner or with future partners.

Hepatitis. Five different viruses (hepatitis viruses A, B, C, D, and E) account for almost all cases of viral hepatitis in humans. While only

hepatitis B is considered an STI, hepatitis A and C are discussed here. Hepatitis D and E viruses, common among users of intravenous drugs and recipients of multiple blood transfusions, are not included in this discussion.

Hepatitis A. Hepatitis A virus (HAV) infection is acquired primarily through a fecal–oral route by ingestion of contaminated food, particularly milk, shellfish, or polluted water, or person-to-person contact. People who are at risk for developing HAV include travellers to or immigrants from HAV-endemic areas, drug users (injectable and non-injectable), household contacts of adopted children from countries with endemic HAV, and individuals living in some Indigenous communities (Government of Canada, 2021a). HAV infection is characterized by flu-like symptoms with malaise, fatigue, anorexia, nausea, pruritus, fever, and upper right quadrant pain. Serological testing to detect the immunoglobulin M (IgM) antibody is done to confirm acute infections. Because HAV infection is self-limited and does not result in chronic infection or chronic liver disease, treatment is usually supportive and includes bed rest, balanced nutrition, and avoidance of alcohol or other medications that cause liver damage (e.g., acetaminophen ethyl alcohol) (Government of Canada, 2021a). Patients who become dehydrated from nausea and vomiting or who have fulminating hepatitis A may need to be hospitalized. Hepatitis A vaccine is effective in preventing most HAV infections and is recommended for persons travelling to areas with high levels of HAV or with other increased risks of developing HAV.

Hepatitis B. Hepatitis B virus (HBV) infection is an STI and is the virus most threatening to the fetus and newborn. It is caused by a large DNA virus and is associated with three antigens and their antibodies: hepatitis B surface antigen (HBsAg), HBV antigen (HBeAg), HBV core antigen (HBcAg), antibody to HBsAg (anti-HBs), antibody to HBeAg (anti-HBe), and antibody to HBcAg (anti-HBc). HBsAg has been found in blood, saliva, sweat, tears, vaginal secretions, and semen. Screening for active or chronic disease or disease immunity is based on testing for these antigens and their antibodies.

Populations at greatest risk for HBV are listed in Box 7.8. Perinatal transmission most often occurs in infants of a pregnant parent who has acute hepatitis infection late in the third trimester or during the intrapartum or postpartum periods from exposure to HBsAg-positive vaginal secretions, blood, amniotic fluid, saliva, or breast milk. HBsAg has also been transmitted by artificial insemination. Although HBV can be transmitted via blood transfusion, the incidence of such infections has decreased significantly since the testing of blood for HBsAg became routine. The prevalence of HBV in Canada is estimated to be 0.5 to 1.0%, with an increased rate among immigrants and Indigenous populations (PHAC, 2014).

HBV infection is a disease of the liver and is often a silent infection. In the adult, its course can be fulminating and the outcome fatal. Symptoms of HBV infection are similar to those of hepatitis A: arthralgias, arthritis, lassitude, anorexia, nausea, vomiting, headache, fever, and mild abdominal pain. Later the person may have clay-coloured stools, dark urine, increased abdominal pain, and jaundice. Approximately 5% of individuals with HBV have persistent HBsAg and become chronic hepatitis B carriers.

Screening and diagnosis. All people at high risk for contracting HBV should be screened on a regular basis. Screening should also be done routinely in the following situations: pregnancy, HIV or HCV infection, planned therapy with immunosuppressive/immunoregulatory agents, or a compromised immune system. Screening for the presence of HBsAg is recommended in all pregnant patients at the first prenatal visit or on admission for labour and birth if prenatal test results are not available (PHAC, 2014). It is important to maintain a high index of suspicion for HBV, as infection is frequently asymptomatic; 30% of infections have no identified risk factors (PHAC, 2014).

The HBsAg screening test is usually performed, given that a rise in HBsAg occurs at the onset of clinical symptoms and usually indicates an active infection. If HBsAg persists in the blood, the person is identified as a carrier. If the HBsAg test result is positive, further laboratory studies may be ordered: anti-HBe, anti-HBc, serum glutamic-oxaloacetic transaminase (SGOT), alkaline phosphatase, and liver panel. HBV is a notifiable disease in all provinces and territories in Canada and must be reported to the regional/local Medical Officer of Health.

Collaborative care. There is no specific treatment for hepatitis B. Recovery is usually spontaneous in 3 to 16 weeks for 95% of people with the infection. Pregnancies complicated by acute viral hepatitis are managed on an outpatient basis. Patients should be advised to increase bed rest; eat a high-protein, low-fat diet; and increase their fluid intake. They should avoid using alcohol and medications metabolized in the liver. Pregnant patients with a definite exposure to HBV should be given hepatitis B immunoglobulin (HBIG) and begin the hepatitis B vaccine series within 14 days of the most recent contact to prevent infection (Castillo et al., 2017). Pregnant patients who are not immune to HBV may be vaccinated, and those who are at risk of HBV infection should be vaccinated during pregnancy, as vaccination during pregnancy is not thought to pose risks to the fetus (Castillo, et al., 2017: Government of Canada, 2020).

Patient education includes explanation of the meaning of hepatitis B infection, including transmission, state of infectivity, and sequelae. The nurse should also explain the need for immunoprophylaxis for

BOX 7.8 High-Risk Groups for Hepatitis B

- Birth in a region with intermediate or high endemicity
- Infants born to hepatitis B surface antigen (HBsAg)-positive mothers
- Exposure before 7 years of age (e.g., child's immediate and/or extended family immigrated from a region of intermediate or high endemicity and/or child visited such a region)
- Family history of hepatitis B or hepatoma
- Exposure to HBsAg-positive person (e.g., percutaneous, sexual/household contact)
- High-risk sexual activities (e.g., unprotected sex, multiple sexual partners)
- Substance use with sharing of equipment (e.g., injection or inhalation drug use)
- Exposure to blood or blood products in endemic regions without routine precautions or screening
- Transfusion recipient or medical procedure in Canada before 1970
- Use of shared or contaminated materials or equipment (e.g., instruments or tools used for personal services procedures such as tattooing or piercing and body modifications, or any alternative health care that has the potential to break the skin)
- Use of shared or contaminated medical devices (e.g., glucometers)
- Occupational exposure to blood or body fluids
- Travel to or residence in a region of intermediate or high endemicity
- Incarceration
- Institutionalization (particularly in institutions for developmentally challenged persons)

Government of Canada. (2014). *Primary care management of hepatitis B—Quick reference (HBV-QR).* https://www.canada.ca/en/public-health/services/reports-publications/primary-care-management-hepatitis-b-quick-reference.html#intro. Reproduced with permission from the Minister of Health, 2016.

household members and sexual contacts. To decrease transmission of the virus, patients with hepatitis B or who test positive for HBV should be advised to maintain a high level of personal hygiene (e.g., wash hands after using the toilet; carefully dispose of tampons, pads, and bandages in plastic bags; not share razor blades, toothbrushes, needles, or manicure implements; have a male partner use a condom if he is unvaccinated and without hepatitis; avoid sharing saliva through kissing or through sharing of silverware or dishes; and wipe up blood spills immediately with soap and water). Patients should inform all health care providers of their carrier state. Postpartum patients should be reassured that breastfeeding is not contraindicated and patients with chronic HBV infection who wish to breastfeed should be encouraged to do so (Castillo et al., 2017).

Prevention. Primary prevention of HBV should be the focus for treatment. Primary prevention includes counselling and education regarding risky behaviours, harm reduction strategies (needle exchange programs), and hepatitis B vaccination (pre-exposure). All provinces and territories have either a universal school-based hepatitis B vaccination program aimed at children aged 9 to 13 or a newborn vaccination program, although the Canadian Paediatric Society (CPS) and the Society of Obstetricians and Gynaecologists of Canada (SOGC) are advocating for the harmonization of immunization schedules in Canada and for universal HBV immunization for newborns (Castillo et al., 2017). Hepatitis B vaccine should also be offered to high-risk groups (see Box 7.8). The vaccine is given in a series of three (four if rapid protection is needed) doses over a 7-month period, with the first two doses given at least 1 month apart.

Secondary prevention is the administration of HBIG. This should be offered to affected individuals, including pregnant patients who have percutaneous (needlestick) or mucosal exposure, up to 7 days after exposure and to sexual contacts within 14 days of exposure (ideally within 48 hours), followed by hepatitis B vaccine. For infants born to an HBV-infected parent, the first dose of hepatitis B vaccine and HBIG should be administered within 12 hours of birth (Castillo et al., 2017).

Hepatitis C. Hepatitis C virus (HCV) is an important cause of chronic liver disease and is becoming a major public health concern worldwide. It is estimated that there are approximately 220 000 people with chronic hepatitis C, and many people are unaware of their infection (Ha et al., 2016). The most common risk factor is sharing drug use equipment (injection, intranasal, or inhalation), even once. Other risk factors include exposure to nonsterile equipment during hemodialysis, needle stick injury, tattooing or body piercing, sharing of personal care items, or during surgical procedures; receipt of blood, blood product, or organ transplant prior to 1992 in Canada; invasive medical procedures in countries where infection prevention and control practices are not standardized; engaging in high-risk sexual behaviour; and being born to a mother who is HCV-positive (Government of Canada, 2021b).

Most patients with HCV are asymptomatic or have general flu-like symptoms similar to those of hepatitis A. HCV infection is confirmed by the presence of anti-C antibody during laboratory testing. Routine HCV testing is recommended for people with risk factors (Boucher & Gruslin, 2017).

The treatment of hepatitis C involves direct-acting antivirals for nearly all patients. The treatment of infected patients should be individualized to maximize chance of success, especially for difficult-to-cure populations, including patients with renal failure, decompensated cirrhosis, and active substance use disorders (Shah et al., 2018). Harm reduction strategies for drug use is an important adjunct for many persons with HCV.

Currently, there is no vaccine to prevent hepatitis C. Transmission of HCV through breastfeeding has not been reported, although individuals with cracked, bleeding nipples are advised to stop breastfeeding until the nipples heal. Hepatitis C is reportable to local public health authorities in all provinces and territories.

Human Immunodeficiency Virus (HIV). The number of people living with HIV (including acquired immunodeficiency syndrome [AIDS]) continues to rise, with an estimated 62 050 Canadians living with HIV at the end of 2018 (CATIE, 2021). One reason for the increase in the number of people living with HIV is that new infections continue to increase at a greater number than HIV-related deaths, as new treatments have improved survival. An estimated 23% of cases of HIV are among women, and 10% of all people with HIV are Indigenous (CATIE, 2021). Behaviours that place people at risk have been well documented; nonetheless, all patients should be assessed for the possibility of HIV exposure.

Severe depression of the cellular immune system associated with HIV infection characterizes AIDS. The most commonly reported opportunistic diseases are *Pneumocystis carinii* pneumonia, *Candida* esophagitis, and wasting syndrome. Other viral infections such as HSV and cytomegalovirus infections seem to be more prevalent in women than in men. There is a higher incidence of adnexal masses in patients with PID who are also HIV-positive, but antibiotics are often as effective in HIV-positive patients with PID as they are in HIV-negative patients with PID (Gardella et al., 2017). The clinical course of HPV infection in women with HIV infection is accelerated and recurrence is more frequent.

Once HIV enters the body, seroconversion to HIV positivity usually occurs within 6 to 12 weeks. Although HIV seroconversion may be totally asymptomatic, it usually is accompanied by a viremic, influenza-like response. Symptoms include fever, headache, night sweats, malaise, generalized lymphadenopathy, myalgias, nausea, diarrhea, weight loss, sore throat, and rash.

Laboratory studies may reveal leukopenia, thrombocytopenia, anemia, and an elevated erythrocyte sedimentation rate. HIV has a strong affinity for surface-marker proteins on T lymphocytes. This affinity leads to significant T-cell destruction. Both clinical and epidemiological studies have shown that declining CD4 levels are strongly associated with increased incidence of AIDS-related diseases and death in many different groups of HIV-infected persons.

Screening and diagnosis. Screening for HIV, as well as teaching and counselling on risk factors, indications for being tested, and testing, are important roles for nurses. A number of behaviours place people at risk for HIV infection, including intravenous drug use, high-risk sex practices, multiple sex partners, and a previous history of multiple STIs. In Canada, HIV infection is screened for by using fourth-generation HIV tests, which can detect both the p24 antigen and anti-HIV antibodies. These HIV tests are sometimes referred to as *antigen–antibody combination tests*. Fourth-generation HIV tests can detect HIV infection in 50% of people by 18 days after infection, 95% of people by 34 days after infection, and 99% of people by one and a half months after infection (CATIE, 2020). An alternative method of rapid testing for HIV is available, which involves using a blood sample obtained by fingerstick or venipuncture, serum, or plasma. The tests have accuracy rates of 98 to 99%. Currently, there are two rapid HIV screening tests that have been approved in Canada. These rapid tests are the point-of-care test and the self-test, both of which can provide results within minutes (CATIE, 2020). If results to this test are reactive, this must be confirmed with an additional blood test.

Transmission of the virus from pregnant patient to fetus can occur throughout the perinatal period. Exposure may occur to the fetus through parental circulation as early as the first trimester of pregnancy, to the newborn during labour and birth by inoculation or ingestion of

parental blood and other infected fluids, or to the newborn through breast milk (Bitnum et al., 2014). Thus all pregnant patients should have HIV screening with appropriate counselling. This testing must be voluntary; no one should be tested without their knowledge (Keenan-Lindsay & Yudin, 2017). Because the HIV antibody crosses the placenta, a definite diagnosis of HIV in children younger than 18 months is based on laboratory evidence of HIV in blood or tissues by culture, nucleic acid, or antigen detection (Bitnum et al., 2014).

Counselling about HIV testing. Counselling before and after HIV testing is standard practice. It is a nurse's responsibility to assess a person's understanding of the information that such a test would provide and to ensure that they thoroughly understand the emotional, legal, and medical implications of a positive or negative test, before taking an HIV test. Given the strong social stigma attached to HIV infection, nurses must consider the issue of confidentiality and documentation before providing counselling and offering HIV testing to patients.

Unless rapid testing is done, there is generally a 1- to 3-week waiting period for results after testing for HIV; this can be a very anxious time for the patient. The nurse should inform them that this time period between blood drawing and test results is routine. Test results must always be communicated in person, and patients should be told in advance that this is the procedure. Whenever possible, the person who provided the pretest counselling should also be the one to give the patient the test results.

The person's reaction to a negative test should be explored by asking, "How do you feel?" Counselling sessions for patients with an HIV-negative result are another opportunity to provide education. Emphasis can be placed on ways in which a person can remain HIV-free. Patients should be encouraged to have ongoing testing if high-risk behaviours continue.

In post-test counselling of an HIV-positive patient, privacy with no interruptions is essential. Adequate time for the counselling sessions should also be provided. The nurse should make sure that the person understands what a positive test means and review the reliability of the test results. Risk-reduction practices should be re-emphasized. Referral for appropriate medical evaluation and follow-up should be made, and the need or desire for psychosocial or psychiatric referrals assessed. The public health unit needs to be notified regarding the positive status, as HIV is a reportable disease in Canada. Disclosure issues should be discussed with the patient, including the medicolegal requirement to disclose the HIV status to a potential sexual or drug-injecting partner. In general, persons with HIV infection should inform their primary health care provider and consider informing other health care providers (e.g., dentist). Disclosure in the workplace is usually not mandatory but should be individualized (e.g., where the person with HIV infection has direct patient-care responsibilities). The nurse should also discuss disclosing the diagnosis to friends or family; while not essential, this might be considered if there is potential for a positive outcome (e.g., positive family support).

The importance of early medical evaluation (to determine baseline health status) and the benefits of treatment and follow-up need to be stressed. If possible, the nurse should make a referral or appointment for the patient at the post-test counselling session.

Collaborative care. During the initial contact with an HIV-infected person, the nurse should establish what the person knows about HIV infection and determine whether they are being cared for by a medical practitioner or facility with expertise in caring for persons with HIV infections, including AIDS. Psychological referral also may be indicated. Resources such as counselling for financial assistance and legal advocacy may be appropriate. Patients who are drug users should be offered referral to a substance-use cessation program. A major focus of counselling is prevention of transmission of HIV to partners.

Nurses counselling seropositive persons wishing for contraceptive information can recommend oral contraceptives and latex condoms, or tubal sterilization or vasectomy and latex condoms. Female condoms or abstinence should be suggested to patients whose male partners will not wear condoms.

No cure is available for HIV infections at this time, although proper treatment and care have slowed disease progression to such a degree that HIV infection is now considered a chronic, manageable condition. Opportunistic infections and concurrent diseases caused by HIV can be managed vigorously with treatment specific to the infection or disease. Routine gynecological care for HIV-positive patients should include a pelvic examination with thorough Pap screening every 6 months, twice and then at least annually depending on the results (PHAC, 2016). Thorough Pap screening is essential because of the greatly increased incidence of abnormal findings on examination. In addition, HIV-positive patients should be screened for syphilis, gonorrhea, chlamydia, and other vaginal infections and treated if infections are present. General health promotion strategies are an important part of care (e.g., smoking cessation, sound nutrition), as is antiretroviral therapy (ART). Discussion of the medical care of HIV-positive patients or patients with AIDS is beyond the scope of this chapter because of the rapidly changing recommendations. The reader is referred to the Centers for Disease and Prevention (CDC) (https://www.cdc.gov/hiv/default.html) and to Internet websites such as the Canadian Aids Treatment Information Exchange (http://www.catie.ca) for current information and recommendations. For care of the pregnant patient with HIV see Chapter 15.

! NURSING ALERT

Counselling associated with HIV testing has two components: pretest and post-test. During pretest counselling, a personalized risk assessment is conducted, the meaning of positive and negative test results is explained, informed consent for HIV testing is obtained, and the patient is helped to develop a realistic plan for reducing risk and preventing infection. Post-test counselling includes informing the patient of the test results, reviewing the meaning of the results, and reinforcing prevention messages. All pretest and post-test counselling should be documented.

Zika Virus. The Zika virus is spread by bites from the Aedes mosquito. It is also spread via sexual contact through semen. Patients who become pregnant and are infected by the Zika virus have an increased risk for giving birth to an infant with microcephaly. Zika virus has also been associated with risk for Guillain-Barré syndrome, a neurological condition that can lead to muscle weakness and possibly paralysis (Government of Canada, 2019). The Aedes mosquito has been found predominantly in Africa, Southeast Asia, the Caribbean, Central America, South America, and the Pacific Islands. Currently, the mosquitoes that transmit Zika virus are not established in Canada because of the colder climate, so there is a very low probability of mosquito transmission in Canada (Government of Canada, 2019). Pregnant individuals and those considering becoming pregnant should avoid travelling to areas that are known to have the Aedes mosquito. Male travellers who may have been exposed to the Zika virus should use a condom for 3 months after exposure. Male travellers with a pregnant partner should refrain from unprotected sex for the duration of the pregnancy (Government of Canada, 2019).

Vaginal Infections

Vaginal discharge and itching of the vulva and vagina are among the most common reasons an individual seeks help from a health care provider. Patients cite discomfort from vaginal discharge more than any

other gynecological symptom. Vaginal discharge resulting from infection must be distinguished from normal secretions. Normal vaginal secretions (or leukorrhea) are clear to cloudy in appearance. The discharge may turn yellow after drying; is slightly slimy; is nonirritating; and has a mild, inoffensive odour. Normal vaginal secretions are acidic, with a pH range of 4 to 5. The amount of leukorrhea differs with phases of the menstrual cycle, with greater amounts occurring at ovulation and just before menses. Leukorrhea is also increased during pregnancy. Normal vaginal secretions contain lactobacilli and epithelial cells.

Vaginitis, or abnormal vaginal discharge, is an infection caused by a microorganism. The most common vaginal infections are bacterial vaginosis, candidiasis, and trichomoniasis.

Vulvovaginitis (inflammation of the vulva and vagina) may be caused by vaginal infection; copious leukorrhea, which can cause maceration of tissues; and chemical irritants, allergens, and foreign bodies, which may produce inflammatory reactions.

Bacterial Vaginosis. Bacterial vaginosis (BV), formerly called *nonspecific vaginitis*, *Haemophilus vaginitis*, or *Gardnerella*, is the most common type of vaginitis. The exact etiology of BV is unknown and it is not usually considered an STI. It is a syndrome in which normal hydrogen peroxide–producing lactobacilli are replaced with high concentrations of anaerobic bacteria (*Gardnerella* and *Mobiluncus*). With the proliferation of anaerobes, the level of vaginal amines is raised and the normal acidic pH of the vagina is altered. Epithelial cells slough, and numerous bacteria attach to their surfaces (clue cells). When the amines are volatilized, the characteristic odour of BV occurs.

Screening and diagnosis. A careful history may help distinguish BV from other vaginal infections if the person is symptomatic. Most patients with BV notice a characteristic "fishy odour" in the vaginal area, although not all note it. The odour may be noticed by the patient or their partner after intercourse when semen is present, because semen releases the vaginal amines. When present, the BV discharge is usually profuse; thin; and white, grey, or milky in appearance. Some patients also may experience mild irritation or pruritus. Patients with previous occurrence of similar symptoms, diagnosis, and treatment should be queried because patients with BV often have been treated incorrectly due to misdiagnosis.

Microscopic examination of vaginal secretions is always done (Table 7.4). Both normal saline and 10% potassium hydroxide (KOH) smears should be made. The presence of clue cells confirmed by wet smear is highly diagnostic because the phenomenon is specific to BV (PHAC, 2013c). Vaginal secretions should be tested for pH and amine odour. Nitrazine paper is sensitive enough to detect a pH of 4.5 or greater. The fishy odour of BV will be released when KOH is added to vaginal secretions on the lip of the withdrawn speculum.

Collaborative care. Treatment of BV with oral metronidazole (Flagyl) is most effective (PHAC, 2013c), although vaginal preparations (e.g., metronidazole gel, clindamycin cream) are also used. The decision of which treatment to use should be based on the preference of the patient. Adverse effects of metronidazole are numerous and include a sharp, unpleasant metallic taste in the mouth; furry tongue; CNS reactions; and urinary tract disturbances. When oral metronidazole is taken, the patient is advised not to drink alcoholic beverages, as severe adverse effects of abdominal distress, nausea, vomiting, and headache may occur. Gastrointestinal symptoms are common whether alcohol is consumed or not. Treatment of sexual partners is not recommended because sexual transmission of BV has not been proven. BV during pregnancy is associated with premature rupture of the membranes, chorioamnionitis, preterm labour, preterm birth, and post-Caesarean endometritis (PHAC, 2013c). Therefore, pregnant patients should be treated to relieve vaginal symptoms and the signs of infection.

TABLE 7.4 Wet Smear Tests for Vaginal Infections

Infection	Test	Positive Findings
Trichomoniasis	Saline wet smear (vaginal secretions mixed with normal saline on a glass slide)	Presence of many white blood cell protozoa
Candidiasis	Potassium hydroxide (KOH) prep (vaginal secretions mixed with KOH on a glass slide)	Presence of hyphae and pseudohyphae (buds and branches of yeast cells)
Bacterial vaginosis	Normal saline smear	Presence of clue cells (vaginal epithelial cells coated with bacteria)
	Whiff test (vaginal secretions mixed with KOH)	Release of fishy odour

Candidiasis. Vulvovaginal candidiasis (VVC), or yeast infection, is a common type of vaginal infection in Canada. It is estimated that approximately 75% of women will have at least one episode of VVC in their lifetime, and 5% of patients of reproductive age will have recurrent VVC (four or more episodes of VVC a year) (PHAC, 2013c). Although vaginal candidiasis infections are common in healthy patients, those seen in patients with HIV infection are often more severe and persistent. Genital candidiasis lesions may be painful, and coalescing ulcerations necessitate continuous, prophylactic therapy.

The most common infecting organism is *Candida albicans*. It is estimated that 90% of yeast infections in patients are caused by this organism. In recent years, the incidence of non–*C. albicans* infections has increased steadily. Patients with chronic or recurrent infections often are infected with a higher percentage of non–*C. albicans* species than are patients with their first infection or those who have few recurrences (PHAC, 2013c).

Numerous factors have been identified as predisposing a person to yeast infections. These include antibiotic therapy, particularly broad-spectrum antibiotics such as ampicillin, tetracycline, cephalosporins, and metronidazole; diabetes, especially when uncontrolled; pregnancy; obesity; diets high in refined sugars or artificial sweeteners; use of corticosteroids and exogenous hormones; and immunosuppressed states. Clinical observations and research have suggested that tight-fitting clothing and underwear or pantyhose made of nonabsorbent materials create an environment in which a vaginal fungus can grow.

The most common symptom of yeast infection is vulvar and possibly vaginal pruritus. The itching may be mild or intense, may interfere with rest and activities, and may occur during or after intercourse. Some patients report a feeling of dryness. Others may have painful urination as the urine flows over the vulva. The latter usually occurs in patients who have **excoriations** resulting from scratching. Most often the discharge is thick, white, lumpy, and cottage cheese–like. The discharge may be found in patches on the vaginal walls, cervix, and labia. Commonly the vulva is red and swollen, as are the labial folds, vagina, and cervix. Although there is no odour characteristic of yeast infections, sometimes a yeasty or musty smell is noted.

Screening and diagnosis. In addition to noting the person's symptoms, their onset, and their course, the history is a valuable screening tool for identifying predisposing risk factors. Physical examination should include a thorough inspection of the vulva and vagina. A speculum examination is always done. Commonly, saline and KOH wet

smear and vaginal pH are obtained (see Table 7.4). Vaginal pH is normal (less than 4.5) with a yeast infection. The characteristic pseudohypha (bud or branching of a fungus) may be seen on a wet smear done with normal saline; however, they may be confused with other cells and artifacts.

Collaborative care. A number of antifungal preparations are available for the treatment of *C. albicans*. Fluconazole in a single dose can be prescribed, and other medications (e.g., miconazole [Monistat] and clotrimazole [Canesten]) are available as OTC agents. Fluconazole is contraindicated in pregnancy. Exogenous lactobacillus (in the form of dairy products [yogurt] or powder, tablet, capsule, or suppository supplements) and garlic have been suggested for prevention and treatment of vulvovaginal candidiasis but have not been found to be effective (Gardella et al., 2017). The first time a person suspects that they have a yeast infection they should see a health care provider for confirmation of the diagnosis and for treatment recommendation. If they have another infection, they may wish to purchase an OTC preparation and self-treat. Treatments should begin to work in 2 to 3 days. If the person elects to do this, they should always be counselled to seek care for numerous recurrent or chronic yeast infections. If vaginal discharge is extremely thick and copious, vaginal **débridement** with a cotton swab followed by application of vaginal medication may be effective.

Patients who have extensive irritation, swelling, and discomfort of the labia and vulva may find sitz baths helpful in decreasing inflammation and increasing comfort. Adding colloidal oatmeal powder to the bath may also increase the person's comfort. Not wearing underpants to bed may help decrease symptoms and prevent recurrences. Completion of the full course of treatment prescribed is essential to removing the pathogen. Medication should be continued even during menstruation. Patients should be counselled not to use tampons during menstruation because the medication will be absorbed by the tampon. If possible, intercourse should be avoided during treatment; if this is not feasible, the patient's partner should be encouraged to use a condom if appropriate, to prevent introduction of more organisms. Suggested measures to prevent genital tract infections are in the Patient Teaching Box, Prevention of Genital Tract Infections.

PATIENT TEACHING

Prevention of Genital Tract Infections

- Practise genital hygiene.
- Choose underwear or hosiery with a cotton crotch.
- Avoid tight-fitting clothing (especially tight jeans).
- Select cloth car seat covers instead of vinyl.
- Limit the time spent in damp exercise clothes (especially swimsuits, leotards, and tights).
- Limit exposure to bath salts or bubble bath.
- Avoid coloured or scented toilet tissue.
- If sensitive, discontinue use of feminine hygiene deodorant sprays.
- Use condoms.
- Void before and after intercourse.
- Decrease dietary sugar.
- Drink yeast-active milk and eat yogourt (with lactobacilli).
- Do not douche.

Trichomoniasis. *Trichomonas vaginalis* is almost always an STI and is also a common cause of vaginal infection (5 to 50% of all vaginitis) and discharge (Gardella et al., 2017). Trichomoniasis is caused by *Trichomonas vaginalis*, an anaerobic, one-celled protozoan with characteristic flagella. Although trichomoniasis may be asymptomatic, commonly patients have yellowish-to-greenish, frothy, mucopurulent, copious, and malodourous discharge. Inflammation of the vulva, vagina, or both may be present, and the patient may report irritation and pruritus. Dysuria and dyspareunia are often present. Typically the discharge worsens during and after menstruation. The cervix and vaginal walls demonstrate the characteristic "strawberry spots" or tiny petechiae in less than 10% of patients, and the cervix may bleed on contact. In severe infections the vaginal walls, cervix, and, occasionally, the vulva may be acutely inflamed.

Screening and diagnosis. In addition to obtaining a history of current symptoms, a thorough sexual history should be taken. The nurse should note any history of similar symptoms in the past and treatment used. The nurse also needs to determine whether the patient's partner or partners were treated and if they have had subsequent relations with new partners.

A speculum examination is always done, even though it may be uncomfortable for the person; relaxation techniques and breathing exercises may help the patient with the procedure. Any of the classic signs may or may not be seen on physical examination. The typical one-celled flagellate trichomonads are easily distinguished on a normal saline wet prep (see Table 7.4). The pH of the discharge is greater than 5.0. Because trichomoniasis is an STI, once diagnosis is confirmed, appropriate laboratory studies for other STIs should be carried out.

Collaborative care. The recommended treatment is metronidazole (Flagyl), 2 g orally in a single dose, or an alternative treatment is 500 mg orally bid for 7 days (PHAC, 2013c). Although a male partner is usually asymptomatic, he should receive treatment also because he often harbours the trichomonads in the urethra or prostate. Nurses need to discuss the importance of partner treatment with their patients. If partners are not treated, the infection will likely recur. Patients should be taught that they should not drink alcohol during and for 24 hours after therapy as there is a risk of a disulfiram (Antabuse) reaction. Symptoms of this reaction include dizziness, headache, shortness of breath, palpitation, and nausea and vomiting.

In pregnant patients trichomoniasis may be associated with premature rupture of the membranes, preterm birth, and low birth weight. Symptomatic pregnant patients should be treated with metronidazole (PHAC, 2013c).

Patients with trichomoniasis need to understand the sexual transmission of this disease. Patients must know that the organism may be present without observable symptoms, perhaps for several months, and that determining when they became infected is impossible. Trichomoniasis is a reportable disease in some jurisdictions.

CONCERNS OF THE BREAST

Benign Problems

Fibrocystic Changes. Approximately 50% of patients have a breast concern at some point in their adult lives. The most common benign breast issue is fibrocystic change (Sandadi et al., 2017). Fibrocystic changes occur to varying degrees in breasts of healthy individuals. The etiological agent responsible for these changes has not been found. One theory is that estrogen excess and progesterone deficiency in the luteal phase of the menstrual cycle may cause changes in breast tissue.

Fibrocystic changes are characterized by lumpiness, with or without tenderness, in both breasts. Single simple cysts can also occur. Symptoms usually develop approximately a week before menstruation begins and subside approximately a week after menstruation ends. Symptoms include dull, heavy pain and a sense of fullness and tenderness, often in the upper outer quadrants of the breasts. Physical examination may reveal excessive nodularity that feels like peas (Sandadi et al., 2017). Larger cysts are often described as feeling like water-filled balloons.

Patients in their 20s report the most severe pain. Patients in their 30s have premenstrual pain and tenderness; small, multiple nodules are usually present. Patients in their 40s usually do not report severe pain, but cysts are tender and often regress in size (Sandadi et al., 2017).

Steps in the workup of a breast lump may begin with an ultrasound to determine whether it is fluid filled or solid. Fluid-filled cysts are aspirated, and the patient is monitored on a routine basis for the development of other cysts. If the lump is solid, a mammogram may be obtained if the patient is older than age 50 years. A fine-needle aspiration (FNA) is performed, regardless of the patient's age, to determine the nature of the lump (Sandadi et al., 2017).

A low-fat, nutrient-dense diet with decreased saturated fat is recommended, and sometimes, despite lack of clear evidence, eliminating methylxanthines (colas, coffee, tea, chocolate) is also advised. Some practitioners suggest that patients take mild diuretics shortly before menses, as well as decreasing alcohol intake (Sandadi et al., 2017). Other pain-relief measures include taking analgesics or NSAIDs, wearing a supportive bra, and applying heat or cold to the breasts.

Evening primrose oil and vitamin E supplements may be effective for some people, although more research on these treatments is needed. Oral contraceptives, danazol, bromocriptine, and tamoxifen have also been used with varying degrees of success.

Fibroadenomas. The next most common benign neoplasm of the breast is a **fibroadenoma**. It is the single most common type of tumour seen in the adolescent population, although it can also occur in people in their 30s. Fibroadenomas are discrete, usually solitary lumps averaging 2.5 cm in diameter (Sandadi et al., 2017). Occasionally the person with a fibroadenoma experiences tenderness in the tumour during the menstrual cycle. Fibroadenomas do not increase in size in response to the menstrual cycle as cysts do. They increase in size during pregnancy and decrease in size as the patient ages. The cause of fibroadenomas is unknown.

Diagnosis is made by reviewing the patient history and physical examination. Mammography, ultrasound, or magnetic resonance imaging (MRI) helps determine the type of lesion. FNA may be used to determine underlying pathological conditions. Surgical excision may be necessary if the lump is suspicious for malignancy or if the symptoms are severe. Periodic observation of masses by professional physical examination or mammography may be all that is necessary for masses not needing surgical intervention (Sandadi et al., 2017). Individuals need to recognize changes in their breasts and seek further evaluation from a clinician.

Lipomas. A *lipoma* is a tumour composed of fat that is soft and has discrete borders. The cause of lipoma is unknown. Lipomas are often found in individuals over 45 years of age, usually on the chest wall and breast. They are characterized as palpable soft masses that are mobile and nontender. Mammograms can be used to make a diagnosis; biopsy usually is not needed. Lipomas can be surgically excised if removal is desired.

Nipple Discharge. Nipple discharge is a common occurrence that affects many patients. Although most nipple discharge is physiological, each patient who has this problem must be evaluated thoroughly, as a small percentage of patients are found to have a serious endocrine disorder or malignancy. Most nipple discharge is elicited (i.e., discharge is a result of the breast being compressed or stimulated) and is usually not a concern unless the patient is postmenopausal or a mass is present in the breast (Sandadi et al., 2017).

Another form of breast discharge not related to malignancy is *galactorrhea*, a bilaterally spontaneous, milky, sticky discharge. It is a normal finding in pregnancy. It can also occur as the result of elevated prolactin levels, caused by a thyroid disorder, pituitary tumour, or chest wall surgery or trauma. Obtaining a complete medication history for each patient is essential, as some medications can precipitate galactorrhea in some people (Sandadi et al., 2017). Diagnostic tests that may be indicated include a physical examination, mammography, ultrasound or MRI, as well as ductoscopy to microscopically evaluate the discharge (Sandadi et al., 2017).

Mammary Duct Ectasia. Mammary duct ectasia is an inflammation of the ducts behind the nipple. It occurs most often in perimenopausal patients and is characterized by a nipple discharge that is thick, sticky, and white, brown, green, or purple. The patient frequently experiences a burning pain, an itching, or a palpable mass behind the nipple.

The diagnostic workup includes a mammogram and aspiration and culture of fluid. Treatment is usually symptomatic; mild pain relievers, warm compresses applied to the breast, or wearing a supportive bra may provide relief. If a mass is present or an abscess occurs, treatment may include a local excision of the affected duct or ducts (Sandadi et al., 2017).

Intraductal Papilloma. Intraductal papilloma is a rare benign condition that develops within the terminal nipple ducts. The cause is unknown. It usually occurs in individuals between 30 and 50 years of age. The papilloma is usually too small to be palpated (less than 0.5 cm), and the characteristic sign is spontaneous unilateral nipple discharge that is serous, serosanguineous, or bloody. After eliminating the possibility of malignancy, the affected segments of the ducts and breasts are surgically excised (Sandadi et al., 2017).

Nursing Care. Assessment should include a careful history and physical examination. Table 7.5 compares common manifestations of benign breast masses. The history should focus on risk factors for breast diseases, events related to the breast mass, and health-maintenance practices. Risk factors for breast cancer are discussed later in this chapter. Information related to the breast mass should include how, when, and by whom the mass was discovered. The nurse should document the following patient information: pain, whether symptoms increase with menses, dietary habits, smoking habits, and the use of oral contraceptives. The patient's emotional status, including stress level, fears, and concerns, should also be assessed.

Physical examination may include assessment of the breasts for symmetry, masses (size, number, consistency, and mobility), and nipple discharge.

Nursing actions might include the following:

- Discuss the intervals for and facets of breast screening mammography (see Table 7.5). Patients with breast implants may require special views of the breast and precautions taken to avoid rupture of the implant during mammography.
- Provide written educational materials in the patient's primary language.
- Encourage expression of fears and concerns about treatment and prognosis.
- Provide specific information regarding the patient's condition and treatment, including dietary changes, medication therapy, comfort measures, stress management, and surgery.
- Describe pain-relieving strategies in detail and collaborate with the primary health care provider to ensure effective pain control.
- Encourage discussion of feelings about body image.

Cancer of the Breast

After skin cancer, breast cancer is the most frequently diagnosed cancer and the second leading cause of cancer deaths in women in Canada.

TABLE 7.5 Comparison of Common Manifestations of Benign Breast Masses

Fibrocystic Changes	Fibroadenoma	Lipoma	Intraductal Papilloma	Mammary Duct Ectasia
Multiple lumps	Single lump	Single lump	Single or multiple	Mass behind nipple
Nodular	Well delineated	Well delineated	Not well delineated	Not well delineated
Palpable	Palpable	Palpable	Nonpalpable	Palpable
Movable	Movable	Movable	Nonmobile	Nonmobile
Round, smooth	Round, lobular	Round, lobular	Small, ball-like	Irregular
Firm or soft	Firm	Soft	Firm or soft	Firm
Tenderness influenced by menstrual cycle	Usually asymptomatic	Nontender	Usually nontender	Painful, burning, itching
Bilateral	Unilateral	Unilateral	Unilateral	Unilateral
May or may not have nipple discharge	No nipple discharge	No nipple discharge	Serous or bloody nipple discharge	Thick, sticky nipple discharge

Mortality rates from breast cancer have declined slightly since 1990. Nonetheless, 1 in 8 Canadian women will develop breast cancer in their lifetime, and 1 out of every 33 is expected to die from it. The prognosis for and survival of the patient are improved with early detection. Therefore, patients must be educated about risk factors, early detection, and screening.

Although the exact cause of breast cancer is still unknown, researchers have identified certain factors that increase the risk for developing a malignancy. These factors are listed in Box 7.9.

Although most breast cancers are not related to genetic factors, the identification of the *BRCA1* and *BRCA2* genes demonstrated the role of heredity and genetic mutations in this disease. Only 5 to 10% of breast cancers are attributed to heredity. Individuals who have abnormalities in the *BRCA1* and *BRCA2* genes have up to an 85% chance of developing breast cancer (CCS, 2021b).

During breast cancer risk counselling, facts should be presented to patients by their health care provider in a supportive, nondirective way, without personal opinions or preferences. Discussion should also include treatment options and prognosis of breast cancer, as well as risks and benefits of alternative methods of prevention and early diagnosis. A patient's recognition of having increased breast cancer risk can carry psychological consequences such as anxiety, guilt, depression, and reduced self-esteem. Enormous guilt may be experienced by high-risk patients who pass specific genetic mutations on to their children. Psychological intervention may be offered to assist individuals in coping with these significant adverse sequelae.

Genetic Testing for Breast Cancer Risk. Although knowing whether one is hereditarily predisposed to breast cancer may have benefits, the extent to which an individual can benefit from this information remains unclear. Confirming one's mutation status may provide a sense of control in life plans or it may create high levels of anxiety and distress. Genetic testing can alter decisions regarding family and intimate relationships, childbearing, body image, and quality of life. Regardless of whether results are positive or negative for *BRCA1* and *BRCA2* mutations, the results can have a highly negative impact on individual's lives. Patients at increased risk for breast cancer need comprehensive information about the benefits and limitations of genetic testing to ensure that informed decisions about genetic testing can be made. Because decisions regarding genetic testing, genetic counselling, and breast cancer risk assessment are highly individualized, health care providers should be careful in making any generalizations about individuals at risk for breast cancer.

Prevention. Patients who are at high risk for breast cancer have options to consider that can reduce the risk of developing cancer. Chemoprevention includes the use of tamoxifen, which is an antiestrogen medication. It block the effects of estrogen in some tissues,

BOX 7.9 Risk Factors for Breast Cancer

There is convincing evidence that the following factors increase the risk for breast cancer:

- Previous history of breast cancer
- Family history of breast cancer and other cancers, especially if a first-degree relative had breast cancer diagnosed before menopause
- Inherited genetic mutations in *BRCA1* and *BRCA2* genes
- Dense breasts
- Certain rare genetic conditions (e.g., Li-Fraumeni syndrome, ataxia telangiectasia [AT], Cowden syndrome, or Peutz-Jeghers syndrome)
- Other gene mutations (e.g., *CHEK2* or *PALB2*)
- Ashkenazi Jewish ancestry
- Reproductive history: early menarche (11 years or younger); Late menopause (after age 55); nulliparity or first pregnancy after age 30; not breastfeeding
- Exposure to ionizing radiation
- Use of hormone replacement therapy
- Use of oral contraceptives
- Atypical hyperplasia (in breasts)
- Alcohol consumption
- Obesity
- Physical inactivity
- Higher socioeconomic status
- Tall adult height

Possible Risk Factors

- Increased adult weight gain
- Smoking or exposure to secondhand smoke
- Night shift worker
- Some noncancerous breast conditions
- Never having breastfed

Source: Canadian Cancer Society. (2021). *Risk factors for breast cancer.* https://www.cancer.ca/en/cancer-information/cancer-type/breast/risks/?region=on

such as breast tissue, and acts like estrogen in other tissues. Tamoxifen reduces the risk of breast cancer, especially in patients with *BRCA2* gene mutations, although it increases the risk of uterine (endometrial) cancer. Patients need information in order to weigh the risks and benefits of taking these medications. Surgical prophylaxis (bilateral mastectomy, oophorectomy) can reduce the risk of breast cancer, but it should be considered only for people at very high risk (CCS, 2021b).

Screening and Diagnosis. Breast cancer in its earliest form can be detected by a mammogram before it is felt by a patient. More than half of all lumps are discovered in the upper outer quadrant of the breast. The most common presenting symptom is a lump or thickening of the breast. The lump may feel hard and fixed or soft and spongy. It may have well-defined or irregular borders. It may be fixed to the skin, thereby causing dimpling to occur. A nipple discharge that is bloody or clear also may be present. Early detection and diagnosis reduce the risk for mortality because cancer is found when it is smaller, lesions are more localized, and the tendency is to have a lower percentage of positive nodes.

In Canada, screening mammography (X-ray filming of the breast) (Figure 7.13) is recommended as the only method used to detect early breast cancers. Individuals at low risk for developing breast cancer who are between the ages of 50 and 69 should have screening mammograms done every 2 to 3 years. Individuals aged 40 to 49 are not recommended to have regular mammography, but some individuals may wish to be screened on the basis of their values and preferences; in this circumstance, care providers should engage in shared decision making with patients who express an interest in being screened (Canadian Task Force on Preventative Health Care [CTFPHC], 2018). Patients over 70 years of age should discuss with their health care provider how often mammograms should be done (CTFPHC, 2018).

From an early age, patients should be familiar with how their breasts look and feel; however, routine breast self-examination (BSE) is no longer recommended, as BSE does not save lives and leads to more unnecessary biopsies. Individuals who wish to continue to perform BSE need to be given appropriate information that includes performing an examination of the breasts when they are not tender or swollen. Clinical breast examination (CBE) by a qualified health care provider is also not recommended in patients with a low risk for breast cancer (CTFPHC, 2018).

All provinces and territories have organized breast cancer screening programs for patients 50 to 69 years of age. Individuals are automatically invited to take part in the breast screening program and are sent letters reminding them of their next screening mammogram.

Cultural factors may influence a patient's decision to participate in breast cancer screening. Knowledge of these factors and use of culturally sensitive tailored messages and materials that appeal to the unique concerns, beliefs, and reading abilities of identified groups of patients who do not participate in breast screening may assist the nurse in helping patients overcome barriers to seeking care (see Cultural Awareness box).

CULTURAL AWARENESS

Breast Screening Practices

Some individuals do not take part in breast cancer screening. More than half of recent immigrants (less than 10 years) have not had a screening mammogram, compared to 25% of Canadian-born patients. Many factors play a role in influencing the screening practices of patients, including lack of awareness of mammography screening, gender and modesty concerns unique to cultural beliefs, and fear resulting from a sense of vulnerability to breast cancer. Income, marital status, education, and language difficulties also influence rates of screening.

Interventions that encourage all patients to participate in early breast cancer screening practices require patients' input to improve our understanding of the barriers that individuals have to getting screened. This information could contribute to the design of community-driven interventions to enhance accessibility of breast cancer screening services. Existing research has suggested various strategies that place an emphasis on the need to develop tailored and culturally appropriate interventions for patients to overcome knowledge and structural barriers, address misconceptions, and promote screening practices. Mobile breast cancer screening units may help patients overcome these various obstacles to accessing this preventive care. Interventions that encourage individuals to participate in early breast cancer screening practices begin with the development of culturally sensitive community education programs designed to help patients deal with barriers to reaching optimal levels of health.

When a suspicious finding on a mammogram is noted or when a lump is detected, diagnosis is confirmed by means of diagnostic mammogram, FNA, core needle biopsy, or surgical excision (Figure 7.14). Ultrasound may also be used to assess a specific area of abnormality found during a mammogram procedure (CCS, 2021b). Patients need specific information regarding advantages and disadvantages of these procedures to make a decision about which one is most appropriate for them.

Laboratory examination of breast tissue determines if cancer is present and, if so, the extent. Other tests performed to determine the spread of the cancer include chest X-ray film examination, bone scan, CT, MRI, and positron emission tomography (PET) scan (CCS, 2021b).

An important step in evaluating a breast cancer is to test for the presence of estrogen and progesterone receptors in the biopsied

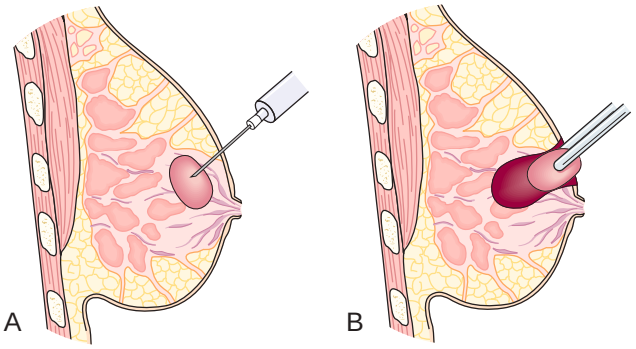

Fig. 7.14 Diagnosis of breast abnormality. **A**, Needle aspiration. **B**, Open biopsy. (Redrawn from National Women's Health Resource. [1995]. *National Women's Health Report, 13*[5], 3.)

tissue. Cancer cells may contain one, both, or neither of these receptors. Breast cancers that contain estrogen receptors are often called *ER-positive* cancers, whereas those containing progesterone receptors are called *PR-positive* cancers. Patients with hormone-positive tumours tend to respond better to treatment and have higher survival rates than individuals with hormone-negative results (Sandadi et al., 2017).

An HER2/neu test also may be performed on the biopsied breast tissue. HER2/neu is a growth-promoting hormone. In approximately 18 to 20% of breast cancers, excessive amounts of the hormone are present, causing the cancer to be more aggressive in spreading than other types of breast cancer (Sandadi et al., 2017).

Breast Cancer During Pregnancy. Although breast cancer is the most common cancer diagnosed during pregnancy, it is rare. About 1 out of every 3 000 pregnant patients is diagnosed with breast cancer. Treatment decisions for breast cancer in pregnancy are based on the stage of breast cancer and the age of the fetus. Ending a pregnancy (therapeutic abortion) is not considered a necessary part of treatment because it does not improve a patient's prognosis or survival.

Treatment for breast cancer during pregnancy often begins immediately and may include the following:

- Surgery to remove the lump or the affected breast. Surgery can be carried out at any stage in pregnancy.
- Chemotherapy—not given during the first 13 weeks of pregnancy as it may cause abnormalities in the fetus
- Radiation—not usually offered as a treatment option until after the birth
- Tamoxifen—not recommended during pregnancy as there seems to be an increased risk of fetal abnormalities when taken during pregnancy. The evidence is limited, so patients require counselling regarding its use (Schurman et al., 2019).

Many individuals who are diagnosed with breast cancer during pregnancy are concerned that they can pass the breast cancer cells to their baby. There is no evidence that a fetus can get cancer from the parent with cancer while in the womb. Patients also cannot pass cancer cells to the baby through breastfeeding. Patients need correct information regarding how breast cancer treatment may affect fertility. The medical team should take into account any plans for future pregnancies and offer chemotherapy medications that are less likely to affect fertility.

Collaborative Care. Controversy continues regarding the best treatment for breast cancer. Nodal involvement, tumour size, receptor status, and aggressiveness are important variables for treatment selection. Medical management of breast cancer includes surgery, breast reconstruction, radiation therapy, adjuvant hormone therapy, biological targeted therapy, and chemotherapy. Many patients face difficult decisions about the various treatment options. Treatment plans are designed to meet the unique needs of each person with cancer and are based on the following: stage of the breast cancer; if the person has reached menopause; hormone receptor status of the cancer; HER2 status of the cancer; risk for recurrence (with early-stage breast cancer); the overall health of the patient; and the patient's personal decision about certain treatments (CCS, 2021b).

For further information on the medical treatment and nursing care of breast cancer, refer to a medical surgical nursing text book as well as the Canadian Cancer Society.

KEY POINTS

- The female's reproductive tract structures and breasts respond predictably to changing levels of sex steroids across her lifespan.
- The myometrium of the uterus is uniquely designed to expel the fetus and promote hemostasis after birth.
- Normal feedback regulation of the menstrual cycle depends on an intact hypothalamic–pituitary–gonadal mechanism.
- Menstrual disorders may diminish the quality of life for affected patients and their families.
- Primary dysmenorrhea is a condition associated with ovulatory cycles and is related to the release of prostaglandins with menses.
- PMS is a disorder with both physiological and psychological characteristics.
- Endometriosis is characterized by dysmenorrhea, infertility, and, less often, alterations in menstrual cycle bleeding and dyspareunia.
- Abnormal uterine bleeding has many causes; the treatment chosen is based on managing the cause of the bleeding.
- Menopause is a healthy transition that has different symptoms and may require different treatments.
- Key strategies for preventing STIs are the practice of and education in safer sex behaviours.
- STIs are responsible for substantial mortality and morbidity, personal suffering, and a heavy economic burden in Canada.
- HIV is transmitted through body fluids—primarily blood, semen, and vaginal secretions.
- HPV is the most common viral STI.
- Syphilis has re-emerged as a common STI.
- Rates of chlamydia are increasing, and it is the most common cause of PID.
- The development of breast neoplasms, whether benign or malignant, can have a significant physical and emotional effect on an individual and their family.
- Approximately 50% of individuals experience a breast issue at some point in their adult lives; the risk of a Canadian woman developing breast cancer is 1 in 8.

Infertility, Contraception, and Abortion

Lisa Keenan-Lindsay
Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. List common causes of infertility.
2. Discuss the psychological impact of infertility.
3. Describe common diagnoses and treatments for infertility.
4. Compare reproductive alternatives for couples experiencing infertility.
5. State the advantages and disadvantages of the following methods of contraception: fertility awareness–based methods, barrier methods, hormonal methods, intrauterine contraception, and sterilization.
6. Explain common nursing interventions that facilitate contraceptive use.
7. Describe the techniques used for medical and surgical interruption of pregnancy.
8. Recognize ethical, legal, cultural, and religious considerations related to infertility, contraception, and elective abortion.

INFERTILITY

Incidence

Infertility is a serious concern that affects the quality of life of approximately 16% of reproductive-age couples in Canada (Public Health Agency of Canada [PHAC], 2019). Commonly, infertility is considered a diagnosis for couples who have not achieved pregnancy after 1 year of regular, unprotected intercourse when the woman is less than 35 years of age or after 6 months when the woman is older than 35. *Fecundity* is the term used to describe the chance of achieving pregnancy and subsequent live birth within one menstrual cycle. Fecundity averages 20% in couples who are not experiencing reproductive difficulties.

The incidence of **infertility** has increased in Canada. A probable cause of infertility includes the trend toward delaying pregnancy until later in life, a time when fertility decreases naturally and the prevalence of diseases such as endometriosis and ovulatory dysfunction increases (Liu & Case, 2017). Infertility increases with the age of the woman, with fertility rates in women ages 40 to 45 being 95% lower than that for women ages 20 to 24. It is unknown whether there has been an actual increase in male infertility or whether male infertility is more readily identified because of improvements in diagnosis.

For the couple experiencing infertility, diagnosis and treatment require considerable physical, emotional, and financial investments over an extended period of time. Feelings connected with infertility are many and complex, often interfering with quality of life. It is common for infertile couples to experience anxiety from the need to undergo many tests and examinations and from a perception of feeling "different" from their fertile friends and relatives.

Factors Associated With Infertility

Although exact percentages vary somewhat with populations, approximately 80% of couples have an identifiable cause of infertility, with about 40% of these causes being related to factors in the female partner, 30% related to factors in the male partner, and 20% related to factors in both partners. About 10% or more couples will experience unexplained, or idiopathic, causes of infertility (PHAC, 2019). Nevertheless, the focus of infertility treatment has shifted from attempting to correct a specific pathology to recommending and initiating the treatment that is most effective in achieving pregnancy for this unique couple at this time in their reproductive lifespan. Assisted human reproduction (AHR) has proven to be effective, even in couples who experience unexplained infertility.

Unassisted human conception requires a normally developed reproductive tract in both the male and female partners. For simplification, each live birth necessitates synchronization of the following:

- Sperm that has the capacity to fertilize an egg must be deposited close to the cervix at the time of ovulation. The sperm must be able to ascend through the uterus and fallopian tubes (sperm factor).
- The cervix must be sufficiently open to allow semen to enter the uterus and provide a nurturing environment for sperm (cervical factor).
- The fallopian tubes must be able to capture the ovum, transport semen to the ovum, and transport the fertilized embryo to the uterus (tubal factor).
- Ovulation of a healthy oocyte must occur, ideally within the parameters of a regular, predictable menstrual cycle (ovarian factor).
- The uterus must be receptive to implantation of the embryo and capable of nourishing the growth and development of the fetus throughout the normal duration of pregnancy (uterine factor).

An alteration in one or more of these structures, functions, or processes results in some degree of impaired fertility. Boxes 8.1 and 8.2 list factors affecting female and male infertility. For conception to occur, both partners must have normal, intact hypothalamic–pituitary–gonadal hormonal axes that support the formation of sperm in the male and ova in the female. Sperm can remain viable within a woman's reproductive tract for at least 3 days and for as long as 7 days. The oocyte can only be successfully fertilized for up to 24 hours after ovulation (Blackburn, 2018). The couple seeking pregnancy should be taught about the menstrual cycle and ways to detect ovulation (see discussion later in the chapter). They should be counselled to have intercourse two to three times a week; or, if timed intercourse does not increase anxiety, they should be encouraged to engage in intercourse the day before and the day of ovulation. Fertility decreases markedly 24 hours after ovulation.

BOX 8.1 Factors Affecting Female Fertility

Ovarian Factors
- Developmental anomalies
- Anovulation—primary
  - Pituitary or hypothalamic hormone disorder
  - Adrenal gland disorders (rare)
  - Congenital adrenal hyperplasia (rare)
- Anovulation—secondary
  - Disruption of hypothalamic–pituitary–ovarian axis
  - Anorexia
  - Insufficient fat in athletic women
  - Increased prolactin levels
  - Thyroid disorders
  - Premature ovarian failure
  - Polycystic ovarian syndrome

Tubal/Peritoneal Factors
- Developmental anomalies of the tubes
- Reduced tubal motility
- Inflammation within the tube
- Tubal adhesions
- Disruption caused by tubal pregnancy
- Endometriosis

Uterine Factors
- Developmental anomalies of the uterus (see Figure 8.1)
- Endometrial and myometrial tumours
- Asherman syndrome (uterine adhesions or scar tissue)

Vaginal–Cervical Factors
- Vaginal–cervical infections
- Cervical mucus inadequate
- Isoimmunization (development of sperm antibodies)

Other Factors
- Nutritional deficiencies
- Thyroid dysfunction
- Obesity
- Idiopathic conditions

BOX 8.2 Factors Affecting Male Fertility

Hormonal Disorders
- Congenital disorders
- Tumours of the pituitary and hypothalamus
- Trauma to the pituitary or hypothalamus
- Hyperprolactinemia
- Excess of androgens, estrogen, cortisol
- Drugs and substance use (recreational and prescribed medications)
- Chronic illnesses
- Nutritional deficiencies
- Obesity
- Endocrine disorders (e.g., diabetes)

Testicular Factors
- Congenital disorders
- Undescended testes
- Hypospadias
- Varicocele
- Viral infections (e.g., mumps)
- Sexually transmitted infections (gonorrhea, chlamydial infection)
- Obstructive lesions of the epididymis and vas deferens
- Environmental toxins
- Trauma
- Torsion
- Castration
- Systemic illnesses
- Changes in sperm from cigarette smoking or use of heroin, marijuana, amyl-nitrate, butyl nitrate, ethyl chloride, or methaqualone
- Decrease in libido from use of heroin, methadone, selective serotonin reuptake inhibitors, or barbiturates
- Impotence from use of alcohol or antihypertensive medications
- Antisperm antibodies

Factors Associated With Sperm Transport
- Medications
- Sexually transmitted infections of the epididymis
- Ejaculatory dysfunction
- Premature ejaculation

Idiopathic Male Infertility

Nursing Care

Nurses who care for infertile couples should consider the following four goals:

- Provide the couple with accurate information about human reproduction, infertility treatments, and prognosis for pregnancy. Dispel any myths or inaccuracies from friends or the mass media that the couple may believe to be true.
- Help the couple and the health care team accurately identify and treat possible causes of infertility.
- Provide emotional support. The couple may benefit from anticipatory guidance, counselling, and support group meetings, either face-to-face or online. Fertility Matters and RESOLVE are organizations that provide support, advocacy, and education about infertility for those experiencing infertility as well as for health care providers (see Additional Resources at the end of the chapter).
- Guide and educate those who fail to conceive biologically as a couple about other forms of treatment, such as in vitro fertilization (IVF), donor eggs or semen, surrogate motherhood, and adoption. Support the couple in their decisions regarding their future family.

Nurses should also remember that among healthy women and men, promotion of normal reproduction and prevention of infertility may be assisted if both partners maintain a normal body mass index (BMI), avoid contracting sexually transmitted infections (STIs), and avoid exposures to substances or habits (such as smoking) that impair reproductive ability. As they make plans for their future family, adults should also know that, realistically, fertility decreases with age.

Infertility care management includes a team of health care providers, including an obstetrical care provider, fertility specialist, embryologist, genetic counsellor, and mental health provider or counsellor. The nurse is a key member of the care management team and assists in the assessment and education of the infertile couple. As part of the assessment process, the nurse obtains information from the couple through interview and physical examination, regardless of whether this couple's situation is one of primary (never experienced pregnancy) or secondary (previous pregnancy) infertility. Religious, cultural, and ethnic data may place restrictions on use of available treatments. Care providers should seek to understand the patient's religious views and how beliefs affect their perception of health care, especially in relation to infertility. Patients may wish to seek infertility treatment but have questions about proposed diagnostic and therapeutic procedures because of religious proscriptions. These individuals should be encouraged to consult their minister, rabbi, priest, or other spiritual leader for advice. The Cultural Awareness box notes some cultural rituals and beliefs regarding fertility. See Nursing Process: Infertility, on Evolve.

In addition, the nurse will obtain and monitor results of diagnostic testing. Some of the information and data needed to investigate impaired fertility are of a sensitive, personal nature. The couple may experience feelings of invasion of privacy, and the nurse must exercise tact and express concern for their well-being throughout the interview. The tests and examinations associated with infertility diagnosis and treatment are occasionally painful and often intrusive. The couple's intimacy and feelings of romantic attachment are often frayed as they engage in this process. A high level of motivation is needed to endure the investigation and subsequent treatment. Because multiple factors involving both partners are common, the investigation of impaired fertility is conducted systematically and simultaneously for both male and female partners. Both partners must be interested in the solution to the problem. The medical investigation requires time (3 to 4 months) and considerable financial expense. Box 8.3 describes the status of insurance coverage in Canada for infertility treatment.

BOX 8.3 Insurance Coverage for Infertility

The cost for in vitro fertilization (IVF) treatment can be very high and unaffordable for many people. All provinces in Canada cover the cost of diagnostic testing and some medical and surgical treatment of infertility through provincial insurance plans. Presently, four provinces will provide some coverage for IVF treatment. Ontario will pay for one IVF cycle with only one embryo to be transferred, for women who are less than 43 years of age. Québec and Manitoba currently provide a tax credit, and New Brunswick pays a one-time grant for infertility treatment. The Canadian Fertility and Andrology Society strongly advocates for both regulation and public funding of IVF across the country. Private insurance plans may pay for some aspects of treatment. Patients need information about what they can expect from their private insurers and are encouraged to contact companies to obtain more complete information.

CULTURAL AWARENESS

Fertility and Infertility

In some cultures, women are not considered to be socially acceptable if they cannot have their own biological child. The social stigma of childlessness still leads to isolation and abandonment in many developing countries. Differences between the developed and developing world in ability to bear children are emerging because of the differing availability for infertility care. In many cultures the responsibility for infertility is usually attributed to the woman and it may not be acceptable for the man to seek fertility assessment. In many developing countries, infertile women live without hope as access to infertility treatment is not available. Nurses need to be aware of cultural influences on fertility (Gerrits et al., 2012; World Health Organization, 2010).

Assessment of Female Infertility. Evaluation for infertility should be offered to couples who have failed to become pregnant after 1 year of regular intercourse or after 6 months if the woman is over 35. Investigation of impaired fertility begins for the woman with a complete history and physical examination. A complete general physical examination should include height and weight and estimation of BMI. Both obesity and being underweight are associated with anovulation disorders. Signs and symptoms of polycystic ovarian syndrome (PCOS), which can be caused by high levels of androgens or insulin, should be noted, such as excess body hair, pigmentation changes, weight gain, or difficulty losing weight. The general physical examination is followed by a specific assessment of the reproductive tract. A history of infection of the genitourinary system and any signs of infections, especially STIs that could impair tubal patency, should be assessed. Bimanual examination of internal organs may reveal lack of mobility of the uterus or abnormal contours of the uterus and adnexa. A woman may have an abnormal uterus and tubes (Figure 8.1) as a result of congenital abnormalities during fetal development. These uterine abnormalities increase risk for early pregnancy loss.

Laboratory data, including routine urine and blood tests, are collected. The initial clinic visit serves as a preconception visit and as initial assessment of possible causes of infertility. The woman should be taking folic acid supplements, and all immunizations should be current to prepare for possible pregnancy.

Diagnostic testing. The basic infertility survey of the female involves evaluation of the cervix, uterus, tubes, and peritoneum; detection of **ovulation**; and hormone analysis. Timing and descriptions of common tests are presented in Table 8.1. Previous status regarding ovulation can be evaluated through menstrual history, serum hormone studies, and use of an ovulation predictor kit. If the patient is over

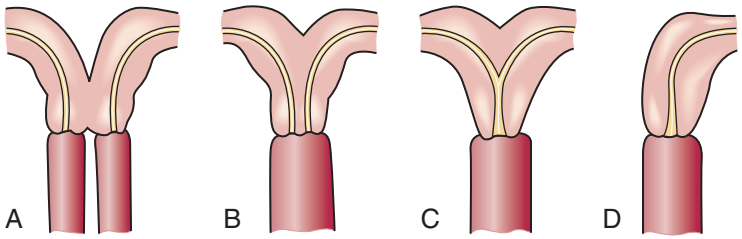

Fig. 8.1 Abnormal uterus. **A:** Complete bicornuate uterus with vagina divided by a septum. **B:** Complete bicornuate uterus with normal vagina. **C:** Partial bicornuate uterus with normal vagina. **D:** Unicornuate uterus.

TABLE 8.1 General Tests for Impaired Fertility

Test or Examination	Timing (Menstrual Cycle Days)	Rationale
Hysterosalpingogram (HSG) (uterine abnormalities, tubal patency)	7–10	Late follicular, early proliferative phase; will not disrupt a fertilized ovum; may open uterine tubes before time of ovulation
Chlamydia immunoglobulin G antibodies (tubal patency)	Variable	Negative antibody test may indicate tubal patency assessment (HSG); not needed in low-risk patients
Hysterosalpingo-contrast sonography (uterine abnormalities, tubal patency)	7–10	Late follicular, early proliferative phase; will not disrupt a fertilized ovum; evaluates tubal patency, uterine cavity, and myometrium
Serum progesterone (ovulation)	7 days before expected menses	Midluteal-phase progesterone levels; check adequacy of corpus luteum progesterone production
Assessment of cervical mucus (ovulation)	Variable, ovulation	Cervical mucus should have low viscosity, high spinnbarkeit (ability to stretch) during ovulation
Basal body temperature (ovulation)	Chart entire cycle	Elevation occurs in response to progesterone; documents ovulation
Urinary or salivary ovulation predictor kit (ovulation)	Variable, ovulation	Detects timing of lutein hormone surge before ovulation
Semen analysis (sperm factor)	2–7 days after abstinence	Detects ability of sperm to fertilize egg
Sperm penetration assay (sperm factor)	After 2 days but $\leq$1 week of abstinence	Evaluation of ability of sperm to penetrate egg
Follicle-stimulating hormone (FSH) level (ovarian reserve)	Day 3	High FSH levels (>20) indicate that pregnancy will not occur with patient's own eggs; value <10 indicates adequate ovarian reserve
Clomiphene citrate challenge test (CCCT) (ovarian reserve)	Administer clomiphene 100 mg days 3 through 10	Assess FSH on days 3 and 10 in presence of clomiphene stimulation; high FSH levels (>20) indicate that pregnancy will not occur with patient's own eggs; FSH <15 suggestive of adequate ovarian reserve

age 35, the clinician may choose to assess "ovarian reserve," or how many potential ova remain within the ovaries. A common evaluation of ovarian reserve is measurement of follicle-stimulating hormone (FSH) levels on the third day of the menstrual cycle. The uterus and fallopian tubes can be visualized for abnormalities and tubal patency through hysterosalpingogram (X-ray film examination of the uterine cavity and tubes after instillation of radiopaque contrast material through the cervix). If the individual is at risk for endometriosis (implants of endometrial tissue outside of the uterus) or adhesions, diagnostic laparoscopy may be indicated. Test findings favourable to fertility are summarized in Box 8.4.

Assessment of Male Infertility. The systematic investigation of infertility in the male patient begins with a thorough history and physical examination. Assessment of the male patient proceeds in a manner similar to that of the female patient, starting with noninvasive tests.

Diagnostic testing and semen analysis. The basic test for male infertility is **semen analysis**. A complete semen analysis, study of the effects of cervical mucus on sperm forward motility and survival, and evaluation of the sperm's ability to penetrate an ovum provide basic information. Sperm counts vary from day to day and depend on emotional and physical status and sexual activity. Therefore, a single analysis may be inconclusive. A minimum of two analyses must be performed several weeks apart to assess male fertility.

Semen is collected by ejaculation into a clean container or a plastic sheath that does not contain a spermicidal agent. The specimen is usually collected by masturbation following 2 to 5 days of abstinence from **ejaculation**. The semen is examined at the collection site or taken to the laboratory in a sealed container within 2 hours of ejaculation. Exposure of the semen to excessive heat or cold should be avoided. Commonly accepted values for semen characteristics are given in Box 8.5. If results are in the fertile range, no further sperm evaluation is necessary.

BOX 8.4 Summary of Findings Favourable to Fertility

1. Follicular development, ovulation, and luteal development are supportive of pregnancy:
   a. Basal body temperature (presumptive evidence of ovulatory cycles) is biphasic, with temperature elevation that persists for 12 to 14 days before menstruation (see Figure 8.7).
   b. Cervical mucus characteristics change appropriately during phases of the menstrual cycle (see discussion later in the chapter).
   c. Days 3 to 10 follicle-stimulating hormone (FSH) levels are low enough to verify presence of adequate ovarian follicles.
   d. Day 3 estradiol levels are low enough to verify presence of adequate ovarian follicles.
   e. Patient reports a history of regular, predictable menses with consistent premenstrual and menstrual symptoms.
2. The luteal phase is supportive of pregnancy:
   a. Levels of plasma progesterone are adequate to indicate ovulation.
   b. Luteal phase of menstrual cycle is of sufficient duration to support pregnancy.
3. Cervical factors are receptive to sperm during expected time of ovulation:
   a. Cervical os is open.
   b. Cervical mucus is clear, watery, abundant, and slippery and demonstrates good spinnbarkeit and arborization (fern pattern) at time of ovulation.
   c. Cervical examination reveals no lesions or infections.
4. The uterus and uterine tubes support pregnancy:
   a. Uterine and tubal patency are documented by (1) spillage of dye into the peritoneal cavity and (2) outlines of uterine and tubal cavities of adequate size and shape, with no abnormalities.
   b. Laparoscopic examination verifies normal development of internal genitals and absence of adhesions, infections, endometriosis, and other lesions.
5. The male partner's reproductive structures are normal:
   a. There is no evidence of developmental anomalies of the penis (e.g., hypospadias), testicular atrophy, or varicocele (varicose veins on the spermatic vein in the groin).
   b. There is no evidence of infection in the prostate, seminal vesicles, and urethra.
   c. Testes are more than 4 cm in largest diameter.
6. Semen is supportive of pregnancy:
   a. Sperm (number per millilitre) are adequate in ejaculate.
   b. Most sperm show normal morphology.
   c. Most sperm are motile, forward moving.
   d. No autoimmunity exists.
   e. Seminal fluid is normal.

BOX 8.5 Semen Analysis

- Semen volume: 2–5 mL/ejaculation
- pH: 7.1–8.0
- Sperm concentration/density ≥20 million/mL
- Normal morphological features >30% (normal oval)
- Motility: At least 50% of sperm exhibit normal forward movement after 1 hour
- Liquefaction: 20–30 minutes after collection

Source: MyHealth.Alberta.ca. (2018). *Semen analysis*. https://myhealth.alberta.ca/health/Pages/conditions.aspx?hwid=hw5612#hw5641

Note: These values are not absolute but are only relative to final evaluation of the couple as a single reproductive unit. Normal values vary from lab to lab.

If results are not within this range, the test is repeated. If subsequent results are still in the subfertile range, further evaluation is needed to identify the problem.

Hormone analyses are done for testosterone, gonadotropin, FSH, and luteinizing hormone (LH). The sperm penetration assay and other alternative tests can be used to evaluate the ability of sperm to penetrate an egg. Testicular biopsy may be warranted. Scrotal ultrasound is used to examine the testes for presence of **varicoceles** and to identify abnormalities in the scrotum and spermatic cord. Transrectal ultrasound is used to evaluate the ejaculatory ducts, seminal vesicles, and vas deferens.

Assessment of the Couple. The postcoital test (PCT) is one method used to test for adequacy of coital technique, cervical mucus, sperm, and degree of sperm penetration through cervical mucus. The test is performed within several hours after ejaculation of semen into the vagina. A specimen of cervical mucus is obtained from the cervical os and examined under a microscope. The quality of mucus and the number of forward-moving sperm are noted. A PCT with good mucus and motile sperm is associated with fertility.

Intercourse is synchronized with the expected time of ovulation (as determined from evaluation of basal body temperature [BBT], cervical mucus changes, and usual length of menstrual cycle or use of LH detection kit to determine LH surge). Intercourse should occur only in the absence of vaginal infection. Couples may experience some difficulty abstaining from intercourse for 2 to 4 days before expected ovulation and then having intercourse with ejaculation on schedule. Sex on demand may strain the couple's relationship. A problem may arise if the expected day of ovulation occurs when facilities or the health care provider is unavailable (such as over a weekend or holiday).

Psychosocial Considerations. Infertility is recognized as a major life stressor that can affect **self-esteem**; relations with the partner, family, and friends; and careers. Psychological responses to the diagnosis of infertility may tax a couple's capacity for giving and receiving physical and sexual closeness. The prescriptions and proscriptions for achieving conception may add tension to a couple's sexual functioning. Couples may report decreased desire for intercourse, orgasmic dysfunction, or midcycle **erectile disorders**. Treatment for infertility is complex and stressful, and many couples quit treatment before becoming pregnant, due to the stress. Couples need support and encouragement to express their concerns about infertility treatment.

In order to deal comfortably with a couple's sexuality, nurses must be comfortable with their own sexuality so that they can better help couples understand why the private act of lovemaking needs to be shared with health care providers. Nurses need current factual knowledge about human sexual practices and must be accepting of the preferences and activities of others without being judgemental. They must be skilled in interviewing and in therapeutic use of self, sensitive to the nonverbal cues of others, and knowledgeable about each couple's sociocultural and religious beliefs (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Infertility

Diane is a 39-year-old accountant who has recently married for the first time. Charles is 41 and has two children from a previous marriage. Diane has a history of amenorrhea when she was in college and a member of the track team.

Continued

CLINICAL REASONING CASE STUDY—CONT'D

Currently her menstrual periods are irregular. She wants to have a baby "before it's too late," and she and Charles have been having unprotected sex for almost a year. They have come to the fertility clinic today for an evaluation. Diane tells the nurse that she has heard a lot about the success of in vitro fertilization (IVF) and wants to know if she will be able to have it performed. How should the nurse respond to Diane's comments and questions?

Questions

1. Evidence—Is evidence sufficient to draw conclusions about what response the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Age and fertility: Is Diane's age a factor in her concern regarding infertility?
   b. Infertility as a major life stressor: To what extent can infertility or the fear of being infertile cause stress?
   c. Success rates for IVF pregnancy and birth: Is IVF a reasonable treatment to consider (after having a thorough workup)?
   d. Causes of female infertility: What are some of the reasons that Diane may be infertile?
   e. Costs of infertility treatment: What are the different costs (financial, physical, and psychological) that must be considered when undergoing infertility treatment?
3. What implications and priorities for nursing care can be drawn at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may be caring for Diane and Charles.

Either member of the couple facing infertility may exhibit behaviours of the grieving process that are associated with other types of loss. The loss of one's genetic continuity with the generations to come can lead to a loss of self-esteem, a sense of inadequacy as a woman or a man, a loss of control over one's destiny, and a reduced sense of self. Infertile individuals can perceive greater dissatisfaction with their partner relationships. Not all people will have all of these reactions, nor can it be predicted how long any reaction will last for any one individual. Often a mental health counsellor with experience and expertise dealing with infertility can be very helpful to an individual or couple.

If the couple conceives, their concerns and difficulties with infertility may not be over. Many couples are overjoyed with the pregnancy; however, some are not. Some couples rearrange their lives, sense of self, and personal goals based on accepting their infertile state. The couple may think that those who worked with them to identify and treat impaired fertility expect them to be happy with the pregnancy. They may be shocked to find that they feel resentment because the pregnancy, once a cherished dream, now necessitates another change in goals, aspirations, and identities. The normal ambivalence toward pregnancy may be perceived as reneging on the original choice to become parents.

If the couple does not conceive, they should be assessed regarding their desire to be referred for help with adoption, donor eggs or semen, surrogacy, or other reproductive alternatives. The couple may choose to continue to not have a child. The couple may find helpful a list of agencies, support groups, and other resources in their community.

Nonmedical Treatments

Both men and women can benefit from healthy lifestyle changes that result in a BMI within the normal range; moderate daily exercise; and abstinence from alcohol, nicotine, and recreational drugs. For the woman with a BMI >27 and PCOS, losing just 5 to 10% of body weight can restore ovulation within 6 months. Anovulatory women with a BMI <17 who have eating disorders or intense exercise regimens benefit from weight gain. This population sometimes is reluctant to alter their behaviours, and counselling may be required.

Simple changes in lifestyle may be effective in the treatment of subfertile men. Only water-soluble lubricants should be used during intercourse because many commonly used lubricants contain **spermicides** or have spermicidal properties. High scrotal temperatures may be caused by daily hot tub baths or saunas that keep the testes at temperatures too high for efficient spermatogenesis. These conditions lead to only lessened fertility and should not be used as a means of contraception.

Most herbal remedies have not been proven clinically to promote fertility or to be safe in early pregnancy and should be taken by the patient only as prescribed by a health care provider who has expertise in herbology. Relaxation, osteopathy, stress management (e.g., aromatherapy, yoga), and nutritional and exercise counselling have been reported to increase pregnancy rates in some individuals. Herbs to avoid using while trying to conceive include licorice root, yarrow, wormwood, ephedra, fennel, goldenseal, lavender, juniper, flaxseed, pennyroyal, passionflower, wild cherry, cascara, sage, thyme, and periwinkle. All supplements or herbs should be purchased from trusted sources to ensure that they do not contain contaminants.

Medical Therapy

One goal of infertility assessment and treatment is to determine which couples could respond to conventional therapies in a timely manner. Another goal is to refer couples who will need AHR technologies to conceive early in the process. In general, any fertility treatment is more likely to result in a live birth in women who are younger than age 35, with successful outcomes decreasing for women over age 40.

Pharmacological therapy for female infertility is often directed at treating ovulatory dysfunction by either stimulating or enhancing ovulation so more oocytes mature. These medications include (a) clomiphene citrate as initial therapy for many patients with intermittent anovulation; (b) a combination of clomiphene and metformin for patients with anovulation and insulin resistance; (c) human menopausal gonadotropin (HMG), FSH, and recombinant FSH (rFSH) to stimulate follicle formation in patients who do not respond to clomiphene therapies; (d) human chorionic gonadotropin to induce ovulation when follicles are ripe; (e) gonadotropin-releasing hormone (GnRH) agonists at the beginning of a cycle to sequence HMG therapies; (f) progesterone to support the luteal phase of the cycle; and (g) bromocriptine for patients who have excess prolactin (Lobo, 2017).

Treatment of certain medical conditions can result in improved fertility. The patient who is hypothyroid benefits from thyroid hormone supplementation. Treatment of endometriosis could include trials of danazol, progesterone, continuous combined oral contraceptives, or GnRH agonists to suppress menstruation and shrink endometrial implants. This regimen would be followed by ovulation induction. It is important to note that danazol is contraindicated in pregnancy. Adrenal hyperplasia is treated with prednisone. Any infections present in the infertile couple should be treated with appropriate antimicrobial formulations.

Clomiphene citrate (with the possible addition of metformin) is often the initial pharmacological treatment of the infertile patient because it is inexpensive and the adverse effect profile is less than that of other medications that induce ovulation. There is an increased risk of giving birth to twins or higher-order multiples with clomiphene therapy.

The more powerful medications used to induce ovulation include GnRH agonists followed by gonadotropin therapy. These medications are extremely potent and require daily ovarian ultrasonography and monitoring of estradiol levels to prevent hyperstimulation of the

ovaries. Combinations of these medications are used as AHR to stimulate ovulation before harvesting eggs.

Medication therapy may be indicated for male infertility. Abnormalities of the thyroid or adrenal glands are corrected with appropriate medications. Infections are identified and treated with antimicrobials. FSH, HMG, and clomiphene may be used to stimulate spermatogenesis in men with hypogonadism. Men who do not respond to these therapies are candidates for intracytoplasmic sperm injection (ICSI), a procedure in which sperm is injected directly into the egg as part of IVF. ICSI has enabled men with very low sperm counts to achieve biological reproduction.

The primary care provider is responsible for fully informing patients about the prescribed medications. The nurse must be ready to answer patients' questions and to confirm their understanding of the medication, its administration, potential adverse effects, and expected outcomes. Because information varies with each medication, the nurse must consult the medication package inserts, pharmacology references, the physician, and the pharmacist, as necessary. The nurse should also provide anticipatory guidance regarding the time needed for a medication trial before referral to a specialist in AHR would be indicated if the couple wants to continue to attempt becoming pregnant.

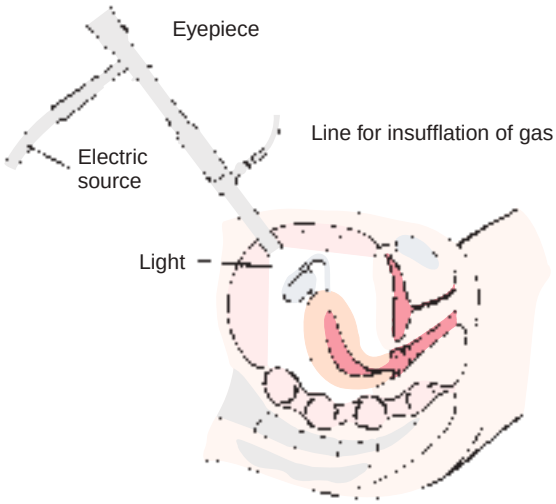

Fig. 8.3 Laparoscopy.

Surgical Therapies. A number of surgical procedures can be used for female infertility issues. Ovarian tumours must be excised. Whenever possible, functional ovarian tissue is left intact. Scar tissue adhesions caused by chronic infections may cover much or all of the ovary. These adhesions usually necessitate surgery to free and expose the ovary so that ovulation can occur.

Hysterosalpingography is useful for identification of tubal obstruction and for the release of blockage (Figure 8.2). During laparoscopy, delicate adhesions may be divided and removed, and endometrial implants may be destroyed by electrocoagulation or laser (Figure 8.3). Laparotomy and even microsurgery may be required for extensive repair of the damaged tube. Prognosis depends on the degree to which tubal patency and function can be restored. In general, laparoscopic surgery for tubal patency is most effective in younger women with distal tubal damage.

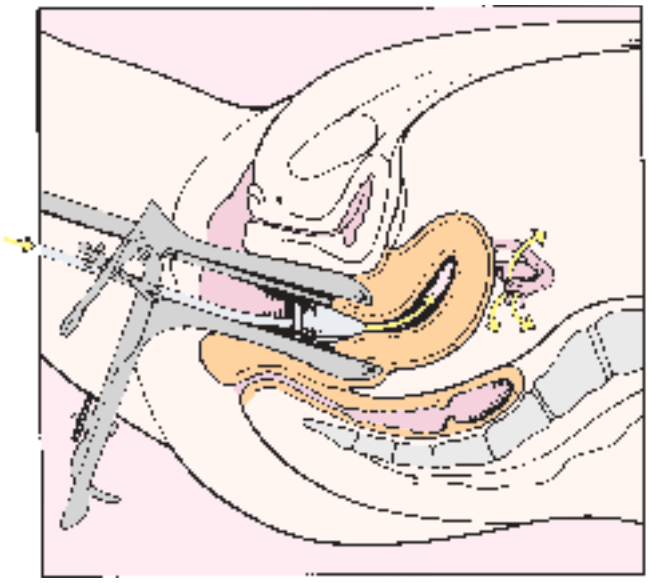

Fig. 8.2 Hysterosalpingography. Note that the contrast medium flows through the intrauterine cannula and out through the uterine tubes.

Older women or those with significant proximal disease should be referred for ARTs that bypass the fallopian tube.

In women with uterine abnormalities, reconstructive surgery (e.g., the unification operation for **bicornuate uterus**) can improve the ability to conceive and carry the fetus to term. Surgical removal of tumours or fibroids involving the endometrium or muscular walls of the uterus could also improve the woman's chance of conceiving and maintaining the pregnancy to viability, depending on the location and size of the fibroid or tumour. Surgical treatment of uterine tumours or maldevelopment that results in successful pregnancy may require birth by Caesarean surgery near term gestation because the enlarging uterus can rupture as a result of weakness in the area of reconstructive surgery.

Chronic inflammation and infection can be eliminated by radial chemocautery (destruction of tissue with chemicals) or thermocautery (destruction of tissue with heat, usually electrical) of the cervix, cryosurgery (destruction of tissue by application of extreme cold, usually liquid nitrogen), or conization (excision of a cone-shaped piece of tissue from the endocervix). When the cervix has been deeply cauterized or frozen or when extensive conization has been performed, the cervix may produce less mucus. Therefore, the absence of a mucous bridge from the vagina to the uterus can make sperm migration difficult or impossible. Therapeutic intrauterine insemination may be necessary for the sperm to be carried directly through the internal os of the cervix.

Surgical procedures may also be used for problems causing male infertility. Surgical repair of varicocele has been relatively successful in increasing sperm count but not fertility rates. Microsurgery to reanastomose (restore tubal continuity) the sperm ducts after vasectomy can restore fertility.

Assisted Human Reproduction

Assisted human reproduction (AHR), also called *assisted reproductive technology (ART),* is defined as fertility treatments in which medical procedures are used to assist with getting someone pregnant. AHR can include the use of ovulation-inducing medications, often called "fertility drugs"; intrauterine insemination (IUI), when a thin tube (catheter) carries sperm directly into the womb (uterus) through the vagina; or IVF, which is the manipulation of both sperm and eggs outside the body to help with fertilization (PHAC, 2019).

Some of the AHR treatments of infertility include in vitro fertilization–embryo transfer (IVF-ET), gamete intrafallopian transfer

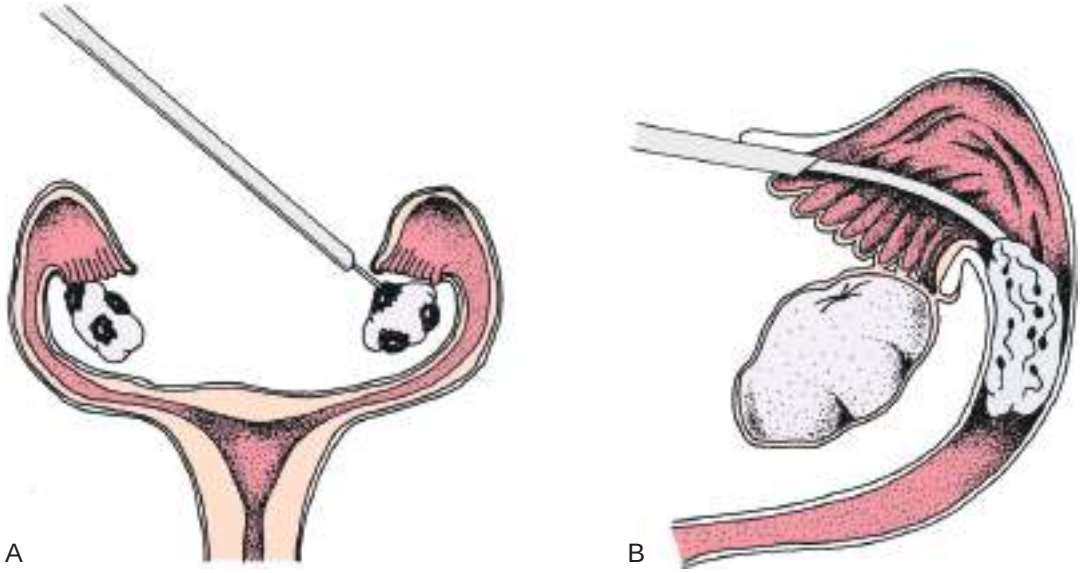

Fig. 8.4 Gamete intrafallopian transfer (GIFT). **A:** Through laparoscopy a ripe follicle is located, and fluid containing the egg is removed. **B:** The sperm and egg are placed separately in the uterine tube, where fertilization occurs.

TABLE 8.2 Assisted Human Reproduction

Procedure	Definition	Indications
In vitro fertilization–embryo transfer (IVF-ET)	Oocytes are retrieved from the ovary, fertilized in the laboratory with sperm, and transferred to the uterus after normal embryo development has occurred.	Tubal disease or blockage; severe male infertility; endometriosis; unexplained infertility; cervical factor; immunological infertility
Gamete intrafallopian transfer (GIFT)	Oocytes are retrieved from the ovary, placed in a catheter with washed motile sperm, and immediately transferred into the fimbriated end of the uterine tube. Fertilization occurs in the uterine tube (see Fig. 8.4).	Same as for IVF-ET, except there must be normal tubal anatomy, patency, and absence of previous tubal disease in at least one uterine tube
IVF-ET and GIFT with donor sperm	This process is the same as that described for IVF-ET and GIFT except in cases where the man's fertility is severely compromised and donor sperm can be used; if donor sperm are used, the woman must have indications for IVF and GIFT.	Severe male infertility; azoospermia; indications for IVF-ET or GIFT
Zygote intrafallopian transfer (ZIFT)	This process is similar to IVF-ET; after IVF the ova are placed in one uterine tube during the zygote stage.	Same as for GIFT
Donor oocyte	Eggs are donated by an IVF procedure and the donated eggs are inseminated. The embryos are transferred into the recipient's uterus, which is hormonally prepared with estrogen–progesterone therapy.	Early menopause; surgical removal of ovaries; congenitally absent ovaries; autosomal or sex-linked disorders; lack of fertilization in repeated IVF attempts because of subtle oocyte abnormalities or defects in oocyte–spermatozoa interaction
Donor embryo (embryo adoption)	A donated embryo is transferred to the uterus of an infertile person at the appropriate time (normal or induced) of the menstrual cycle.	Infertility not resolved by less aggressive forms of therapy; absence of ovaries; male partner is azoospermic or severely compromised
Gestational carrier (embryo host); surrogate mother	A couple undertakes an IVF cycle, and the embryo(s) is transferred to another person's uterus (the carrier), who has contracted with the couple to carry the baby to term. The carrier has no genetic investment in the child. Surrogate mother means a female person who—with the intention of surrendering the child at birth to a donor or another person—carries an embryo or a fetus, conceived through an assisted reproduction procedure, and derived from the genes of a donor or donors.	Congenital absence or surgical removal of uterus; a reproductively impaired uterus, myomas, uterine adhesions, or other congenital abnormalities; LGBTQ2 couple; a medical condition that might be life-threatening during pregnancy, such as diabetes, immunological disorders, or severe heart, kidney, or liver disease **It is illegal in Canada to pay someone to be a surrogate.**
Therapeutic donor insemination (TDI)	Donor sperm are used to inseminate the female partner.	Male partner is azoospermic or has a very low sperm count; couple has a genetic defect; male partner has antisperm antibodies; lesbian couple
Intracytoplasmic sperm injection	One sperm cell is selected to be injected directly into the egg to achieve fertilization. It is used with IVF.	Same as TDI
Assisted hatching	The zona pellucida is penetrated chemically or manually to create an opening for the dividing embryo to hatch and implant into the uterine wall.	Recurrent miscarriages; to improve implantation rate in women with previously unsuccessful IVF attempts; advanced age

BOX 8.6 Issues to Be Addressed by Infertile Couples Before Using Assisted Human Reproduction

- Risks of multiple gestation
- Possible need for multifetal reduction
- Possible need for donor oocytes, sperm, or embryos or for gestational carrier (surrogate mother)
- Whether or how to disclose facts of conception to offspring
- Freezing embryos for later use
- Possible risks of long-term effects of medications and treatment on infertile persons, children, and families
- Cost of treatment (emotional, monetary, and time)
- Potential mental health effects (anxiety, depression) related to infertility treatment

(GIFT) (Figure 8.4), zygote intrafallopian transfer (ZIFT), ovum transfer (oocyte donation), embryo adoption, embryo hosting and surrogate motherhood, therapeutic donor insemination (TDI), ICSI, assisted embryo hatching, and preimplantation genetic diagnosis (PGD). Table 8.2 describes these procedures and the possible indications for AHRs. Donor sperm and donor eggs can be used with AHR. In addition, surrogates may carry the couple's biological child.

The Canadian Fertility and Andrology Society reported that in 2017 there were approximately 33 092 AHR cycles with approximately 39% of these resulting in a pregnancy. Of the viable pregnancies, approximately 92% were singletons and 8% were multiple pregnancies, with the majority being twins (Canadian Assisted Reproductive Technology Registered [CARTR] Plus, 2018). The number of multiple pregnancies has been decreasing steadily because of a concerted effort among specialists to promote elective single embryo transfer, as well as improvements in technology (Canadian Fertility and Andrology Society, 2016).

AHR is associated with many ethical and legal issues (Box 8.6). The *Assisted Human Reproduction Act* sets legislation for all aspects of AHR in Canada. The act prohibits human cloning and other unacceptable activities, while protecting the health and safety of people who use AHR (Health Canada, 2021). Nurses can provide relevant information to couples so that they have an accurate understanding of their chances for a successful pregnancy and live birth and can make an informed decision. Couples need to be counselled about the risks of AHR, the costs, and what next steps are available if the treatment is not successful, in order to make an informed decision. Nurses also can provide anticipatory guidance about the moral and ethical dilemmas regarding the use of AHR. If a couple is fortunate enough to have multiple embryos available, they may choose to preserve these for later implantation, which has potential legal implications.

LEGAL TIP

Cryopreservation of Human Embryos

Couples who have excess embryos frozen for later transfer must be fully informed before consenting to the procedure in order to make decisions about the disposal of embryos in the event of death, divorce, or the decision at a later time that the couple no longer wants the embryos.

Complications. Other than the established risks associated with laparoscopy and general anaesthesia, few risks are associated with IVF-ET, GIFT, and ZIFT. The more common transvaginal needle aspiration requires only local or intravenous analgesia. Congenital anomalies occur no more frequently than among naturally conceived embryos, although the risk of pregnancy loss and chromosomal abnormality increases with maternal age. There is an increased risk for maternal morbidity in women who have had infertility treatment, including severe postpartum hemorrhage (i.e., requiring transfusion of red blood cells or other interventions), maternal admission to a critical care unit, puerperal sepsis, hysterectomy, and cardiac conditions (Dayan et al., 2019). Multiple gestations are more likely and are associated with increased risks for both the mother and fetuses. With increased risk in multiple pregnancy for adverse maternal, obstetrical, and perinatal outcomes, couples need to be thoroughly counselled about the risks of multiple pregnancies associated with all AHR treatments.

The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends a policy of elective single embryo in couples with good prognosis for success (Okun et al., 2014). To reduce the incidence of multiple pregnancy, health care policies that support public funding for AHR, with regulations promoting best practice regarding elective single embryo transfer, should be strongly encouraged (Okun et al., 2014).

LGBTQ2 Couples

Many LGBTQ2 couples use AHR in order to have biologically related children. Couples need correct information in order to make informed choices. Health care providers need to provide sensitive and respectful care to these couples and ensure that language, materials, and websites used to provide relevant information reflect and affirm LGBTQ2 clients (i.e., using images depicting LGBTQ2 families, gender-neutral language, open-ended questions). It is beyond the scope of this text to discuss all options available to LGBTQ2 couples; readers are referred to the Additional Resources at the end of this chapter for some excellent resources.

Adoption

Couples may choose to build their family by adopting children who are not genetically related. With increased availability of birth control and abortion and an increase in single mothers who choose to keep their babies, the availability of healthy newborn infants for adoption is extremely limited. Infants with diverse ethnic and racial heritages, infants with special needs, older children, and international adoptions are options that require careful consideration and sometimes significant time and financial investment. Parents who adopt a child who has special needs or is from a different ethnic background face challenges that those who adopt a newborn may not. Often they must wait several years prior to adopting a child, and this time can be challenging. Support groups can be an invaluable resource for these couples waiting for a child.

CONTRACEPTION

Contraception is the intentional prevention of pregnancy during sexual intercourse. *Birth control* is the device or practice used to decrease the risk of conceiving, or bearing, offspring. *Family planning* is the conscious decision regarding when to conceive or to avoid pregnancy throughout the reproductive years. The nurse can play a vital role in preventing unwanted pregnancy through counselling and education regarding family planning, contraception, and effective birth control. Nurses who work with postpartum women also need to teach about contraceptive options. With the wide assortment of birth control options available, it is possible for a woman to use several different contraceptive methods at various stages throughout her fertile years. Nurses interact with the woman or couple to compare and contrast available options, especially since a large percentage of sexually active Canadian women who do not wish to conceive do not use a contraceptive method consistently, thus putting them at risk of unintended pregnancy (Black et al., 2019). Factors to consider include reliability, relative cost of the method, any protection from STIs, the individual's

comfort level, and the partner's willingness to use a particular birth control method. Those who use contraception can still be at risk for pregnancy if their choice of contraceptive method results in one that is not used correctly. Providing adequate instruction about how to use a contraceptive method, when to use a backup method, and when to use emergency contraception can decrease the risk of unintended pregnancy.

Nursing Care

A multidisciplinary approach may help a person choose and correctly use an appropriate contraceptive method (see Nursing Process: Contraception, on Evolve). Nurses, midwives, nurse practitioners, and other advanced practice nurses and physicians have the knowledge and expertise to assist a patient in making decisions about contraception that will satisfy the patient's personal, social, cultural, and interpersonal needs.

Assessment for the couple desiring contraception involves assessment of the patient's reproductive history (menstrual, obstetrical, gynecological, contraceptive), physical examination, and sometimes current laboratory tests. The nurse must determine the patient's knowledge about reproduction, contraception, and STIs and possibly their sexual partner's commitment to any particular method (Figure 8.5). The nurse obtains information about the frequency of intercourse, number of sexual partners (present and past), and any objections that they or their partner might have about specific birth control methods. In addition, the nurse must determine a patient's willingness to touch their genitals. Religious and cultural factors may influence a person's choice regarding a particular contraceptive method. Unbiased patient teaching is fundamental to initiating and maintaining any form of contraception. The nurse should counter myths with facts, clarify misinformation, and fill in gaps of knowledge. The ideal contraceptive should be safe, easily available, economical, acceptable, simple to use, and promptly reversible. Although no method may ever achieve all of these objectives, significant advances in the development of new contraceptive technologies have occurred over the past 40 years.

Contraceptive failure rate refers to the percentage of contraceptive users expected to have an unplanned pregnancy during the first year even when they use a method consistently and correctly. Contraceptive effectiveness varies from person to person and depends on both the properties of the method and the characteristics of the user (Box 8.7). Effectiveness of a method can be expressed as theoretical (i.e., how effective the method is with perfect use) and typical (i.e., how effective the method is with typical use). Failure rates decrease over time, either because a user gains experience with and uses a method more appropriately or because a less effective user stops using the method. Safety of a method may be affected by a patient's medical history (e.g., thromboembolic concerns and contraceptive methods containing estrogen). Nevertheless, in most instances pregnancy would be more dangerous to the patient with medical issues than a particular contraceptive method. In addition, many contraceptive methods have health promotion effects. For instance, barrier methods such as the male condom offer some protection from acquiring STIs, and oral contraceptives lower the incidence of ovarian and endometrial cancer.

Fig. 8.5 Nurse counselling woman about contraceptive methods (iStock.com/Katarzyna Bialasiewicz)

BOX 8.7 Factors Affecting Contraceptive Method Effectiveness

- Frequency of intercourse
- Motivation to prevent pregnancy
- Understanding of how to use the method
- Adherence to the method
- Consistent use of the method
- Provision of short-term or long-term protection

Following assessment and analysis, the individual or couple determines possible contraceptive methods that are appropriate for their unique situation. Factors to consider when determining a contraceptive method are effectiveness, convenience, affordability, duration of action of method, reversibility of method, time of return to fertility, effects on uterine bleeding patterns, adverse effects, health promotion effects of methods, effect of method on transmission of STIs, and medical contraindications for use.

The most effective reversible contraceptive methods at preventing pregnancy are the long–acting, reversible contraceptive (LARC) methods (e.g., contraceptive implants, intrauterine contraception). With these methods theoretical and typical pregnancy rates are the same because the method requires no user intervention after correct insertion. Effective methods include those that prevent pregnancy through exogenous hormones (estrogen or progestins), such as contraceptive injections, oral contraceptive pills, contraceptive patches, and vaginal rings. Each of these methods involves user interventions; thus typical-use pregnancy rates are higher than pregnancy rates with perfect use. The least effective contraceptive methods include the barrier methods and natural family planning. Examples include condoms, diaphragms, cervical caps, spermicides, withdrawal, and periodic abstinence during perceived ovulation. Effectiveness rates for these methods vary from user to user, depending on correct application of the method and consistency of use.

Expected outcomes related to contraceptive counselling are that the individual or couple will verbalize understanding about appropriate contraceptive methods, state that they are satisfied with the method chosen, use the method correctly and consistently, experience no adverse sequelae as a result of the chosen contraceptive method, and prevent unplanned pregnancy. The nurse assists with obtaining appropriate informed consent concerning contraception or sterilization, provides appropriate education to the couple, and documents the patient's or couple's understanding of the contraceptive method chosen. Evaluation involves achievement of patient-centred outcomes when the couple engages in effective use of the chosen contraceptive device, experiences no adverse sequelae, and achieves pregnancy only when they desire to do so.

Methods of Contraception

The following discussion of contraceptive methods provides the nurse with information needed for patient teaching. After

implementing the appropriate teaching for contraceptive use, the nurse supervises return demonstrations and practice to assess patient understanding (see Clinical Reasoning Case Study box). The individual or couple is given written instructions and telephone numbers or email contact information for questions. If the patient has difficulty understanding written instructions, they or their partner, if available, are offered graphic material, a telephone number to call as necessary, and an opportunity to return for further instruction. An excellent resource for information on all methods of contraception can be obtained from Sex & U (see Additional Resources at the end of the chapter).

CLINICAL REASONING CASE STUDY

Contraception for Adolescents

Marie is a 16-year-old Indigenous woman who comes to the nursing station on the reserve, seeking contraception. She has recently become sexually active and tells the nurse that she is concerned that her mother will find out. She also has many questions about the type of contraception to use. She seeks the nurse's advice to help in her decision making.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about what advice to give Marie? What is the age of consent?
2. Assumptions—What assumptions can be made about contraception for adolescents:
   a. Types of contraception: What methods are appropriate (safe and effective) for an adolescent young woman?
   b. Legal issues: Is this young woman engaging in consensual sexual intercourse? Does she need parental consent to obtain contraception?
   c. Implications of culture on choice: Are there any cultural issues?
3. What implications and priorities for nursing care can be drawn at this time?
4. What are the opportunities for interprofessional practice? Which members of the interprofessional health care team might be involved in providing care for Marie?

Natural Family Planning. *Natural family planning (NFP)* refers to methods of contraception that do not rely on medical devices, compounds, or medications. There are a range of NFP contraceptive strategies, including fertility awareness–based methods, lactational amenorrhea, coitus interruptus (withdrawal), and abstinence from penile–vaginal intercourse. The effectiveness of natural birth control methods depends on the users' ability to follow the plan. If a patient's cycle does not follow a regular pattern, the use of natural birth control methods may be more difficult. Natural birth control methods do not protect against acquiring STIs or human immunodeficiency virus (HIV) infection.

Fertility awareness–based methods. In fertility awareness–based (FAB) methods, patients learn how to determine the beginning and the end of the fertile period of their menstrual cycle. The individual would then avoid unprotected intercourse during this "fertile window." When educating patients about the menstrual cycle, three phases are identified:

1. Infertile phase: before ovulation
2. Fertile phase: about 5 to 7 days around the middle of the cycle, including several days before and during ovulation and the day afterward
3. Infertile phase: after ovulation

The human ovum usually must be fertilized no later than 16 to 24 hours after ovulation. While motile sperm have been recovered from the uterus and the oviducts as long as 7 days after **coitus**, their ability to fertilize the ovum probably lasts no longer than 24 hours. Pregnancy is unlikely to occur if a couple abstains from intercourse for 4 days before and 3 or 4 days after ovulation (fertile period). Unprotected intercourse on the other days of the cycle (safe period) should not result in pregnancy. Nevertheless, the exact time of ovulation cannot be predicted accurately, and couples may find it difficult to abstain from sexual intercourse for several days before and after ovulation. In general, FAB methods are not recommended for patients with the following difficulties: irregular cycles, inability to interpret the fertility signs correctly, or persistent infections that affect the signs of fertility. Individuals with irregular menstrual periods have the greatest risk of failure with this form of contraception. With typical use, the 1-year pregnancy rate for all FAB methods is approximately 24% (Black et al., 2015b). With perfect use, some methods have much lower pregnancy rates.

Although ovulation can be unpredictable in many patients, teaching the patient about how they can directly observe their fertility patterns is an empowering tool. In addition, knowledge about the signs and symptoms of ovulation can be very helpful when the patient desires pregnancy. There are many categories of FAB methods. To prevent pregnancy, each one uses a combination of charts, records, calculations, tools, observations, and either abstinence or barrier methods of birth control during the fertile period in the menstrual cycle. The charts and calculations associated with these methods can also be used to increase the likelihood of detecting the optimal timing of intercourse to achieve conception.

Advantages of these methods include low to no cost, absence of intake of chemicals and hormones, and lack of alteration in the menstrual flow pattern. Disadvantages of FAB include adherence to strict record keeping, three to six cycles to learn, unintentional interference from external influences that may alter the patient's core body temperature and vaginal secretions, decreased effectiveness in patients with irregular cycles (particularly adolescents who have not established regular ovulatory patterns), decreased spontaneity of coitus, and the necessity of attending possibly time-consuming training sessions by qualified instructors. FAB methods involve several techniques to identify high-risk, fertile days. The following discussion includes the most common techniques.

Calendar days method. Practice of the calendar rhythm method is based on the number of days in each cycle, counting from the first day of the menstrual cycle. The fertile period is determined after accurately recording the length of menstrual cycles for 6 to 12 months. The beginning of the fertile period is estimated by subtracting 20 days from the length of the shortest cycle. The end of the fertile period is determined by subtracting 10 days from the length of the longest cycle. If the shortest cycle is 24 days and the longest is 30 days, application of the formula to calculate the fertile period is as follows:

Shortest cycle, 24 − 20 = day 4
Longest cycle, 30 − 10 = day 20

To avoid conception, the couple would abstain during the fertile period, days 4 through 20.

If the patient has very regular cycles of 28 days each, the formula indicates the fertile days to be as follows:

Shortest cycle, 28 − 20 = day 8
Longest cycle, 28 − 10 = day 18

To avoid conception, the couple would abstain days 8 through 18.

A major drawback of the calendar method is that one is trying to predict future events with past data. The unpredictability of the menstrual cycle is also not taken into consideration. The calendar method has been replaced by the standard days method but may be useful for patients whose cycle is not in the range of 26 to 32 days (Black et al., 2015b).

Fig. 8.6 CycleBeads. Red bead marks the first day of the menstrual cycle. White beads mark days that are likely to be fertile days; therefore, unprotected intercourse should be avoided. Brown beads are days when pregnancy is unlikely and unprotected intercourse is permitted. (Courtesy Dee Lowdermilk.)

Standard days method. The standard days method (SDM) is essentially a modified form of the calendar method that has a "fixed" number of days of fertility for each cycle (i.e., days 8 to 19 in individuals who have a menstrual cycle from 26 to 32 days in length). A CycleBeads necklace (i.e., a colour-coded string of beads), Web-based trackers, or mobile applications can be used to track fertility (Black et al., 2015b) (Figure 8.6). Day 1 of the menstrual flow is counted as the first day to begin the counting. Patients who use this device are taught to avoid unprotected intercourse on days 8 to 19 (white beads on CycleBeads necklace). Although this method is useful to patients whose cycles are 26 to 32 days long, it is unreliable for those who have longer or shorter cycles.

Basal body temperature method. The **basal body temperature (BBT)** is the lowest body temperature of a healthy person, taken immediately after waking, after at least 6 hours of sleep and before getting out of bed. The BBT usually varies from 36.2° to 36.3°C during menses and for approximately 5 to 7 days afterward (Figure 8.7).

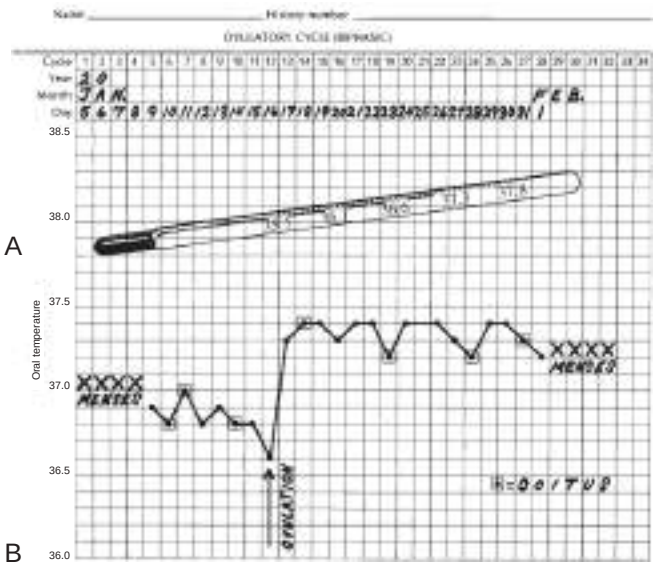

Fig. 8.7 **A:** Special thermometer for recording basal body temperature, marked in tenths to enable the person to read more easily. **B:** Basal temperature record shows decrease and sharp increase at time of ovulation. Biphasic curve indicates ovulatory cycle.

About the time of ovulation, a slight drop in temperature (approximately 0.5°C) may occur in some patients, but others may have no decrease at all. After ovulation, in concert with the increasing progesterone levels of the early luteal phase of the cycle, the BBT increases slightly (approximately 0.5°C). The temperature remains on an elevated plateau until 2 to 4 days before menstruation. Then BBT decreases to the low levels recorded during the previous cycle unless pregnancy has occurred. In pregnant patients the temperature remains elevated. If ovulation fails to occur, the pattern of lower body temperature continues throughout the cycle.

To use this method, the fertile period is defined as the day of first temperature drop, or first elevation, through 3 consecutive days of elevated temperature. Abstinence begins the first day of menstrual bleeding and lasts through 3 consecutive days of sustained temperature rise. The decrease and subsequent increase in temperature are referred to as the *thermal shift*. When the entire month's temperatures are recorded on a graph, the pattern described is more apparent. It is more difficult to perceive day-to-day variations without the entire picture (see Guidelines box: Basal Body Temperature). The thermometer used must measure the temperature within one-tenth of a degree. Infection, fatigue, less than 6 hours of sleep per night, awakening late, and anxiety may cause temperature fluctuations and alter the expected pattern. If a new BBT thermometer is purchased, this fact is noted on the chart because the readings may vary slightly. Jet lag, alcohol taken the evening before, or sleeping in a heated waterbed must also be noted on the chart because each affects the BBT. Therefore, the BBT alone is not a reliable method of predicting ovulation.

GUIDELINES

Basal Body Temperature

- Discuss basal body temperature (BBT) with the patient.
- Show the patient a diagram depicting the phases of the menstrual cycle.
- Discuss the hormones in the patient's body that are responsible for their menstrual cycle and ovulation. Leave time for questions.
- Show the patient a sample BBT graph (see Figure 8.7) and the biphasic line seen in ovulatory cycles.
- Show the patient the BBT thermometer and how it is calibrated.
- Provide a demonstration of how to take an oral temperature.
- Encourage the patient to demonstrate taking and reading the thermometer and graphing the temperature while the nurse watches.
- Encourage the patient to start a log to keep track of any other activity that might interfere with their true BBT.

Cervical mucus ovulation-detection method. The cervical mucus ovulation-detection method (i.e., Billings method) requires that the patient recognize and interpret the cyclic changes in the amount and consistency of cervical mucus before and during ovulation to facilitate and promote the viability and motility of sperm. Without adequate cervical mucus, coitus does not result in conception. This method requires that a patient check the quantity and character of mucus on the vulva or introitus with their fingers or with tissue paper each day for several months. This way they can learn how their cervical mucus responds to ovulation during their menstrual cycle. To ensure an accurate assessment of changes, the cervical mucus should be free from semen, contraceptive gels, and blood or discharge from vaginal infections for at

least one full cycle. Other factors that create difficulty in identifying mucus changes include douches and vaginal deodorants, being in the sexually aroused state (which thins the mucus), and taking medications such as antihistamines, which dry the mucus. Intercourse is considered safe without restriction beginning on the fourth day after the last day of wet, clear, slippery mucus, which would indicate that ovulation has occurred 2 to 3 days previously. After ovulation, mucus first becomes thick, opaque, and reduces in volume.

Some patients find this method unacceptable if they are uncomfortable touching their genitals. Regardless of whether a patient wants to use this method for contraception, it is to their advantage to learn to recognize mucus characteristics at ovulation (see Guidelines box: Cervical Mucus Characteristics). Self-evaluation of cervical mucus can be highly accurate and useful diagnostically for any of the following purposes:

- To alert the couple to the re-establishment of ovulation while breastfeeding and after discontinuation of oral contraception
- To note anovulatory cycles at any time and at the beginning of menopause
- To assist couples in planning a pregnancy

Symptothermal method. The symptothermal method is a method that combines BBT and cervical mucus methods along with awareness of secondary, cycle phase-related symptoms. The person gains fertility awareness as they learn the psychological and physiological symptoms that mark the phases of their cycle. Secondary symptoms include increased libido, midcycle spotting, mittelschmerz (cramplike pain before ovulation), pelvic fullness or tenderness, and vulvar fullness.

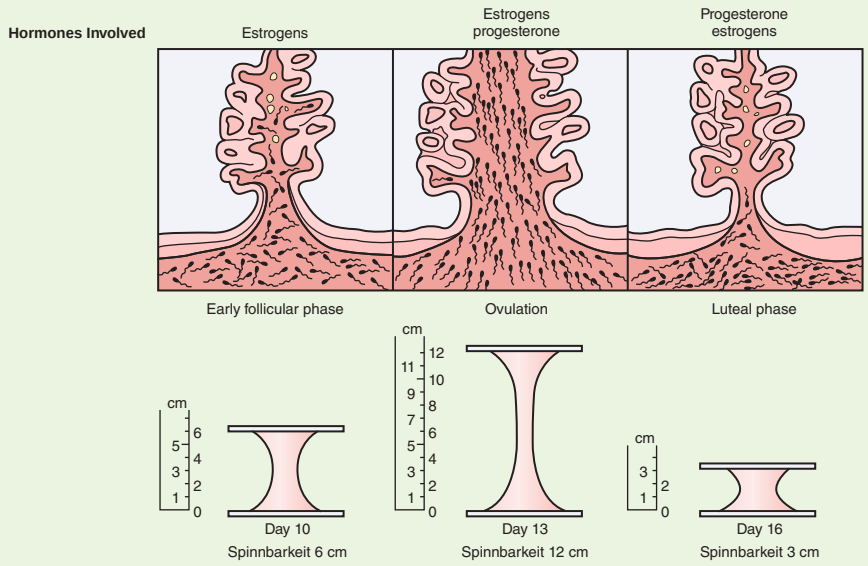
The patient is taught to palpate their cervix to assess for changes indicating ovulation: the cervical os dilates slightly, the cervix softens and rises in the vagina, and cervical mucus is copious and slippery. The patient notes days on which coitus, changes in routine, and illness have occurred (Figure 8.8). Calendar calculations and cervical mucus changes are used to estimate the onset of the fertile period; changes in cervical mucus and the BBT are used to estimate its end.

Two-day method. The two-day method involves an evaluation of cervical mucus to determine a patient's fertility. If cervical secretions were present "today" and "yesterday" a patient is very fertile. If the secretions were present either "today" or "yesterday" they are fertile. If there was no cervical mucus "today" or "yesterday" the fertility is low (Black et al., 2015b). Individuals are taught to ask themselves two questions each

GUIDELINES

Cervical Mucus Characteristics

Setting the Stage



- Show charts of the menstrual cycle along with changes in the cervical mucus.
- Have the patient practise assessing mucus using raw egg white.
- Explain that the assessment of cervical mucus characteristics is best when mucus is not mixed with semen, contraceptive jellies, or discharge from infections.

Content Related to Cervical Mucus

- Explain to the patient (or couple) that an individual with a regular cycle will have the following sequence of events:
  - 3 to 7 days of menstruation
  - Several days when they do not feel or see mucus in their vagina or on their vulva
  - Several days of a "wet" or "slippery" sensation at their vulva or in the vagina where they see or feel mucus. It is white or cream-coloured, thick to slightly stretchy, and breaks easily when stretched. As ovulation approaches, mucus becomes more abundant, clearer, and more elastic. It feels like a lubricant and can be stretched approximately 12 cm between the thumb and forefinger (similar to egg white); this is called *spinnbarkeit* (see figure below). This characteristic indicates the period of maximum fertility. Sperm deposited in this type of mucus can survive until ovulation occurs.
  - After ovulation the mucus disappears from the vulva, and the vulva and vagina feel "drier."

Assessment Technique

- Hand hygiene is imperative to begin and end all self-assessments.
- Start observation from last day of menstrual flow.
- Assess cervical mucus several times a day for several cycles. Mucus can be obtained from vaginal introitus; there is no need to reach into the vagina to the cervix.

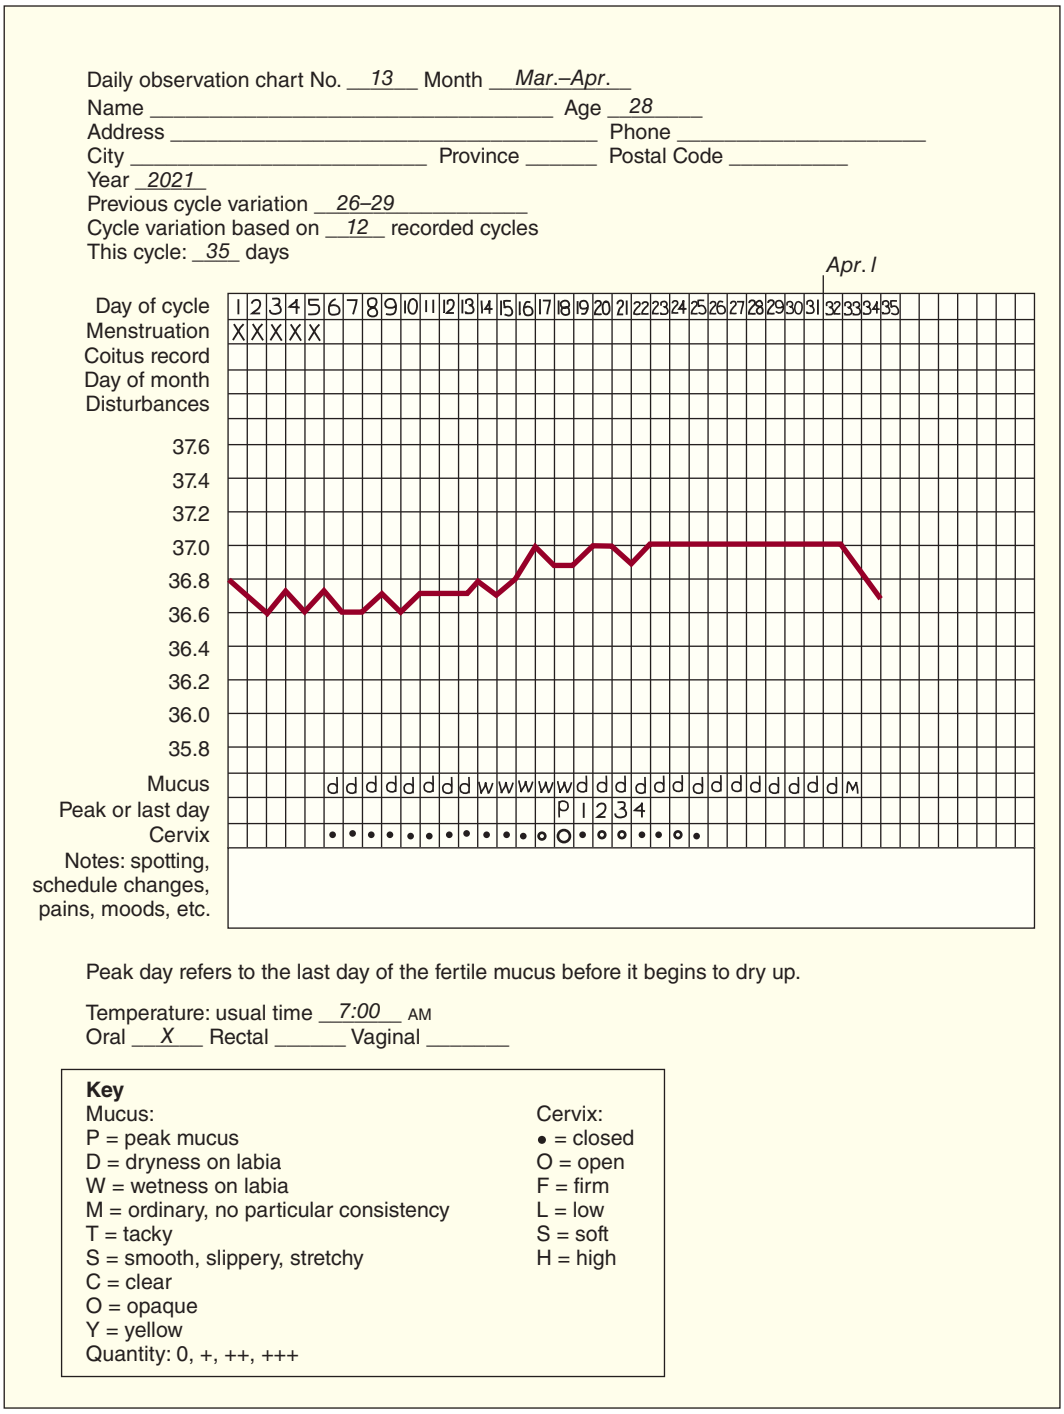


Fig. 8.8 Example of completed symptothermal chart.

day: (1) "Did I note secretions today?" and (2) "Did I note secretions yesterday?" If the answer to either question is yes, they should avoid coitus or use a backup method of birth control. If the answer to both questions is no, their probability of getting pregnant is low.

Home predictor test kits for ovulation. All the methods previously discussed are indicative of ovulation but do not prove its occurrence or exact timing. A home predictor test for ovulation is a major addition to the NFP methods to help patients who want to plan the time of their pregnancies and for those who are trying to conceive. The urine or saliva predictor test for ovulation detects the sudden surge of LH that occurs approximately 12 to 24 hours before ovulation. Unlike BBT, the test is not affected by illness, emotional upset, or physical activity. For home use, a test kit contains sufficient material for several days' testing during each cycle. A positive response indicating an LH surge is noted by a colour change that is easy to read. Directions for use of home predictor test kits vary with the manufacturer.

Coitus interruptus. **Coitus interruptus** (withdrawal) involves the male partner withdrawing their penis from the individual's vagina before they ejaculate. Although coitus interruptus has been criticized as being an ineffective method of contraception, it is a good choice for couples who do not have another contraceptive method available. Effectiveness is similar to barrier methods and depends on the ability of the person to withdraw

their penis before ejaculation. The percentage of patients who will experience an unintended pregnancy within the first year of typical use (failure rate) of withdrawal is about 22% (Black et al., 2015b). According to a survey completed by the SOGC in 2016, a large number of Canadians are using this as their main method of birth control (Black et al., 2019). Coitus interruptus does not protect against STIs or HIV infection.

Breastfeeding: Lactational amenorrhea method. The lactational amenorrhea method (LAM) can be a highly effective, temporary method of birth control, although three factors are necessary for it to be effective:

- the patient is less than 6 months postpartum;
- they are fully or nearly fully breastfeeding; and
- their period has not returned (Black et al., 2015a).

When the infant suckles at the breast, a surge of prolactin hormone is released, which inhibits estrogen production and suppresses ovulation and the return of menses. LAM has a 90% effectiveness rate when used correctly (Black et al., 2015b). Effectiveness is enhanced by frequent feedings at intervals of less than 4 hours during the day and no more than 6 hours during the night, long duration of each feeding, and no bottle supplementation or limited supplementation by spoon or cup. The person should be counselled that disruption of the breastfeeding pattern or supplementation can increase the risk of pregnancy and after 6 months, fertility could resume at any time.

Abstinence. *Abstinence* refers to avoiding vaginal intercourse. From a family planning perspective, it is only necessary for couples to use periodic abstinence, which is the avoidance of sexual acts that involve the introduction of seminal contents into the vagina during the fertile window. Abstinence may not prevent certain STIs that can be transmitted by skin-to-skin contact (Black et al., 2015b). Nurses need to help support individuals who choose abstinence and assist them with negotiation and planning skills to use abstinence effectively. It is important that health care providers not use an "abstinence-only" approach when counselling, especially with teenagers, as this does not provide appropriate sexual education to them (Black et al., 2015b).

Barrier Methods. Barrier contraceptives have gained in popularity, not only as a contraceptive method but also as protection against the spread of STIs such as human papilloma virus (HPV) and herpes simplex virus (HSV). Some male condoms and female vaginal methods provide a physical barrier to several STIs, and some male condoms provide protection against HIV. **Spermicides** serve as chemical barriers against semen and inhibit the ability of sperm to fertilize the ovum.

The nurse should remember that any user of a barrier method of contraception must also be aware of emergency contraception options in case there is a failure of the method (see Emergency Contraception section later in chapter). An example of a barrier method failure would be if a condom broke during intercourse. In this instance, emergency contraception would be indicated to prevent unplanned pregnancy.

Spermicides. Spermicides such as nonoxynol-9 (N-9) work by reducing the sperm's mobility; the chemicals attack the sperm flagella and body, thereby preventing the sperm from reaching the cervical os. N-9, the most commonly used spermicidal chemical in Canada, is a surfactant that destroys the sperm cell membrane; however, data now suggest that frequent use (more than two times a day) of N-9 or use as a lubricant during anal intercourse may cause genital irritation, which may increase the transmission of HIV (Black et al., 2015c). There is also an increased risk of urinary tract infections with the use of spermicides. Individuals with high-risk behaviours that increase their likelihood of contracting HIV are advised to avoid the use of spermicidal products containing N-9, including lubricated condoms and the contraceptive sponge to which N-9 is added. Spermicides are recommended for individuals with low-risk behaviour.

Intravaginal spermicides are marketed and sold without prescriptions as aerosol foams or films. Preloaded, single-dose applicators small enough to be carried in a small purse are available. Effectiveness of spermicides depends on consistent and accurate use. The spermicide should be inserted high into the vagina so that it makes contact with the cervix, not more than 1 hour before sexual intercourse. Spermicide must be reapplied for each additional act of intercourse, even if a barrier method is used. Vaginal spermicides are among the least effective of all modern family planning methods, with a failure rate in the first year of use from 18% with perfect use to 28% with typical use (Black et al., 2015c) and are more effective if used along with another method of contraception.

Male condoms. The male condom is a thin, stretchable sheath that covers the penis before genital, oral, or anal contact and is removed when the penis is withdrawn from the partner's orifice after ejaculation. Condoms are made of latex rubber; polyurethane (strong, thin plastic); or natural membranes (animal tissue). In addition to providing a physical barrier for sperm, nonspermicidal latex condoms also provide a barrier for STIs (particularly gonorrhea, chlamydia, and trichomonas) and HIV transmission. Condoms lubricated with N-9 are not recommended for preventing STIs or HIV and do not increase protection against pregnancy (Black et al., 2015c). Latex condoms break down with oil-based lubricants (e.g., petroleum jelly and suntan oil) and should be used only with water-based lubricants. Because of the growing number of people with latex allergies, condom manufacturers have begun using polyurethane, which is thinner and stronger than latex.

! NURSING ALERT

All patients should be questioned about the potential for latex allergy. Latex condom use is contraindicated for patients with latex sensitivity.

Although polyurethane condoms are as effective for STI prevention as latex condoms, they are more likely to slip or lose contour than are latex condoms. Therefore, with perfect use, latex condoms offer better protection against pregnancy. Polyurethane condoms do offer pregnancy protection equivalent to that of most barrier products. A small percentage of condoms are made from lamb cecum (natural skin). Natural skin condoms do not provide the same protection against STIs and HIV infection as that of latex condoms. Natural skin condoms contain small pores that could allow passage of viruses such as hepatitis B, HSV, and HIV and are not generally recommended.

A functional difference in condom shape is the presence or absence of a sperm reservoir tip. To enhance vaginal stimulation, some condoms are contoured and rippled or have ribbed or roughened surfaces. Thinner construction increases heat transmission and sensitivity; a variety of colours increases condom acceptability and attractiveness. A wet jelly or dry powder lubricates some condoms. Typical failure rate for the first year of use of the male condom is 18% (Black et al., 2015c). Effective condom use is a skill that must be taught. Box 8.8 summarizes advantages and disadvantages of male condoms.

! NURSING ALERT

It is a false assumption that everyone knows how to use condoms. To prevent unintended pregnancy and the spread of STIs, it is essential that condoms be used correctly. Proper instruction in use must be provided (see Box 8.8). All types of condoms must be discarded after each single use. Condoms are available without prescription from a variety of sources, including vending machines.

BOX 8.8 Male Condoms

Mechanism of Action

The sheath is applied over the erect penis before insertion or loss of pre-ejaculatory drops of semen. Used correctly, condoms prevent sperm from entering the cervix. Spermicide-coated condoms cause ejaculated sperm to be immobilized rapidly, thus increasing contraceptive effectiveness.

Failure Rate

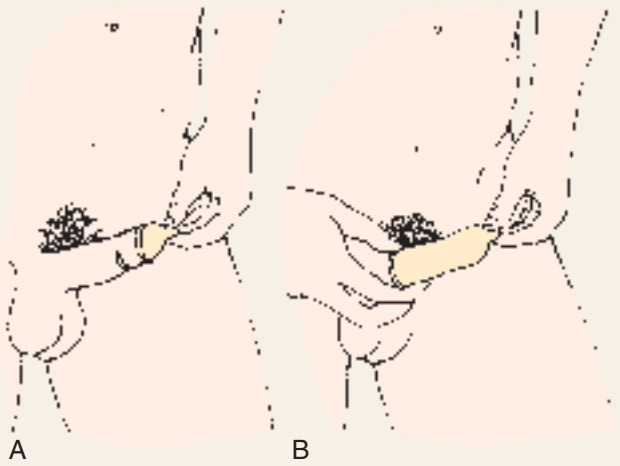
- Typical users, 18%
- Correct and consistent users, 2%

Advantages

- Safe
- Inexpensive
- No side effects
- Readily available
- Premalignant changes in cervix can be prevented or ameliorated in patients whose partners use condoms
- Method of male nonsurgical contraception
- Allows the male partner to assume some responsibility for birth control

Disadvantages

- Must be available at time of intercourse
- May reduce sexual spontaneity and sensitivity for either partner
- Sensation may be altered
- Must be stored and handled properly
- Condoms occasionally may tear during intercourse.
- People with latex allergies cannot use latex condoms.
- Use of spermicide may cause irritation of the vaginal and rectal walls and increase the risks of contracting HIV
- May interfere with the maintenance of an erection



STI Protection

If a condom is used throughout the act of intercourse and there is no unprotected contact with another person's genitals, a latex rubber condom, which is impermeable to viruses, can act as a protective measure against sexually transmitted infections (STIs).

Nursing Considerations

Teach the man or partner or both to do the following:

- Use a new condom (check expiration date) for each act of sexual intercourse or other acts between partners that involve contact with the penis.
- Place the condom after the penis is erect and before intimate contact.
- Place the condom on the head of the penis (Figure A) and unroll it all the way to the base (Figure B).
- Leave an empty space at the tip (Figure A); remove any air remaining in the tip by gently pressing air out toward the base of the penis.

- If a lubricant is desired, use water-based products such as K-Y lubricating jelly. Do not use petroleum-based products because they can cause the condom to break.
- After ejaculation, carefully withdraw the still-erect penis from the vagina, holding onto the condom rim; remove and discard the condom.
- Store unused condoms in a cool, dry place.
- Do not use condoms that are sticky, brittle, or obviously damaged.

Source: Black, A., Guilbert, E., Costescu, J., et al., (2015). SOGC clinical practice guideline. Canadian contraception consensus: Chapter 5—Barrier methods. *Journal of Obstetricians & Gynaecologists of Canada, 37*(11), S12–S24; Sex & U. (2019). *Male condom.* https://www.sexandu.ca/contraception/non-hormonal-contraception/#tc1

Female condoms. The female condom is a soft, loose-fitting, seamless nitrile polymer sheath and has flexible rings at both ends (Figure 8.9, *A*). The closed end of the pouch is inserted into the vagina and anchored around the cervix; the open ring covers the labia. The sheath is coated on the inside with a silicone-based lubricant. It can be placed in the vagina up to 8 hours before intercourse (Black et al., 2015c). A patient whose partner will not wear a male condom can use this as a protective mechanical barrier. Rewetting drops or oil- or water-based lubricants can be used to help decrease the distracting noise that is produced while penile thrusting occurs. The female condom is available in one size, is intended for single use only, and is sold over the counter. Disadvantages include difficulty for some patients to insert them correctly and the slightly increased cost per use over a male condom. The female condom can also be inserted into the anus of both men and women for anal intercourse. When used this way, the inner ring of the condom is inserted into the rectum and the outside ring rests on the anus. Male condoms should not be used concurrently because they may adhere to one another and slip or be displaced (Black et al., 2015c). The typical failure rate is 21% (Black et al., 2015c).

Diaphragm. The contraceptive **diaphragm** is a shallow, dome-shaped, latex or silicone device with a flexible rim that covers the cervix. The diaphragm, along with the use of a gel, is a mechanical barrier to the meeting of sperm with the ovum. Diaphragms are available in a wide range of diameters (65 to 95 mm) and differ in the inner construction of the circular rim. The types of rims are coil spring, arcing spring, and wide-seal rim. The diaphragm should be the largest size the person can wear without being aware of its presence. It is 88% effective with typical use but it is possible that the failure rate can be reduced to 6% with correct and consistent use (Black et al., 2015c). These rates are based on diaphragm use in conjunction with a spermicidal jelly or gel, which is no longer available in Canada. Diaphragm users should use an acid-buffering lubricant such as the SILCS diaphragm gel or Contragel, which forms a physical barrier in front of the cervix and lowers the pH of the vaginal fluid, thereby inhibiting sperm motility (Black et al., 2015c).

Fig. 8.9 Barrier methods. **A**: Female condom. **B**: FemCap. **C**: Contraceptive sponge. (A, Courtesy The Female Health Company, Chicago, IL. B, Courtesy FemCap, Del Mar, CA. C, Courtesy Allendale Pharmaceuticals, Allendale, NJ.)

Nursing considerations. The person using a diaphragm needs an annual gynecological examination to assess the fit of the diaphragm and to replace the device. The diaphragm may need to be refitted after a 5-kg weight loss or gain, birth, or second-trimester miscarriage and after any abdominal or pelvic surgery. Because various types of diaphragms are on the market, the nurse should use the package insert when teaching the patient how to use and care for the diaphragm (see Guidelines box: Use and Care of the Diaphragm). A newer diaphragm, called SILCS, that is sold over the counter and comes in only one size, has been approved by Health Canada. It needs to be replaced only every 2 years.

GUIDELINES

Use and Care of the Diaphragm

Positions for Insertion of Diaphragm

Squatting

- Squatting is the most commonly used position, and most patients find it satisfactory.

Chair Method

- Another practical method for diaphragm insertion is to sit far forward on the edge of a chair.

Leg-Up Method

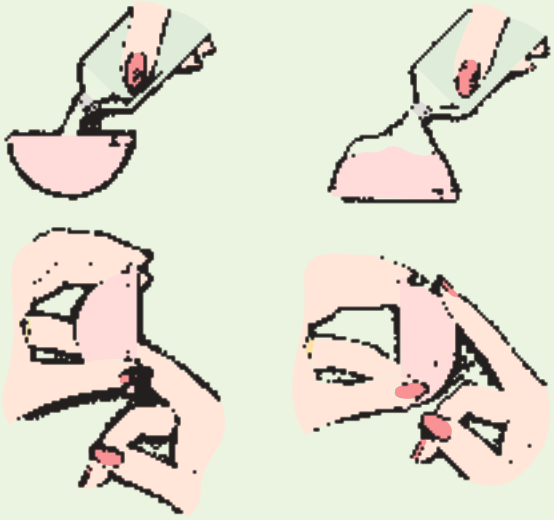
- Another position is to raise the left foot (if right hand is used for insertion) on a low stool and, while in a bending position, insert the diaphragm.

Reclining

- Some individuals prefer inserting the diaphragm while in a semi-reclining position in bed.

Continued

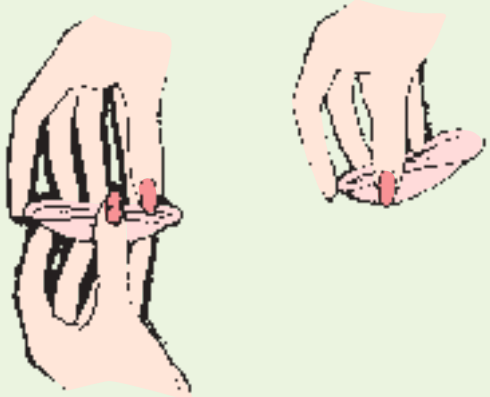
GUIDELINES—CONT'D



Inspection of Diaphragm

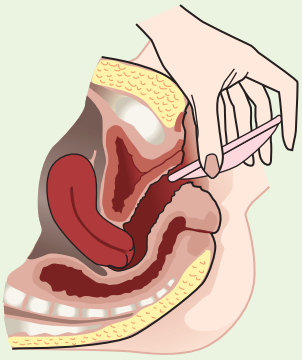
The diaphragm must be inspected carefully before each use. The best way to do this is to do the following:

- Hold the diaphragm up to a light source. Carefully stretch the diaphragm at the area of the rim, on all sides, to make sure that there are no holes. Remember, it is possible to puncture the diaphragm with sharp fingernails.
- Another way to check for pinholes is to carefully fill the diaphragm with water. If there is any problem, it will be seen immediately.
- If the diaphragm is puckered, especially near the rim, this could mean thin spots.
- The diaphragm should not be used if you see any of these; consult your health care provider.

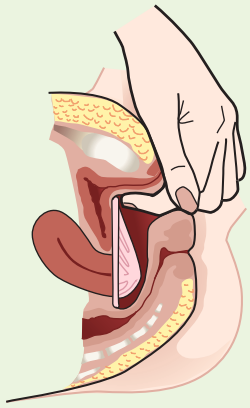


Preparation of Diaphragm

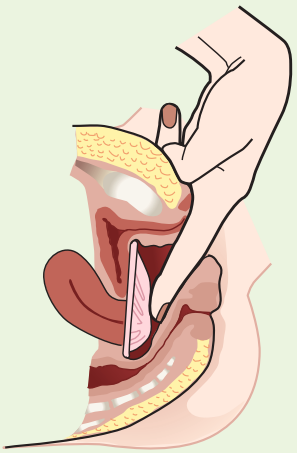
- Rinse off cornstarch. The diaphragm should be used with an acid-buffering lubricant to be more effective. Pregnancy cannot be prevented effectively by using the diaphragm alone.
- Always empty your bladder before inserting the diaphragm. Place about 10 mL of contraceptive jelly on the side of the diaphragm that will rest against the cervix (or whichever way you have been instructed). Spread it around to coat the surface and the rim. This aids in insertion and offers a more complete seal. Many individuals also spread some jelly on the other side of the diaphragm.



Insertion of Diaphragm



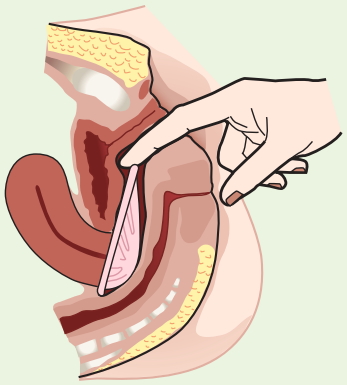
- The diaphragm can be inserted as long as 6 hours before intercourse. Hold the diaphragm between your thumb and fingers. The dome can either be up or down. Place your index finger on the outer rim of the compressed diaphragm.



- Use the fingers of the other hand to spread the labia (lips of the vagina). This will assist in guiding the diaphragm into place.
- Insert the diaphragm into the vagina. Direct it inward and downward as far as it will go to the space behind and below the cervix.

- Tuck the front of the rim of the diaphragm behind the pubic bone so that the rubber hugs the front wall of the vagina.

- Feel for the cervix through the diaphragm to be certain it is properly placed and securely covered by the rubber dome.



General Information

- Regardless of the time of the month, use your diaphragm every time intercourse takes place. The diaphragm must be left in place for at least 6 hours after the last intercourse. If you remove the diaphragm before the 6-hour period, your chance of becoming pregnant could be greatly increased. If you have repeated acts of intercourse, you must add more spermicide for each act of intercourse.

Removal of Diaphragm

- The only proper way to remove the diaphragm is to insert your forefinger up and over the top side of the diaphragm and slightly to the side.
- Next turn the palm of your hand downward and backward, hooking the forefinger firmly on top of the inside of the upper rim of the diaphragm, breaking the suction.
- Pull the diaphragm down and out. This avoids the possibility of tearing it with the fingernails. You should not remove the diaphragm by trying to catch the rim from below the dome.

Care of Diaphragm

- When using a vaginal diaphragm, avoid using oil-based products such as body lubricants, mineral oil, baby oil, vaginal lubricants, or vaginitis preparations. These products can weaken the rubber.
- A little care means longer wear for your diaphragm. After each use, wash the diaphragm in warm water and mild soap. Do not use detergent soaps, cold-cream soaps, deodorant soaps, or soaps containing oil products because they can weaken the rubber.
- After washing, dry the diaphragm thoroughly. All water and moisture should be removed with a towel. Dust the diaphragm with cornstarch. Scented talc, body powder, baby powder, and the like should not be used because they can weaken the rubber.
- To clean the introducer (if one is used), wash with mild soap and warm water, rinse, and dry thoroughly.
- Place the diaphragm back in the plastic case for storage. Do not store it near a radiator or heat source or exposed to light for an extended period.

Disadvantages of diaphragm use include the reluctance of some individuals to insert and remove the diaphragm. Although it can be inserted up to 2 hours before intercourse, a cold diaphragm and a cold gel temporarily reduce vaginal response to sexual stimulation if insertion of the diaphragm occurs immediately before intercourse. Some couples object to the messiness of the gel. These annoyances of diaphragm use, along with failure to insert the device once foreplay has begun, are the most common reasons for failures of this method. The diaphragm must remain in place for at least 6 hours following intercourse and removal before this time increases the risk of pregnancy. Side effects may include increased risk of urinary tract infections.

The diaphragm is not a good option for patients with poor vaginal muscle tone or recurrent urinary tract infections. For proper placement, the diaphragm must rest behind the pubic symphysis and completely cover the cervix. To decrease the chance of exerting urethral pressure, the woman should be reminded to empty her bladder before diaphragm insertion and immediately after intercourse.

Diaphragms are contraindicated for patients with pelvic relaxation (uterine prolapse) or a large **cystocele**. Patients with a latex allergy should not use latex diaphragms. **Toxic shock syndrome (TSS)**, although very rare, can occur in association with the use of the contraceptive diaphragm and cervical caps. The nurse should instruct the patient about ways to reduce their risk for TSS. These measures include removal within 24 hours after intercourse, not using the diaphragm or cervical caps during menses, and learning and watching for danger signs of TSS.

! NURSING ALERT

The nurse should alert the patient who uses a diaphragm or cervical cap as a contraceptive method for signs of TSS. The most common signs include a sunburn type of rash, diarrhea, dizziness, faintness, weakness, sore throat, aching muscles and joints, sudden high fever, and vomiting.

Cervical cap. The **cervical cap** is made of silicone rubber and has a soft dome and firm brim (see Figure 8.9, *B*). The only cervical cap available in Canada is the FemCap, which can be purchased online or with a prescription. Replacement is recommended every year. The cap comes in three sizes based on pregnancy history (Black et al., 2015c). The cap fits snugly around the base of the cervix close to the junction of the cervix and vaginal fornices. It is recommended that the cap remain in place no less than 6 hours and not more than 48 hours at a time. It is left in place at least 6 hours after the last act of intercourse. The seal provides a physical barrier to sperm, but it should also be used with an acid-buffering lubricant to inhibit sperm mobility. The extended period of wear may be an added convenience for some people.

Instructions for the actual insertion and use of the cervical cap closely resemble the instructions for use of the contraceptive diaphragm. The cap can be inserted up to 2 hours before the act of intercourse, and additional application of a lubricant is required with each repeated act of intercourse or if it has been more than 2 hours since the device/gel was originally inserted and intercourse has not yet occurred. An applicator is necessary for this repeat insertion (Black et al., 2015c). See Evolve resource for how to insert a cervical cap. There are currently no data on the effectiveness of the cervical cap that is used in Canada, but it appears to have a greater failure rate than other types of contraception (Sex & U, 2021).

The angle of the uterus, the vaginal muscle tone, and the shape of the cervix may interfere with the ease of fitting and use of the cervical cap. Correct fitting requires time, effort, and skill of both the patient and the clinician. The cap should be refitted after any gynecological surgery or birth and after major weight loss or gain. Otherwise, the size should be checked at least once a year.

Individuals who are not good candidates for wearing the cervical cap include those with abnormal Pap test results, those who cannot be fitted properly with the existing cap sizes or who find the insertion and removal of the device too difficult, those with a history of TSS or with vaginal or cervical infections, and those who experience allergic responses to the cap or to the lubricant.

Contraceptive sponge. The vaginal sponge is a small, disposable, round, polyurethane sponge that contains N-9 spermicide (see Figure 8.9, *C*). The only contraceptive sponge available in Canada is The Today sponge. It is designed to fit over the cervix (one size fits all). The side that is placed next to the cervix is concave for better fit. The opposite side has a woven polyester loop to be used for removal of the sponge.

The sponge must be moistened with water before it is inserted into the vagina to cover the cervix. It provides protection for up to 24 hours

TABLE 8.3 Hormonal Contraception

Composition	Route of Administration	Duration of Effect
Combination estrogen and progestin (synthetic estrogens and progestins in varying doses and formulations)	Oral	24 hours; extended cycle—12 weeks
	Transdermal patch	7 days
	Vaginal ring insertion	3 weeks
Progestin Only		
Norethindrone, norgestrel	Oral	24 hours
Medroxyprogesterone acetate	Intramuscular or subcutaneous injection	3 months
Levonorgestrel	Intrauterine system	5 years
Etonogestrel (not available in Canada)	Subdermal implant	3 years

and for repeated instances of sexual intercourse. The sponge should be left in place for at least 6 hours after the last act of intercourse. Wearing it longer than 24 to 30 hours may put the person at risk for TSS. The typical failure rate in the first year of use is 20% for parous patients and 9% for nulliparous patients (Black et al., 2015c).

Hormonal Methods. There are many different types of hormonal contraceptive formulations available in Canada. General classes of hormonal contraception are described in Table 8.3. Because of the wide variety of preparations available, the patient and nurse must read the package insert for information about specific products prescribed. Formulations include combined estrogen–progestin steroidal medications or progestin-only agents. The formulations are administered orally, transdermally, vaginally, or by injection.

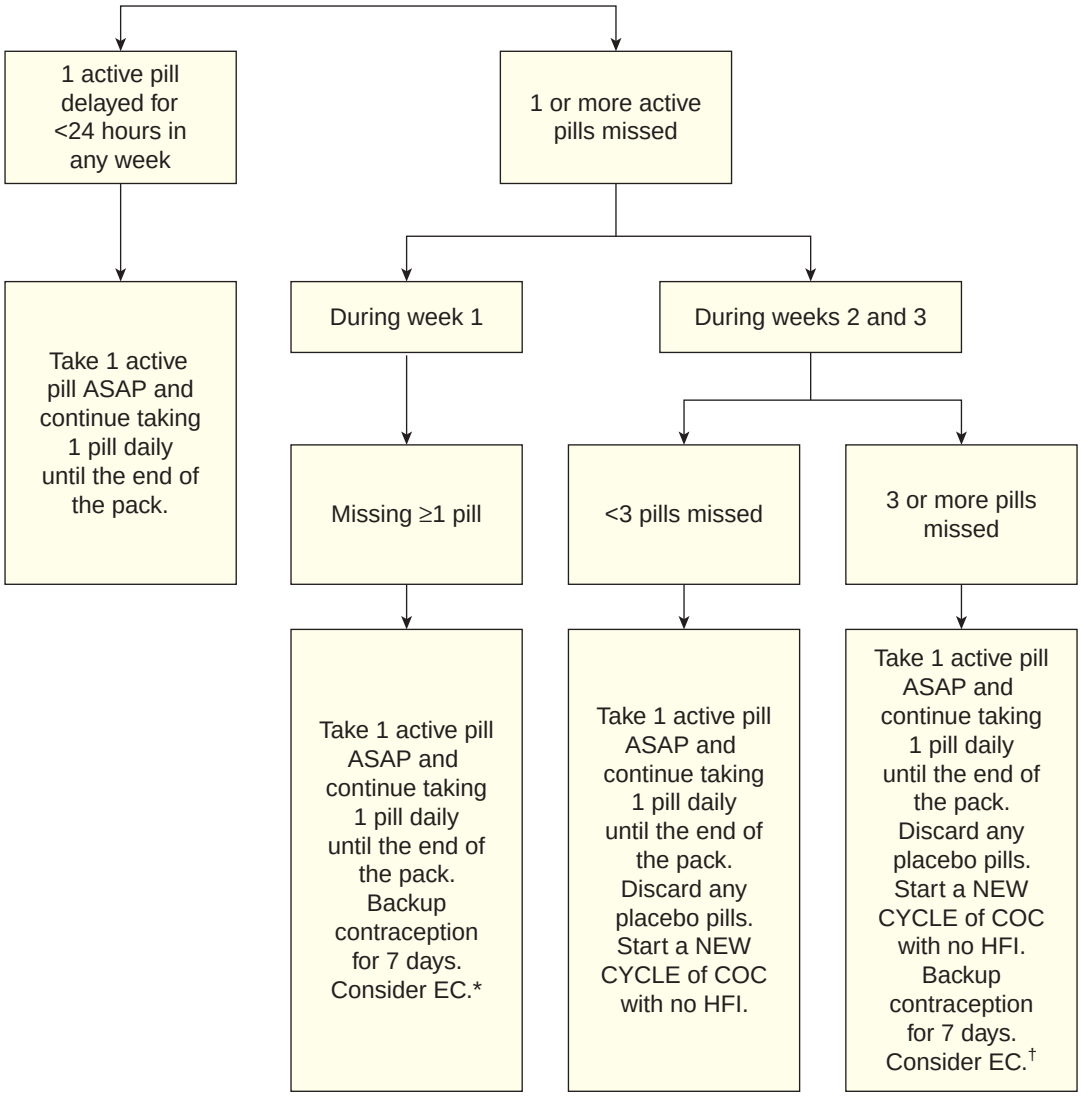
Combined hormonal contraceptives. *Combined hormonal contraceptives (CHCs)* refers to contraceptive methods that contain both an estrogen and a progestin. There are several forms available in Canada, including combined oral contraceptive pills (COCs), the transdermal contraceptive patch, and the vaginal contraceptive ring.

Combined oral contraceptives. The normal menstrual cycle is maintained by a feedback mechanism. FSH and LH are secreted in response to fluctuating levels of ovarian estrogen and progesterone. Regular ingestion of COCs suppresses the action of the hypothalamus and anterior pituitary, leading to insufficient secretion of FSH and LH; therefore, follicles do not mature, and ovulation is inhibited.

Other contraceptive effects are induced by the combined steroids. Maturation of the endometrium is altered, making the uterine lining a less favourable site for implantation. COCs also have a direct effect on the endometrium; thus from 1 to 4 days after the last COC is taken, the endometrium sloughs and bleeds as a result of hormone withdrawal. The withdrawal bleeding is usually less profuse than that of normal menstruation and may last only 2 to 3 days. Some patients have no bleeding at all. The cervical mucus remains thick from the effect of the progestin. Cervical mucus under the effect of progesterone does not provide as suitable an environment for sperm penetration as does the thin, watery mucus at ovulation.

Current COC formulations may be monophasic (each tablet contains a fixed amount of estrogen and progestin) or multiphasic. Monophasic pills provide fixed dosages of estrogen and progestin. They alter the amount of progestin and sometimes the amount of estrogen within each cycle. These preparations reduce the total dosage of hormones in a single cycle without sacrificing contraceptive efficacy. To maintain adequate hormone levels for contraception, COCs should be taken at the same time each day. Taken exactly as directed, COCs prevent ovulation, and pregnancy cannot occur and the overall effectiveness rate is almost 100%. Typical use failure rates in the first year is 9% (Black et al., 2017), which is usually due to not taking the pills as directed.

Because taking the pill does not relate directly to the sexual act, its acceptability may be increased. Improvement in sexual response may occur once the possibility of pregnancy is not an issue. For some individuals it is convenient to know when to expect the next menstrual flow.



Contraindications for COC use include a history of thromboembolic disorders, cerebrovascular or coronary artery disease, breast cancer, estrogen-dependent tumours, pregnancy, impaired liver function, liver tumour, lactation less than 6 weeks postpartum, smoking if older than 35 years of age, migraine with aura, surgery with prolonged immobilization or any surgery on the legs, hypertension (160/100), and diabetes mellitus (of more than 20 years' duration) with vascular disease.

The effectiveness of COCs may be affected by other medications, including but not limited to some anticonvulsants, some antiretrovirals, rifampicin, and griseofulvin. Oral contraceptives may also affect the serum levels of other medications, including some anticonvulsants and antiretrovirals (Black et al., 2017). It is important to assess what medications a patient is taking and to be aware of potential medication interactions with oral contraceptives. After discontinuing oral contraception, fertility usually returns within 1 to 3 months to a patient's baseline fertility (Black et al., 2017).

Oral contraceptives have been shown to have benefits that are not related to birth control, including regulation and reduction of both menstrual bleeding and dysmenorrhea, and treatment of premenstrual syndrome, menstrual migraines, acne, and hirsutism. There are also some long-term benefits, such as reduced rates of endometrial, ovarian, and colorectal cancer (Black et al., 2017).

Many different preparations of oral hormonal contraceptives are available. Because of the wide variations, each patient must be clear about the unique dosage regimen for the preparation prescribed for them and follow directions on the package insert. Directions for care after missing one or two tablets vary. Figure 8.10 illustrates a standard approach to missed pills. Patients need to be instructed to consider emergency contraception or backup contraception, depending on when during the month the pills are missed and how many pills are missed. The SOGC's Stay-on-Schedule (SOS) app can also help patients determine what to do when a dose is missed (see Additional Resources). Signs of potential complications associated with the use of oral contraceptives must be reviewed with the patient (Box 8.9). Oral contraceptives do not protect a person against STIs. Male condoms used in combination with COCs provide protection against STIs, and this combination gives excellent protection against unplanned pregnancy.

Transdermal contraceptive system. The **transdermal contraceptive patch** delivers continuous levels of progesterone and ethynyl estradiol. The patch can be applied to the lower abdomen, upper outer arm, buttock, or upper torso (except the breasts). Application is on the same day once a week for 3 weeks but not at the same site, followed by a week without the patch. Withdrawal bleeding occurs during the "no patch" week. Mechanisms of action, contraindications, and effectiveness rates are similar to those of COCs. The contraceptive patch may be less effective in patients who weight more than 90 kg (Black et al., 2017). Compared with the COCs, the transdermal patch is associated with less breakthrough bleeding and spotting but more breast discomfort or pain, nausea and vomiting, and dysmenorrhea (Black et al., 2017).

*If unprotected intercourse within the last 5 days.
†If repeated or prolonged omission.

Fig. 8.10 Flowchart for missed contraceptive pills. *ASAP*, As soon as possible; this may mean that two pills are taken on that day; *COC*, combined oral contraceptive; *EC*, emergency contraception; *HFI*, hormone-free interval. (Courtesy Society of Obstetricians and Gynaecologists of Canada [2008]. SOGC clinical practice guideline: Missed hormonal contraceptives: New recommendations. *Journal of Obstetrics and Gynaecology Canada, 30*[11], 1050–1061. Printed with permission from the SOGC.)

BOX 8.9 Signs of Potential Complications: Oral Contraceptives

The woman should be alerted to immediately stop taking the pill and report the following symptoms to the health care provider. The word *ACHES* helps in remembering this list:

A—Abdominal pain: may indicate an issue with the liver or gallbladder
C—Chest pain or shortness of breath: may indicate possible clot within lungs or heart
H—Headaches (sudden or persistent): may be caused by cardiovascular accident or hypertension
E—Eye conditions: may indicate vascular accident or hypertension
S—Severe leg pain: may indicate a thromboembolic process

Contraceptive vaginal ring. The **contraceptive vaginal ring** (NuvaRing) is a flexible, soft, transparent ring made of copolymer ethylene vinyl that delivers continuous levels of progesterone and ethynyl estradiol, which is absorbed through the vaginal epithelium. One vaginal ring is worn for 3 weeks, followed by a week without the ring. Withdrawal bleeding occurs during the "no ring" week. The ring can be inserted by the patient and does not have to be fitted. Some wearers may experience vaginal discomfort, usually related to increased vaginal discharge, but other wearers report that the ring alleviates symptoms of vaginitis. Mechanisms of action, contraindications, and adverse effects are similar to those of COCs. The perfect use failure rate is 0.3% and a typical use failure rate is 9% during the first year of use (Black et al., 2017).

Progestin-only contraception. Progestin-only methods impair fertility by inhibiting ovulation, thickening and decreasing the amount of cervical mucus, thinning the endometrium, and altering cilia in the uterine tubes. Because progestin-only methods do not contain estrogen, they may be used in certain instances such as lactation, when estrogen would not be recommended.

Oral progestins (minipill). Progestin-only pills contain a lower dose of progestin and must be taken at the same time every day. If the pill is taken more than 3 hours late (27 hours after the last pill), a backup contraceptive method must be initiated. They are as effective as COCs and with perfect use have a failure rate of 0.3% in the first year of use. Effectiveness depends on consistent pill taking, hence the typical use failure rate is 9%, the same as for COCs (Black et al., 2016b). Much of the contraceptive effectiveness of the minipill depends on progestin-induced changes in cervical mucus, and this effect lasts about 24 hours after oral ingestion of the pill. Users often find they have irregular vaginal bleeding. The minipill can be used by any patient, although it is used most often in patients who are parous, postpartum, or breastfeeding (Black et al., 2016b).

Injectable progestins. Depot medroxyprogesterone acetate (DMPA) is given subcutaneously or intramuscularly in the deltoid or gluteus maximus muscle. DMPA should be initiated during the first 5 days of the menstrual cycle and administered every 12 to 13 weeks.

! NURSING ALERT

When administering an injection of DMPA, the site should not be massaged after the injection because this action can hasten the absorption and shorten the period of effectiveness.

Advantages of DMPA include a contraceptive effectiveness comparable to that of COCs, long-lasting effects, requirement of injections only four times a year, and the unlikelihood of lactation being impaired. DMPA is a highly effective form of contraception with a perfect use failure rate of 0.2% and a typical failure rate of 6%, which is usually due to not following up for a next dose (Black et al., 2016b). Adverse effects at the end of a year include decreased bone mineral density, weight gain, lipid changes, increased risk of venous thrombosis and thromboembolism, irregular vaginal spotting, decreased libido, and breast changes. Other disadvantages include no protection against STIs. Return to fertility may be delayed as long as up to 18 months after discontinuing DMPA.

! NURSING ALERT

Patients who use DMPA may lose significant bone mineral density with increasing duration of use. It is unknown if this effect is reversible. It is unknown if use of DMPA during adolescence or early adulthood, a critical period of bone accretion, will reduce peak bone mass and increase the risk of osteoporotic fracture in later life. Patients who receive DMPA should be counselled about vitamin D and calcium intake as well as exercise in order to protect bone health.

Implantable progestins. Contraceptive implants consist of one or more nonbiodegradable flexible tubes or rods that are inserted under the skin of a person's arm. These implants contain a progestin hormone and are effective for contraception for at least 3 years. They must be removed at the end of the recommended time. This method of contraception is currently not available in Canada, although it is important for nurses to be aware of it as they may have patients from other countries who have had this implanted. It is a very effective method of contraception.

Continuous and extended hormonal contraception. Continuous hormonal contraception, with no breaks, is being used increasingly to suppress menstruation, for medical reasons (e.g., severe dysmenorrhea, abnormal uterine bleeding, and premenstrual dysphoric disorders—see Chapter 7) and patient's preferences. Patients undergoing cancer treatment, those at risk for iatrogenic thrombocytopenia, and patients with developmental disabilities may also be considered for menstrual suppression. Continuous or extended use of combined hormonal contraceptive may use low-dose COCs, the transdermal contraceptive patch, or the vaginal contraceptive ring. The SOGC has a guideline that should be referred to specifically for these situations (Kirkham et al., 2019). Those individuals who use hormonal contraception continuously should be counselled about expected bleeding patterns. Bleeding or spotting is normal in the first 3 months and then bleeding significantly decreases. The short-term safety of continuous or extended hormonal contraceptive regimens is similar to that of cyclic regimens and patients should be counselled regarding this (Black et al., 2017).

Emergency Contraception. Emergency contraception (EC) offers protection against pregnancy after intercourse occurs in instances such as broken condoms, sexual assault, dislodged cervical cap, disruption of use of any other method, or any other case of unprotected intercourse. There are two types of EC methods to choose from:

1. Hormonal EC methods:
   a. A special formulation containing progestin only (Plan B, Nor-Levo, Option 2, Next Choice®)
   b. A series of four contraceptive pills called the Yuzpe method (combined estrogen and progestin)
2. A copper **intrauterine device (IUD)** insertion within 120 hours of intercourse

In Canada, the progestin-only methods are available without a prescription. EC should be taken by a person as soon as possible but within 5 days of unprotected intercourse or birth control mishap (e.g., broken condom, dislodged ring or cervical cap, missed oral contraceptive pills, late for injection) to prevent unintended pregnancy (Black et al., 2015a). If taken before ovulation, EC prevents ovulation by inhibiting follicular development. If taken after ovulation occurs, there is little effect on ovarian hormone production or the endometrium. To minimize the adverse effect of nausea that occurs with high doses of estrogen and progestin (Yuzpe regimen), the patient can be advised to take an over-the-counter antiemetic 1 hour before each dose. Nausea is not as common with the progestin-only regimen. If the patient vomits within 1 hour after taking the medication they will need to repeat the dose. No medical contraindications for EC exist, except pregnancy. If the patient does not begin menstruation within 21 days after taking the pills or having an IUD inserted, they should be evaluated for pregnancy (Black et al., 2015a). EC is ineffective if the patient was already pregnant prior to taking the EC, as the pills do not disturb an implanted pregnancy.

IUDs containing copper (see discussion below and Figure 8.11, *A*) provide another EC option. The IUD should be inserted within 5 days of unprotected intercourse (Black et al., 2015a). The risk of pregnancy is

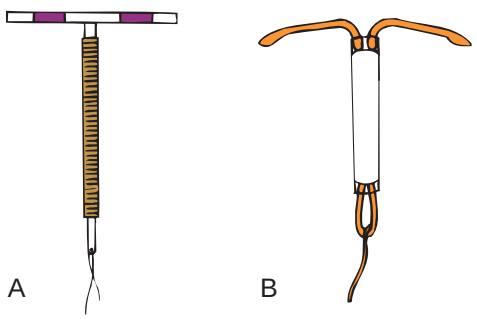


Fig. 8.11 Intrauterine contraception. **A:** Copper T intrauterine device (IUD). **B:** Levonorgestrel-releasing intrauterine system (LNG-IUS).

reduced by as much as 99% with emergency insertion of the copper-releasing IUD. An IUD must be inserted by a health care provider and is only available by prescription, which makes it less accessible than hormonal EC methods.

Contraceptive counselling should be provided to all patients requesting EC, including a discussion of modification of risky sexual behaviours to prevent STIs and unwanted pregnancy.

Intrauterine Contraception (IUC). IUC is a long-acting reversible contraception that is used worldwide and is the most highly effective method of birth control. A device is inserted through the cervix into the uterine cavity. It is T-shaped with bendable arms for insertion. Two strings hang from the base of the stem through the cervix and protrude into the vagina for the person to feel, for assurance that the device has not been dislodged. Depending on the type of IUC, the device can remain in place for 3 to 12 years. There are two types of IUCs available in Canada. The copper IUD is made of radiopaque polyethylene and fine solid copper (see Figure 8.11, *A*). The copper serves primarily as a spermicide and inflames the endometrium, preventing fertilization. Sometimes patients experience an increase in bleeding and cramping within the first year after insertion, but nonsteroidal anti-inflammatory drugs (NSAIDs) can provide pain relief. The typical failure rate in the first year of use of the copper IUD is 0.8% (Black et al., 2016a).

The levonorgestrel-releasing intrauterine system (LNG-IUS) (see Figure 8.11, *B*) releases levonorgestrel from its vertical reservoir. Effective for 3 to 10 years (depending on the system used), it impairs sperm motility, irritates the lining of the uterus, and has some anovulatory effects. Uterine cramping and uterine bleeding are usually decreased with this device, although irregular spotting is common in the first few months following insertion. The risk of uterine perforation is a rare complication of the use of LNG-IUS. This risk is increased in individuals after pregnancy, during lactation, and with abnormal uterine anatomy. The effectiveness of the LNG-IUS is similar to that of permanent sterilization, with a failure rate in the first year of use of 0.2% (Black et al., 2016a).

IUC offers constant contraception without the need to remember to take pills each day or engage in other manipulation before or between coital acts. If pregnancy can be excluded, either device (copper IUD or levonorgestrel IUS) can be placed at any time during the menstrual cycle. These devices may be inserted shortly after childbirth or first-trimester abortion. When pregnancy is desired, the health care provider removes the device and fertility returns to normal levels immediately after removal. The SOGC states that IUC is a safe, effective option for contraception for all women, and health care providers should offer it as a first-line method of contraception to both nulliparous and multiparous women (Black et al., 2016a; Caddy et al., 2014).

Disadvantages of IUD use include increased risk of pelvic inflammatory disease within the first 20 days after insertion, especially if infection is present at the time of insertion. There is also a slight risk of uterine perforation. The copper IUD is more likely to be associated with regular menses that may have heavier flow. Patients who have the LNG-IUS are more likely to experience scant, irregular episodes of vaginal bleeding or amenorrhea. IUC offers no protection against STIs or HIV.

The patient should be taught to check for the presence of the device's thread after menstruation to rule out expulsion of the device. If pregnancy occurs with IUC in place, the system should be removed as early as possible. The patient also needs to be assessed for ectopic pregnancy, as the risk for this is higher in patients with IUC in place when they become pregnant. Retention of IUC during pregnancy increases the risk of spontaneous abortion, septic miscarriage, and preterm birth (Black et al., 2016a). Signs of potential complications are listed in Box 8.10.

Sterilization. *Sterilization* refers to surgical procedures intended to render the person infertile. Most procedures involve the occlusion of the passageways for the ova and sperm (Figure 8.12, *A*). For the female, the oviducts (uterine tubes) are occluded; for the male, the sperm ducts (vas deferens) are occluded (see Figure 8.12, *B*). Only surgical removal of the ovaries (oophorectomy) or uterus (hysterectomy) or both results in absolute sterility for the woman. All other sterilization procedures have a small but definite failure rate (i.e., pregnancy may result).

Female sterilization. Female sterilization (bilateral **tubal ligation**) may be done immediately after giving birth (within 24 to 48 hours), concomitantly with abortion, or as an interval procedure (during any phase of the menstrual cycle). Sterilization procedures can be done safely on an outpatient basis. The failure rate for methods of female sterilization vary by method and the patient's age, but this is a very effective and safe method and should be considered irreversible.

BOX 8.10 Signs of Potential Complications: Intrauterine Devices or Intrauterine Systems

Signs of potential complications related to intrauterine devices can be remembered using the *PAINS* mnemonic:

P—Period late, abnormal spotting or bleeding
A—Abdominal pain, pain with intercourse
I—Infection exposure, abnormal vaginal discharge
N—Not feeling well, fever, or chills
S—String missing; shorter or longer

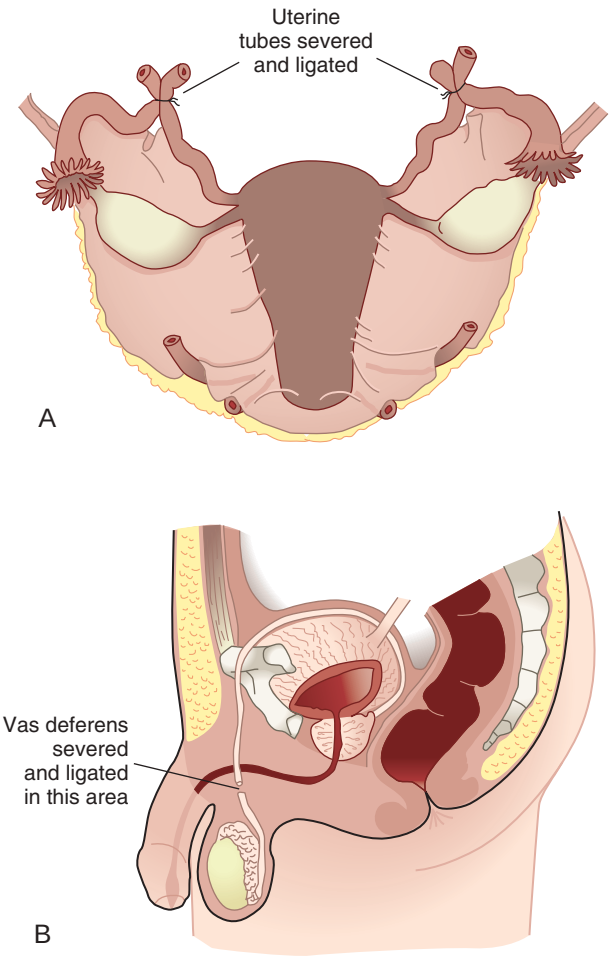

Fig. 8.12 Sterilization. **A:** Uterine tubes ligated and severed (tubal ligation). **B:** Sperm duct ligated and severed (vasectomy).

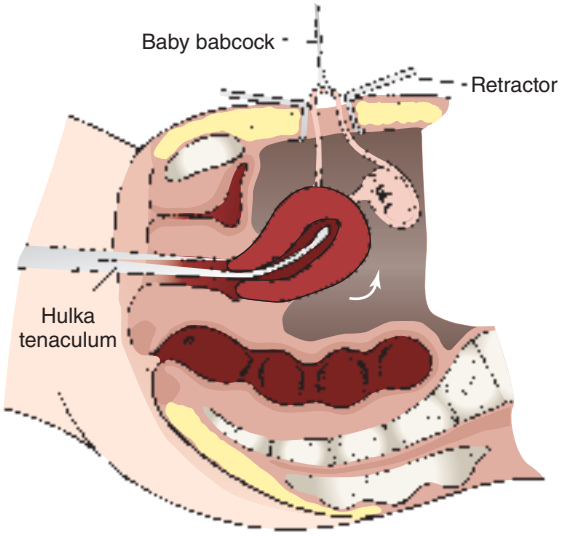

Fig. 8.13 Use of minilaparotomy to gain access to uterine tubes for occlusion procedures. Tenaculum is used to lift uterus upward (*arrow*) toward incision.

Tubal occlusion. A laparoscopic approach or a minilaparotomy may be used for tubal ligation (Figure 8.13), tubal electrocoagulation, or the application of bands or clips. Electrocoagulation and ligation are considered to be permanent methods. Essure is another permanent method in which a soft insert is placed into each fallopian tube, forming a barrier that grows around the inserts. The couple is told to use a backup contraceptive method for the first 3 months. Use of bands or clips has the theoretical advantage of possible removal and return of tubal patency, although patients should be counselled that this may not work and can be expensive (see Patient Teaching box).

PATIENT TEACHING

What to Expect After Tubal Ligation

- You should expect no change in hormones and their influence.
- Your menstrual period will be about the same as before the sterilization.
- You may feel pain at ovulation.
- The ovum disintegrates within the abdominal cavity.
- It is highly unlikely that you will become pregnant.
- You should not have a change in sexual functioning; you may enjoy sexual relations more because you will not be concerned about becoming pregnant.
- Sterilization offers no protection against sexually transmitted infections. Therefore, you may need to use condoms.

Tubal reconstruction. Restoration of tubal continuity (reanastomosis) and function is technically feasible except after laparoscopic tubal electrocoagulation. Sterilization reversal is costly, difficult (requiring microsurgery), and uncertain. The success rate varies with the extent of tubal destruction and removal.

Male sterilization. *Vasectomy* is the sealing, tying, or cutting of a man's vas deferens so that the sperm cannot travel from the testes to the penis. Vasectomy is the easiest and most commonly used operation for male sterilization. It can be done with local anaesthesia on an outpatient basis. Pain, bleeding, infection, and other postsurgical complications are considered the disadvantages to the surgical procedure.

Two methods are used for scrotal entry: conventional and no-scalpel vasectomy. The surgeon identifies and immobilizes the vas deferens through the scrotum. Then the vas is ligated or cauterized (see Figure 8.12, *B*). Surgeons vary in their techniques to occlude the vas deferens: ligation with sutures, division, cautery, application of clips, excision of a segment of the vas, fascial interposition, or some combination of these methods.

Vasectomy has no effect on potency (ability to achieve and maintain erection) or volume of ejaculate. Endocrine production of testosterone continues so that secondary sex characteristics are not affected. Sperm production continues, but sperm are unable to leave the epididymis and are lysed by the immune system. Males will need to be instructed to engage in a number of ejaculations until there are no viable sperm remaining above the area of the surgery. Until this occurs, as documented by semen analysis, the couple should use backup contraception. Vasectomy does not change the man's transmission of the HIV virus if he is infected.

Complications after bilateral vasectomy are uncommon and usually not serious. They include bleeding (usually external), suture reaction, and reaction to the anaesthetic agent. Men occasionally may develop a hematoma, infection, or epididymitis. Less common are painful granulomas from accumulation of sperm. Approximately 2% of women who rely on vasectomy in their partner as a method of contraception will become pregnant (Black et al., 2015d)

Tubal reconstruction. Microsurgery to reanastomose (restore tubal continuity) the sperm ducts can be accomplished successfully (i.e., sperm in the ejaculate) in about 90% of cases; however, the fertility rate is only about 40 to 80% (Black et al., 2015d). The rate of success decreases as the time since the procedure increases. The vasectomy may result in permanent changes in the testes that leave men unable to father children. The changes are those ordinarily seen only in older men (e.g., interstitial fibrosis [scar tissue between the seminiferous tubules]). Some men develop antibodies against their own sperm (autoimmunization).

Laws and regulations. All provinces have strict regulations for informed consent. Health care providers must ensure that while obtaining informed consent they need to explain the benefits, risks, and options and determine whether the person is competent to understand the information. Explanation must be made in the person's own language, or an interpreter must be provided to ensure that the person understands all information. Although the partner's consent is not required by law, the patient is encouraged to discuss the situation with their partner. Only individuals who have the capacity to give informed consent can agree to a permanent contraceptive procedure (Black et al., 2015d). Sterilization of minors or mentally incompetent individuals is illegal.

Nursing considerations. The nurse plays an important role in helping people with decision making so that all requirements for informed consent are met. Some patients may not be aware of other contraception options, so the nurse can also provide information about alternatives to sterilization, such as long-acting reversible contraception.

Information must be given about what is entailed in the various procedures, how much discomfort or pain can be expected, and what type of care is needed. Many individuals fear sterilization procedures because of the imagined effect on their sexual life. They need reassurance concerning the hormonal and psychological basis of sexual functioning. The fact that uterine tube occlusion or vasectomy has no biological sequelae in terms of sexual adequacy needs to be communicated and reinforced.

Preoperative care includes health assessment, which involves a psychological assessment, physical examination, and laboratory tests. The nurse needs to confirm the patient's understanding of printed instructions. Ambivalence and extreme fear of the procedure should be reported to the health care provider.

Postoperative care depends on the procedure performed (e.g., laparoscopy, laparotomy for tubal occlusion, or vasectomy). General care includes recovery after anaesthesia, vital signs, fluid–electrolyte balance (intake and output, laboratory values), prevention or early identification and treatment of infection or hemorrhage, management of discomfort, and assessment of emotional response to the procedure and recovery.

Discharge planning depends on the type of procedure performed. In general, the patient is given written instructions about observing for and reporting symptoms and signs of complications, the type of recovery to be expected, and the date and time for a follow-up appointment.

LGBTQ2 Issues Regarding Contraception

For transsexual men and women, it is important to discuss fertility and contraception with them prior to the use of any hormone therapy. For trans men, pregnancy is a contraindication to testosterone use and the patient must take precautions against becoming pregnant while taking it. Patients who are sexually active with people with sperm should be counselled on contraceptive options, including progesterone-only oral contraception or IUC. While many trans men have become pregnant intentionally after discontinuing testosterone to pursue pregnancy, patients may wish to consider postponing testosterone initiation if they would like to become pregnant in the future, since fertility may be permanently affected (Bourns, 2015). Transgender women should also be cautioned regarding the need for birth control if sexually active with partners who may become pregnant, since hormonal impact on fertility in trans women is also variable (Bourns, 2015).

For further information on current fertility options for trans people, see Rainbow Health Ontario's fact sheet "Reproductive Options for Trans People" (see Additional Resources at the end of the chapter).

ABORTION

Induced abortion is the purposeful interruption of a pregnancy before 20 weeks of gestation. (Spontaneous abortion or miscarriage is discussed in Chapter 14.) If the abortion is performed at the patient's request, the term **elective abortion** is usually used; if performed for reasons of maternal or fetal health or disease, the term **therapeutic abortion** applies. Many factors contribute to a patient's decision to have an abortion. Indications include (1) preservation of the life or health of the pregnant parent, (2) genetic disorders of the fetus, (3) sexual assault, and (4) the pregnant person's request. The control of birth, given that it concerns human sexuality and the question of life and death, is one of the most emotional components of health care.

Abortion in Canada is safe and legal, although accessibility varies between provinces. The laws for abortion in Canada have changed over the last 45 years, from being very restricted before 1969 to unrestricted in 1988. Today, Canada is one of the only countries in the world without abortion regulation. Abortion is available throughout pregnancy, although more than 90% are performed in the first trimester and only 2 to 3% are performed after 16 weeks. Hospitals maintained by Roman Catholics and some of those maintained by strict fundamentalists forbid abortion (and often sterilization) despite legal challenges.

In 2017, in Canada there were approximately 94 000 reported induced abortions (Canadian Institute for Health Information [CIHI], 2019). Prior to 2017, women in Prince Edward Island had to travel to another province to obtain an abortion, but they are now available to people in that province.

Rates of biological complications after abortions, such as ectopic pregnancy, infection, or hemorrhage, tend to be low if the patient aborts during the first trimester. Psychological sequelae of induced abortion are not common but may be related to circumstances and support systems surrounding the pregnant patient, such as the attitudes reflected by friends, family, and health care workers. The patient facing an abortion is pregnant and will exhibit the emotional responses shared by all pregnant patients, including the possibility of depression.

Nurses and other health care providers often struggle with the same values and moral convictions as those of the pregnant patient. The conflicts and doubts of the nurse can be readily communicated to patients who are already anxious. Regardless of personal views on abortion, nurses who provide care to patients seeking abortion have an ethical responsibility to counsel patients about their options and to make appropriate referrals.

LEGAL TIP

Nurses' Rights and Responsibilities Related to Abortion

If nurses are requested to provide care that is against their religious or moral beliefs, they must continue to provide safe, compassionate, competent, ethical care until alternative arrangements can be made. If a nurse anticipates a conflict of conscience, the nurse has an obligation to notify their employer so that alternative arrangements can be made. Declaring a conflict with conscience or "conscientious objection" is a serious matter that must be addressed. Nurses' rights and responsibilities related to caring for abortion patients should be protected through policies that describe how the institution will accommodate the nurse's ethical or moral beliefs and what the nurse should do to avoid patient abandonment in such situations. Nurses should know what policies are in place in their institutions and encourage such policies to be *written.*

Nursing Care

A thorough assessment is conducted through history, physical examination, and laboratory tests. The length of pregnancy and the condition of the patient must be determined in order to select the appropriate type of abortion procedure. An ultrasound examination should be performed before a second-trimester abortion is done. If the patient is Rh-negative and more than 7 weeks' gestation the patient is a candidate for prophylaxis against Rh isoimmunization (Costescu et al., 2016). They should receive Rh_o(D) immune globulin within 72 hours after the abortion if they are D-negative and if Coombs' test results are negative (if the patient is unsensitized or isoimmunization has not developed).

The patient's understanding of alternatives, the types of abortions, and expected recovery needs to be assessed. Misinformation and gaps in knowledge should be identified and corrected. The record must be reviewed for signed informed consent and the patient's understanding verified. General preoperative, operative, and postoperative assessments are also performed.

Counselling about abortion includes helping the patient identify how they perceive the pregnancy, providing information about the choices available (i.e., having an abortion or carrying the pregnancy to term and then either keeping the infant or placing the baby for adoption), and informing the patient about the types of abortion procedures (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Termination of Pregnancy

Angelica is a 19-year-old single woman whose contraceptive failed. She is 6 weeks pregnant and is seeking termination of the pregnancy. She has many questions for the nurse in the family planning clinic: Which procedure is most likely to be chosen at this gestation? What are the risks associated with the procedure?

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about what information the nurse should provide Angelica?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Angelica's reaction: What are some normal physical, psychological, and emotional reactions to termination of pregnancy?
   b. Implications for future childbearing: What are the implications for future fertility?
   c. Relationship with her boyfriend: Does the boyfriend need to give consent prior to the procedure?
   d. Contraception options: What would be some options for contraception that a nurse could teach Angelica?
3. What implications and priorities for nursing care can be drawn at this time?

First-Trimester Abortion

Methods for performing early elective abortion (less than 10 weeks of gestation) include surgical (aspiration) and medical methods (mifepristone with prostaglandin and methotrexate with misoprostol). The majority of abortions (90%) that occur in Canada are performed during the first trimester (CIHI, 2019). Patients should be provided with the choice of method of termination, if possible, as this can increase their level of satisfaction with the procedure (Costescu et al., 2016).

Surgical (Aspiration) Abortion. Aspiration (vacuum or suction curettage) is the most common procedure done in the first trimester. Aspiration abortion is usually performed under local anaesthesia in a health care provider's office, a clinic, or a hospital. The ideal time for performing this procedure is 8 to 12 weeks after the last menstrual period. The suction procedure for performing an early elective abortion usually requires less than 5 minutes.

Ultrasound should be done prior to an induced abortion to assess gestational age (Costescu & Guilbert, 2018). A speculum is inserted, and the cervix is anaesthetized with a local anaesthetic agent. The cervix is dilated, if necessary, and a cannula connected to suction is inserted into the uterine cavity. The products of conception are evacuated from the uterus.

During the procedure, the patient is kept informed about what to expect next (e.g., menstrual-like cramping and sounds of the suction machine). The nurse needs to assess the patient's vital signs. The aspirated uterine contents must be carefully inspected to ascertain whether all fetal parts and adequate placental tissue have been evacuated. After the abortion, the patient can rest on the table until they are ready to stand. They remain in the recovery area or waiting room for 1 to 3 hours for detection of excessive cramping or bleeding, then they are discharged.

Bleeding after the operation is normally about the equivalent of a heavy menstrual period, and cramps are rarely severe. Excessive vaginal bleeding and infection such as endometritis or salpingitis are the most common complications of induced abortion. Retained products of conception may be the cause of vaginal bleeding (Costescu & Guilbert, 2018). Evacuation of the uterus, uterine massage, and administration of oxytocin or methylergonovine may be necessary. Prophylactic antibiotics to decrease the risk of infection are recommended. Postabortion pain can be relieved with NSAIDs such as ibuprofen (Costescu & Guilbert, 2018).

BOX 8.11 Complications From Induced Abortion

The patient should call their health care provider if they have any of the following signs:

- Fever greater than 38°C lasting more than 6 hours
- Chills
- Flulike symptoms
- Bleeding greater than two saturated pads per hour for 2 consecutive hours
- Foul-smelling vaginal discharge
- Severe abdominal pain, cramping, or backache
- Abdominal tenderness (when pressure applied)
- Absence of menstruation for 8 weeks after procedure

Source: Costescu, D., & Guilbert, E. (2018). SOGC clinical practice guideline: Induced abortion: Surgical abortion and second trimester medical methods. *Journal of Obstetricians and Gynecologists of Canada, 40*(6), 750–783.

Nursing care. Instructions following a surgical abortion differ among health care providers (e.g., tampons should not be used for at least 3 days or should be avoided for up to 3 weeks, and resumption of sexual intercourse may be permitted within 1 week or discouraged for 2 weeks). The patient may shower daily. They should be instructed to watch for excessive bleeding and other signs of complications (Box 8.11) and to avoid douches of any type. The patient may expect their menstrual period to resume 4 to 6 weeks after the day of the procedure. The nurse should offer information about the birth control method the patient prefers, if this has not been done during the counselling interview that usually precedes the decision to have an abortion. The patient should be strongly encouraged to return for their follow-up visit so that complications can be detected and a contraceptive method prescribed. A pregnancy test may also be performed to determine if the pregnancy has been terminated successfully.

Medical Abortion. Medical abortions are available in Canada for up to 9 weeks after the last menstrual period and should be considered in patients who will be diligent with follow-up. Mifepristone/misoprostol (MIFE/MISO) or methotrexate/misoprostol (MTX/MISO) are the medications used in the current regimens to induce early abortion.

Misoprostol (Cytotec) is a prostaglandin analogue that acts directly on the cervix to soften and dilate it and on the uterine muscle to stimulate contractions. Use of mifepristone was approved by Health Canada in 2015. It works by binding to progesterone receptors and blocking the action of progesterone, which is necessary for maintaining pregnancy. The MIFE/MISO regimen includes taking one 200-mg mifepristone tablet on the first day. Twenty-four to 48 hours after taking MIFE, the patient places four MISO tablets (800 mg total) between the cheeks and teeth and leaves them in place for 30 minutes. The misoprostol can also be given vaginally or sublingually. Follow-up is required in 7 to 14 days to ensure that the treatment was successful (Costescu et al., 2016).

Methotrexate is a cytotoxic drug that causes early abortion by blocking folic acid in fetal cells so they cannot divide. Intramuscular/oral methotrexate and vaginal/buccal misoprostol (MTX/MISO) is 84 to 97% effective up to 63 days after the last menstrual period. The risk of ongoing pregnancy is 0.4 to 4.3% (Costescu et al., 2016).

Patients commonly have nausea, vomiting, and cramping after the misoprostol insertion. The patient returns for a follow-up visit to

confirm that the abortion is complete. If abortion does not occur, misoprostol is repeated, or vacuum aspiration is performed. Misoprostol can also be used alone. Misoprostol 800 mcg is placed high in the vagina every 24 to 48 hours for up to three applications. Blood work at 7 days confirms whether this regimen was successful. One major difference between these MTX/MISO and MIFE/MISO regimens is the longer delay to obtain complete abortion (Costescu et al., 2016).

With any medical abortion regimen, the patient usually will experience bleeding and cramping. Adverse effects of the medications include nausea, vomiting, diarrhea, headache, dizziness, fever, and chills. These are attributed to misoprostol and usually subside in a few hours after administration (Costescu et al., 2016).

Second-Trimester Abortion

Second-trimester abortion is associated with more complications than are first-trimester abortions. Medical induction and dilation and evacuation (D&E) following cervical preparation are both safe and effective methods for terminations in the second trimester. However, D&E is considered slightly safer.

Dilation and Evacuation. D&E can be performed at any point up to 20 weeks of gestation. The cervix requires more dilation because the products of conception are larger. Often laminaria are inserted into the cervix several hours or several days before the procedure to assist in dilating the cervix, or misoprostol can be applied to the cervix to soften the tissue. The procedure is similar to that of vaginal aspiration, except that a larger cannula is used and other instruments may be needed to remove the fetus and placenta. Nursing care includes monitoring vital signs, providing emotional support, administering analgesics, and postoperative monitoring.

Medical Induction. In general, medical administration of a second-trimester abortion involves the same medications (misoprostol and mifepristone) used in medical termination of pregnancy during the first trimester (Costescu & Guilbert, 2018). Prior to medical induction, patients may require cervical ripening with osmotic dilators, prostaglandins, or the insertion of a balloon catheter, especially if this is done later in gestation. Intra-amniotic injections of hypertonic solutions (e.g., saline) injected directly into the uterus and uterotonic agents (e.g., prostaglandin) are effective. Extra-amniotic prostaglandin can also be used. Labour may also be induced using concentrated oxytocin infusion or misoprostol (orally or vaginally). The particular method that is used should be based on the expertise of the health care provider and the wishes of the patient (Costescu & Guilbert, 2018).

Emotional Considerations Regarding Abortion

The patient considering an abortion will need help exploring the meaning of the various alternatives and consequences to themselves and their significant others. It is often difficult for a patient to express their true feelings (e.g., what abortion means to them now and in the future and what support or regret their friends and peers may demonstrate). A calm, matter-of-fact approach from the nurse can be helpful. Clarifying, restating, and reflecting statements; open-ended questions; and feedback are communication techniques that can be used to maintain a focus on the reality of the situation and bring the patient's concerns into the open. If family or friends cannot be involved, scheduling time for nursing personnel to give the necessary support is an essential component of the care plan.

Information about alternatives to abortion, such as referral to adoption agencies or to support services if the patient chooses to keep their baby, should be provided. If a decision is made to have an abortion, the patient must be assured of continued support. Information about what is entailed in various procedures, how much discomfort or pain can be expected, and what type of care is needed must be given. The various feelings, including depression, guilt, regret, and relief, that the patient might experience after the abortion should be discussed. Information about community resources for postabortion counselling may be needed.

Emotional responses to abortion are highly variable. Risk factors that may be related to emotional distress include the patient's age, pressure in pregnancy decision-making or high decisional conflict, lack of perceived social support, low socioeconomic status, interpersonal violence, history of depression, moral discomfort with abortion, and existence of co-occurring stressors (Costescu et al., 2016). Because symptoms can vary among patients who have had abortions, nurses must assess patients for grief reactions and facilitate the grieving process through active listening and nonjudgemental support and care.

KEY POINTS

- Infertility is the inability to conceive and carry a fetus to term gestation at a time the couple has chosen to do so.
- Infertility affects about 16% of otherwise healthy adults. It increases in patients older than 35 years.
- In Canada, about 40% of infertility is related to female causes, 30% to male causes, and 20% to both partners; 10% of the causes are unexplained.
- Common etiological factors of infertility include decreased sperm production, ovulation disorders, polycystic ovary syndrome, tubal occlusion, and endometriosis.
- Reproductive alternatives for family building include IVF-ET, GIFT, ZIFT, oocyte donation, embryo donation, TDI, surrogacy, and adoption.
- Infertility treatment can involve emotional and monetary costs for those involved.
- A variety of contraceptive methods with various effectiveness rates, advantages, and disadvantages are available.
- Individuals and their partners should choose the contraceptive method(s) best suited to them.
- Effective contraceptives are available through both prescription and nonprescription sources.
- Proper concurrent use of latex condoms provides protection against STIs.
- Tubal ligations and vasectomies are permanent sterilization methods.
- Emergency contraception pills should be taken as soon as possible after unprotected intercourse but no later than 120 hours.
- Induced abortion performed in the first trimester is safer and less complex than an abortion performed in the second trimester.
- The most common complications of induced abortion include infection, retained products of conception, and excessive vaginal bleeding.

Genetics, Conception, and Fetal Development

Lisa Keenan-Lindsay

Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explain the key concepts of basic human genetics.
2. Describe roles for nurses in genetics and genetic counselling.
3. Examine ethical dimensions of genetic screening.
4. Identify genetic disorders commonly tested for using prenatal testing.
5. Identify the potential effects of teratogens during vulnerable periods of embryonic and fetal development.
6. Summarize the process of fertilization.
7. Describe the development, structure, and functions of the placenta.
8. Describe the composition and functions of the amniotic fluid.
9. Identify three organs or tissues arising from each of the three primary germ layers.
10. Summarize the significant changes in growth and development of the embryo and fetus.

This chapter presents a brief discussion of **genetics** and the role of the nurse in genetics. It also provides an overview of the processes of fertilization and development of the normal embryo and fetus.

GENETICS

Genetic counselling is an important aspect of preconception and prenatal care. Recent advances in molecular biology and genomics have revolutionized the field of health care by providing the tools needed to determine the hereditary component of many diseases and improve our ability to predict susceptibility to disease, onset and progression of disease, and response to medications (Calzone et al., 2013). With this increase in genetic knowledge, there has been a gradual shift from genetics to genomics. *Genetics* is the study of individual genes and their effect on relatively rare single-gene disorders, whereas *genomics* is the study of all the genes in the human genome together, including their interactions with each other, the environment, and the influence of other psychosocial factors and cultural factors. Genetics is recognized as a contributing factor in virtually all human illnesses. Epigenetics is another more recent concept. *Epigenetics* refers to the variations in phenotype that occur due to the influence of the environment and a person's lifestyle on genetics.

With growing public interest in *personalized genomic information* (information about much or all of an individual's genome), increasing development of practice guidelines, mounting commercial pressures, and ever-increasing opportunities for individuals, families, and communities to participate in the direction and design of their genomic health care, genetic services are rapidly becoming an integral part of routine health care (Manolio et al., 2013). Moreover, many individuals and families have participated in *direct-to-consumer genetic testing* (testing marketed directly to consumers through television, print advertisements, and websites). Although much of the information provided by direct-to-consumer testing companies is recreational, some of the information provided is health related and could be interpreted as diagnostic. Patients and families who choose to undergo this type of testing and who are subsequently found to be carriers of an inherited condition have to be made aware, prior to testing, that access to formal genetic counselling may be limited. As well, additional confirmatory testing may be required, but access may be limited by local resources or availability of the test in accredited laboratories. Because of this, direct-to-consumer testing that is provided without the involvement of competent health care professionals may be not only unhelpful but also harmful (Wilson et al., 2016).

Genetic disorders affect people of all ages, from all socioeconomic levels, and from all racial and ethnic backgrounds. Genetic disorders affect not only individuals but also families, communities, and society. Advances in genetic testing and genetically based treatments have altered the care provided to affected individuals. Improvements in diagnostic capability have resulted in earlier diagnosis and have enabled individuals who previously would have died in childhood to survive

into adulthood. For most genetic conditions, therapeutic or preventive measures do not exist or are very limited. Consequently, the most useful means of reducing the incidence of these disorders is by preventing their transmission. It is standard practice to assess all pregnant patients for heritable disorders in order to identify potential complications.

Relevance of Genetics to Nursing

Because the potential impact of genetic disease on families and the community is significant (Box 9.1), genetics must be, and increasingly have been, integrated into nursing education and practice. In addition, genetic information, technology, and testing must be incorporated into health care services.

Expanded or new roles for nurses with expertise in genetics and genomics are developing in many areas of maternity and women's health nursing. These areas include but are not limited to preconception counselling and preimplantation diagnosis for patients at risk for the transmission of a genetic disorder; prenatal screening and testing; prenatal care for patients with psychiatric disorders that have a genetic component, such as bipolar disorder and schizophrenia; newborn screening and testing; the care of families who have lost a fetus or a child affected by a genetic condition; the identification and care of children with genetic conditions, and their families; and the care of patients with genetic conditions who require specialized care during pregnancy, such as persons with congenital heart disease, cystic fibrosis (CF), Marfan syndrome, or factor V Leiden.

Although diagnosis and treatment of genetic disorders require specialized medical skills, nurses can use their nursing skills as they assume important roles in counselling people about genetically transmitted or genetically influenced conditions (Box 9.2). Most diseases have a genetic component; nurses can make a significant contribution to supporting those persons affected by genetic challenges (Barr et al., 2018). Community health nurses can identify groups within populations that are at high risk for illness and provide care to individuals, families, and groups. They are a vital link in follow-up for newborns who may need newborn screening.

Probably the most important of all nursing functions with regard to genetic counselling is providing emotional support to the family during all aspects of the counselling process. Feelings that arise under the real or imagined threat posed by a genetic disorder are as varied as the people being counselled.

Gene Identification and Genetic Testing

Initial efforts to sequence and analyze the human genome have proven invaluable in the identification of genes involved in disease and in the development of genetic tests. In an effort to bridge the transition from discovery to diagnostics and treatments, the US National Institutes of Health developed the Genetic Testing Registry (GTR), which is a free, online tool that can be used to obtain a list of available genetic tests (see Additional Resources at the end of this chapter). The GTR website also includes links to other resources, such as *GeneReviews,* which is a collection of expert-authored, peer-reviewed disease descriptions presented in a standardized format and focused on clinically relevant and medically actionable information on the diagnosis, management, and genetic counselling of individuals and families with specific inherited conditions.

Genetic testing involves the analysis of human DNA; **ribonucleic acid (RNA)**, which has a major role in protein synthesis; **chromosomes** (threadlike packages of genes and other DNA in the nucleus of a cell); or proteins to detect abnormalities related to an inherited condition. Genetic tests can be used to directly examine the DNA and RNA that make up a gene (direct or molecular testing), look at markers that are coinherited with a gene that causes a genetic condition (linkage analysis), examine the protein products of genes (biochemical testing), or examine chromosomes (cytogenetic testing). Cytogenetic analysis of malignant tissue has become a mainstay of oncology.

Most of the genetic tests now being offered in clinical practice are tests for single-gene disorders in patients with clinical symptoms or who have a family history of a genetic disease, although new technology can now determine if patients are getting the correct medication for their genetic makeup. Some of these genetic tests are prenatal tests or tests used to identify the genetic status of a pregnancy at risk for a genetic condition. Current prenatal testing options include the following:

- Preimplantation genetic diagnosis (genetic profiling of the embryo prior to implantation) (see discussion below)
- First-trimester screening for abnormalities such as Down syndrome or trisomy 18 (blood work along with ultrasound for nuchal translucency)
- Maternal blood testing for markers of certain conditions in the fetus (noninvasive prenatal testing [NIPT])
- Invasive procedures (amniocentesis and chorionic villus sampling)

See further discussion regarding prenatal testing in Chapter 13.

Other tests are carrier screening tests, which are used to identify individuals who have a gene mutation for a genetic condition but do not show symptoms of the condition because it is a condition that is inherited in an autosomal recessive form (e.g., CF, sickle cell disease, Tay-Sachs disease).

Another type of genetic testing is predictive testing, which is used to clarify the genetic status of asymptomatic family members. The two types of predictive testing are presymptomatic and predispositional. Mutation analysis for Huntington disease (HD), a neurodegenerative disorder, is an example of presymptomatic testing. If the gene mutation

BOX 9.1 Potential Impact of Genetic Disease on Family and Community

- Financial cost to family
- Decrease in planned family size
- Loss of geographical mobility
- Decreased opportunities for siblings
- Loss of family integrity
- Loss of career opportunities and job flexibility
- Social isolation
- Lifestyle alterations
- Reduction in contributions to their community by families
- Disruption of partner relationships
- Threatened family self-concept
- Coping with intolerant public attitudes
- Psychological effects
- Stresses and uncertainty of treatment
- Physical health problems
- Loss of dreams and aspirations
- Cost to society of institutionalization or home or community care
- Cost to society because of additional problems and needs of other family members
- Cost of long-term care
- Housing and living arrangement changes

Source: Kasper, C. E., Schneidereith, T. A., & Lashley, F. R. (2015). *Lashley's essentials of clinical genetics in nursing practice* (2nd ed.). Springer.

BOX 9.2 Nursing Skills Used in Genetic Counselling

- Taking detailed family histories
- Developing treatment plans that incorporates genetic and genomic assessment information
- Teaching risk reduction and health promotion
- Recognizing when one's own attitudes and values related to genetics may affect care provided to patients
- Providing patients with credible, accurate, appropriate, and current genetic and genomic information, resources, services, and/or technologies that is culturally appropriate to facilitate informed decision making
- Making referrals for specialized genetic services or follow-up resources as needed
- Working in interprofessional teams

Adapted from Parikh, A. S., & Mitchell, A. L. (2015). Congenital anomalies. In R. J. Martin, A. A. Fanaroff, & M. C. Walsh (Eds.), *Fanaroff and Martin's neonatal-perinatal medicine: Diseases of the fetus and infant* (10th ed.). Elsevier.

for HD is present, symptoms of HD are certain to appear if the individual lives long enough. Testing for a *BRCA1* gene mutation, to determine breast cancer susceptibility, is an example of predispositional testing. Predispositional testing differs from presymptomatic testing in that a positive result (indicating that a *BRCA1* mutation is present) does not indicate a 100% risk of developing the condition (breast cancer).

In addition to using genetic tests to test for single-gene disorders in patients with clinical symptoms or who have a family history of a genetic disease, genetic tests are used for population-based screening (e.g., province-mandated newborn screening for phenylketonuria [PKU] and many other inborn errors of metabolism [IEMs]) (see Chapter 26 for further discussion).

Preimplantation Genetic Diagnosis. Preimplantation genetic diagnosis (PGD) is a form of early genetic testing designed to eliminate embryos with serious genetic diseases before implantation through assisted human reproduction technologies and to avoid future termination of pregnancy for genetic reasons.

Micromanipulation allows removal of a single cell from a multicellular embryo for genetic study (i.e., embryo biopsy) (Okun et al., 2014). Preimplantation screening for aneuploidy is associated with inconsistent findings for improving pregnancy outcomes as there is no guarantee that the embryo will implant or that a full term pregnancy will result (Public Health Agency of Canada, 2013). Patients need to know that, currently, there is no adequate information on the long-term effect of embryo single-cell biopsy (Okun et al., 2014). Couples must be counselled about their options and the implications of their choices when genetic analysis is considered. There may be an extra cost related to this testing.

Factors Influencing the Decision to Undergo Genetic Testing. Decisions about genetic testing are shaped, and in many instances constrained, by factors such as social norms, cost, and where care is received. Most pregnant patients in Canada now have at least one ultrasound examination and undergo some type of multiple-marker screening, and a growing number of patients undergo other types of prenatal testing. The range of prenatal testing options available to a pregnant patient and their family may vary significantly, based on where the pregnant patient receives prenatal care. Certain types of prenatal testing may not be available in smaller communities and rural settings (e.g., chorionic villus sampling and fluorescent in situ hybridization analysis). In addition, certain types of genetic testing may not be offered in conservative medical communities (e.g., preimplantation diagnosis). NIPT may only be covered by some provincial health care plans in certain situations, so the cost must be covered by the pregnant patient and their family.

There are also ethical dimensions to making the decision to be tested. The decision to undergo testing is seldom an autonomous one based solely on the needs and preferences of the individual being tested. Instead, it is often a decision based on feelings of responsibility and commitment to others. For example, a patient who has a family history of CF may decide to have genetic testing, but then decisions must be made about the outcome of the pregnancy depending on the results of the testing.

Ethical, Legal, and Social Implications. Because of widespread concern about misuse of the information gained through genetics research, the ethical, legal, and social implications (ELSIs) of genetic testing must be taken into account. The following issues must be considered:

- Privacy and fairness in the use and interpretation of genetic information
- Clinical integration of new genetic technologies
- Issues surrounding genetics research, such as possible discrimination and stigmatization
- Education for professionals and the general public about genetics, genetics health care, and the ELSIs of human genome research

Educational and health care programs must address the potential that genetic information may be used to discriminate against individuals or for eugenic purposes. Informed consent is very difficult to ensure when some of the outcomes, benefits, and risks of genetic testing remain unknown. Continued awareness of and vigilance against such misuse of information is the collective responsibility of health care providers, ethicists, and society. Some ethical considerations include the following: What is "normal" or a "disability" and who decides? Are disabilities diseases that need to be prevented or cured? Who will have access to these expensive therapies? Who will pay for them?

Clinical Genetics

Genetic Transmission. Human development is a complicated process that depends on the systematic unravelling of instructions found in the genetic material of the egg and the sperm. Development from conception to birth of a healthy newborn occurs without incident in most cases; however, occasionally some anomaly in the genetic code of the embryo creates a birth defect or disorder. Scientists in genetics seeks to explain the underlying causes of congenital disorders (disorders present at birth) and the patterns in which inherited disorders are passed from generation to generation.

Genes and Chromosomes. The hereditary material carried in the nucleus of each somatic (body) cell determines an individual's physical characteristics. This material, called *DNA*, forms threadlike strands known as *chromosomes*. Each chromosome is composed of many smaller segments of DNA referred to as *genes*. Genes or combinations of genes contain coded information that determines an individual's unique characteristics. The code consists of the specific linear order of the molecules that combine to form the strands of DNA. Genes control both the types of proteins that are made and the rate at which they are produced. Genes never act in isolation; they always interact with other genes and the environment.

All normal human **somatic cells** contain 46 chromosomes arranged as 23 pairs of homologous (matched) chromosomes; one chromosome of each pair is inherited from each parent. There are 22 pairs of **autosomes**, which control most traits in the body, and one pair of sex chromosomes, which determines sex and some other traits. The larger female chromosome is called the *X*; the smaller male chromosome is the *Y*. Whereas the Y chromosome is primarily concerned with sex determination, the X chromosome contains genes that are involved in much more than sex determination. Generally, the presence of a Y chromosome causes an embryo to develop as a male; in the absence of a Y chromosome, the individual develops as a female. Thus, in a female, the homologous pair of sex chromosomes is XX, and in a male, the homologous pair is XY.

Homologous chromosomes (except the X and Y chromosomes in males) have the same number and arrangement of genes. In other words, if one chromosome has a gene for hair colour, its partner chromosome also will have a gene for hair colour, and these hair colour genes will have the same loci or be located in the same place on the two chromosomes. Although both genes code for hair colour, they may not code for the same hair colour. Genes at corresponding loci on homologous chromosomes that code for different forms or variations of the same trait are called **alleles**. An individual with two copies of the same allele for a given trait is said to be **homozygous** for that trait. With two different alleles the person is **heterozygous** for the trait.

The term **genotype** typically is used to refer to the genetic makeup of an individual in the context of discussing a specific gene pair, but at times *genotype* is used to refer to an individual's entire genetic makeup or all the genes that the individual can pass on to future generations. **Phenotype** refers to the observable expression of an individual's genotype, such as physical features, a biochemical or molecular trait, and even a psychological trait. A trait or disorder is considered *dominant* if it is expressed or phenotypically apparent when only one copy of the gene is present. It is considered *recessive* if it is expressed only when two copies of the gene are present.

As more is learned about genetics, the concepts of dominance and recessivity have become more complex, especially in X-linked disorders. For example, traits considered to be recessive may be expressed even when only one copy of a gene located on the X chromosome is present. This occurs frequently in males because males have only one X chromosome; thus they have only one copy of the genes located on the X chromosome. Whichever gene is present on the one X chromosome determines which trait is expressed. Conversely, females have two X chromosomes; thus they have two copies of the genes located on the X chromosome. However, in any female somatic cell, only one X chromosome is functioning (otherwise there would be inequality in gene dosage between males and females). This process, known as *X-inactivation*, or the *Lyon hypothesis*, is generally a random occurrence (i.e., there is a 50:50 chance of the maternal X or the paternal X being inactivated). Occasionally, the percentage of cells that have the X with an abnormal or mutant gene is very high. This helps explain why hemophilia, an X-linked recessive disorder, can clinically manifest itself in a female known to be a heterozygous carrier (a female who has only one copy of the gene mutation). It also helps explain why traditional methods of carrier detection are less effective for X-linked recessive disorders; the possible range for enzyme activity values can vary greatly, depending on which X chromosome is inactivated.

Chromosomal Abnormalities. Chromosomal abnormalities are a major cause of reproductive loss, congenital issues, and gynecological disorders. The incidence of chromosome aberrations is estimated to be 0.5 to 0.7% in live newborns. Approximately 60% of miscarriages and 6% of stillbirths and perinatal deaths are caused by chromosomal abnormalities (Blackburn, 2018). Errors resulting in chromosome abnormalities can occur in mitosis or meiosis (see later discussion in the chapter). These errors can occur in either the autosomes or the sex chromosomes. Even without the presence of obvious structural malformations, small deviations in chromosomes can cause issues in fetal development.

The pictorial analysis of the number, form, and size of an individual's chromosomes is known as a **karyotype**. Cells are grown in a culture and arrested when they are in metaphase (during metaphase, the chromosomes are condensed and visible with a light microscope) and then dropped onto a slide. This breaks the cell membranes and spreads the chromosomes, making them easier to visualize. Next, the cells are stained with special stains (e.g., Giemsa stain) that create striping or "banding" patterns. These patterns aid in the analysis because they are consistent from person to person. Once the chromosome spreads are photographed or scanned by a computer, they are cut out and arranged in a specific numeric order according to their length and shape. The chromosomes are numbered from largest to smallest, 1 to 22, and the sex chromosomes are designated by the letter X or Y. Each chromosome is divided into two "arms" designated by p (short arm) and q (long arm). A female karyotype is designated as 46, XX, and a male karyotype is designated as 46, XY. Figure 9.1 illustrates the chromosomes in a body cell and a karyotype. Karyotypes can be used to determine the sex of a child and the presence of any gross chromosomal abnormalities.

Autosomal abnormalities. Autosomal abnormalities involve differences in the number or structure of autosome chromosomes (pairs 1 to 22) resulting from unequal distribution of the genetic material during **gamete** (egg and sperm) formation.

Abnormalities of chromosome number. A **euploid cell** is a cell with the correct number of chromosomes within the cell. Because most gametes are **haploid** (1N, 23 chromosomes) and most somatic cells are **diploid** (2N, 46 chromosomes), they are both considered euploid cells. Deviations from the correct number of chromosomes can be one of two types: (1) **polyploidy**, in which the deviation is an exact multiple of the haploid number of chromosomes, or one chromosome set (23 chromosomes), or (2) **aneuploidy**, in which the numeric deviation is not an exact multiple of the haploid set. A triploid (3 N) cell is an example of a polyploidy. It has 69 chromosomes. A tetraploid (4 N) cell, also an example of a polyploidy, has 92 chromosomes.

Aneuploidy is the most commonly identified chromosome abnormality in humans and the leading genetic cause of intellectual disability. A **monosomy** is the product of the union between a normal gamete and a gamete that is missing a chromosome. Monosomic individuals have only 45 chromosomes in each of their cells. The product of the union of a normal gamete with a gamete containing an extra chromosome is a **trisomy**. The most common autosomal aneuploid conditions involve trisomies. Trisomic individuals have 47 chromosomes in most or all of their cells.

The vast majority of trisomies occur during **oogenesis** (the process by which a premeiotic female germ cell divides into a mature egg); the incidence of these types of chromosomal errors increases exponentially with advancing maternal age. Although variation exists among trisomies with regard to the parent and stage of origin of the extra chromosome, most trisomies are maternal meiosis I (MI) errors. This means that most trisomies are caused by nondisjunction during the first meiotic division. The first meiotic division involves the segregation of homologous or similar chromosomes. One pair of chromosomes fails to separate. One resulting cell contains both chromosomes, and the other contains none. The fact that most trisomies are maternal MI errors is not that surprising, because maternal MI occurs over a long time span. It is initiated in precursor cells during fetal development, but it is not completed until the time those cells undergo ovulation after menarche.

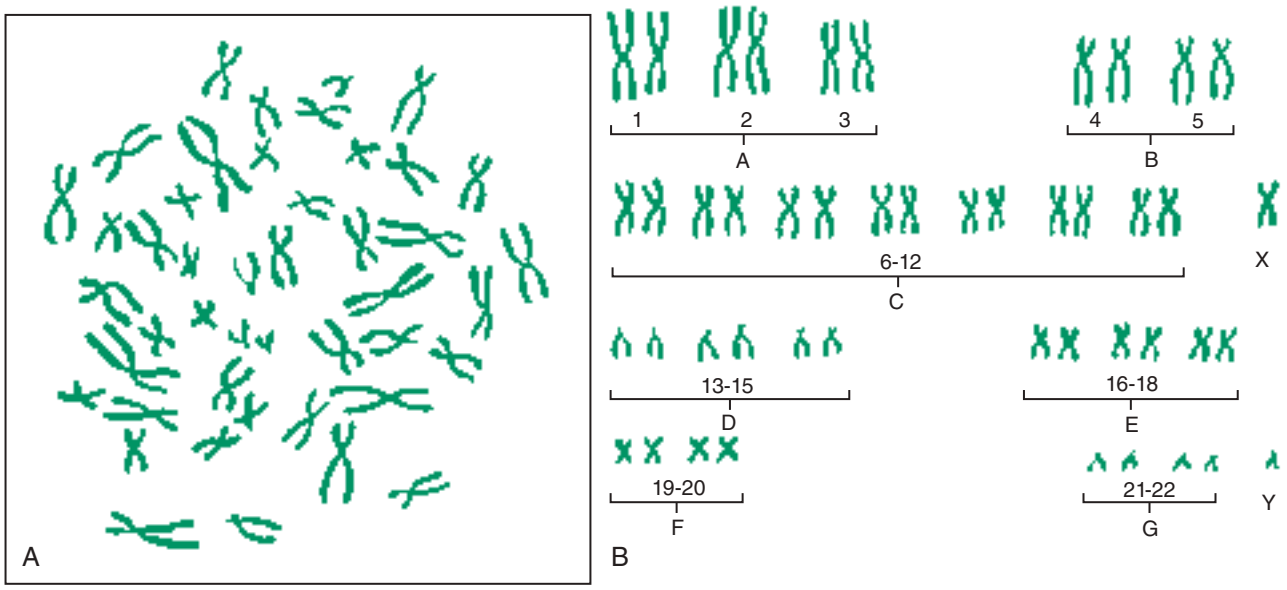

Fig. 9.1 Chromosomes during cell division. **A:** Example of photomicrograph. **B:** Chromosomes arranged in karyotype; female and male sex-determining chromosomes.

The most common trisomy abnormality is Down syndrome (DS). Approximately 1 in every 750 newborns has DS (Government of Canada, 2017). Ninety-five percent of individuals with DS have trisomy 21 (nondisjunction), or an extra chromosome 21 (47,XX+21, female with DS; or 47,XY+21, male with DS). Another type of DS, translocation, occurs when extra chromosome 21 material is present in every cell of the individual but it is attached to another chromosome. In the third type of DS, mosaicism, extra chromosome 21 material is found in some but not all of the cells.

Although the risk of having a child with DS increases with maternal age (incidence is approximately 1 in 1 200 for a 25-year-old mother; 1 in 350 for a 35-year-old mother; and 1 in 30 for a 45-year-old mother), children with DS can be born to mothers of any age; 50% of children with DS are born to mothers younger than 35 years (Government of Canada, 2017). The Society of Obstetricians and Gynaecologists of Canada recommends that screening patients on the basis of age should be abandoned and that all pregnant patients, regardless of age, should be offered the option of prenatal screening for DS and other common fetal aneuploidies (Chitayat et al., 2017). The risk of a mother having a second child with DS is about 1% when the cause of the DS is trisomy 21 (see also Figure 42.5 and discussion in Chapter 42).

Other autosomal trisomies that perinatal nurses might see are trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome). Trisomy 18 is more common than trisomy 13; it occurs in about 1 of 5 000 live births versus 1 of 16 000 live births for trisomy 13 (Genetics Home Reference, 2021). Infants with trisomy 18 and trisomy 13 usually have severe to profound intellectual disabilities. Although both conditions have a poor prognosis, with the vast majority of affected infants dying before they reach their first birthday, a growing number of infants with these trisomies are living longer, and a small number are actually living into their 40s and 50s.

Nondisjunction can also occur during mitosis. If this occurs early in development, when cell lines are forming, the individual has a mixture of cells, some with a normal number of chromosomes and others either missing a chromosome or containing an extra chromosome. This condition is known as *mosaicism.* The most common form of mosaicism in autosomes is mosaic DS.

Abnormalities of chromosome structure. Structural abnormalities can occur in any chromosome. Types of structural abnormalities include translocation, duplication, deletion, microdeletion, and inversion. **Translocation** occurs when there is an exchange of chromosome material between two chromosomes. Exposure to certain drugs, viruses, and radiation can cause translocations, but often they arise for no apparent reason.

The two major types of translocation are reciprocal and robertsonian. Reciprocal translocations are the most common type. In a *reciprocal* translocation, either the parts of the two chromosomes are exchanged equally (balanced translocation) or a part of a chromosome is transferred to a different chromosome, creating an unbalanced translocation because there is extra chromosomal material—extra of one chromosome but correct amount or deficient amount of the other chromosome. In a balanced translocation, the individual is phenotypically normal because there is no extra chromosome material; it is just rearranged. In an unbalanced translocation, the individual will be both genotypically and phenotypically abnormal.

In a *robertsonian* translocation, the short arms (p arms) of two different acrocentric chromosomes (chromosomes with very short p arms) break, leaving sticky ends that then cause the two long arms (q arms) to stick together. This forms a new, large chromosome that is made of the two long arms. The individual with a balanced robertsonian translocation has 45 chromosomes. Because the short arm of acrocentric chromosomes contains genes for ribosomal RNA and these genes are represented elsewhere, the individual usually does not show any symptoms. The individual may produce an unbalanced gamete (sperm or egg with too many or two few genes). This can lead to reproductive difficulties such as miscarriages or birth defects.

In *duplication*, there is an extra chromosomal segment within the same homologous or another nonhomologous chromosome. Clinical findings are highly variable and depend on which of the chromosomal segments are involved.

Deletions result in the loss of chromosomal material and partial monosomy for the chromosome involved. *Microdeletions* are deletions too small to be detected by standard cytogenetic techniques. Whenever a portion of a chromosome is deleted from one chromosome and added to another, the gamete produced may have either extra copies of genes

or too few copies. The clinical effects produced may be mild or severe depending on the amount of genetic material involved. Two of the more common conditions are the deletion of the short arm of chromosome 5 (cri du chat syndrome) and the deletion of the long arm of chromosome 18.

Inversions are deviations in which a portion of the chromosome has been rearranged in reverse order. Few birth defects have been attributed to the presence of inversions, but it is suspected that inversions may be responsible for problems with infertility and miscarriages.

Sex chromosome abnormalities. Several sex chromosome abnormalities are caused by nondisjunction during gametogenesis in either parent. The most common deviation in females is *Turner syndrome*, or monosomy X (45,X). The affected female exhibits juvenile external genitalia with undeveloped ovaries. They are usually short in stature, often has webbing of the neck, a low hairline in the back, low-set ears, and lymphedema of hands and feet. Intelligence may be impaired. Most affected embryos miscarry spontaneously. In most cases of Turner syndrome, it is the paternal X or Y that is lost. Turner syndrome is a common cause of infertility.

The most common deviation in males is *Klinefelter syndrome*, or trisomy XXY. The affected male has poorly developed secondary sexual characteristics and small testes. These individuals are infertile, usually tall, and may be slow to learn. Males who have mosaic Klinefelter syndrome may be fertile.

Patterns of Genetic Transmission

Heritable characteristics are those that can be passed on to offspring. The patterns by which genetic material is transmitted to the next generation are affected by the number of genes involved in the expression of the trait. Many phenotypic characteristics result from two or more genes on different chromosomes acting together (referred to as *multifactorial inheritance*); others are controlled by a single gene (*unifactorial inheritance*). Specialists in genetics (e.g., geneticists, genetics counsellors, and nurses with advanced expertise in genetics) predict the probability of the presence of an abnormal gene from the known occurrence of the trait in the individual's family and the known patterns by which the trait is inherited.

Multifactorial Inheritance. Most common congenital malformations result from multifactorial inheritance, a combination of genetic and environmental factors. Examples are cleft lip, cleft palate, congenital heart disease, neural tube defects, and pyloric stenosis. Each malformation may range from mild to severe, depending on the number of genes for the defect present or the amount of environmental influence. A neural tube defect may range from spina bifida (a bony defect in the lumbar region of the vertebrae with little or no neurological impairment) to anencephaly (the absence of brain development, which is always fatal). Some malformations occur more often in one sex. For example, pyloric stenosis and cleft lip are more common in males, and cleft palate is more common in females.

Unifactorial Inheritance. If a single gene controls a particular trait, disorder, or defect, its pattern of inheritance is referred to as *unifactorial Mendelian* or *single-gene inheritance*. The number of single-gene disorders far exceeds the number of chromosomal abnormalities. Potential patterns of inheritance for single-gene disorders include autosomal dominant, autosomal recessive, and X-linked dominant and recessive modes of inheritance (Figure 9.2).

Autosomal dominant inheritance. *Autosomal dominant inheritance disorders* are those in which only one copy of a variant allele is needed for phenotypic expression. The variant allele may appear as a result of a *mutation*, a spontaneous and permanent change in the normal gene structure. In this case, the disorder occurs for the first time in the family. Usually an affected individual comes from multiple generations having the disorder. An affected parent who is heterozygous for the trait has a 50% chance of passing the variant allele to each offspring (see Figure 9.2, *B* and *C*). There is a vertical pattern of inheritance (there is no skipping of generations; if an individual has an autosomal dominant disorder, such as HD, so must one of their parents). Males and females are affected equally.

Autosomal dominant disorders are not always expressed with the same severity of symptoms. For example, a patient who has an autosomal dominant disorder may show few symptoms and may not become aware of their diagnosis until after they give birth to a severely affected child. The predicting of whether an offspring will have a minor or severe abnormality is not possible. Sometimes an individual can acquire a fresh mutation (new mutation that spontaneously occurred in a gene carried by an individual germ cell) that can result in an autosomal dominant disorder (Blackburn, 2018). These types of mutations are fairly common. Examples of autosomal dominant disorders are Marfan syndrome, neurofibromatosis, myotonic dystrophy, Stickler syndrome, Treacher Collins syndrome, and achondroplasia (dwarfism).

Autosomal recessive inheritance. *Autosomal recessive inheritance disorders* are those in which both genes of a pair must be abnormal for the disorder to be expressed. Heterozygous individuals have only one variant allele and are unaffected clinically because their normal gene overshadows the variant allele. They are known as *carriers* of the recessive trait. Because these recessive traits are inherited by generations of the same family, an increased incidence of the disorder occurs in consanguineous matings (closely related parents). For the trait to be expressed, two carriers must each contribute a variant allele to the offspring (see Figure 9.2, *C*). The chance of the trait occurring in each child is 25%. A clinically normal offspring may be a carrier of the gene. Autosomal recessive disorders have a horizontal pattern of inheritance rather than the vertical pattern seen with autosomal dominant disorders (i.e., autosomal recessive disorders are usually observed in one or more siblings but not in earlier generations). Males and females are equally affected.

Inborn errors of metabolism (IEM). More than 350 IEMs have been recognized. Most IEMs, such as PKU, galactosemia, maple syrup urine disease, Tay-Sachs disease, sickle cell anemia, and CF, are autosomal recessive inherited disorders. Individually, IEMs are relatively rare, but collectively they are common (1 in 800 to 2 500 live births) (Reid, 2020). IEMs occur when a gene mutation reduces the efficiency of encoded enzymes to a level at which normal metabolism cannot occur. Defective enzyme action interrupts the normal series of chemical reactions from the affected point onward. The result may be an accumulation of a damaging product, such as phenylalanine in PKU, or the absence of a necessary product, such as the lack of melanin in albinism caused by lack of tyrosinase. Diagnostic and carrier testing are available for a growing number of IEMs. In addition, many provinces in Canada have started screening for specific IEMs as part of their expanded newborn screening programs, using tandem mass spectrometry. However, many of the deaths caused by IEMs are the result of enzyme variants not currently screened for in many of the newborn screening programs (Jorde et al., 2020). (See discussion of IEMs in Chapter 29.)

X-linked dominant inheritance. X-linked dominant inheritance disorders occur in males and heterozygous females, but because of X inactivation, affected females are usually less severely affected than affected males, and they are more likely to transmit the variant allele to their offspring. Heterozygous females (females who have one wild-type allele and one variant allele) have a 50% chance of transmitting the variant allele to each offspring. The variant allele is often lethal

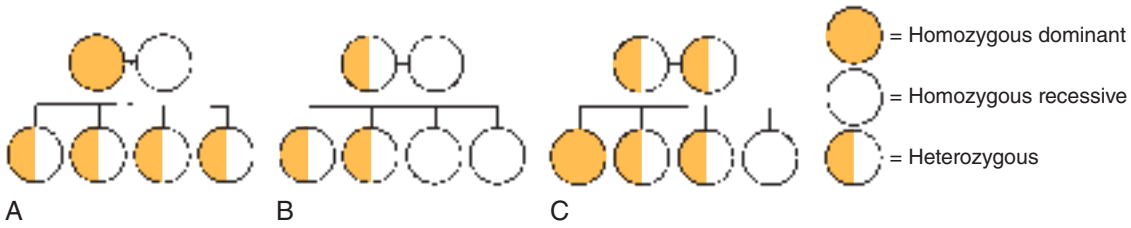

Fig. 9.2 Possible offspring in three types of matings. **A:** Homozygous-dominant parent and homozygous-recessive parent. Children: all heterozygous, displaying dominant trait. **B:** Heterozygous parent and homozygous-recessive parent. Children: 50% heterozygous, displaying dominant trait; 50% homozygous, displaying recessive trait. **C:** Both parents heterozygous. Children: 25% homozygous, displaying dominant trait; 25% homozygous, displaying recessive trait; 50% heterozygous, displaying dominant trait.

in affected males because, unlike affected females, they have no normal gene (wild-type allele). Mating of an affected male and an unaffected female is uncommon as a result of the tendency for the variant allele to be lethal in affected males. Relatively few X-linked dominant disorders have been identified. Two examples are Rett syndrome and vitamin D–resistant rickets.

X-linked recessive inheritance. Abnormal genes for X-linked recessive inheritance disorders are carried on the X chromosome. Females may be heterozygous or homozygous for traits carried on the X chromosome because they have two X chromosomes. Males are hemizygous because they have only one X chromosome carrying genes, with no alleles on the Y chromosome. Therefore, X-linked recessive disorders are most often manifested in the male, with the abnormal gene on his single X chromosome. Hemophilia, colour blindness, and Duchenne muscular dystrophy are all X-linked recessive disorders.

The male receives the disease-associated allele from the mother who is a carrier on their affected X chromosome. Female carriers (those heterozygous for the trait) have a 50% probability of transmitting the disease-associated allele to each offspring. An affected male can pass the disease-associated allele to his daughters but not to his sons. The daughters will be carriers of the trait if they receive a normal gene on the X chromosome from their mother. They will be affected only if they receive a disease-associated allele on the X chromosome from both their mother and their father.

Genetic Counselling

It is standard practice in perinatal care to determine whether a heritable disorder exists in a couple or in anyone in either of their families. The goal of screening is to detect or define risk for disease in low-risk populations and to identify those for whom diagnostic testing may be appropriate. A nurse can obtain a genetic history using a questionnaire or checklist such as the one in Figure 9.3.

Genetic counselling is a professional service that provides genetics information, education, and support to individuals and families with ongoing or potential genetic health concerns. It is typically provided by a team of genetics specialists that includes clinical geneticists (physicians), medical geneticists, genetics counsellors, and, advanced practice genetics nurse specialists. Cytogeneticists, biochemical geneticists, and molecular geneticists support the clinical genetics team by providing laboratory expertise that helps with the diagnosis and management of individuals and families affected by genetic conditions.

Genetic counselling can occur in major medical centres, some community hospitals, and in a variety of community resources as well as over the Internet. Health providers should become familiar with people who provide genetic counselling and the places that offer counselling services in their area of practice (see Community Focus box).

COMMUNITY FOCUS

Resources for Genetic Disorders

- Search for genetic counselling resources that are available in your community. How accessible are these?
- Search the Internet for a hereditary condition (e.g., neurofibromatosis, cystic fibrosis, Marfan syndrome, Down syndrome) that has a support organization.
- Access the website for the organization. What services and resources are available for families? Are these services and resources free, or must the family pay for them? Is there a branch of the organization available in your city? If there is no branch of the organization available in your city, where could families go for information and assistance? Is preconception counselling offered?
- While reviewing the website assess the appearance, readability, and information contained in the site. Is the information available in different languages?
- For your selected genetic disorder, prepare a list of resources for families.

Individuals and families seek out or are referred for genetic counselling for a wide variety of reasons and at all stages of their lives. Some seek preconception or prenatal information; others are referred after the birth of a child with a birth defect or a suspected genetic condition; still others seek information because they have a family history of a genetic condition. Regardless of the setting or the individual and family's stage of life, genetic counselling should be offered and available to all individuals and families who have questions about genetics and their health.

Estimation of Risk. Most families with a history of genetic disease want an answer to the following question: What is the chance that our future children will have this disease? Because the answer to this question may have profound implications for individual family members and the family as a whole, health care providers must be able to answer this question as accurately as they can in a timely manner. In some cases, estimation of risk is rather straightforward; in other cases, it is complicated.

If a couple has not yet had children but is known to be at risk for having children with a genetic disease, they will be given an *occurrence risk*. Once a couple has produced one or more children with a genetic disease, the couple will be given a *recurrence risk*. Both occurrence and recurrence risks are determined by the mode of inheritance for the genetic disease in question. For genetic diseases caused by a factor that segregates during cell division (genes and chromosomes), risk can be estimated with a high degree of accuracy by application of the Mendelian principles.

In an autosomal dominant disorder, both the occurrence and recurrence risk is 50%, or 1 in 2, that a subsequent offspring

Risk Factors for Genetic Disorders

It's a good idea to review your risk factors before you see your health care provider to discuss prenatal screening and diagnostic testing. It may be helpful for you to talk with your and your partner's family members for information about diseases or conditions that run in your families.

_____What is your age?

_____What is the baby's father's age?

_____If you or the baby's father is of Mediterranean or Asian descent, do either of you or anyone in your families have thalassemia?

_____Is there a family history of neural tube defects?

_____Have you or the baby's father ever had a child with a neural tube defect?

_____Is there a family history of congenital heart defects?

_____Is there a family history of Down syndrome?

_____Have you or the baby's father ever had a child with Down syndrome?

_____If you or the baby's father is of Eastern European Jewish, French Canadian, or Cajun descent, is there a family history of Tay–Sachs disease?

_____If you or your partner is of Eastern European Jewish descent, is there a family history of Canavan disease or any other genetic disorders?

_____Is there a family history of sickle cell disease or sickle cell trait?

_____Is there a family history of hemophilia?

_____Is there a family history of muscular dystrophy?

_____Is there a family history of Huntington disease?

_____Does anyone in your family or the family of the baby's father have cystic fibrosis?

_____Does anyone in your family or the baby's father's family have an intellectual disability? Or have they had early menopause or tremors at an early age?

_____If so, was that person tested for fragile X syndrome?

_____Do you, the baby's father, anyone in your families, or any of your children have any other genetic diseases, chromosomal disorders, or birth defects?

_____Do you have a metabolic disorder such as diabetes mellitus or phenylketonuria?

_____Do you have a history of pregnancy issues (miscarriage or stillbirth)?

Fig. 9.3 Questionnaire for identifying couples having increased risk for offspring with genetic disorders. (Reprinted with permission from American College of Obstetricians and Gynecologists [ACOG]. [2016]. *Your pregnancy and childbirth: Month to month*. [Revised 6th ed.]. Author.)

will be affected when one parent is affected and the other is not. The recurrence risk for autosomal recessive disorders is 25%, or 1 in 4, if both parents are carriers. Occasionally an individual homozygous for a recessive disease gene mates with an individual who is a carrier of the same recessive gene and in this case, the recurrence risk is 50%, or 1 in 2. If two individuals affected by an autosomal recessive disorder mate, all of their children will be affected. For X-linked disorders, recurrence is related to the sex of the child. Translocation chromosomes have a high risk of recurrence.

A number of autosomal disorders display complex patterns of inheritance, which makes the estimation of risk more difficult. In some situations, a genetic disease may not be in a family history and may be due to a new mutation. If this occurs, the recurrence risk for the parents' subsequent children is low (1 to 2%), although not as low as for the general population. Offspring of the affected child may have a substantially elevated occurrence risk as well.

The risk of recurrence for multifactorial conditions can be estimated empirically. An empiric risk is based not on genetics theory but rather on experience and observation of the disorder in other families. Recurrence risks are determined by applying the frequency of a similar disorder in other families to the case under consideration.

An important concept that must be emphasized to families is that *each pregnancy is an independent event*. For example, in monogenic disorders in which the risk factor is 1 in 4 that the child will be affected, the risk remains the same no matter how many affected children are already in the family. Families may make the erroneous assumption that the presence of one affected child ensures that the next three will be free of the disorder. However, "chance has no memory." The risk is

1 in 4 for each pregnancy. In a family with a child who has a disorder with multifactorial causes, however, the risk increases with each subsequent child born with the disorder.

Interpretation of Risk. The guiding principle for genetics counsellors has traditionally been the principle of nondirectiveness. According to the principle of nondirectiveness, the individual who is providing genetics counselling respects the right of the individual or family being counselled to make autonomous decisions. Counsellors using a nondirective approach avoid making recommendations, and they try to communicate genetics information in an unbiased manner. The first step in providing nondirective counselling is becoming aware of one's own values and beliefs. Another important step is recognizing how one's values and beliefs can influence or interfere with the communication of genetics information.

The counsellor provides appropriate information about the nature of the disorder, the extent of the risks in the specific case, the probable consequences, and (if appropriate) alternative options available; however, the final decision to become pregnant or to continue a pregnancy must be left to the family. An important nursing role is reinforcing the information that families are given and continuing to interpret this information on their level of understanding.

Nongenetic Factors Influencing Development

Congenital disorders may be inherited or may be caused by environmental factors or by inadequate maternal nutrition. *Congenital* means that the condition was present at birth. Some congenital malformations may be the result of *teratogens*, that is, environmental substances or exposures that result in functional or structural disability. In contrast to other forms of developmental disabilities, disabilities caused by teratogens are theoretically totally preventable. Known human teratogens are drugs and chemicals, infections, exposure to radiation, and certain maternal conditions such as diabetes and PKU (Box 9.3). A teratogen has the greatest effect on the organs and parts of an embryo during its periods of rapid growth and differentiation. This occurs during the embryonic period, specifically from days 15 to 60. During the first 2 weeks of development, teratogens either have no effect on the embryo or have effects so severe that they cause miscarriage. Brain growth and development continue during the fetal period, and teratogens can severely affect mental development throughout gestation (Figure 9.4).

In addition to genetic makeup and the influence of teratogens, the adequacy of maternal nutrition influences development. The embryo and fetus must obtain the nutrients they need from the pregnant parent's diet; they cannot tap the parental reserves. Malnutrition during pregnancy produces low-birth-weight newborns who are susceptible to infection and other conditions. Malnutrition also affects brain development during the latter half of gestation and may result in learning disabilities in the child. Inadequate folic acid is associated with neural tube defects (see Chapter 12 for more information).

PROCESS OF CONCEPTION

Cell Division

Cells are reproduced by two different methods: **mitosis** and **meiosis**. In *mitosis*, the body cells replicate to yield two cells with the same genetic makeup as the parent cell. First the cell makes a copy of its DNA, and then it divides. Each daughter cell receives one copy of the genetic material. Mitotic division facilitates growth and development or cell replacement.

Meiosis, the process by which germ cells divide and decrease their chromosome number by half, produces gametes (eggs and sperm). Each homologous pair of chromosomes contains one chromosome received from the mother and one from the father; thus meiosis results in cells that contain 1 of each of the 23 pairs of chromosomes. Because these germ cells contain 23 single chromosomes, half of the genetic material of a normal somatic cell, they are called *haploid*. This halving of the genetic material is accomplished by replicating the DNA once and then dividing twice. When the female gamete (egg or ovum) and the male gamete (spermatozoon) unite to form the zygote, the diploid number of human chromosomes (46, or 23 pairs) is restored.

The process of DNA replication and cell division in meiosis allows different alleles (genes on corresponding loci that code for variations of the same trait) for genes to be distributed at random by each parent and then rearranged on the paired chromosomes. The chromosomes then separate and proceed to different gametes. Because the two parents have genotypes derived from four different grandparents, many combinations of genes on each chromosome are possible. This random mixing of alleles accounts for the variation of traits seen in the offspring of the same two parents.

Gametogenesis

Oogenesis, the process of egg (ovum) formation, begins during fetal life of the female. All the cells that may undergo meiosis in a female's lifetime are contained in her ovaries at birth. The majority of the estimated 2 million primary oocytes (the cells that undergo the first meiotic division) degenerate spontaneously. Only 400 to 500 ova will mature during the approximately 35 years of a person's reproductive life. The primary oocytes begin the first meiotic division (i.e., they replicate their DNA) during fetal life but remain suspended at this stage until puberty (Figure 9.5, *A*). Then, usually monthly, one primary oocyte matures and completes the first meiotic division, yielding two unequal cells: the secondary oocyte and a small polar body. Both contain 22 autosomes and one X sex chromosome.

At ovulation, the second meiotic division begins. However, the ovum does not complete the second meiotic division unless fertilization occurs. At fertilization, a second polar body and the **zygote** (the united egg and sperm) are produced (see Figure 9.5, *C*). The three polar bodies degenerate.

BOX 9.3 Etiology of Human Malformations

Environmental
- Maternal conditions
- Alcohol intake, diabetes, endocrinopathies, phenylketonuria, smoking, nutritional deficits
- Infectious agents
- Rubella, toxoplasmosis, syphilis, herpes simplex, cytomegalic inclusion disease, varicella, Venezuelan equine encephalitis, parvovirus B19, Zika virus
- Mechanical problems (deformations)
- Amniotic band constrictions, umbilical cord constraint, disparity in uterine size and uterine contents
- Chemicals, medications, recreational drugs, radiation, hyperthermia
- Lead, methyl mercury

Genetic
- Single-gene disorders
- Chromosomal abnormalities

Unknown
- Polygenic or multifactorial (gene–environment interactions)
- "Spontaneous" errors of development
- Other unknowns

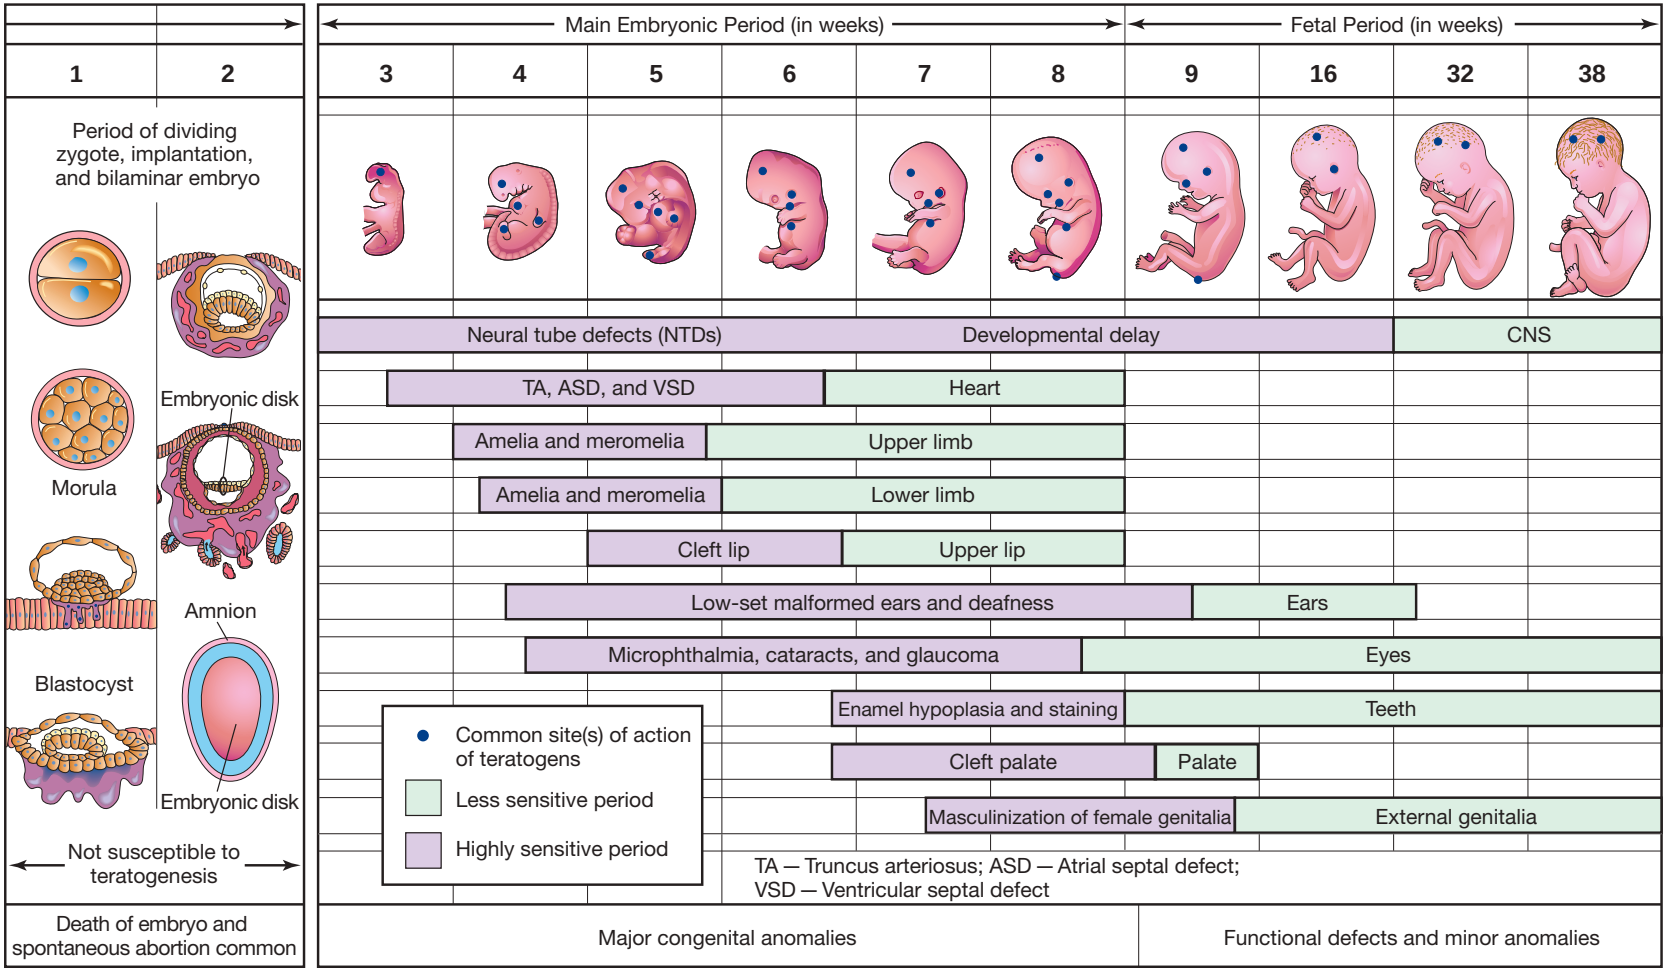

Fig. 9.4 Sensitive, or critical, periods in human development. *Light purple* denotes highly sensitive periods; *light green* indicates stages that are less sensitive to teratogens. *CNS,* Central nervous system. (From Moore, K. L., Persaud, T. V. N., & Torchia, M. G. [2013]. *Before we are born: Essentials of embryology and birth defects* [8th ed.]. Saunders.)

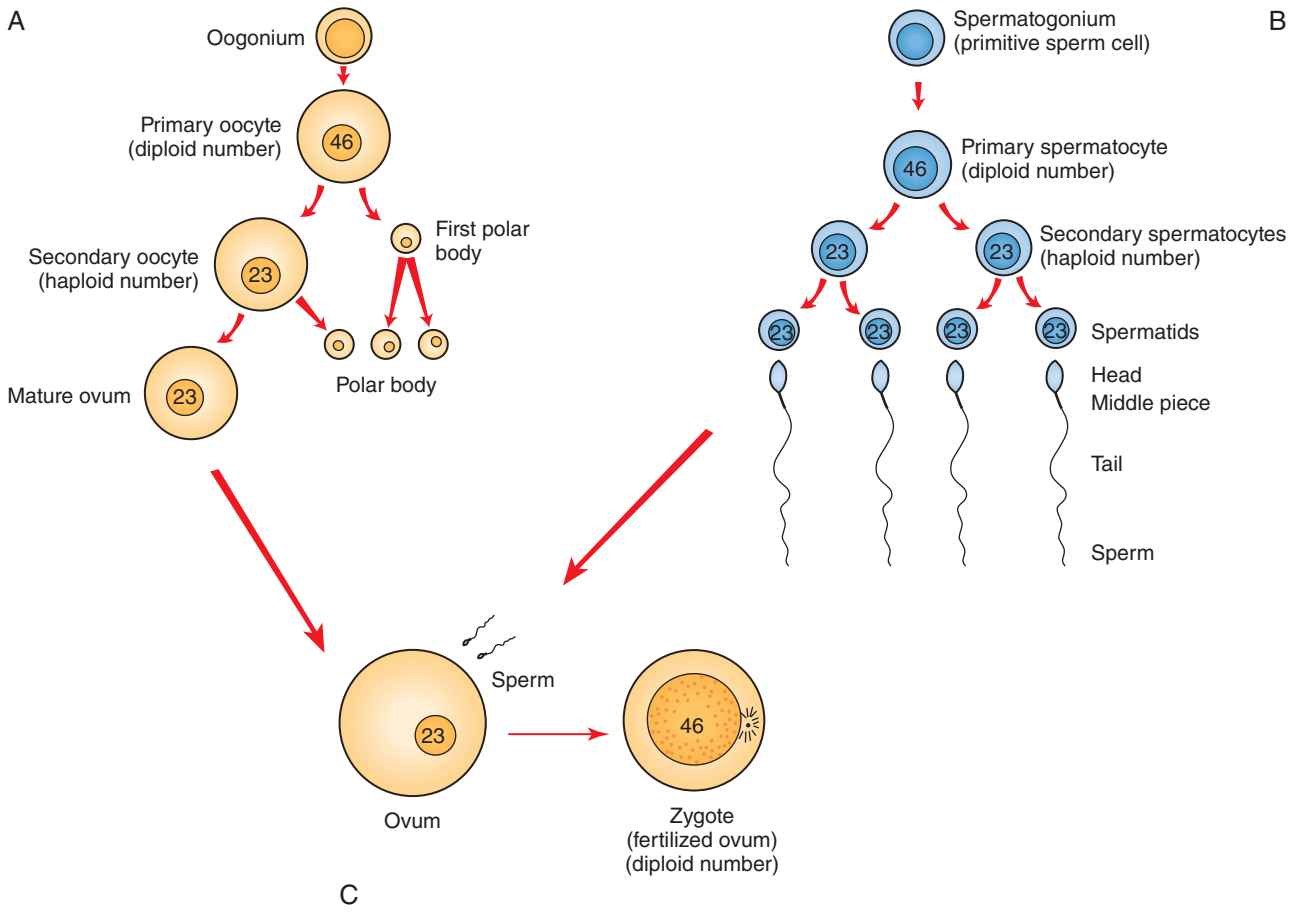

Fig. 9.5 Gametogenesis and fertilization. **A:** Oogenesis. Gametogenesis in the female produces one mature ovum and three polar bodies. Note relative difference in overall size between ovum and sperm. **B:** Spermatogenesis. Gametogenesis in the male produces four mature gametes, the sperm. **C:** Fertilization results in the single-cell zygote and restoration of the diploid number of chromosomes.

When a male reaches puberty, his testes begin the process of **spermatogenesis**. The cells that undergo meiosis in the male are called *spermatocytes*. The primary spermatocyte, which undergoes the first meiotic division, contains the diploid number of chromosomes. The cell has already copied its DNA before division, thus four alleles for each gene are present. Because the copies are bound together (i.e., one allele plus its copy on each chromosome), the cell is still considered diploid.

During the first meiotic division, two haploid secondary spermatocytes are formed. Each secondary spermatocyte contains 22 autosomes and one sex chromosome; one contains the X chromosome (plus its copy), and the other the Y chromosome (plus its copy). During the second meiotic division, the male produces two gametes with an X chromosome and two gametes with a Y chromosome, all of which will develop into viable sperm (see Figure 9.5, *B*).

Conception

Conception, defined as the union of a single egg and sperm, marks the beginning of a pregnancy. Conception occurs not as an isolated event but as part of a sequential process. This sequential process includes gamete (egg and sperm) formation, ovulation (release of the egg), union of the gametes (which results in an embryo), and implantation in the uterus.

Ovum. Meiosis occurs in the female in the ovarian follicles and produces an egg, or ovum. Each month one ovum matures with a host of surrounding supportive cells. At ovulation, the ovum is released from the ruptured ovarian follicle. High estrogen levels increase the motility of the uterine tubes so that their cilia are able to capture the ovum and propel it through the tube toward the uterine cavity. An ovum cannot move by itself.

Two protective layers surround the ovum (Figure 9.6). The inner layer is a thick, acellular layer called the *zona pellucida*. The outer layer, called the *corona radiata*, is composed of elongated cells. Ova are considered fertile for approximately 24 hours after ovulation. If unfertilized by a sperm, the ovum degenerates and is resorbed.

Sperm. Ejaculation during sexual intercourse normally propels about a teaspoon of semen containing as many as 200 to 500 million sperm into the vagina. The sperm swim by means of the flagellar movement of their tails. Some sperm can reach the site of fertilization within 5 minutes, but average transit time is 4 to 6 hours. Sperm remain viable within the female's reproductive system for an average of 2 to 3 days but may survive as long as 7 days. Most sperm are lost in the vagina, within the cervical mucus, or in the endometrium, or they enter the tube that contains no ovum.

As sperm travel through the female reproductive tract, enzymes are produced to aid in their capacitation. *Capacitation* is a physiological change that removes the protective coating from the heads of the sperm. Small perforations then form in the acrosome (a cap on the sperm) and allow enzymes (e.g., hyaluronidase) to escape (see

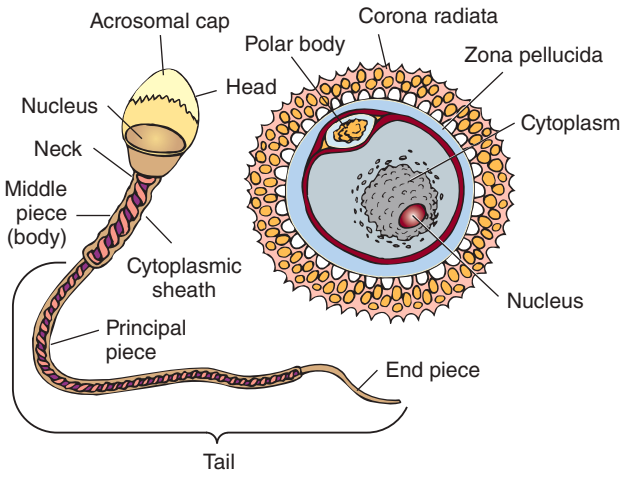

Fig. 9.6 Sperm and ovum.

Figure 9.6). These enzymes are necessary for the sperm to penetrate the protective layers of the ovum before fertilization.

Fertilization. Fertilization takes place in the *ampulla* (the outer third) of the uterine tube. When a sperm successfully penetrates the membrane surrounding the ovum, both sperm and ovum are enclosed within the membrane, and the membrane becomes impenetrable to other sperm; this process is termed the *zona reaction*. The second meiotic division of the secondary oocyte is then completed, and the ovum nucleus becomes the female pronucleus. The head of the sperm enlarges to become the male pronucleus, and the tail degenerates. The nuclei fuse, and the chromosomes combine, restoring the diploid number (46) (Figure 9.7). Fertilization, the formation of the zygote (the first cell of the new individual), has been achieved.

Mitotic cellular replication, called *cleavage*, begins as the zygote travels the length of the uterine tube into the uterus. This voyage takes 3 to 4 days. Because the fertilized egg divides rapidly with no increase in size, successively smaller cells, called *blastomeres*, are formed with each division. A 16-cell morula, a solid ball of cells, is produced within 3 days and is still surrounded by the protective zona pellucida (Figure 9.8, *A*). Further development occurs as the morula floats freely within the uterus. Fluid passes through the zona pellucida into the intercellular spaces between the blastomeres, separating them into two parts: the *trophoblast* (which gives rise to the placenta) and the *embryoblast* (which gives rise to the embryo). A cavity forms within the cell mass as the spaces come together, forming a structure called the *blastocyst cavity*. When the cavity becomes recognizable, the whole structure of the developing embryo is known as the *blastocyst*. Stem cells are derived from the inner cell mass of the blastocyst. The outer layer of cells surrounding the cavity is the trophoblast. The trophoblast differentiates into villous and extravillous trophoblast (Figure 9.9).

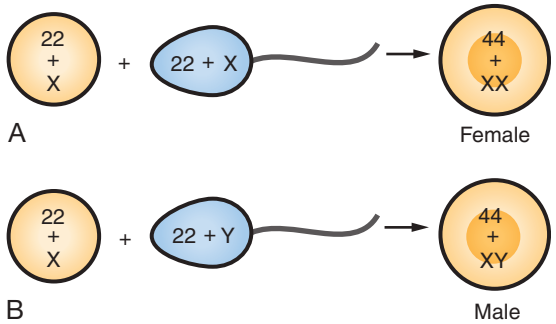

Fig. 9.7 Fertilization. **A:** Ovum fertilized by X-bearing sperm to form female zygote. **B:** Ovum fertilized by Y-bearing sperm to form male zygote.

Implantation

The zona pellucida degenerates; the trophoblast cells displace endometrial cells at the implantation site; and the blastocyst embeds in the endometrium, usually in the anterior or posterior fundal region. Between 6 and 10 days after fertilization, the trophoblast secretes enzymes that enable it to burrow into the endometrium until the entire blastocyst is covered. This is known as *implantation*. Endometrial blood vessels erode, and some patients have implantation bleeding (slight spotting and bleeding during the time of the first missed menstrual period). *Chorionic villi*, fingerlike projections, develop out of the trophoblast and extend into the blood-filled spaces of the endometrium. These villi are vascular processes that obtain oxygen and nutrients from the maternal bloodstream and dispose of carbon dioxide and waste products into the maternal blood.

After implantation, the endometrium is called the *decidua*. The portion directly under the blastocyst, where the chorionic villi tap into the maternal blood vessels, is the *decidua basalis*. The portion covering the blastocyst is the *decidua capsularis*, and the portion lining the rest of the uterus is the *decidua vera* (Figure 9.10).

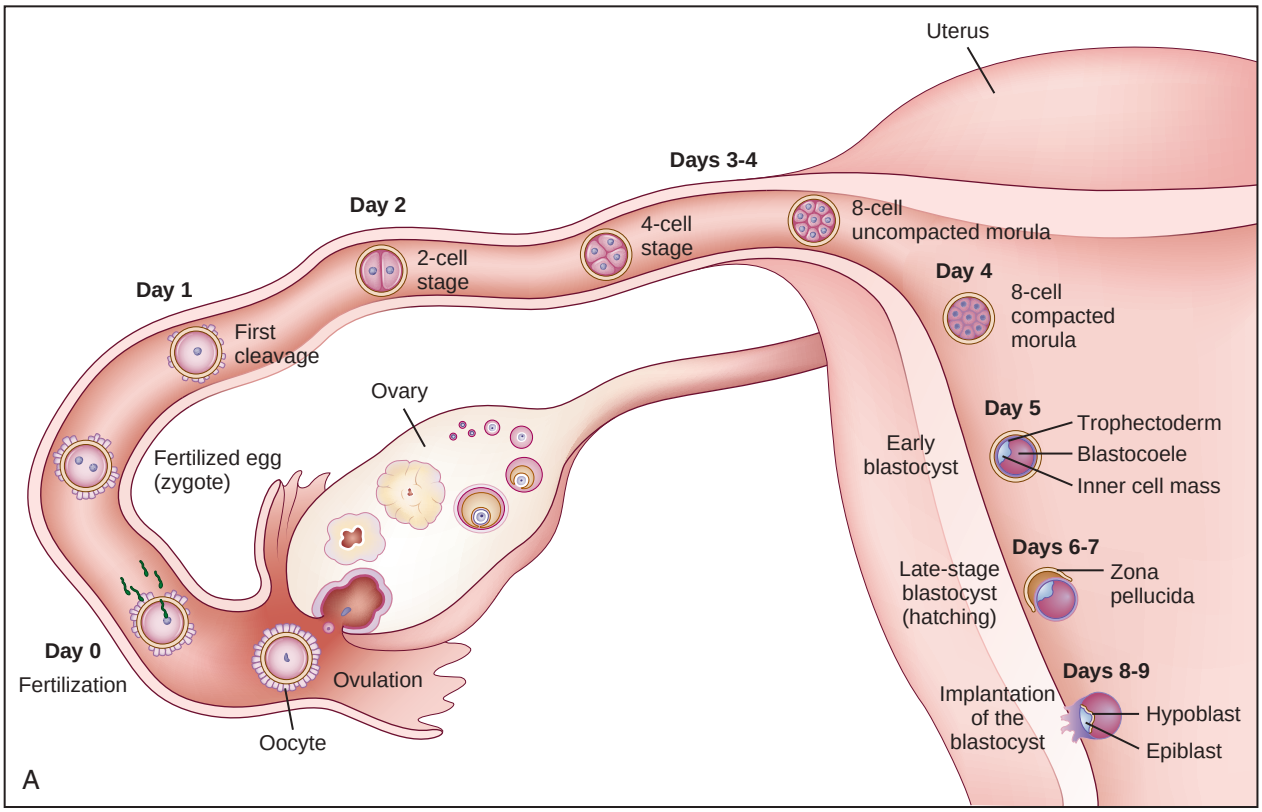
THE EMBRYO AND FETUS

Pregnancy lasts approximately 10 lunar months, 9 calendar months, 40 weeks, or 280 days. Length of pregnancy is computed from the first day of the last menstrual period (LMP) until the day of birth. However, conception occurs approximately 2 weeks after the first day of the LMP. Thus the postconception age of the fetus is 2 weeks less, for a total of 266 days, or 38 weeks. Postconception age is used in the discussion of fetal development.

Intrauterine development is divided into three stages: ovum or pre-embryonic, **embryo**, and **fetus** (see Figure 9.4). The stage of the ovum lasts from conception until day 14. This period covers cellular replication, blastocyst formation, initial development of the embryonic membranes, and establishment of the primary germ layers.

Primary Germ Layers

During the third week after conception, the embryonic disk differentiates into three primary germ layers: the ectoderm, mesoderm, and endoderm (or entoderm) (see Figure 9.8, *B*). All tissues and organs of the embryo develop from these three layers.



The *ectoderm*, the upper layer of the embryonic disk, gives rise to the epidermis, glands (anterior pituitary, cutaneous, and mammary), nails and hair, central and peripheral nervous systems, lens of the eye, tooth enamel, and floor of the amniotic cavity.

The *mesoderm*, the middle layer, develops into the bones and teeth, muscles (skeletal, smooth, and cardiac), dermis and connective tissue, cardiovascular system and spleen, and urogenital system.

The *endoderm*, the lower layer, gives rise to the epithelium lining of the respiratory and digestive tracts, including the oropharynx, liver and pancreas, urethra, bladder, and vagina. The endoderm forms the roof of the yolk sac.

Development of the Embryo

The stage of the embryo lasts from day 15 until approximately 8 weeks after conception, when the embryo measures approximately 3 cm from crown to rump. The embryonic stage is the most critical time in the development of the organ systems and the main external features.

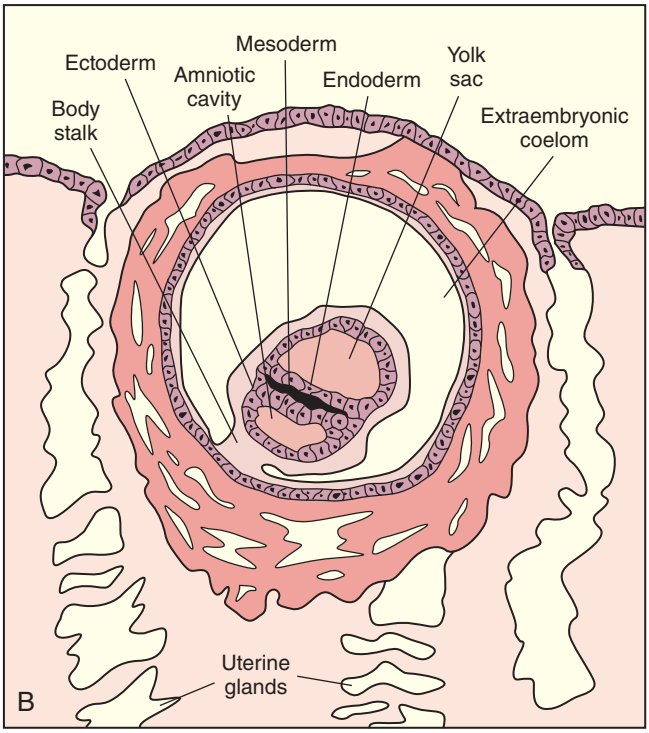


Fig. 9.8 **A:** First days of human development. Follicular development in ovary, ovulation, fertilization, and transport of early embryo down the uterine tube and into the uterus, where implantation occurs. **B:** Blastocyst embedded in the endometrium. Germ layers are forming. (*A:* From Creasy, R. K., Resnik, R., Iams, J. D., et al. [Eds.]. [2014]. *Creasy & Resnik's maternal-fetal medicine: Principles and practice* [7th ed.]. Elsevier. *B:* Adapted from Langley, L., Rockford, I. R., & Christensen, J. B. [1980]. *Dynamic human anatomy and physiology* [5th ed.]. McGraw-Hill.)

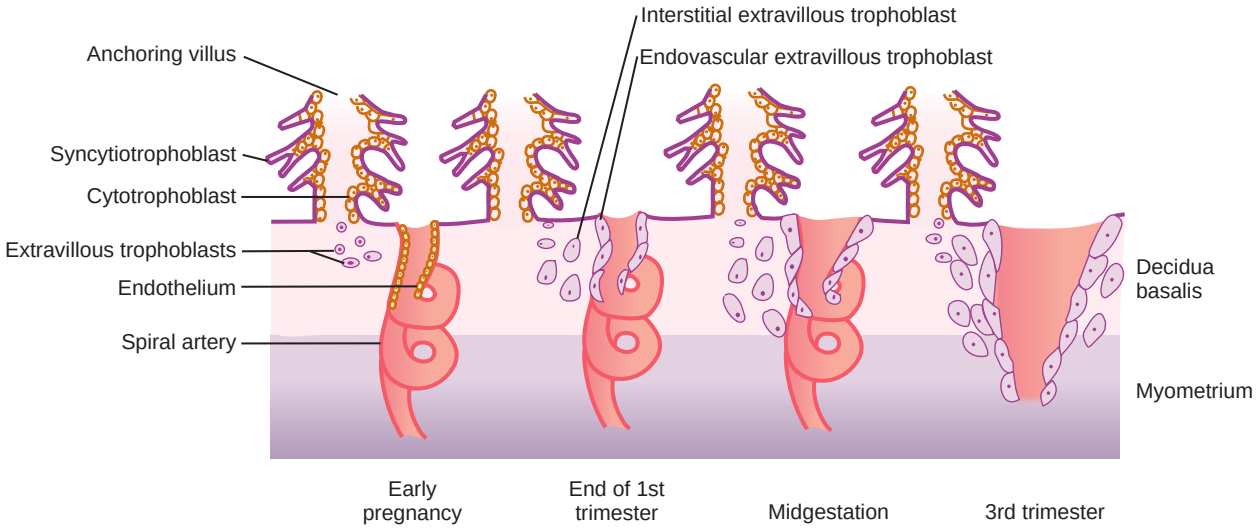

Fig. 9.9 Extravillous trophoblasts are found outside the villus and can be subdivided into endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries. (From Cunningham, F., Leveno, K., Bloom, S., et al. [2014]. *Williams obstetrics* [24th ed.]. McGraw-Hill.)

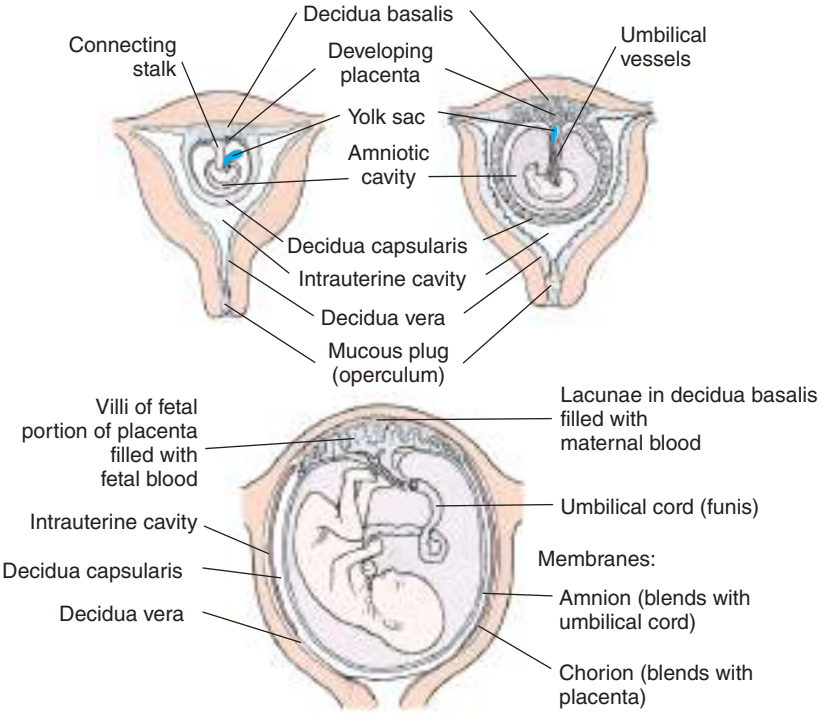

Fig. 9.10 Development of fetal membranes. Note gradual obliteration of intrauterine cavity as decidua capsularis and decidua vera meet. Also note thinning of uterine wall. Chorionic and amnionic membranes are in apposition to each other but may be peeled apart.

Developing areas with rapid cell division are the most vulnerable areas to malformation caused by environmental teratogens (substances or exposure that causes abnormal development). At the end of the eighth week, all organ systems and external structures are present, and the embryo is unmistakably human (see Figure 9.4).

Membranes

At the time of implantation, two fetal membranes that will surround the developing embryo begin to form. The *chorion* develops from the trophoblast and contains the chorionic villi on its surface. The villi burrow into the decidua basalis and increase in size and complexity as the vascular processes develop into the placenta. The chorion becomes the covering of the fetal side of the placenta. It contains the major umbilical blood vessels that branch out over the surface of the placenta. As the embryo grows, the decidua capsularis stretches. The chorionic villi on this side atrophy and degenerate, leaving a smooth chorionic membrane.

The inner cell membrane, the *amnion*, develops from the interior cells of the blastocyst. The cavity that develops between this inner cell

mass and the outer layer of cells (trophoblast) is the *amniotic cavity* (see Figure 9.8, *B*). As it grows larger, the amnion forms on the side opposite the developing blastocyst (see Figure 9.8, *B*, and Figure 9.10). The developing embryo draws the amnion around itself to form a fluid-filled sac. The amnion becomes the covering of the umbilical cord and covers the chorion on the fetal surface of the placenta. As the embryo grows larger, the amnion enlarges to accommodate the embryo, then the fetus and the surrounding amniotic fluid. The amnion eventually comes in contact with the chorion surrounding the fetus.

Amniotic Fluid

At first the amniotic cavity derives its fluid by diffusion from the maternal blood. Fluid secreted by the respiratory and gastrointestinal tracts of the fetus also enters the amniotic cavity. The amount of fluid increases weekly, and 700 to 1 000 mL of transparent liquid is normally present at term. The volume of amniotic fluid changes constantly. The fetus swallows fluid, and fluid flows into and out of the fetal lungs. Beginning in week 11, the fetus urinates into the fluid, increasing the volume.

The amniotic fluid serves many functions for the embryo and fetus including the following:

- Maintaining a constant body temperature
- Preventing the embryo from tangling with the membranes, facilitating symmetrical growth. If the embryo does become tangled with the membranes, amputations of extremities or other deformities can occur from constricting amniotic bands.
- Acting as a barrier to infection
- Allowing freedom of movement for musculoskeletal development
- Acting as a cushion to protect the fetus and the umbilical cord from trauma by blunting and dispersing outside forces
- Serving as a source of oral fluid and as a repository for waste
- Enhancing fetal lung development

The volume of amniotic fluid is an important factor in assessing fetal well-being. Having less than 300 mL of amniotic fluid (**oligohydramnios**) is associated with fetal renal abnormalities. Having more than 2 L of amniotic fluid *(polyhydramnios)* is associated with gastrointestinal and other malformations.

Amniotic fluid contains albumin, urea, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, fructose, fat, leukocytes, proteins, epithelial cells, enzymes, and lanugo hair. Study of fetal cells in amniotic fluid through amniocentesis yields much information about the fetus.

Yolk Sac

At the same time the amniotic cavity and amnion are forming, another blastocyst cavity forms on the other side of the developing embryonic disk (see Figure 9.8, *B*). This cavity becomes surrounded by a membrane, forming the yolk sac. The *yolk sac* aids in transferring maternal nutrients and oxygen, which have diffused through the chorion, to the embryo. Blood vessels form to aid transport. Blood cells and plasma are manufactured in the yolk sac during the second and third weeks while uteroplacental circulation is being established and forming primitive blood cells until hematopoietic activity begins. At the end of the third week, the primitive heart begins to beat and circulate the blood through the embryo, connecting stalk, chorion, and yolk sac.

The folding in of the embryo during the fourth week results in incorporation of part of the yolk sac into the body of the embryo as the primitive digestive system. Primordial germ cells arise in the yolk sac and move into the embryo. The shrinking remains of the yolk sac degenerate (see Figure 9.8, *B*), and by the fifth or sixth week the remnant has separated from the embryo.

Umbilical Cord

By day 14 after conception, the embryonic disk, amniotic sac, and yolk sac are attached to the chorionic villi by the connecting stalk. During the third week, the blood vessels develop to supply the embryo with maternal nutrients and oxygen. During the fifth week, the embryo has curved inward on itself from both ends, bringing the connecting stalk to the ventral side of the embryo. The connecting stalk becomes compressed from both sides by the amnion and forms the narrower umbilical cord (see Figure 9.10). Two arteries carry blood from the embryo to the chorionic villi, and one vein returns blood to the embryo. Approximately 1% of umbilical cords contains only two vessels: one artery and one vein. This occurrence is sometimes associated with congenital malformations.

The cord rapidly increases in length. At term the cord is 2 cm in diameter and ranges from 30 to 90 cm in length (with an average of 55 cm). It twists spirally on itself and loops around the embryo or fetus. A true knot is rare, but false knots occur as folds or kinks in the cord and may jeopardize circulation to the fetus. Connective tissue called *Wharton's jelly* prevents compression of the blood vessels and ensures continued nourishment of the embryo and fetus. Compression can occur if the cord lies between the fetal head and the pelvis or is twisted around the fetal body. When the cord is wrapped around the fetal neck, it is called a **nuchal cord**.

Because the placenta develops from the chorionic villi, the umbilical cord is usually located centrally. The blood vessels are arrayed out from the centre to all parts of the placenta (Figure 9.11, *B*). A peripheral location is less common and is known as a *battledore placenta* (see Figure 14.14, *B*).

Placenta

Structure. The placenta begins to form at implantation. During the third week after conception, the trophoblast cells of the chorionic villi continue to invade the decidua basalis. As the uterine capillaries are tapped, the endometrial spiral arteries fill with maternal blood. The chorionic villi grow into the spaces with two layers of cells: the outer syncytium and the inner cytotrophoblast. A third layer develops into anchoring septa, dividing the projecting decidua into separate areas called *cotyledons*. In each of the 15 to 20 cotyledons the chorionic villi branch out, and a complex system of fetal blood vessels forms. Each cotyledon is a functional unit. The whole structure is the placenta (see Figure 9.11).

The maternal–placental–embryonic circulation is in place by day 17, when the embryonic heart starts beating. By the end of the third week, embryonic blood is circulating between the embryo and the chorionic villi. In the intervillous spaces, maternal blood supplies oxygen and nutrients to the embryonic capillaries in the villi (Figure 9.12). Waste products and carbon dioxide diffuse into the maternal blood.

The placenta functions as a means of metabolic exchange. Exchange is minimal at this time because the two cell layers of the villous membrane are too thick. Permeability increases as the cytotrophoblast thins and disappears; by the fifth month only the single layer of syncytium is left between the maternal blood and the fetal capillaries. The syncytium is the functional layer of the placenta. By the eighth week, genetic testing may be done on a sample of chorionic villi obtained by aspiration biopsy; however, limb defects have been associated with chorionic villi sampling done before 10 weeks (see Chapter 13). The structure of the placenta is complete by the twelfth week. The placenta continues to grow wider until 20 weeks, when it covers about half of the uterine surface. It then continues to grow thicker. The branching villi continue to develop within the body of the placenta, increasing the functional surface area.

Functions. One of the early functions of the placenta is as an endocrine gland that produces four hormones necessary to maintain the pregnancy and support the embryo and fetus. The hormones are produced in the syncytium.

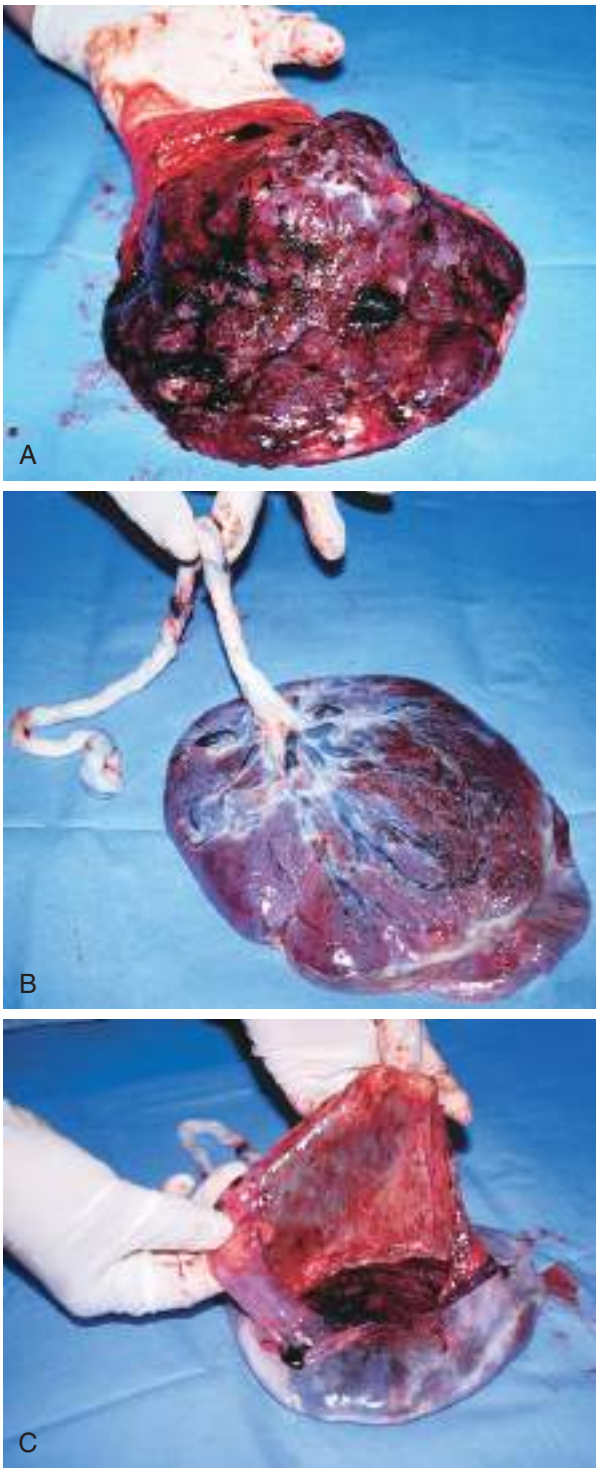

Fig. 9.11 Full-term placenta. **A:** Maternal (or uterine) surface, showing cotyledons and grooves. **B:** Fetal (or amniotic) surface, showing blood vessels running under amnion and converging to form umbilical vessels at attachment of umbilical cord. **C:** Amnion and smooth chorion are arranged to show that they are (1) fused and (2) continuous with margins of placenta. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

The protein hormone human chorionic gonadotropin (hCG) can be detected in the maternal serum by 8 to 10 days after conception, shortly after implantation. This hormone is the basis for pregnancy tests. The hCG preserves the function of the ovarian corpus luteum, ensuring a continued supply of estrogen and progesterone needed to maintain the pregnancy. Miscarriage occurs if the corpus luteum stops functioning before the placenta can produce sufficient estrogen and progesterone. The hCG reaches its maximum level at 50 to 70 days and then begins to decrease.

The other protein hormone produced by the placenta is human placental lactogen (hPL), also known as human chorionic somatomammotropin (hCS). This substance is similar to a growth hormone and stimulates maternal metabolism to supply needed nutrients for fetal growth. This hormone increases the resistance to insulin, facilitates glucose transport across the placental membrane, and stimulates maternal breast development to prepare for lactation (Figure 9.13).

The placenta eventually produces more of the steroid hormone progesterone than the corpus luteum does during the first few months of pregnancy. Progesterone maintains the endometrium, decreases the contractility of the uterus, and stimulates maternal metabolism and development of breast alveoli.

By 7 weeks after fertilization, the placenta is producing most of the maternal estrogens, which are steroid hormones. The major estrogen secreted by the placenta is estriol, whereas the ovaries produce mostly estradiol. Measuring estriol levels is a clinical assay for placental functioning. Estrogen stimulates uterine growth and uteroplacental blood flow. It causes a proliferation of the breast glandular tissue and stimulates myometrial contractility. Placental estrogen production increases greatly toward the end of pregnancy. One theory for the cause of the onset of labour is the decrease in circulating levels of progesterone and the increased levels of estrogen (Figure 9.14).

The metabolic functions of the placenta are respiration, nutrition, excretion, and storage. Oxygen diffuses from the maternal blood across the placental membrane into the fetal blood, and carbon dioxide diffuses in the opposite direction. In this way, the placenta functions as a lung for the fetus.

Carbohydrates, proteins, calcium, and iron are stored in the placenta for ready access to meet fetal needs. Water, inorganic salts, carbohydrates, proteins, fats, and vitamins pass from the maternal blood supply across the placental membrane into the fetal blood, supplying nutrition. Water and most electrolytes with a molecular weight less than 500 readily diffuse through the membrane. Hydrostatic and osmotic pressures aid in the flow of water and some solutions. Facilitated and active transport assist in the transfer of glucose, amino acids, calcium, iron, and substances with higher molecular weights. Amino acids and calcium are transported against the concentration gradient between the maternal blood and fetal blood.

The fetal concentration of glucose is lower than the glucose level in the maternal blood because of its rapid metabolism by the fetus. This fetal requirement demands larger concentrations of glucose than simple diffusion can provide. Therefore, maternal glucose moves into the fetal circulation by active transport.

Pinocytosis is a mechanism used for transferring large molecules such as albumin and gamma (γ) globulins across the placental membrane. This mechanism conveys the maternal immunoglobulins that provide early passive immunity to the fetus.

Metabolic waste products of the fetus cross the placental membrane from the fetal blood into the maternal blood. The maternal kidneys then excrete them. Many viruses can cross the placental membrane and infect the fetus. Some bacteria and protozoa first infect the placenta and then infect the fetus. Medications can also cross the placental membrane and may harm the fetus. Caffeine, alcohol, nicotine, carbon monoxide and other toxic substances in cigarette smoke, and prescription and recreational drugs (such as cannabis and cocaine) readily cross the placenta.

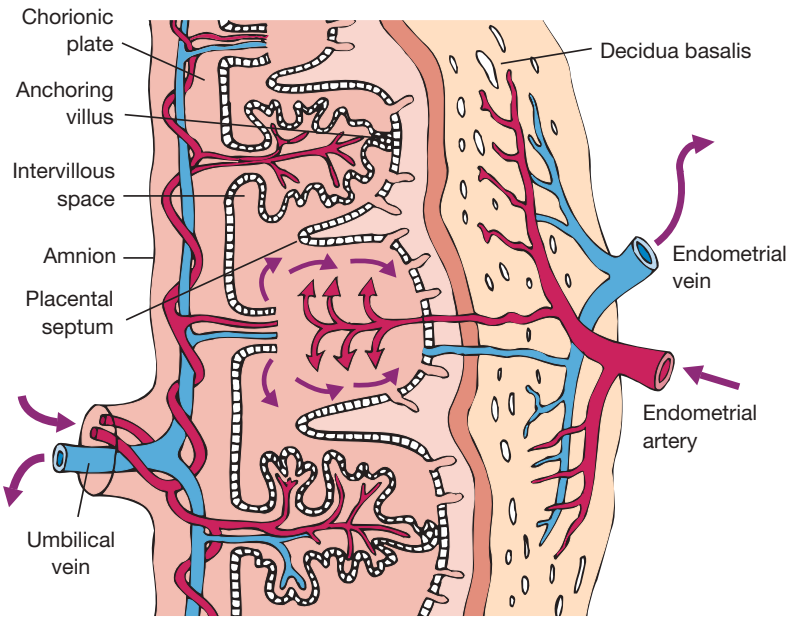

Fig. 9.12 Schematic drawing of the placenta illustrating how it supplies oxygen and nutrition to the embryo and removes its waste products. Deoxygenated blood leaves the fetus through the umbilical arteries and enters the placenta, where it is oxygenated. Oxygenated blood leaves the placenta through the umbilical vein, which enters the fetus via the umbilical cord.

Although no direct link exists between the fetal blood in the vessels of the chorionic villi and the maternal blood in the intervillous spaces, only one cell layer separates them. Breaks occasionally occur in the placental membrane. Fetal erythrocytes then leak into the maternal circulation, and the pregnant patient may develop antibodies to the fetal red blood cells. This is often the way the Rh-negative patient becomes sensitized to the erythrocytes of their Rh-positive fetus. (See discussion of isoimmunization in Chapter 29.)

Although the placenta and fetus are analogous to living tissue transplants, they are not destroyed by the host mother. Either the placental hormones suppress the immunological response or the tissue evokes no response.

Placental function depends on the maternal blood pressure supplying the circulation. Maternal arterial blood, under pressure in the small uterine spiral arteries, spurts into the intervillous spaces (see Figure 9.12). As long as rich arterial blood continues to be supplied, pressure is exerted on the blood already in the intervillous spaces, pushing it toward drainage by the low-pressure uterine veins. At term gestation, 10% of the pregnant person's cardiac output goes to the uterus.

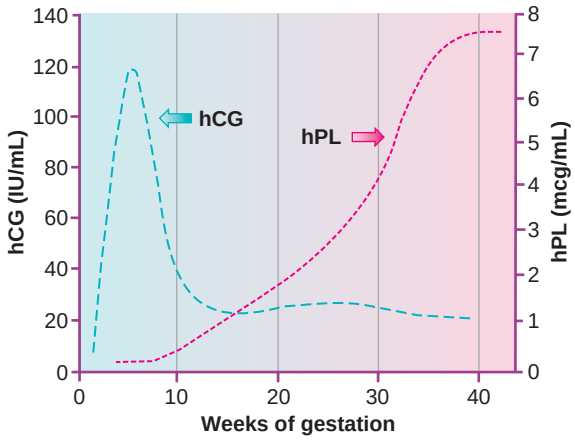

Fig. 9.13 Distinct profile for the concentrations of human chorionic gonadotropin (hCG) and human placental lactogen (hPL) in serum of women through normal pregnancy. *IU,* International Units. If there is interference with the circulation to the placenta, the placenta cannot supply the embryo or fetus. Vasoconstriction such as that caused by hypertension or cocaine use diminishes uterine blood flow. Decreased maternal blood pressure or decreased cardiac output also diminishes uterine blood flow.

When a pregnant patient lies on their back with the pressure of the uterus compressing the vena cava, blood return to the right atrium is diminished. (See Figure 17.4 and the discussion of supine hypotension in Chapter 11.) Excessive exercise in the pregnant patient that diverts blood to the muscles away from the uterus compromises placental circulation. Optimum circulation is achieved when the patient is lying at rest on their side. Decreased uterine circulation may lead to intrauterine growth restriction of the fetus and infants who are small for gestational age.

Uterine contractions seem to enhance the movement of blood through the intervillous spaces, aiding placental circulation. However, prolonged contractions or too-short intervals between contractions during labour can reduce blood flow to the placenta.

Fetal Maturation

This stage of the fetus lasts from 9 weeks (when the fetus becomes recognizable as a human being) until the pregnancy ends. Changes during the fetal period are not as dramatic because refinement of structure and function is taking place. The fetus is less vulnerable to teratogens, except for those that affect central nervous system functioning.

Viability refers to the capability of the fetus to survive outside the uterus. With modern technology and advances in maternal and neonatal care, infants who are 22 to 25 weeks of gestation are now considered to be on the threshold of viability (Lemyre et al., 2017). The limitations on survival outside the uterus when an infant is born at this early stage

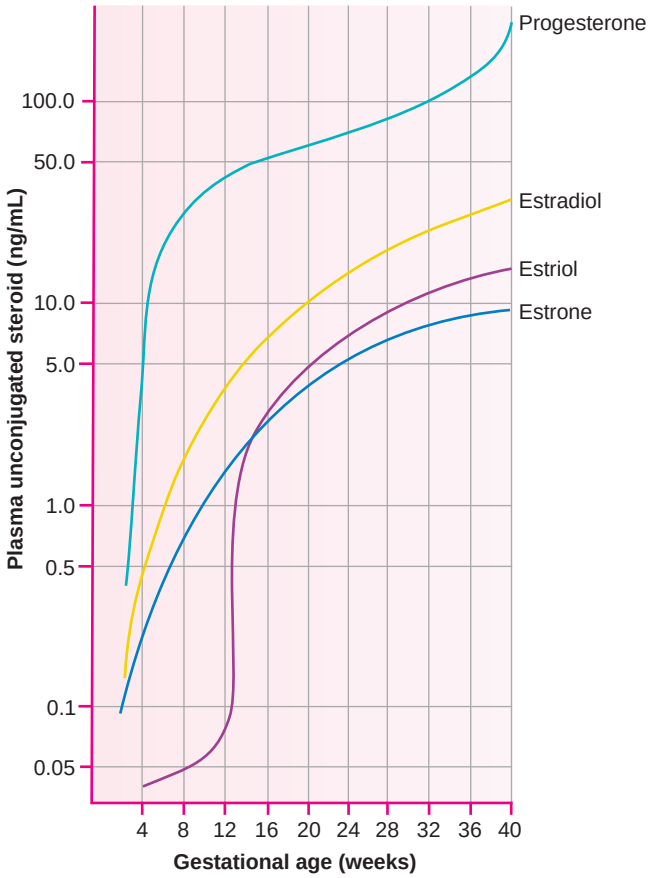

Fig. 9.14 Plasma levels of progesterone, estradiol, estrone, and estriol in women during the course of gestation. are based on central nervous system function and oxygenation capability of the lungs.

Respiratory System. The respiratory system begins development during embryonic life and continues through fetal life and into childhood. The development of the respiratory tract begins in week 4 and continues through week 17 with formation of the larynx, trachea, bronchi, and lung buds. Between 16 and 24 weeks, the bronchi and terminal bronchioles enlarge, and vascular structures and primitive alveoli are formed. Between 24 weeks and term birth, more alveoli form. Specialized alveolar cells, type I and type II cells, secrete pulmonary surfactants to line the interior of the alveoli. After 32 weeks sufficient surfactant is present in developed alveoli to provide newborns with a good chance of survival.

Pulmonary surfactants. The detection of the presence of pulmonary **surfactants**, surface-active phospholipids, in amniotic fluid has been used to determine the degree of fetal lung maturity, or the ability of the lungs to function after birth. Lecithin (L) is the most critical alveolar surfactant required for postnatal lung expansion. It is detectable at approximately 21 weeks and increases in amount after week 24. Another pulmonary phospholipid, sphingomyelin (S), remains constant in amount. Thus the measure of lecithin in relation to sphingomyelin, or the L/S ratio, is used to determine fetal lung maturity. When the L/S ratio reaches 2:1, the infant's lungs are considered to be mature. This occurs at approximately 35 weeks of gestation (Kamath-Rayne & Jobe, 2019).

Certain maternal conditions that cause decreased maternal placental blood flow, such as hypertension, placental dysfunction, infection, or corticosteroid use, accelerate lung maturity. This apparently is caused by the resulting fetal hypoxia, which stresses the fetus and increases the blood levels of corticosteroids that accelerate alveolar and surfactant development.

Conditions such as gestational diabetes and chronic glomerulonephritis can delay fetal lung maturity. The use of intrabronchial synthetic surfactant in the treatment of respiratory distress syndrome in the newborn has greatly improved the chances of survival for preterm infants (see Chapter 28).

Fetal respiratory movements have been seen on ultrasound examination as early as week 11. These fetal respiratory movements may aid in development of the chest wall muscles and regulate lung fluid volume. The fetal lungs produce fluid that expands the air spaces in the lungs. The fluid drains into the amniotic fluid or is swallowed by the fetus.

Shortly before birth, secretion of lung fluid decreases. The normal birth process squeezes out approximately one third of the fluid. Infants born by Caesarean do not benefit from this squeezing process; thus they may have more respiratory difficulty at birth. The fluid remaining in the lungs at birth is usually resorbed into the infant's bloodstream within 2 hours of birth.

Circulatory System. The cardiovascular system is the first organ system to function in the developing human. Blood vessel and blood cell formation begins in the third week and supplies the embryo with oxygen and nutrients from the mother. By the end of the third week, the tubular heart begins to beat, and the primitive cardiovascular system links the embryo, connecting stalk, chorion, and yolk sac. During the fourth and fifth weeks, the heart develops into a four-chambered organ. By the end of the embryonic stage, the heart is developmentally complete.

The fetal lungs do not function for respiratory gas exchange; thus a special circulatory pathway, the ductus arteriosus, bypasses the lungs. Oxygen-rich blood from the placenta flows rapidly through the umbilical vein into the fetal abdomen (Figure 9.15). When the umbilical vein reaches the liver, it divides into two branches. One branch circulates some oxygenated blood through the liver. Most of the blood passes through the ductus venosus into the inferior vena cava. There it mixes with the deoxygenated blood from the fetal legs and abdomen on its way to the right atrium. Most of this blood passes straight through the right atrium and through the foramen ovale, an opening into the left atrium. There it mixes with the small amount of deoxygenated blood returning from the fetal lungs through the pulmonary veins.

The blood flows into the left ventricle and is squeezed out into the aorta, where the arteries supplying the heart, head, neck, and arms receive most of the oxygen-rich blood. This pattern of supplying the highest levels of oxygen and nutrients to the head, neck, and arms enhances the **cephalocaudal** (head-to-rump) development of the embryo and fetus.

Deoxygenated blood returning from the head and arms enters the right atrium through the superior vena cava. This blood is directed downward into the right ventricle, where it is squeezed into the pulmonary artery. A small amount of blood circulates through the resistant lung tissue, but the majority follows the path with less resistance through the ductus arteriosus into the aorta, distal to the point of exit of the arteries supplying the head and arms with oxygenated blood. The oxygen-poor blood flows through the abdominal aorta into the internal

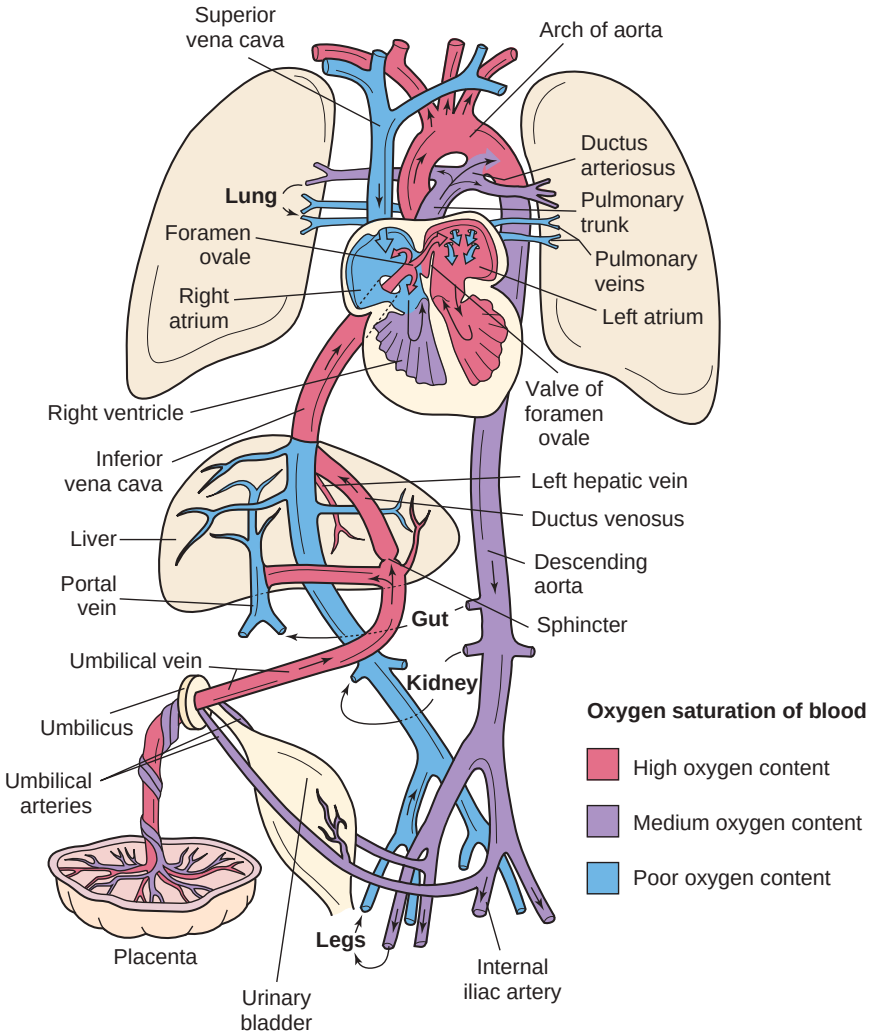

Fig. 9.15 Schematic illustration of fetal circulation. The *colours* indicate the oxygen saturation of the blood, and the *arrows* show the course of the blood from the placenta to the heart. The organs are not drawn to scale. Observe that three shunts permit most of the blood to bypass the liver and lungs: (1) ductus venosus, (2) foramen ovale, and (3) ductus arteriosus. The poorly oxygenated blood returns to the placenta for oxygen and nutrients through the umbilical arteries. (From Moore, K. L., Persaud, T. V. N., & Torchia, M. G. [2013]. *Before we are born: Essentials of embryology and birth defects* [8th ed.]. Saunders.)

iliac arteries, where the umbilical arteries direct most of it back through the umbilical cord to the placenta. There the blood gives up its wastes and carbon dioxide in exchange for nutrients and oxygen. The blood remaining in the iliac arteries flows through the fetal abdomen and legs, ultimately returning through the inferior vena cava to the heart.

The following three special characteristics enable the fetus to obtain sufficient oxygen from the maternal blood:

- Fetal hemoglobin carries 20 to 30% more oxygen than maternal hemoglobin.
- The hemoglobin concentration of the fetus is about 50% greater than that of the mother.
- The fetal heart rate is 110 to 160 beats per minute, making the cardiac output per unit of body weight higher than that of an adult.

Hematopoietic System. **Hematopoiesis**, the formation of blood, occurs in the yolk sac (see Figure 9.8, *B*), beginning in the third week. Hematopoietic stem cells seed the fetal liver during the fifth week, and hematopoiesis begins there during the sixth week. This accounts for the relatively large size of the liver between the seventh and ninth weeks. Stem cells seed the fetal bone marrow, spleen and thymus, and lymph nodes between weeks 8 and 11.

The antigenic factors that determine blood type are present in the erythrocytes soon after the sixth week. For this reason, the Rh-negative patient is at risk for isoimmunization in any pregnancy that lasts longer than 6 weeks after fertilization.

Gastrointestinal System. During the fourth week, the shape of the embryo changes from being almost straight to a C shape as both ends fold in toward the ventral surface. A portion of the yolk sac is incorporated into the body from head to tail as the primitive gut (digestive system).

The foregut produces the pharynx, part of the lower respiratory tract, the esophagus, the stomach, the first half of the duodenum, the liver, the pancreas, and the gallbladder. These structures evolve during the fifth and sixth weeks. Malformations that can occur in these areas include esophageal atresia, hypertrophic pyloric stenosis, duodenal stenosis or atresia, and biliary atresia (see Chapter 46).

The midgut becomes the distal half of the duodenum, the jejunum and ileum, the cecum and appendix, and the proximal half of the colon. The midgut loop projects into the umbilical cord between weeks 5 and 10. A malformation, *omphalocele*, results if the midgut fails to return to the abdominal cavity, causing the intestines to protrude from the umbilicus. Meckel diverticulum is the most common malformation of the midgut. It occurs when a remnant of the yolk stalk that has failed to degenerate attaches to the ileum, leaving a blind sac.

The hindgut develops into the distal half of the colon, the rectum and parts of the anal canal, the urinary bladder, and the urethra. Anorectal malformations are the most common abnormalities of the digestive system.

The fetus swallows amniotic fluid beginning in the fifth month. Gastric emptying and intestinal peristalsis occur. Fetal nutrition and elimination needs are taken care of by the placenta. As the fetus nears term, fetal waste products accumulate in the intestines as dark green–to-black, tarry meconium. Normally this substance is passed through the rectum within 24 hours of birth. Sometimes with a breech presentation or fetal hypoxia, meconium is passed in utero into the amniotic fluid. The failure to pass meconium after birth may indicate atresia somewhere in the digestive tract; an imperforate anus (see Figure 46.12); or meconium ileus, in which a firm meconium plug blocks passage (seen in infants with CF).

The metabolic rate of the fetus is relatively low, but the infant has great growth and development needs. Beginning in week 9, the fetus synthesizes glycogen for storage in the liver. Between 26 and 30 weeks, the fetus begins to lay down stores of brown fat in preparation for extrauterine cold stress. Thermoregulation in the newborn requires increased metabolism and adequate oxygenation.

The gastrointestinal system is mature by 36 weeks. Digestive enzymes (except pancreatic amylase and lipase) are present in sufficient quantity to facilitate digestion. The newborn cannot digest starches or fats efficiently. Little saliva is produced.

Hepatic System. The liver and biliary tract develop from the foregut during the fourth week of gestation. The embryonic liver is prominent, occupying most of the abdominal cavity. Bile, a constituent of meconium, begins to form in the twelfth week.

Glycogen is stored in the fetal liver beginning at week 9 or 10. At term, glycogen stores are twice those of the adult. Glycogen is the major source of energy for the fetus and for the newborn stressed by in utero hypoxia, extrauterine loss of the maternal glucose supply, the work of breathing, or cold stress.

Iron is also stored in the fetal liver. If maternal intake is sufficient, the fetus can store enough iron to last for 6 months after birth.

During fetal life the liver does not have to conjugate bilirubin for excretion because the unconjugated bilirubin is cleared by the placenta. Therefore, the glucuronyl transferase enzyme needed for conjugation is present in the fetal liver in amounts less than those required after birth. This predisposes the newborn, especially the preterm infant, to hyperbilirubinemia.

Coagulation factors II, VII, IX, and X cannot be synthesized in the fetal liver because of the lack of vitamin K synthesis in the sterile fetal gut. This coagulation deficiency persists after birth for several days and is the rationale for the prophylactic administration of vitamin K to the newborn.

Renal System. The kidneys form during the fifth week and begin to function approximately 4 weeks later. Urine is excreted into the amniotic fluid and forms a major part of the amniotic fluid volume. Oligohydramnios is indicative of renal dysfunction. Because the placenta acts as the organ of excretion and maintains fetal water and electrolyte balance, the fetus does not need functioning kidneys while in utero. However, at birth the kidneys are required immediately for excretory and acid–base regulatory functions.

A fetal renal malformation can be diagnosed in utero. Corrective or palliative fetal surgery may treat the malformation successfully, or plans can be made for treatment immediately after birth.

At term the fetus has fully developed kidneys. However, the glomerular filtration rate (GFR) is low, and the kidneys lack the ability to concentrate urine. This makes the newborn more susceptible to both overhydration and dehydration.

Neurological System. The nervous system originates from the ectoderm during the third week after fertilization. The open neural tube forms during the fourth week. It initially closes at what will be the junction of the brain and spinal cord, leaving both ends open. The embryo folds in on itself lengthwise at this time, forming a head fold in the neural tube at this junction. The cranial end of the neural tube closes, then the caudal end closes. During week 5, different growth rates cause more flexures in the neural tube, delineating three brain areas: the forebrain, midbrain, and hindbrain.

The *forebrain* develops into the eyes (cranial nerve II) and cerebral hemispheres. The development of all areas of the cerebral cortex continues throughout fetal life and into childhood. The olfactory system (cranial nerve I) and thalamus also develop from the forebrain. Cranial nerves III and IV (oculomotor and trochlear) form from the *midbrain*. The *hindbrain* forms the medulla, the pons, the cerebellum, and the remainder of the cranial nerves. Brain waves can be recorded on an electroencephalogram by week 8.

The spinal cord develops from the long end of the neural tube. Another ectodermal structure, the neural crest, develops into the peripheral nervous system. By the eighth week, nerve fibres traverse throughout the body. By week 11 or 12, the fetus makes respiratory movements, moves all extremities, and changes position in utero. The fetus can suck their thumb, swim in the amniotic fluid pool, and turn somersaults and can occasionally tie a knot in the umbilical cord.

At term, the fetal brain is approximately one fourth the size of an adult brain. Neurological development continues. Stressors on the fetus and newborn (e.g., chronic poor nutrition or hypoxia, drugs, environmental toxins, trauma, disease) damage the central nervous system long after the vulnerable embryonic time for malformations in other organ systems. Neurological insult can result in neuromuscular impairment, intellectual disability, learning disabilities, and occasionally cerebral palsy.

Sensory awareness. Purposeful movements of the fetus have been demonstrated in response to a firm touch transmitted through the pregnant person's abdomen. Because it can feel, the fetus requires anaesthesia when invasive procedures are done.

Fetuses respond to sound by 24 weeks. Different types of music evoke different movements. The fetus can be soothed by the sound of the parent's voice. Acoustic stimulation can be used to evoke a fetal heart rate response. The fetus becomes accustomed (habituates) to noises heard repeatedly. Hearing is fully developed at birth.

The fetus is able to distinguish taste. By the fifth month, when the fetus is swallowing amniotic fluid, a sweetener added to the fluid causes the fetus to swallow faster. The fetus also reacts to temperature changes. A cold solution placed into the amniotic fluid can cause fetal hiccups.

The fetus can see. Eyes have both rods and cones in the retina by the seventh month. A bright light shone on the mother's abdomen in late pregnancy causes abrupt fetal movements. During sleep time rapid eye movements have been observed similar to those occurring in children and adults while dreaming.

Endocrine System. The thyroid gland develops along with structures in the head and neck during the third and fourth weeks. The secretion of thyroxine begins during the eighth week. Maternal thyroxine does not readily cross the placenta; therefore, the fetus that does not produce thyroid hormones will be born with congenital hypothyroidism. If untreated, hypothyroidism can result in severe developmental delay. Screening for hypothyroidism is included in the newborn screening done after birth.

The adrenal cortex is formed during the sixth week and produces hormones by the eighth or ninth week. As term approaches, the fetus produces more cortisol. This is believed to aid in initiation of labour by decreasing the maternal progesterone and stimulating production of prostaglandins.

The pancreas forms from the foregut during the fifth through eighth weeks. The islets of Langerhans develop during the twelfth week. Insulin is produced by week 20. In infants of mothers with uncontrolled diabetes, maternal hyperglycemia produces fetal hyperglycemia, stimulating hyperinsulinemia and islet cell hyperplasia. This results in a macrosomic (large-size) fetus. The hyperinsulinemia also blocks lung maturation, placing the newborn at risk for respiratory distress and hypoglycemia when the parental glucose source is lost at birth. Control of the glucose level before and during pregnancy minimizes concerns for the fetus and newborn.

Reproductive System. Sex differentiation begins in the embryo during the seventh week. Female and male external genitalia are indistinguishable until after the ninth week. Distinguishing characteristics appear around the ninth week and are fully differentiated by the twelfth week. When a Y chromosome is present, testes are formed. By the end of the embryonic period, testosterone is being secreted and causes formation of the male genitalia. By week 28, the testes begin descending into the scrotum. After birth, low levels of testosterone continue to be secreted until the pubertal surge.

The female, with two X chromosomes, forms ovaries and female external genitalia. By the sixteenth week, oogenesis has been established. At birth, the ovaries contain the female's lifetime supply of ova. Most female hormone production is delayed until puberty. However, the fetal endometrium responds to maternal hormones, and withdrawal bleeding or vaginal discharge (**pseudomenstruation**) may occur at birth when these hormones are lost. The high level of estrogen in the pregnant parent also stimulates mammary engorgement and secretion of fluid in newborn infants of both sexes.

Musculoskeletal System. Bones and muscles develop from *somites*, which are masses of mesoderm, by the fourth week of embryonic development. The mesoderm next to the neural tube forms the vertebral column and ribs. The parts of the vertebral column grow toward each other to enclose the developing spinal cord. *Ossification*, or bone formation, begins. If there is a defect in the bony fusion, various forms of spina bifida may occur. A large defect affecting several vertebrae may allow the membranes and spinal cord to pouch out from the back, producing neurological deficits and skeletal deformity.

The flat bones of the skull develop during the embryonic period, and ossification continues throughout childhood. At birth, connective tissue sutures exist where the bones of the skull meet. The areas where more than two bones meet (called **fontanels**) are especially prominent. The sutures and fontanels allow the bones of the skull to mould, or move during birth, enabling the head to pass through the birth canal.

The bones of the shoulders, arms, hips, and legs appear in the sixth week as a continuous skeleton with no joints. Differentiation occurs, producing separate bones and joints. Ossification continues through childhood to allow growth. Beginning in the seventh week muscles contract spontaneously. Arm and leg movements are visible on ultrasound examination, although the pregnant person usually does not perceive them until sometime between 16 and 20 weeks.

Integumentary System. The epidermis begins as a single layer of cells derived from the ectoderm at 4 weeks. By the seventh week, there are two layers of cells. The cells of the superficial layer are sloughed and become mixed with the sebaceous gland secretions to form the white, cheesy **vernix caseosa**, the material that protects the skin of the fetus. The vernix is thick at 24 weeks but becomes scant by term.

The basal layer of the epidermis is the germinal layer, which replaces lost cells. Until 17 weeks, the skin is thin and wrinkled, with blood vessels visible underneath. The skin thickens, and all layers are present at term. After 32 weeks, as subcutaneous fat is deposited under the dermis, the skin becomes less wrinkled and red in appearance.

By 16 weeks, the epidermal ridges are present on the palms of the hands, the fingers, the bottom of the feet, and the toes. These handprints and footprints are unique to that infant.

Hairs form from hair bulbs in the epidermis that project into the dermis. Cells in the hair bulb keratinize to form the hair shaft. As the cells at the base of the hair shaft proliferate, the hair grows to the surface of the epithelium. Very fine hairs, called **lanugo**, appear first at 12 weeks on the eyebrows and upper lip. By week 20 they cover the entire body. At this time, the eyelashes, eyebrows, and scalp hair are beginning to grow. By week 28, the scalp hair is longer than the lanugo, which thins and may disappear by term gestation.

Fingernails and toenails develop from thickened epidermis at the tips of the digits beginning during the tenth week. They grow slowly. Fingernails usually reach the fingertips by 32 weeks, and toenails reach toe tips by 36 weeks.

Immunological System. During the third trimester, albumin and globulin are present in the fetus. The only immunoglobulin (Ig) that crosses the placenta, IgG, provides passive acquired immunity to specific bacterial toxins. The fetus produces IgM by the end of the first trimester. This is produced in response to blood group antigens, Gram-negative enteric organisms, and some viruses. IgA is not produced by the fetus; however, **colostrum**, the precursor to breast milk, contains large amounts of IgA and can provide passive immunity to the newborn who is breastfed.

The term newborn can fight infection but not as effectively as an older child. The preterm infant is at much greater risk for infection.

Table 9.1 summarizes embryonic and fetal development.

Multifetal Pregnancy

Twins. The rate of twin births was 3.0% in 2016 with higher percentages in older women over the age of 35 (Statistics Canada, 2018). This is partly attributed to delayed childbearing. The use of artificial reproductive technologies such as ovulation-enhancing medications and in vitro fertilization (IVF) if more than one embryo is implanted is another factor.

Dizygotic twins. When two mature ova are produced in one ovarian cycle, both have the potential to be fertilized by separate sperm. This results in two zygotes, or dizygotic twins (Figure 9.16). There are always

0.4–0.5 cm; 0.4 g	2.5–3 cm; 2 g	6–9 cm; 19 g
Gastrointestinal System		
Stomach at midline and fusiform; conspicuous liver; esophagus short; intestine a short tube	Intestinal villi developing; small intestines coil within umbilical cord; palatal folds present; liver very large	Bile secreted; palatal fusion complete; intestines have withdrawn from cord and assume characteristic positions
Musculoskeletal System		
All somites present	First indication of ossification—occiput, mandible, and humerus; fetus capable of some movement; definitive muscles of trunk, limbs, and head well represented	Some bones well outlined, ossification spreading; upper cervical to lower sacral arches and bodies ossify; smooth muscle layers indicated in hollow viscera
Circulatory System		
Heart develops, double chambers visible, begins to beat; aortic arch and major veins completed	Main blood vessels assume final plan; enucleated red cells predominate in blood	Blood forming in marrow
Respiratory System		
Primary lung buds appear	Pleural and pericardial cavities forming; branching bronchioles; nostrils closed by epithelial plugs	Lungs acquire definite shape; vocal cords appear
Renal System		
Rudimentary ureteral buds appear	Earliest secretory tubules differentiating; bladder-urethra separates from rectum	Kidney able to secrete urine; bladder expands as a sac
Nervous System		
Well-marked midbrain flexure; no hindbrain or cervical flexures; neural groove closed	Cerebral cortex begins to acquire typical cells; differentiation of cerebral cortex, meninges, ventricular foramina, cerebrospinal fluid circulation; spinal cord extends along entire length of spine	Brain structural configuration almost complete; cord shows cervical and lumbar enlargements; fourth ventricle foramina are developed; sucking present
Sensory Organs		
Eye and ear appearing as optic vessel and otocyst	Primordial choroid plexuses develop; ventricles large relative to cortex; development progressing; eyes converging rapidly; internal ear developing	Earliest taste buds indicated; characteristic organization of eye attained
Genital System		
Genital ridge appears (fifth week)	Testes and ovaries distinguishable; external genitalia sexless but begin to differentiate	Sex recognizable; internal and external sex organs specific

Continued

TABLE 9.1 Milestones in Human Development Before Birth Since Last Menstrual Period—cont'd

16 Weeks	20 Weeks	24 Weeks
External Appearance Head still dominant; face looks human; eyes, ears, and nose approach typical appearance on gross examination; arm/leg ratio proportionate; scalp hair appears	Vernix caseosa appears; lanugo appears; legs lengthen considerably; sebaceous glands appear	Body lean but fairly well proportioned; skin red and wrinkled; vernix caseosa present; sweat glands forming
		
Crown-to-Rump Measurement; Weight 11.5–13.5 cm; 100 g	16–18.5 cm; 300 g	23 cm; 600 g
Gastrointestinal System Meconium in bowel; some enzyme secretion; anus open	Enamel and dentine depositing; ascending colon recognizable	
Musculoskeletal System Most bones distinctly indicated throughout body; joint cavities appear; muscular movements can be detected	Sternum ossifies; fetal movements strong enough for mother to feel	
Circulatory System Heart muscle well developed; blood formation active in spleen		Blood formation increases in bone marrow and decreases in liver
Respiratory System Elastic fibres appear in lungs; terminal and respiratory bronchioles appear	Nostrils reopen; primitive respiratory-like movements begin	Alveolar ducts and sacs present; lecithin begins to appear in amniotic fluid (wk 26–27)
Renal System Kidney in position; attains typical shape and plan		
Nervous System Cerebral lobes delineated; cerebellum assumes some prominence	Brain grossly formed; cord myelination begins; spinal cord ends at level of first sacral vertebra (S-1)	Cerebral cortex layered typically; neuronal proliferation in cerebral cortex ends
Sensory Organs General sense organs differentiated	Nose and ears ossify	Can hear
Genital System Testes in position for descent into scrotum; vagina open		Testes at inguinal ring in descent to scrotum

28 Weeks	30–31 Weeks	36 and 40 Weeks
External Appearance Lean body, less wrinkled and red; nails appear	Subcutaneous fat beginning to collect; more rounded appearance; skin pink and smooth; has assumed birth position	36 wk—Skin pink, body rounded; general lanugo disappearing; body usually plump 40 wk—Skin smooth and pink; scant vernix caseosa; moderate-to-profuse hair; lanugo on shoulders and upper body only; nasal and alar cartilage apparent
		
Crown-to-Rump Measurement; Weight 27 cm; 1100 g	31 cm; 1800–2100 g	36 wk—35 cm; 2 200–2 900 g 40 wk—40 cm; 3 200+ g

TABLE 9.1 Milestones in Human Development Before Birth Since Last Menstrual Period—cont'd

Musculoskeletal System		
Astragalus (talus, ankle bone) ossifies; weak, fleeting movements; minimum tone	Middle fourth phalanxes ossify; permanent teeth primordia seen; can turn head to side	36 wk—Distal femoral ossification centres present; sustained, definite movements; fair tone; can turn and elevate head
		40 wk—Active, sustained movement; good tone; may lift head
Respiratory System		
Lecithin forming on alveolar surfaces	L/S ratio = 1.2:1	36 wk—L/S ratio ≥ 2:1
		40 wk—Pulmonary branching only two thirds complete
Renal System		
		36 wk—Formation of new nephrons ceases
Nervous System		
Appearance of cerebral fissures, convolutions rapidly appearing; indefinite sleep–wake cycle; cry weak or absent; weak suck reflex		36 wk—End of spinal cord at level of third lumbar vertebra (L3); definite sleep–wake cycle
		40 wk—Myelination of brain begins; patterned sleep–wake cycle with alert periods; cries when hungry or uncomfortable; strong suck reflex
Sensory Organs		
Eyelids reopen; retinal layers completed, light receptive; pupils capable of reacting to light	Sense of taste present; aware of sounds outside parent's body	
Genital System		
	Testes descending to scrotum	40 wk—Testes in scrotum; labia majora well developed

L/S, Lecithin/sphingomyelin.

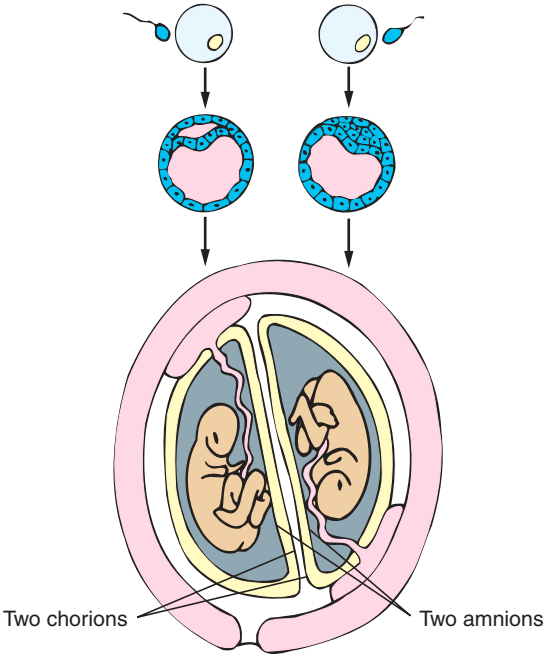

Fig. 9.16 Formation of dizygotic twins. There is fertilization of two ova, two implantations, two placentas, two chorions, and two amnions.

two amnions, two chorions, and two placentas that may be fused together (Figure 9.17). These dizygotic or fraternal twins may be the same sex or different sexes and are genetically no more alike than siblings born at different times. Dizygotic twinning occurs most often in families with a history of twinning. Dizygotic twinning increases in frequency with maternal age up to 35 years, with parity, and with the use of fertility medications.

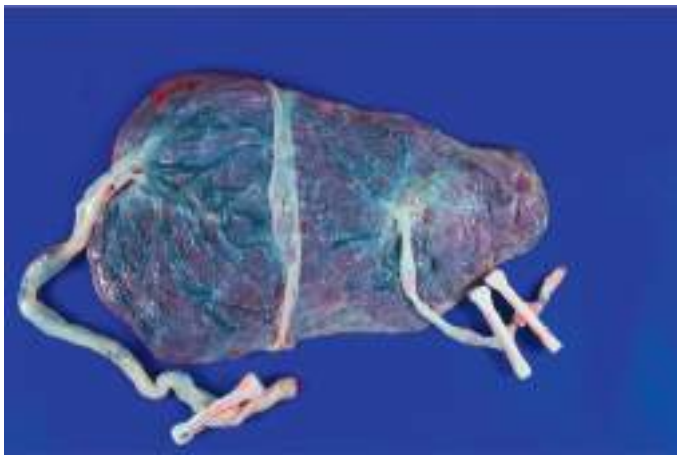

Fig. 9.17 Diamniotic dichorionic (separate) twin placentas. Overview showing prominent, opaque dividing septum and two separate placental beds (From DePaepe, M. [2019]. Multiple gestation: The biology of twinning. In R. Creasy, R. Resnik, J. Iams, et al. [Eds.], *Creasy & Resnik's maternal-fetal medicine: Principles and practice* [8th ed.]. Elsevier.)

Monozygotic twins. Identical or monozygotic twins develop from one fertilized ovum, which then divides (Figure 9.18). They are the same sex and have the same genotype. If division occurs soon after fertilization, two embryos, two amnions, two chorions, and two placentas that may be fused will develop. Most often division occurs between 4 and 8 days after fertilization; there are two embryos, two amnions, one chorion, and one placenta. Rarely, division occurs after the eighth day following fertilization. In this case, there are two embryos within a common amnion and a common chorion with one placenta. This often causes circulatory problems because the umbilical cords may tangle

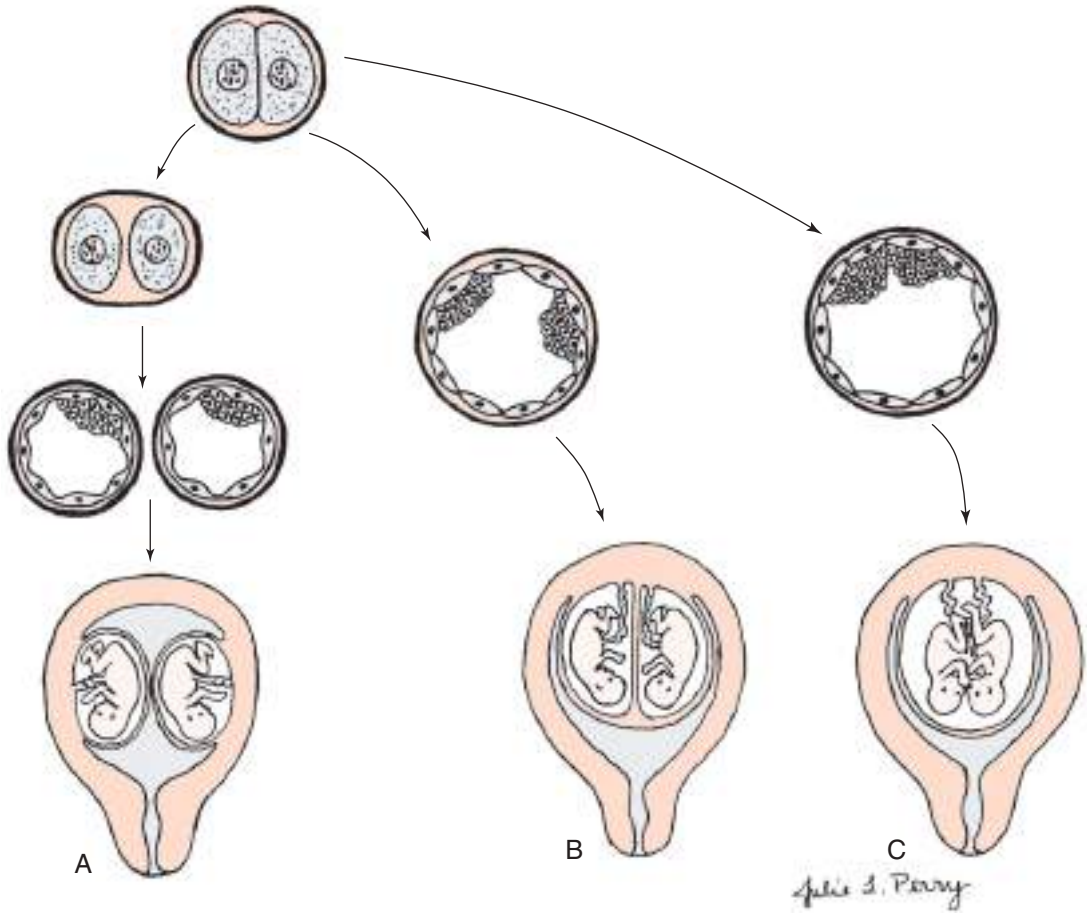

Fig. 9.18 Formation of monozygotic twins. **A:** One fertilization: blastomeres separate, resulting in two implantations, two placentas, and two sets of membranes. **B:** One blastomere with two inner cell masses, one fused placenta, one chorion, and separate amnions. **C:** One blastomere with incomplete separation of cell mass, resulting in conjoined twins.

together, and one or both fetuses may die. If division occurs very late, cleavage may not be complete and conjoined, or "Siamese," twins could result (see Figure 9.18, *C*). Monozygotic twinning occurs in approximately 3 to 4 per 1 000 births (DePaepe, 2019). There is no association with race, heredity, maternal age, or parity. Fertility medications also increase the incidence of monozygotic twinning.

Conjoined twins. Conjoined twins are a type of monozygotic twins in which there is incomplete embryonic division at 13 to 15 days postconception (see Figure 9.18). The estimated frequency is 1 in 50 000 pregnancies and 1 in 250 000 live births (Barnes-Davis et al., 2020). Prenatal diagnosis is possible with three-dimensional ultrasonography. Caesarean birth minimizes trauma to mother and fetuses.

Other Multifetal Pregnancies. The occurrence of **multifetal pregnancies** with three or more fetuses has increased with the use of fertility medications and IVF. The rate of triplet and other higher-order multiples is 114 per 100 000, although this number is decreasing (Barnes-Davis et al., 2020). Triplets can occur from the division of one zygote into two, with one of the two dividing again, producing identical triplets. Triplets can also be produced from two zygotes, one dividing into a set of identical twins and the second zygote a single fraternal sibling, or from three zygotes. Quadruplets, quintuplets, sextuplets, and so on have similar possible derivations.

KEY POINTS

- Genetic disorders affect people of all ages, from all socioeconomic levels, and from all racial and ethnic backgrounds.
- Genetic disorders span every clinical practice specialty.
- Nurses have an important role to play in genetic counselling.
- Genes are the basic units of heredity responsible for all human characteristics. They comprise 23 pairs of chromosomes: 22 pairs of autosomes and 1 pair of sex chromosomes.
- Genetic disorders follow Mendelian inheritance patterns of dominance and segregation and an independent assortment of normal genetic transmission.
- Multifactorial inheritance includes both genetic and environmental contributions.
- Human gestation is approximately 280 days after the LMP or 266 days after conception.
- Fertilization occurs in the uterine tube within 24 hours of ovulation. The zygote undergoes mitotic divisions, creating a 16-cell morula.
- Critical periods occur in human development during which the embryo or fetus is vulnerable to environmental teratogens.
- There has been a steady rise in the incidence of multifetal pregnancies, which is partly due to assisted reproductive technologies.

Anatomy and Physiology of Pregnancy

Lisa Keenan-Lindsay

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Determine obstetrical history using the five-digit system.
2. Describe the various types of pregnancy tests, including timing and interpretation of results.
3. Explain the expected anatomical and physiological adaptations to pregnancy in the gravid patient.
4. Differentiate among presumptive, probable, and positive signs of pregnancy.
5. Identify maternal hormones produced during pregnancy, their target organs, and their major effects on pregnancy.
6. Compare the characteristics of the abdomen, vulva, and cervix of the nullipara and multipara.

The goal of maternity care is a healthy pregnancy with a physically safe and emotionally satisfying outcome for patient, infant, and family. Consistent health care and surveillance are important in order to achieve this goal. However, many adaptations are unfamiliar to pregnant patients and their families. Helping the pregnant patient recognize the relationship between their physical status and the plan for their care can enable them to take part in shared decision-making along with other members of the interprofessional health care team.

OBSTETRICAL TERMINOLOGY

An understanding of the following terms used to describe pregnancy and the pregnant patient is essential to the study of perinatal care (Spong, 2013):

Gravida—A person who is pregnant

Gravidity—Pregnancy

Nulligravida—A person who has never been pregnant and is not currently pregnant

Primigravida—A person who is pregnant for the first time

Multigravida—A person who has had two or more pregnancies

Parity—The number of pregnancies in which the fetus or fetuses have reached 20 weeks of gestation, not the number of fetuses (e.g., twins) born. Parity is not affected by whether the fetus is born alive or is stillborn (i.e., showing no signs of life at birth).

Nullipara—A person who has not completed a pregnancy with a fetus or fetuses beyond 20 weeks of gestation

Primipara—A person who has completed one pregnancy with a fetus or fetuses who have reached 20 weeks of gestation

Multipara—A person who has completed two or more pregnancies to 20 weeks of gestation or more

Viability—Capacity to live outside the uterus; there are no clear limits of gestational age or weight. Infants born at 22 to 25 weeks of gestation are considered to be on the threshold of viability.

Preterm—A pregnancy between 20 weeks and 36 weeks 6 days of gestation

Late Preterm—A pregnancy that has reached between 34 weeks 0 days and 36 weeks 6 days of gestation

Term—A pregnancy from the beginning of week 37 of gestation to the end of week 40 plus 6 days of gestation

Early Term—A pregnancy between 37 weeks and 38 weeks 6 days

Full Term—A pregnancy between 39 weeks and 40 weeks 6 days

Late Term—A pregnancy in the 41st week

Post Term—A pregnancy after 42 weeks

Information about obstetrical history is gathered during history-taking interviews. Obtaining and documenting this information accurately is important in planning care for the pregnant patient.

The five-digit system, separated by hyphens, provides information about the patient's obstetrical history. The first digit represents gravidity (number of all pregnancies); the second digit represents the total number of term births (at 37 or more weeks' gestation); the third indicates the number of preterm births (after 20 weeks to 37 weeks' gestation); the fourth identifies the number of abortions (miscarriage or elective termination of pregnancy); and the fifth is the number of children currently living. The number of births is the actual number of children born during each pregnancy. The acronym GTPAL (**g**ravidity, **t**erm, **p**reterm, **a**bortions, **l**iving children) may be helpful in

TABLE 10.1 Examples of Obstetrical History Information

	FIVE-DIGIT SYSTEM				
Condition	G Gravidity	T Term Birth	P Preterm Births	A Abortions and Miscarriages	L Living Children
Sonia is pregnant for the first time.	1	0	0	0	0
She carries the pregnancy to term, and the newborn survives.	1	1	0	0	1
She is pregnant again.	2	1	0	0	1
Her second pregnancy ends in miscarriage at 10 wk.	2	1	0	1	1
During her third pregnancy she gives birth at 36 wk to twins.	3	1	2	1	3

remembering this system of notation. For example, if a patient who is pregnant only once gives birth at week 35 and the infant survives, the abbreviation that represents this information is "G1-T0-P1-A0-L1." During the next pregnancy the abbreviation would be "G2-T0-P1-A0-L1." Additional examples are given in Table 10.1.

Another system that is sometimes used is gravidity/parity, described as two digits. The first digit (G) indicates the number of pregnancies the patient has had, and the parity (P) indicates the number of pregnancies that have reached 20 weeks' gestation. It is important to remember that *para* refers to pregnancies, not fetuses. This system can be confusing and does not provide enough information about the patient, so it should not be used.

PREGNANCY TESTS

Early detection of pregnancy encourages early initiation of care. Human chorionic gonadotropin (hCG) is the earliest biological marker for pregnancy. Pregnancy tests are based on the recognition of hCG or a beta (β) subunit of hCG. Production of β-hCG begins as early as the day of implantation and can be detected as early as 8 to 10 days after fertilization. The concentration of hCG in blood rises rapidly during early pregnancy, peaks at 9 to 10 weeks, and subsequently declines to a stable level after approximately 20 weeks (Burton et al., 2017). Reduced levels of hCG may indicate miscarriage or abnormal gestation (e.g., fetus with Down syndrome). Higher than normal levels of hCG may indicate molar pregnancy or multiple gestation (Blackburn, 2018).

Serum and urine pregnancy tests are performed in clinics, offices, health centres, public health unit clinics, and laboratory settings. Urine pregnancy tests may be performed at home (see Community Focus box: Home Pregnancy Test Kits). Both serum and urine tests can provide accurate results, although serum testing can give an exact amount of the hCG, which may indicate the approximate gestation. A 7- to 10-mL sample of venous blood is collected for serum testing. Most urine tests require a first-voided morning urine specimen because it contains levels of hCG approximately the same as those in serum. Random urine samples usually have lower levels. Urine tests are less expensive and provide more immediate results than serum tests.

Many different pregnancy tests are available (Figure 10.1). The wide variety of tests precludes discussion of each. The nurse should read the manufacturer's directions for the test that is used and provide appropriate teaching to the patient as needed.

Enzyme-linked immunosorbent assay (ELISA) testing is the most popular method of testing urine for pregnancy. It uses a specific monoclonal antibody (anti-hCG) with enzymes that bond with hCG in urine. ELISA technology is the basis for most over-the-counter home pregnancy tests. With these one-step tests the patient usually applies urine to a strip or absorbent-tipped applicator and reads the results. The test kits come with directions for collection of the specimen, the testing procedure, and reading of results. A positive test result is indicated by a simple colour change reaction or a digital reading. The most common error in performing home pregnancy tests is doing the test too early in pregnancy before a significant rise in hCG level; this can cause a false-negative result (Pagana et al., 2019). (See Clinical Reasoning Case Study.)

COMMUNITY FOCUS

Home Pregnancy Test Kits

- Review web-based information about home pregnancy tests. Explore websites such as www.babycenter.ca and www.parents.com. Assess the accuracy of information.
- Visit a pharmacy in your neighbourhood. How many different types of home pregnancy test kits are available in the pharmacy? Read the labels on three different types of home pregnancy test kits. Do the kits include supplies for more than one test? What is the cost of the kit? Are the directions printed in more than one language? After reading the directions, do you have questions about how to perform the test or how to interpret the results? If so, what does that say about the likelihood that the tests will be used correctly?

Fig. 10.1 Many pregnancy test products are available over the counter. (The Canadian Press/Francis Vachon.)

CLINICAL REASONING CASE STUDY

Pregnancy Testing

When her menstrual period was 10 days late, Regine purchased a home pregnancy test on her way home from work and performed the test that evening. The result was negative. Regine and her partner have been trying to get pregnant so that the baby will be born when she is on summer break from her teaching job at the elementary school. She is disappointed that the test was negative and she calls the clinic to ask the nurse if she should come in for a blood test to see if she is pregnant.

1. Evidence—Is there sufficient evidence to draw conclusions about the advice the nurse should provide to Regine?
2. Assumptions—Describe an underlying assumptions about the following factors:
   a. Proper use of home pregnancy tests
   b. Factors that can affect results of home pregnancy tests
   c. Human chorionic gonadotropin (hCG) levels in pregnancy
3. What are the implications and priorities for providing information to Regine?

Interpreting the results of pregnancy tests requires some judgement. The type of pregnancy test and its degree of sensitivity (the ability to detect low levels of a substance) and specificity (the ability to discern the absence of a substance) must be considered in conjunction with the patient's history. This includes the date of their last normal menstrual period, their usual cycle length, and results of previous pregnancy tests. It is important to know if the patient is taking any medications or has a substance use disorder. Medications such as anticonvulsants and tranquilizers can cause false-positive results, whereas diuretics and promethazine can cause false-negative results (Pagana et al., 2019). Improper collection of the specimen, hormone-producing tumours, and laboratory errors can also cause inaccurate results.

Patients who use a home pregnancy test should be advised about the variations in accuracy reporting and to use caution when interpreting results. Whenever there is any question, further evaluation or retesting may be appropriate.

ADAPTATIONS TO PREGNANCY

Physiological adaptations of the pregnant patient are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues. These adaptations protect the patient's normal physiological functioning, meet the metabolic demands that pregnancy imposes on their body, and provide a nurturing environment for fetal development and growth. Although pregnancy is a normal phenomenon, occasionally problems can occur.

Signs of Pregnancy

Some physiological adaptations are recognized as the signs and symptoms of pregnancy. Three commonly used categories of these signs and symptoms are as follows:

- Presumptive—Subjective changes reported by the patient (e.g., amenorrhea, fatigue, breast changes). These can be caused by conditions other than pregnancy.
- Probable— Objective changes assessed by an examiner (e.g., Hegar sign, ballottement, pregnancy tests). When combined with the presumptive signs and symptoms, these changes strongly suggest pregnancy.
- Positive— Objective signs assessed by an examiner that can be attributed only to the presence of the fetus (e.g., hearing fetal heart tones, visualizing the fetus, palpating fetal movements). These are definitive signs that confirm pregnancy.

Table 10.2 summarizes these signs of pregnancy in relation to when they might occur and gives other possible causes for their occurrence.

Reproductive System and Breasts

Uterus.

Changes in size, shape, and position. High levels of estrogen and progesterone stimulate phenomenal uterine growth in the first

TABLE 10.2 Signs of Pregnancy

Time of Occurrence (Gestational Age)	Sign	Other Possible Cause
Presumptive		
3–4 wk	Breast changes	Premenstrual changes, oral contraceptives
4 wk	Amenorrhea	Stress, vigorous exercise, early menopause, endocrine problems, malnutrition
4–14 wk	Nausea, vomiting	Gastrointestinal virus, gastroenteritis
6–12 wk	Urinary frequency	Infection, pelvic tumours
12 wk	Fatigue	Stress, illness
16–20 wk	Quickening	Gas, peristalsis
Probable		
5–6 wk	Goodell sign	Pelvic congestion
6–8 wk	Chadwick sign	Pelvic congestion
6–12 wk	Hegar sign	Pelvic congestion
4–12 wk	Positive pregnancy test (serum)	Hydatidiform mole, choriocarcinoma
6–12 wk	Positive pregnancy test (urine)	False-positive result may be caused by pelvic infection, tumours
16 wk	Braxton Hicks or prelabour contractions	Myomas, other tumours
16–28 wk	Ballottement	Tumours, cervical polyps
Positive		
5–6 wk	Visualization of fetus by real-time ultrasound examination	No other causes
6 wk	Fetal heart tones detected by ultrasound examination	No other causes
16 wk	Visualization of fetus by radiographic study	No other causes
8–17 wk	Fetal heart tones detected by Doppler ultrasound stethoscope	No other causes
17–19 wk	Fetal heart tones detected by fetal stethoscope	No other causes
19–22 wk	Fetal movements palpated	No other causes
Late pregnancy	Fetal movements visible	No other causes

trimester. Early uterine enlargement results from increased vascularity and dilation of blood vessels, hyperplasia (production of new muscle fibres and fibroelastic tissue) and hypertrophy (enlargement of pre-existing muscle fibres and fibroelastic tissue), and development of the decidua. By 7 weeks of gestation the uterus is the size of a large hen's egg; by 10 weeks it is the size of an orange (twice its nonpregnant size); and by 12 weeks it is the size of a grapefruit. After the third month, uterine enlargement is primarily the result of mechanical pressure of the growing fetus.

As the uterus enlarges, it also changes in shape and position. At conception the uterus is shaped like an upside-down pear. During the second trimester, as the muscular walls strengthen and become more elastic, the uterus becomes spherical or globular. Later, as the fetus lengthens, the uterus becomes larger and more ovoid and rises out of the pelvis into the abdominal cavity.

The pregnancy may "show" after the fourteenth week, although this may depend on the person's height and weight. Abdominal enlargement may be less apparent in the nullipara with good abdominal muscle tone (Figure 10.2). Posture also influences the type and degree of abdominal enlargement that occurs. In normal pregnancies, the uterus enlarges at a predictable rate.

As the uterus grows, it may be palpated above the symphysis pubis sometime between the twelfth and fourteenth weeks of pregnancy (Figure 10.3). The uterus rises gradually to the level of the umbilicus at 20 to 22 weeks of gestation and nearly reaches the xiphoid process at term. Between weeks 38 and 40, fundal height decreases as the fetus begins to descend and engage in the pelvis (**lightening**) (see Figure 10.3, dashed line). Generally, lightening occurs in the nullipara anytime in the last 4 weeks before the onset of labour and in the multipara at the start of labour.

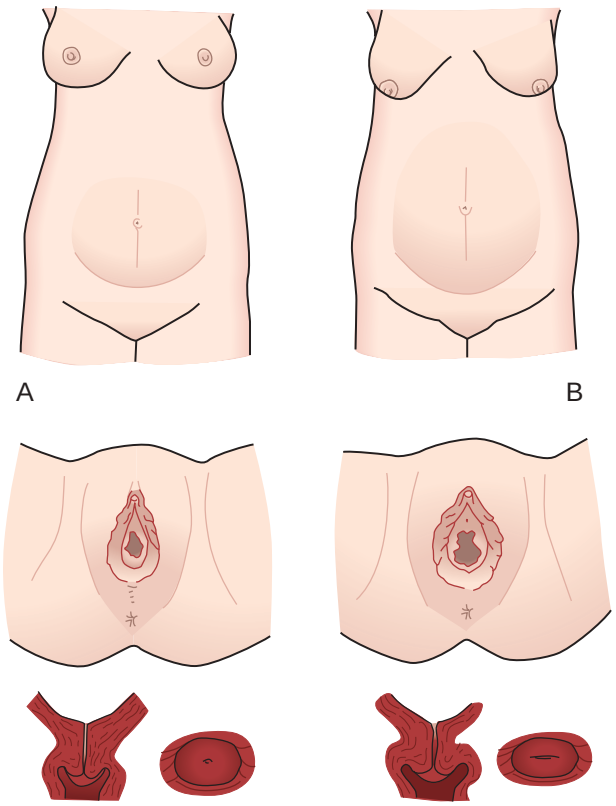

Fig. 10.2 Comparison of abdomen, vulva, and cervix in **A,** nullipara, and **B,** multipara, at the same stage of pregnancy.

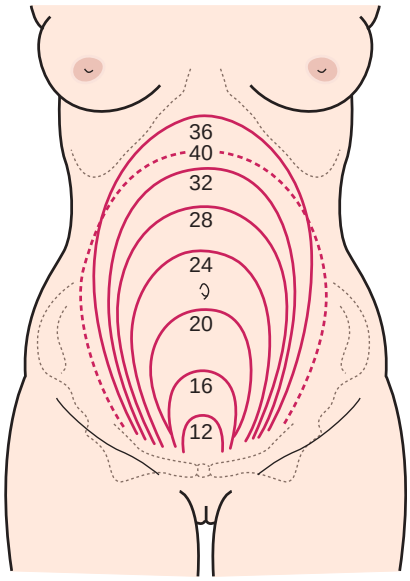

Fig. 10.3 Height of fundus by weeks of normal gestation with a single fetus. *Dashed line,* height after lightening.

Uterine enlargement is determined by measuring fundal height (see Figure 11.6). This measurement is commonly used to estimate the duration of pregnancy. However, variation in the position of the fundus or the fetus, variations in the amount of amniotic fluid present, the presence of more than one fetus, obesity in the pregnant patient, and variation in examiner technique can reduce the accuracy of this estimation.

Generally, the uterus rotates to the right as it elevates, probably because of the presence of the rectosigmoid colon on the left side. However, the extensive hypertrophy (enlargement) of the round ligaments keeps the uterus in the midline. Eventually, the growing uterus touches the anterior abdominal wall and displaces the intestines to either side of the abdomen (Figure 10.4). When a pregnant patient is standing, most of their uterus rests against the anterior abdominal wall; this can alter their centre of gravity.

At approximately 6 weeks of gestation, softening and compressibility of the lower uterine segment (uterine isthmus) occurs (Hegar sign) (Figure 10.5). This results in exaggerated uterine anteflexion during the first 3 months of pregnancy. In this position, the uterine fundus presses on the urinary bladder, causing the patient to have urinary frequency.

Changes in contractility. Soon after the fourth month of pregnancy, uterine contractions can be felt through the abdominal wall. These contractions, referred to as *prelabour contractions* (or **Braxton Hicks contractions**), are irregular and painless contractions that occur intermittently throughout pregnancy. These contractions facilitate uterine blood flow through the intervillous spaces of the placenta and promote oxygen delivery to the fetus. Although prelabour contractions are not painful, some patients are surprised by them and over time may find them to be annoying. After the twenty-eighth week, these contractions become more definite, but they usually cease with walking or exercise. Prelabour contractions can be mistaken for true labour; however, they do not increase in intensity or duration or cause cervical dilation. Conversely, premature labour contractions can be mistaken for prelabour contractions and thus lead to a delay in seeking treatment.

Uteroplacental blood flow. Placental perfusion depends on the blood flow to the uterus. Blood flow increases rapidly as the uterus increases in size. Although uterine blood flow increases 10-fold, the fetoplacental unit grows even more rapidly. Consequently, more

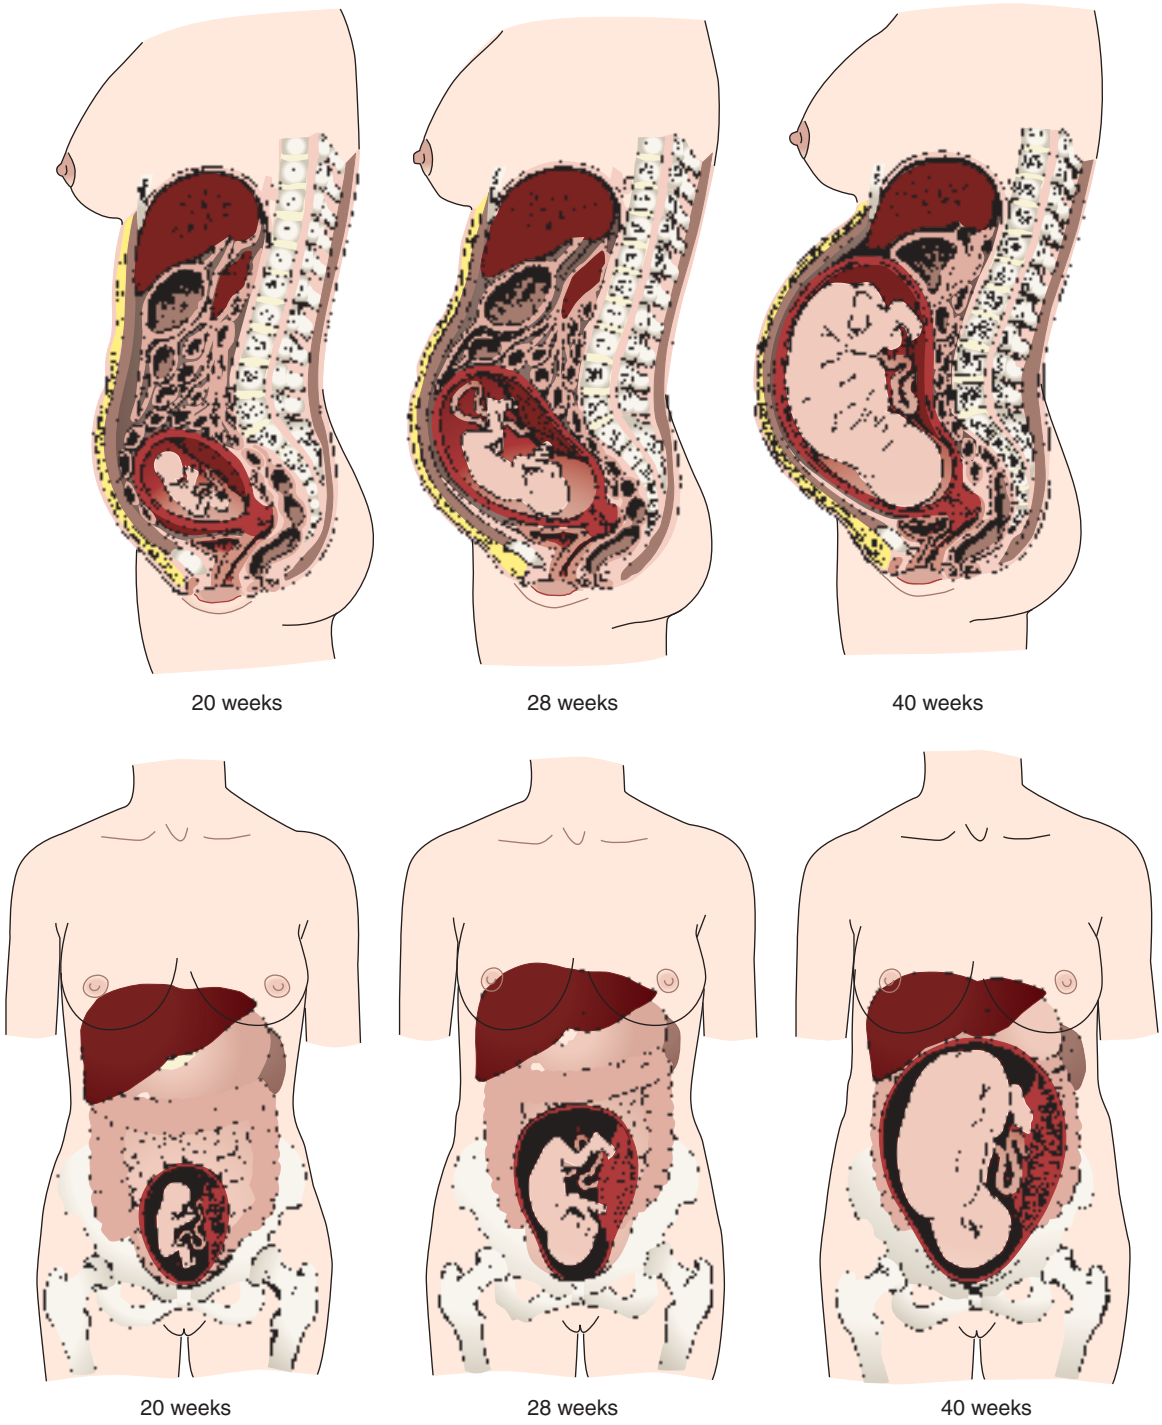

Fig. 10.4 Displacement of internal abdominal structures and diaphragm by the enlarging uterus at 20, 28, and 40 weeks of gestation.

oxygen is extracted from the uterine blood during the latter part of pregnancy (Meschia, 2019). In a normal term pregnancy, one sixth of the patient's total blood volume is within the uterine vascular system. The rate of blood flow through the uterus averages 450 to 650 mL/minute at term, and oxygen consumption of the gravid uterus increases to meet fetal needs. Three factors known to decrease uterine blood flow in the pregnant patient are low arterial pressure, contractions of the uterus, and supine position. Estrogen stimulation may increase uterine blood flow. Doppler ultrasound examination can be used to measure uterine blood flow velocity, especially in pregnancies at risk due to conditions associated with decreased placental perfusion, such as hypertension, intrauterine growth restriction, diabetes mellitus, and multiple gestation (see Figure 13.14).

Using an ultrasound device or a fetal stethoscope, the examiner may hear the uterine souffle or bruit, a rushing or blowing sound of maternal blood flowing through uterine arteries to the placenta that is synchronous with the maternal pulse. The **funic souffle**, which is synchronous with the fetal heart rate and is caused by fetal blood coursing through

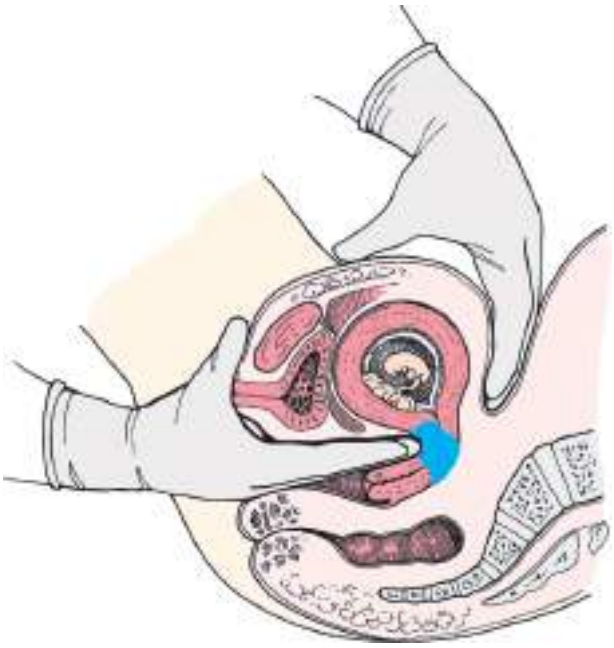

Fig. 10.5 Hegar sign. Bimanual examination for assessing compressibility and softening of isthmus (lower uterine segment) while the cervix is still firm.

the umbilical cord, may also be heard, as well as the actual heartbeat of the fetus (see Figure 11.7).

Cervical changes. The cervix consists primarily of collagen-rich connective tissue and is responsive to hormonal changes of pregnancy. This results in the cervix being a firm, nondistensible, closed structure that maintains the pregnancy and changing to a soft, highly elastic tissue that dilates and becomes almost indistinguishable during labour in preparation for birth.

In a normal, unscarred cervix, a softening of the cervical tip may be observed about the beginning of the sixth week. This probable sign of pregnancy, **Goodell sign**, is brought about by increased vascularity, slight hypertrophy, and hyperplasia (increase in number of cells). The glands near the external os proliferate beneath the stratified squamous epithelium, giving the cervix the velvety appearance characteristic of pregnancy. Friability is increased and can result in slight bleeding after vaginal examination or after coitus with deep penetration.

Pregnancy can also cause the squamocolumnar junction, the site for obtaining cells for cervical cancer screening, to be located away from the cervix. Because of these changes, evaluation of abnormal Papanicolaou (Pap) tests during pregnancy can be complicated. However, careful assessment of all pregnant patients is important—approximately 3% of all cervical cancers are diagnosed during pregnancy (Salani & Copeland, 2017).

The cervix of the nullipara is rounded. Lacerations of the cervix almost always occur during the birth process. After childbirth, with or without lacerations, the cervix becomes more oval in the horizontal plane, and the external os appears as a transverse slit (see Figure 10.2).

Changes related to the presence of the fetus. Passive movement of the unengaged fetus is called **ballottement** and can be identified generally between the sixteenth and eighteenth week. Ballottement is a technique of palpating a floating structure by bouncing it gently and feeling it rebound. To palpate the fetus, the examiner places a finger within the vagina and taps gently upward, causing the fetus to rise. The fetus then sinks, and a gentle tap is felt on the finger (Figure 10.6).

Quickening is the first recognition of fetal movements, or "feeling life." It can be detected as early as the fourteenth week in the multiparous patient. The nulliparous patient may not notice these sensations until between the sixteenth and twentieth week. Quickening is commonly described as a flutter and is difficult to distinguish from peristalsis. Fetal movements gradually increase in intensity and frequency. The week in which quickening occurs provides a tentative clue in dating the duration of gestation.

Vagina and Vulva. Pregnancy hormones prepare the vagina for stretching during labour and birth by causing the vaginal mucosa to thicken, connective tissue to loosen, smooth muscle to hypertrophy, and the vaginal vault to lengthen. Increased vascularity results in a violet-bluish colour of the vaginal mucosa and cervix. The deepened colour, termed **Chadwick sign**, is note noted by the eighth week of pregnancy in primigravidas (Blackburn, 2018).

Leukorrhea is a white or slightly grey mucoid discharge with a faint musty odour. This copious mucoid fluid occurs in response to cervical stimulation by estrogen and progesterone. The fluid is whitish because of the presence of many exfoliated vaginal epithelial cells caused by the hyperplasia of normal pregnancy. This vaginal discharge is never pruritic or blood stained. The mucus fills the endocervical canal, resulting in the formation of the mucous plug (operculum) (Figure 10.7). The operculum acts as a barrier against bacterial invasion.

The vaginal microbiome changes during pregnancy with an increase in at least four species of *Lactobacillus* and a decrease in anaerobic bacteria. This results in a lower pH of vaginal secretions, ranging from about 3.5 to 6.0 (nonpregnant, 4.0 to 5.0). Alterations in the vaginal microbiome help to prevent ascending bacterial infections of the uterus that contribute to preterm labour and birth. However, because of the

Fig. 10.6 Internal ballottement (18 weeks).

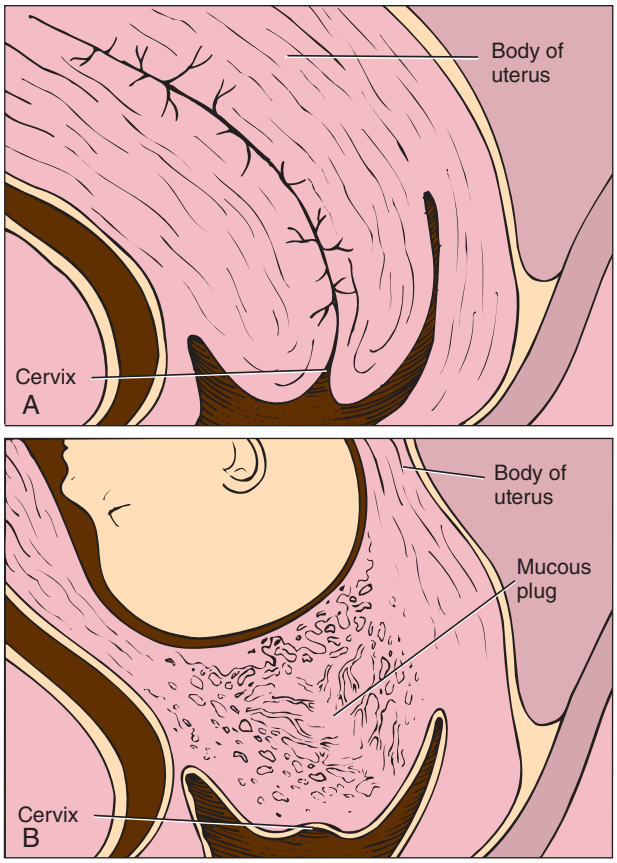

Fig. 10.7 **A:** Cervix in nonpregnant person. **B:** Cervix during pregnancy.

glycogen-rich environment of the vagina, the pregnant patient is more vulnerable to other infections, especially yeast infections, such as *Candida albicans* (Duff, 2019). Changes in the vaginal microbiome during pregnancy may be important in establishing the upper gastrointestinal microbiota of the newborn (Antony et al., 2017).

The increased vascularity of the vagina and other pelvic viscera results in a marked increase in sensitivity. This increased sensitivity may lead to a high degree of sexual interest and arousal, especially during the second trimester of pregnancy. The increased congestion, plus the relaxed walls of the blood vessels and the heavy uterus, may result in edema and varicosities of the vulva. The edema and varicosities usually resolve during the postpartum period.

External structures of the perineum are enlarged during pregnancy because of an increase in vasculature, hypertrophy of the perineal body, and deposition of fat (Figure 10.8). The labia majora of nullipara patients approximate (come together) and obscure the vaginal introitus; those of parous patients separate and gape after childbirth and perineal or vaginal injury. See Figure 10.2 for a comparison of the perineum of the nullipara and that of the multipara in relation to the pregnant abdomen, vulva, and cervix.

Breasts. Fullness, heightened sensitivity, tingling, and heaviness of the breasts begin in the early weeks of gestation in response to increased levels of estrogen and progesterone. Breast sensitivity varies from mild tingling to sharp pain. Nipples and areolae become more pigmented; secondary pinkish areolae develop, extending beyond the primary areolae; and nipples become more erectile. Hypertrophy of the sebaceous (oil) glands embedded in the primary areolae, called **Montgomery tubercles**, may be seen around the nipples. Within the tubercles are sebaceous and sweat glands that secrete lubricating and anti-infective substances to help protect the nipples and areolae during breastfeeding.

The richer blood supply causes the vessels beneath the skin to dilate. Once barely noticeable, the blood vessels become visible, often appearing in an intertwining blue network beneath the surface of the skin. Venous congestion in the breasts is more obvious in primigravidas. **Striae gravidarum** may appear at the outer aspects of the breasts.

During the second and third trimesters, growth of the mammary glands accounts for the progressive breast enlargement (Figure 10.9). The high levels of luteal and placental hormones in pregnancy promote proliferation of the lactiferous ducts and lobule-alveolar tissue so that palpation of the breasts reveals a generalized, coarse nodularity. Glandular tissue displaces connective tissue, and as a result the tissue becomes softer and looser.

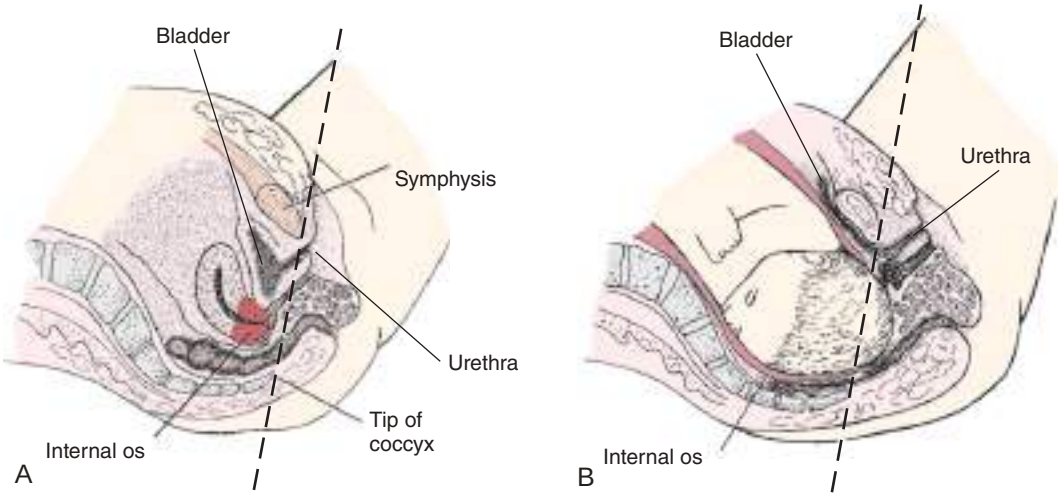

Fig. 10.8 **A:** Pelvic floor in a nonpregnant person. **B:** Pelvic floor during labour. Note marked hypertrophy and hyperplasia below dotted line joining tip of coccyx and inferior margin of symphysis. Note elongation of bladder and urethra as a result of compression. Fat deposits are increased.

Fig. 10.9 Enlarged breasts in pregnancy with venous network and darkened areolae and nipples. (From Ball, J. W., Dains, J. E, Flynn, J. A., et al. [2015]. *Mosby's guide to physical examination* [8th ed.]. Elsevier.)

Prolactin, produced by the anterior pituitary gland, stimulates production of colostrum by the end of the first trimester. During the second trimester, human placental lactogen stimulates secretion of **colostrum**. This is lactogenesis stage I. By the sixteenth week, the breasts are prepared for full lactation; as such, if a patient has a spontaneous or therapeutic abortion after this time, they will produce colostrum. Although development of the mammary glands is functionally complete by midpregnancy, **lactation** is inhibited until the progesterone level decreases after birth (Lawrence & Lawrence, 2016).

General Body Systems

Cardiovascular System. Adjustments to pregnancy in the patient involve extensive anatomical and physiological changes in the cardiovascular system. Cardiovascular adaptations protect the patient's normal physiological functioning, meet the metabolic demands that pregnancy imposes on their body, and provide for fetal developmental and growth needs.

Slight cardiac hypertrophy (enlargement) is probably secondary to increased blood volume and cardiac output that occurs in pregnancy. The heart returns to its normal size within 6 months after childbirth (Antony et al., 2017). As the diaphragm is displaced upward by the enlarging uterus, the heart is elevated upward and rotated forward to the left (Figure 10.10). The apical impulse, a point of maximal intensity, is shifted upward and laterally about 1 to 1.5 cm. The degree of shift depends on the duration of pregnancy and the size and position of the uterus.

The changes in heart size and position and the increases in blood volume and cardiac output contribute to auscultatory changes common in pregnancy. There is more audible splitting of S_1 and S_2, and S_3 may be readily heard after 20 weeks of gestation. In addition, systolic and diastolic murmurs may be best heard over the left sternal border. These changes are transient and disappear in most patients shortly after they give birth, although 20% of individuals will have a persistent murmur at 4 weeks after birth (Mastrobattista & Monga, 2019).

The patient's heart rate begins to increase at about 5 weeks of gestation, reaching a peak of 15 to 20 beats/minute over the prepregnancy baseline by 32 weeks and persisting until term. This represents an increase of approximately 17% over the prepregnancy heart rate (Antony et al., 2017).

Pregnancy has limited effects on cardiac rhythm. Pregnant patients may experience sinus dysrhythmia or premature atrial or ventricular contractions. Patients with pre-existing heart disease need close medical and obstetrical supervision during pregnancy (see Chapter 15).

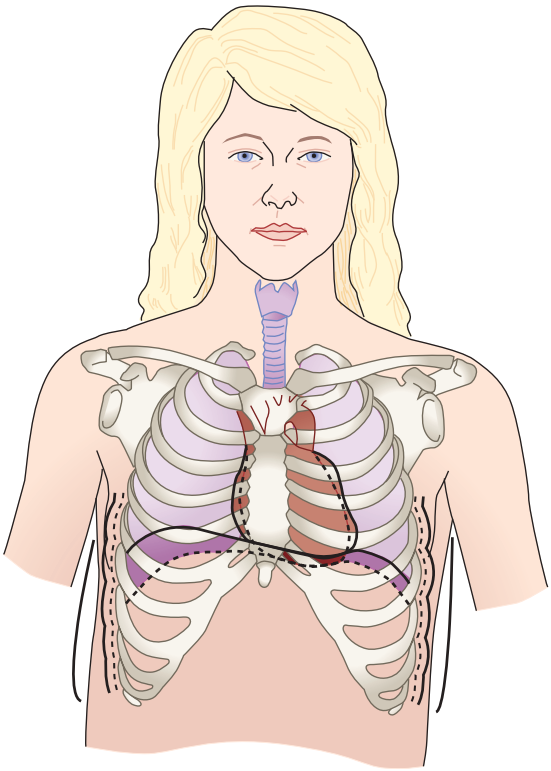

Fig. 10.10 Changes in position of heart, lungs, and thoracic cage in pregnancy. *Broken line*, nonpregnant state; *solid line*, change that occurs in pregnancy.

Cardiac output. Cardiac output increases from 30 to 50% during pregnancy and half of this increase occurs by 8 weeks of gestation. A small decline occurs by term. Compared with nulliparous patients, parous patients have a significantly higher median cardiac output than that of patients with normal twin gestations, and cardiac output increases to an even greater extent from the mid-trimester of pregnancy (Mastrobattista & Monga, 2019). This elevated cardiac output is largely a result of increased stroke volume and heart rate and occurs in response to increased tissue demands for oxygen.

Cardiac output in late pregnancy is appreciably higher when the patient is in the lateral recumbent position than when they are supine. In the supine position, the large, heavy uterus often impedes venous return to the heart and affects blood pressure. Cardiac output increases with any exertion such as labour and birth. Table 10.3 summarizes cardiovascular changes in pregnancy.

Blood pressure. Blood pressure is influenced by two major factors: cardiac output (CO) and systemic vascular resistance (SVR). Although CO increases significantly during pregnancy, blood pressure remains the same or decreases slightly. This is due to reduced SVR caused primarily by the vasodilatory effects of progesterone, prostaglandins, and relaxin. The uteroplacental vascular system holds a large percentage of the blood volume, which also contributes to decreased SVR (Mastrobattista & Monga, 2019). SVR is lowest at 16 to 34 weeks and increases gradually, approximating nonpregnant values by term. During the first trimester, systolic blood pressure usually remains the same as the prepregnancy level but can decrease slightly as pregnancy advances. Diastolic blood pressure begins to decrease in the first trimester, continues to drop until 28 weeks, and gradually increases, returning to prepregnancy levels by term (Mastrobattista & Monga, 2019).

TABLE 10.3 Cardiovascular Changes in Pregnancy

Parameter	Change
Heart rate	Increases 15–20 beats/minute (bpm)
Blood pressure	
Systolic	Slight or no decrease from prepregnancy levels
Diastolic	Slight decrease to midpregnancy (24–32 wk) and gradual return to prepregnancy levels by end of pregnancy
Blood volume	Increases by 1 200–1 500 mL or 40–50% above prepregnancy level
Red blood cell mass	Increases 17%
Hemoglobin	Decreases
Hematocrit	Decreases
White blood cell count	Increases in second and third trimesters
Cardiac output	Increases 30–50%

Data from Antony, K. M., Racusin, D. A., Aagaard, K., & Dildy, G.A. (2017). Maternal physiology. In S. G. Gabbe, J. R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

Various factors influence blood pressure in the pregnant person. These include age, activity level, presence of health issues, pain, circadian rhythm, and use of alcohol, tobacco, or other substances. Additional factors in the patient to consider during pregnancy include anxiety, position, and type of blood pressure apparatus. Anxiety can elevate readings. If an elevated reading is found, the patient is given time to rest and the reading is repeated. See Box 10.1 for procedure on assessing blood pressure in pregnant individuals.

Position of the individual also affects readings. Brachial blood pressure is highest when the patient is sitting, lowest when they are lying in the lateral recumbent position, and intermediate when they are supine, except for some patients who experience supine hypotension. Some degree of compression of the vena cava occurs in all patients who lie on their backs during the second half of pregnancy. Some patients experience a fall of more than 30 mm Hg in their systolic pressure. After 4 to 5 minutes a reflex bradycardia is noted, CO is reduced by half, and the patient feels faint. This condition is called **supine hypotension** (**vena cava syndrome**) (see Chapter 11, Emergency Box).

Compression of the iliac veins and inferior vena cava by the uterus causes increased venous pressure and reduced blood flow in the legs, except when the patient is in the lateral position. These alterations contribute to the dependent edema, varicose veins in the legs and vulva, and hemorrhoids that may develop in the latter part of term pregnancy and can lead to increased risk for venous thromboembolism (VTE).

Blood volume and composition. Total blood volume (TBV), consisting of plasma and red blood cell (RBC) volume, increases significantly during pregnancy by 40 to 50%. During the first half of pregnancy, TBV increases rapidly, peaks around 28 to 34 weeks, and then stabilizes or decreases slightly by term (Antony et al., 2017). In a singleton pregnancy, plasma volume increases by approximately 1 200 to 1 500 mL, or 50% above prepregnancy levels by 30 weeks of gestation, decreasing slightly by term (Antony et al., 2017). Blood volume increases are greater with multiple gestation.

Increased blood volume is a protective mechanism. It is essential for meeting the blood volume needs of the hypertrophied vascular system of the enlarged uterus, for adequately hydrating fetal and maternal tissues when the patient assumes an erect or supine position, and for providing a fluid reserve to compensate for blood loss during birth and postpartum. Peripheral vasodilation allows for a normal blood pressure despite the increased blood volume in pregnancy.

During pregnancy, there is an accelerated production of RBCs (nonpregnant, 4.2 to 5.4 $\times$ 10^{12}/L). The RBC mass increases by 250 to 450 mL, or approximately 20 to 30% over prepregnancy values (Mastrobattista & Monga, 2019). The percentage of increase depends on the amount of iron available. Because the plasma increase is greater than the increase in RBC production, there is a decrease in normal hemoglobin and hematocrit values (see Table 10.3). This state of hemodilution is referred to as **physiological anemia**. The decrease is more noticeable during the second trimester, when rapid expansion of blood volume occurs faster than RBC production. If the hemoglobin value drops to 110 g/L or less or if the hematocrit decreases to 0.32 or less, the patient is considered anemic (Samuels, 2017).

The total white blood cell count increases during the second trimester and peaks during the third trimester. This increase is primarily in the granulocytes; the lymphocyte count stays about the same throughout pregnancy. See Table 10.4 for laboratory values during pregnancy.

Circulation and coagulation times. Pregnancy is considered a hypercoagulable state in which patients are at a five- to six-fold increased risk for thromboembolic disease (Antony et al., 2017). The circulation time decreases slightly by week 32. It returns to near normal by term. There is a greater tendency for blood to coagulate (clot) during pregnancy because of increases in various clotting factors (i.e., factors VII, VIII, IX, and X, and fibrinogen) and decreases in factors that inhibit coagulation (e.g., protein S). This tendency, combined with the fact that fibrinolytic activity (the splitting up or

BOX 10.1 Procedure for Blood Pressure Measurement

- Blood pressure should be measured with the patient in the sitting position with their arm at the level of the heart. The arm used and position of the patient should be documented.
- If possible, allow a period of quiet rest before measuring the blood pressure.
- An appropriately sized cuff (i.e., length 1.5 times the circumference of the arm) should be used. A cuff that is too small yields a falsely high reading; a cuff that is too large yields a falsely low reading.
- Korotkoff phase V should be used to designate diastolic blood pressure.
- If blood pressure is consistently higher in one arm, the arm with the higher values should be used for all blood pressure measurements.
- Blood pressure can be measured using a mercury sphygmomanometer, a calibrated aneroid device, or an automated blood pressure machine that has been validated for use in pre-eclampsia.
- Automated blood pressure machines that have not been validated for use in patients with pre-eclampsia may underestimate or overestimate blood pressure in those patients; a comparison of readings using mercury sphygmomanometry or a calibrated aneroid device is recommended.
- The accuracy of all blood pressure measurement devices used in hospitals or offices should be checked regularly against a calibrated device.

TABLE 10.4 Laboratory Values for Pregnant and Nonpregnant Women

Values	Nonpregnant	Pregnant
Hematological		
Complete Blood Count		
Hemoglobin, g/L	120–160*	>110
Hematocrit, volume fraction	0.37–0.47	>0.33
Red blood cell (RBC) volume, per millilitre	1 400	1 650
Plasma volume, per millilitre	2 400	40–45% increase
RBC count, $\times 10^{12}$/L	4.2–5.4	5–6.25
White blood cells, $\times 10^{9}$/L	3.5–12	5–15
Neutrophils, %	55–70	60–85
Lymphocytes, %	20–40	15–40
Erythrocyte sedimentation rate (ESR), mm/hr	20	Elevated in second and third trimesters
Mean corpuscular hemoglobin concentration (MCHC), g/dL packed RBCs	32–36	No change
Mean corpuscular hemoglobin (MCH), pg/cell	27–31	No change
Mean corpuscular volume, fL	80–95	No change
Blood Coagulation and Fibrinolytic Activity*		
Factor VII	65–140	Increases in pregnancy, returns to normal in early puerperium
Factor VIII	55–145	Increases during pregnancy and immediately after birth
Factor IX	60–140	Same as factor VII
Factor X	45–155	Same as factor VII
Factor XI	65–135	Decreases in pregnancy
Factor XII	50–150	Same as factor VII
Prothrombin time, sec	11–12.5	Decreases slightly in pregnancy
Partial thromboplastin time (PTT), sec	60–70	Decreases slightly in pregnancy and decreases during second and third stage of labour (indicates clotting at placental site)
Bleeding time, min	1–9 (Ivy method)	No appreciable change
Platelets, $\times 10^{9}$/L	150–400	No significant change until 3–5 days after birth and then increases rapidly (may predispose woman to thrombosis) and gradually returns to normal
Fibrinolytic activity		Decreases in pregnancy and then abruptly returns to normal (protection against thromboembolism)
Fibrinogen, g/L	2–5	Levels increase late in pregnancy
Chemistry		
Mineral/Vitamin Concentrations		
Vitamin B_{12}, folic acid, ascorbic acid	Normal	Moderate decrease
Serum Proteins		
Total, g/L	64–83	55–75
Albumin, g/L	35–50	Slight increase
Globulin, total, g/L	23–34	30–40
Blood Glucose		
Fasting, mmol/L	3.3–5.8	Decreases
2-hr postprandial, mmol/L	<8.9	50 gram glucose challenge test: <5.3 fasting, <10.6 at 1 hr and <9.0 at 2 hr (if 1 out of 3 are higher than normal, would be diagnosed as abnormal)
Acid–Base Values in Arterial Blood		
PO_2, mm Hg	80–100	104–108 (increased)
PCO_2, mm Hg	35–45	27–32 (decreased)
Sodium bicarbonate (HCO_3), mmol/L	21–28	18–31 (decreased)
Blood pH	7.35–7.45	7.40–7.45 (slightly increased, more alkaline)
Hepatic		
Bilirubin, total, mcmol/L	3.0–22	Unchanged
Serum cholesterol, mmol/L	<5.2	Increases at 16–32 wk of pregnancy; remains at this level until after birth
Serum alkaline phosphatase, U/L	30–120	Increases from wk 12 of pregnancy to 6 wk after birth

Continued

TABLE 10.4 Laboratory Values for Pregnant and Nonpregnant Women—cont'd

Values	Nonpregnant	Pregnant
Serum albumin, g/L	35–50	Increases slightly
Renal		
Bladder capacity, mL	1300	1500
Renal plasma flow, mL/min	490–700	Increases by 25–30%
Glomerular filtration rate (GFR), mL/min	88–128	Increases by 30–50%
Blood urea nitrogen (BUN), mmol/L	2.5–8.0	Decreases
Serum creatinine, mcmol/L	44–97	Decreases
Serum uric acid, mcmol/L	180–420	Decreases but returns to prepregnancy level by end of pregnancy
Urine glucose	Negative	Present in 20% of pregnant women
Intravenous pyelogram	Normal	Slight to moderate hydroureter and hydronephrosis; right kidney larger than left kidney

dissolving of a clot) is depressed during pregnancy and the postpartum period, provides a protective function to decrease the chance of bleeding but also makes the patient more vulnerable to thrombosis, especially after Caesarean birth.

Respiratory System. Structural and ventilatory adaptations occur during pregnancy to provide for maternal and fetal needs. Maternal oxygen consumption increases during pregnancy by 20 to 40% above nonpregnant levels. This increase is necessary to support the needs of the fetus, placenta, and changes in maternal organs (Antony et al., 2017). As pregnancy progresses, the enlarging uterus places upward pressure on the diaphragm, causing the level of the diaphragm to rise by as much as 4 cm (see Figure 10.10). The costal angle increases, and the lower rib cage appears to flare out. Ligaments of the rib cage relax because of the effects of progesterone, permitting increased chest expansion. The transverse diameter of the thoracic cage increases by about 2 cm and the circumference by 5 to 7 cm. Consequently, there is little change in total lung capacity.

With advancing pregnancy, chest breathing replaces abdominal breathing, and it becomes less possible for the diaphragm to descend with inspiration. Thoracic breathing is primarily accomplished by the diaphragm rather than by the costal muscles (Antony et al., 2017).

The upper respiratory tract becomes more vascular in response to elevated levels of estrogen. As the capillaries become engorged, edema and hyperemia develop within the nose, pharynx, larynx, trachea, and bronchi. This congestion within the tissues of the respiratory tract gives rise to several conditions commonly seen during pregnancy, including nasal and sinus stuffiness, epistaxis (nosebleed), changes in the voice, and marked inflammatory response to even a mild upper respiratory infection (Antony et al., 2017). Increased vascularity of the upper respiratory tract also can cause the tympanic membranes and eustachian tubes to swell, giving rise to symptoms of impaired hearing, earaches, or a sense of fullness in the ears.

Pulmonary function. Tidal volume (the amount of air exchanged during normal inspiration and expiration) increases by 40% during pregnancy. Respiratory rate does not change during pregnancy, although minute ventilation (volume of gas expelled from the lungs per minute) increases by 30 to 50%. This is likely related to increased progesterone and increased basal metabolic rate (Mastrobattista & Monga, 2019).

Pregnancy is a state of chronic mild hyperventilation with reduced arterial carbon dioxide ($PaCO_2$) and increased oxygen (PaO_2) over nonpregnant levels. Respiratory changes in pregnancy are shown in Table 10.5. Progesterone may be responsible for increasing the sensitivity of the respiratory centre receptors so that $PaCO_2$ decreases, the base excess (HCO_3, or bicarbonate) decreases, and pH increases slightly. These alterations in acid–base balance create a state of respiratory alkalosis (see Table 10.4). These changes also facilitate the transport of CO_2.

Renal System. The kidneys are responsible for maintaining electrolyte and acid–base balance, regulating extracellular fluid volume, excreting waste products, and conserving essential nutrients.

Anatomical changes. Changes in renal structure result from hormonal activity (estrogen and progesterone), pressure from an enlarging uterus, and an increase in blood volume. As early as the tenth week of

TABLE 10.5 Respiratory Changes in Pregnancy

Parameter	Change
Respiratory rate	Unchanged or slightly increased
Tidal volume	Increased 33%
Vital capacity	Unchanged
Inspiratory capacity	Increased 6%
Expiratory reserve volume	Decreased 20%
Total lung capacity	Unchanged to slightly decreased
Minute ventilation	Increased 30–50%
Oxygen consumption	Increased 20–40%

Data from Mastrobattista, J. M., & Monga, M. (2019). Maternal cardiovascular, respiratory, and renal adaptation to pregnancy. In R. K. Creasy, R. Resnik, J. D. Iams, et al. (Eds.). *Creasy & Resnik's maternal-fetal medicine: Principles and practice* (8th ed.). Elsevier.

pregnancy, the renal pelvis and the ureters dilate. Dilation of the ureters is more pronounced above the pelvic brim, in part because they are compressed between the uterus and the pelvic brim. In most patients the ureters below the pelvic brim are of normal size. The smooth-muscle walls of the ureters undergo hyperplasia and hypertrophy and muscle tone relaxation. The ureters elongate, become tortuous, and form single or double curves. In the latter part of pregnancy, the renal pelvis and ureter dilate more on the right side than on the left because the heavy uterus is displaced to the right by the sigmoid colon.

Because of these changes, a larger volume of urine is held in the pelvis and ureters and urine flow rate is slowed. Urinary stasis or stagnation has several consequences:

- A lag occurs between the time urine is formed and when it reaches the bladder. Therefore, clearance test results may reflect substances contained in glomerular filtrate several hours before.
- Stagnated urine is an excellent medium for the growth of microorganisms. In addition, the urine of pregnant patients contains more nutrients, including glucose, that increase the pH (making the urine more alkaline). This makes pregnant patients more susceptible to urinary tract infection (Mastrobattista & Monga, 2019).

Bladder irritability, nocturia, and urinary frequency and urgency (without dysuria) are commonly reported in early pregnancy. These bladder symptoms may return near term, especially after lightening occurs.

Increased urinary frequency results initially from increased bladder sensitivity and later from compression of the bladder (see Figure 10.8). In the second trimester, the bladder is pulled up out of the true pelvis into the abdomen. The urethra lengthens to 7.5 cm as the bladder is displaced upward. The pelvic congestion that occurs in pregnancy is reflected in hyperemia of the bladder and urethra. This increased vascularity causes the bladder mucosa to be traumatized and bleed easily. Bladder tone may decrease, which increases the bladder capacity to 1 500 mL. At the same time, the bladder is compressed by the enlarging uterus, resulting in the urge to void even if the bladder contains only a small amount of urine.

Functional changes. In normal pregnancy, renal function is altered considerably. Glomerular filtration rate (GFR) and renal plasma flow increase early in pregnancy (Mastrobattista & Monga, 2019). These changes are caused by pregnancy hormones, an increase in blood volume, and the patient's posture, physical activity, and nutritional intake. The patient's kidneys must manage the increased metabolic and circulatory demands of the pregnant body and also the excretion of fetal waste products. The increase in GFR results in increased creatinine clearance and a reduction in serum creatinine, blood urea nitrogen (BUN), and uric acid levels (Antony et al., 2017).

Renal function is most efficient when the patient lies in the lateral recumbent position and is least efficient when the patient assumes a supine position. A side-lying position increases renal perfusion, which increases urine output and decreases edema. When the pregnant patient is lying supine, the heavy uterus compresses the vena cava and the aorta, and CO decreases. As a result, blood flow to the brain and heart is continued at the expense of other organs, including the kidneys and uterus.

Fluid and electrolyte balance. By term gestation, there is an increase in total body water of 6.5 to 8.5 L. This additional water content can be attributed to expansion of the pregnant patient's blood volume; water content of the fetus, placenta, and amniotic fluid; intracellular fluid in the uterus and breasts; extravascular fluid; and increase in adipose tissue (Antony et al., 2017).

Selective renal tubular resorption maintains sodium and water balance, regardless of changes in dietary intake and losses through sweat, vomitus, or diarrhea. To prevent excessive sodium depletion, the kidneys undergo a significant adaptation by increasing tubular resorption. Because of the need for increased intravascular and extracellular fluid volume in the pregnant patient, additional sodium is needed to expand fluid volume and maintain an isotonic state. About 900 mEq of sodium is normally retained during pregnancy to meet fetal needs, although maternal serum levels of sodium decrease by 3 to 4 mmol/L (Antony et al., 2017).

! NURSING ALERT

As efficient as the renal system is, it can be overstressed by excessive dietary sodium intake or restriction or by use of diuretics. Severe hypovolemia and reduced placental perfusion are two consequences of using diuretics during pregnancy.

The capacity of the kidneys to excrete water is more efficient during the early weeks than later in pregnancy. As a result, some patients feel thirsty in early pregnancy because of the greater amount of water loss. The pooling of fluid in the legs in the latter part of pregnancy decreases renal blood flow and GFR. This pooling is sometimes referred to as *physiological* or *dependent edema* and requires no treatment. The normal diuretic response to the water load is triggered when the patient lies down, preferably on their side, and the pooled fluid re-enters general circulation.

Normally, the kidney resorbs almost all the glucose and other nutrients from the plasma filtrate. However, in pregnant patients, tubular resorption of glucose is impaired so that **glycosuria** occurs at varying times and to varying degrees. Nonpregnant patients excrete less than 100 mg/day, whereas pregnant patients with normal blood glucose levels excrete 1 to 10 g of glucose each day (Antony et al., 2017). Although glucosuria may be found in normal pregnancies (2+ levels may be seen with increased anxiety states), the possibility of diabetes mellitus and gestational diabetes must be considered.

During normal pregnancy, there is an increase in urinary excretion of protein and albumin, most notable after 20 weeks of gestation (Antony et al., 2017). This is due to increased GFR and impaired proximal tubular function. It is considered abnormal when **proteinuria** exceeds 300 mg/24 hours or albuminuria is greater than 30 mg/24 hours.

The amount of protein excreted is not an indication of the severity of renal disease, nor does an increase in protein excretion in a pregnant patient with known renal disease necessarily indicate a progression in their disease. However, a pregnant patient with hypertension and proteinuria must be evaluated carefully because they may be at greater risk for an adverse pregnancy outcome (Antony et al., 2017).

Integumentary System. Alterations in hormone balance and mechanical stretching are responsible for several changes in the integumentary system during pregnancy. Hyperpigmentation is stimulated by the anterior pituitary hormone *melanotropin*, which is increased during pregnancy. Darkening of the nipples, areolae, axillae, and vulva occurs at about the sixteenth week of gestation. Facial melasma (also called *chloasma* or *mask of pregnancy*) is a blotchy, brownish hyperpigmentation of the skin over the cheeks, nose, and forehead, especially in pregnant patients with dark complexions. Chloasma appears in 50 to 70% of pregnant patients, beginning after the sixteenth week and increasing gradually until term. The sun intensifies this pigmentation in susceptible individuals. Chloasma caused by normal pregnancy usually fades after birth but often recurs with oral contraceptive use or subsequent pregnancies (Wang & Kroumpouzos, 2017) (Figure 10.11).

The **linea nigra** (Figure 10.12) is a pigmented line extending from the symphysis pubis to the top of the fundus in the midline. This line is known as the *linea alba* before hormone-induced pigmentation. In primigravidas the extension of the linea nigra, beginning in the third month, keeps pace with the rising height of the fundus; in multigravidas the entire line often appears earlier than the third month. Not all

Fig. 10.11 Facial melasma over the cheeks, nose, upper lip, and forehead.

Fig. 10.12 Striae gravidarum and linea nigra in a dark-skinned person. (Courtesy Shannon Perry, Phoenix, AZ.).

pregnant patients develop lineae nigra, and some patients notice hair growth along the line with or without the change in pigmentation.

Striae gravidarum, or stretch marks (seen over the lower abdomen in Figure 10.12), appear in 50 to 90% of pregnant patients during the second half of pregnancy. Striae reflect separation within the underlying connective (collagen) tissue of the skin. These slightly depressed streaks tend to occur over areas of maximum stretch (the abdomen, thighs, and breasts). The stretching sometimes causes a sensation that resembles itching. The tendency to develop striae may be familial. After birth they usually fade, although they never disappear completely. No topical therapy has been shown to affect the course of striae, although pulsed laser therapy can reduce redness of early lesions, but it is difficult to determine whether the short-term improvement is better than that after long-term observation (Rapini, 2019). The colour of striae varies, depending on the pregnant person's skin colour. The striae appear pinkish on a person with light skin and are lighter than the surrounding skin in dark-skinned patients.

Angiomatas, commonly known as *vascular spiders,* are tiny, star-shaped or branched, slightly raised, and pulsating end-arterioles usually found on the neck, thorax, face, and arms. Angiomatas appear during the second to fifth month of pregnancy as a result of increased blood flow to the skin due to rising estrogen levels during pregnancy and usually disappear within the first 3 months postpartum (Wang & Kroumpouzos, 2017).

Pinkish-red diffusely mottled or well-defined blotches are seen over the palmar surfaces of the hands in about 70% of White patients and 30% of Black patients during pregnancy (Wang & Kroumpouzos, 2017). These colour changes, called *palmar erythema*, are related primarily to increased estrogen levels.

! NURSING ALERT

Integumentary system changes vary greatly among individuals of different ethnic backgrounds. Therefore, when performing physical assessments, the colour of a person's skin should be noted along with any changes that may be attributed to pregnancy.

Some dermatological conditions have been identified as unique to pregnancy or as having an increased incidence during pregnancy. Mild pruritus (pruritus gravidarum) is a relatively common dermatological symptom during pregnancy that usually occurs over the abdomen. The goal of management is to relieve the itching. Topical steroids and emollients are the usual treatment. Less than 2% of patients have significant pruritus that requires further evaluation (Wang & Kroumpouzos, 2017). The problem usually resolves during the postpartum period.

The most common specific dermatosis during pregnancy is **polymorphic eruption of pregnancy (PEP)**, also known as **pruritic urticarial papules and plaques of pregnancy (PUPPP)**. PEP occurs in approximately 1 in 130 to 1 in 300 pregnancies and is associated with increased weight gain in the pregnant patient, multiple gestations, hypertension, and induction of labour (Rapini, 2019). Although it can cause significant discomfort, it is not associated with adverse outcomes for the pregnant patient or fetus. Mild PEP is usually treated with oral antihistamines and topical antipruritic and corticosteroid creams. Oral steroids may be needed in more severe cases (Wang & Kroumpouzos, 2017).

The effect of pregnancy on acne is variable. In some patients, the skin clears and looks radiant. Acne can worsen or occur for the first time during pregnancy or postpartum. Commonly used topical treatments for acne (e.g., benzoyl peroxide, topical antibiotics) are considered safe during pregnancy; topical retinoids should be avoided in the first trimester.

! NURSING ALERT

People with severe acne taking isotretinoin (Accutane) should avoid pregnancy while receiving the treatment because it is teratogenic and associated with major fetal malformations. Given the significant risks of becoming pregnant while taking isotretinoin, Health Canada has instituted a pregnancy prevention program for these patients. Specifically, the program requires patients' written consent, two negative pregnancy tests before starting treatment, monthly tests during treatment and 1 month after stopping, and the use of two reliable methods of birth control through this period (Government of Canada, 2016).

Nail and hair growth may be accelerated. Some patients may notice thinning and softening of the nails. *Hirsutism*, the excessive growth of hair or growth of hair in unusual places, is commonly reported. An increase in fine hair growth may occur but tends to disappear after

pregnancy. However, growth of coarse or bristly hair does not usually disappear after pregnancy. The rate of scalp hair loss slows during pregnancy; increased hair loss may be noted in the postpartum period.

Increased blood supply to the skin leads to increased perspiration. People often feel hotter during pregnancy, possibly related to a progesterone-induced increase in body temperature and the increased basal metabolic rate.

Musculoskeletal System. The gradually changing body and increasing weight of the pregnant patient usually cause noticeable changes in their posture (Figure 10.13). Abdominal distention causes the pelvis to tilt forward, abdominal muscle tone decreases, and weight bearing increases. The person's centre of gravity shifts forward, requiring a realignment of the spinal curvatures. An increase in the normal lumbosacral curve (lordosis) develops, and a compensatory curvature in the cervicodorsal region (exaggerated anterior flexion of the head) develops to help them maintain balance. Aching, numbness, and weakness of the upper extremities may result. Large breasts and a stoop-shouldered stance further accentuate the lumbar and dorsal curves. The ligamentous and muscular structures of the middle and lower spine may be severely stressed. These and related changes often cause musculoskeletal discomfort, especially in older patients or those with a back disorder or a faulty sense of balance.

Slight relaxation and increased mobility of the pelvic joints are normal during pregnancy. These adaptations permit enlargement of pelvic dimensions to facilitate labour and birth. The degree of relaxation varies, but considerable separation of the symphysis pubis and the instability of the sacroiliac joints may cause pain and difficulty in walking. A waddling gait is common. Obesity or multifetal pregnancy tends to increase the pelvic instability. Peripheral joint laxity also increases as pregnancy progresses; the cause for this is not known, although it is hypothesized that it is due to increased relaxin (Antony et al., 2017).

The muscles of the abdominal wall stretch and ultimately lose some tone. During the third trimester, the rectus abdominis muscles may separate (Figure 10.14), allowing abdominal contents to protrude at the midline. The umbilicus flattens or protrudes. After birth, the muscles gradually regain tone. However, separation of the muscles **(diastasis recti abdominis)** may persist.

SAFETY ALERT

Pregnant individuals are at increased risk for falling because of the shifting centre of gravity, impaired balance, and joint laxity.

Neurological System. Little is known about specific alterations in function of the neurological system during pregnancy, aside from hypothalamic–pituitary neurohormonal changes. Specific physiological alterations resulting from pregnancy may cause the following neurological or neuromuscular symptoms:

- Compression of pelvic nerves or vascular stasis caused by enlargement of the uterus may result in sensory changes in the legs.
- Dorsolumbar lordosis may cause pain because of traction on nerves or compression of nerve roots.
- Edema involving the peripheral nerves may result in **carpal tunnel syndrome** during the last trimester. The syndrome is characterized by paresthesia (abnormal sensation such as burning or tingling) and pain in the hand, radiating to the elbow. The sensations are caused by edema that compresses the median nerve beneath the carpal ligament of the wrist. Smoking and alcohol consumption can impair the microcirculation and may worsen the symptoms. The dominant hand is usually affected most, although many patients report symptoms in both hands. Symptoms usually regress after pregnancy. In some cases, surgical treatment is necessary.
- Acroesthesia (numbness and tingling of the hands) is caused by the stoop-shouldered stance (see Figure 10.13, *B*) assumed by some patients during pregnancy. The condition is associated with traction on segments of the brachial plexus.

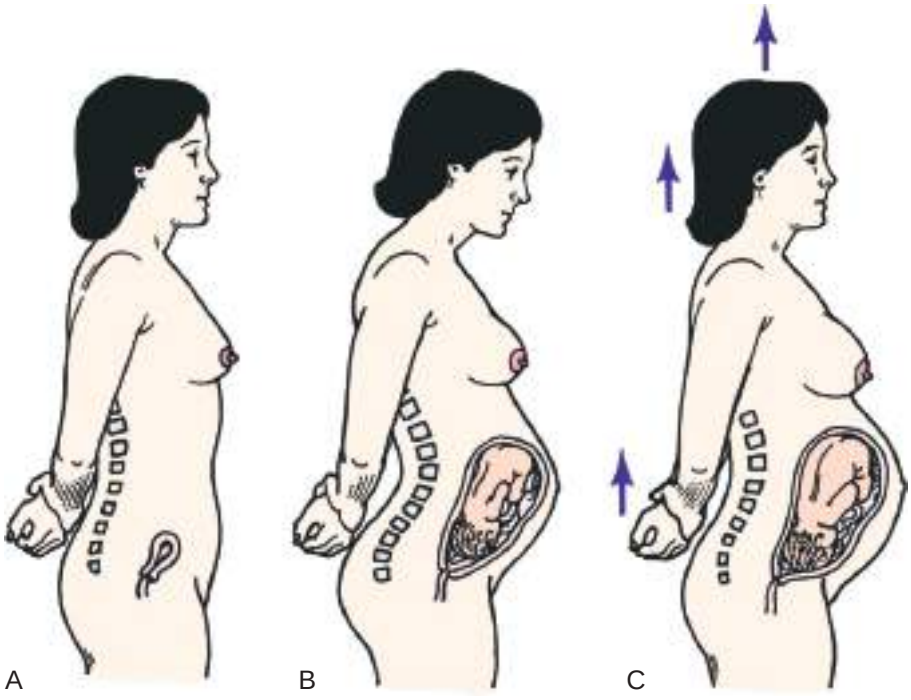

Fig. 10.13 Postural changes during pregnancy. **A:** Nonpregnant. **B:** Incorrect posture during pregnancy. **C:** Correct posture during pregnancy.

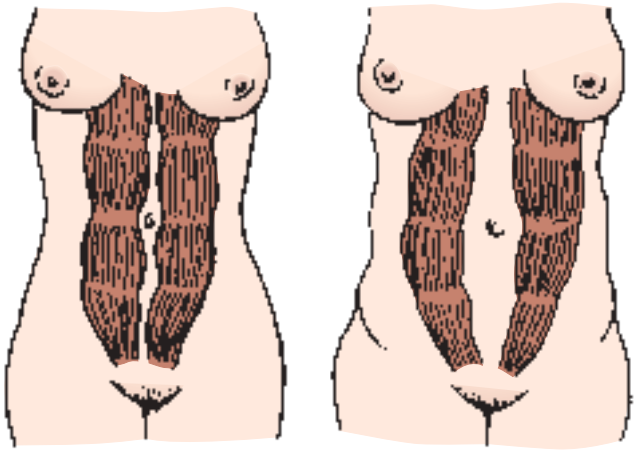

Fig. 10.14 Possible change in rectus abdominis muscles during pregnancy. **A:** Normal position in nonpregnant patients. **B:** Diastasis recti abdominis in pregnant patients.

- Tension headache is common when anxiety or uncertainty complicates pregnancy. However, vision problems such as refractive errors, sinusitis, or migraine may also be responsible for headaches.
- "Light-headedness," faintness, and even syncope (fainting) are common during early pregnancy. Vasomotor instability, postural hypotension, or hypoglycemia may be responsible.
- Hypocalcemia can cause neuromuscular problems such as muscle cramps or tetany.
- Corneal thickening and decreased intraocular pressure occur during pregnancy and resolve within a few weeks after birth (Antony et al., 2017).

Gastrointestinal System.

Appetite. During pregnancy, the patient's appetite and food intake fluctuate. Up to 70 to 80% of pregnant patients experience nausea with or without vomiting ("morning sickness"), possibly in response to increasing levels of hCG and altered carbohydrate metabolism (Antony et al., 2017; O'Connor et al., 2016). Nausea and vomiting of pregnancy (NVP) appears at about 4 to 6 weeks of gestation and usually subsides by the end of the third month (first trimester) of pregnancy (see Table 11.4 for further discussion of NVP). Severity varies from mild distaste for certain foods to more severe vomiting. The condition may be triggered by the sight or odour of various foods. By the end of the second trimester, the appetite increases in response to increasing metabolic needs. Rarely does NVP have harmful effects on the embryo, the fetus, or the pregnant person. If persistent vomiting leads to a weight loss of greater than 5% of prepregnancy weight with associated electrolyte imbalance and ketonuria, the patient may be diagnosed with hyperemesis gravidarum (O'Connor et al., 2016). This occurs in about 1% of pregnancies, and further evaluation and intervention are likely required (see Chapter 14).

Patients may have changes in their sense of taste, leading to cravings and changes in dietary intake. Some patients have nonfood cravings **(pica)** such as for ice, clay, and laundry starch. Pica should be considered a potential factor in cases of iron deficiency anemia or poor weight gain (Antony et al., 2017) (see Chapter 12 for a discussion of nutrition in pregnancy).

Mouth. The gums become hyperemic, spongy, and swollen during pregnancy. They tend to bleed easily because the increasing levels of estrogen cause selective increased vascularity and connective tissue proliferation (a nonspecific gingivitis). An **epulis** (gingival granuloma gravidarum) is a red, raised nodule on the gums that bleeds easily. This lesion may develop around the third month and usually continues to enlarge as pregnancy progresses. It is usually managed by avoiding trauma to the gums (e.g., using a soft toothbrush). An epulis usually regresses spontaneously after birth.

Some pregnant patients have symptoms of **ptyalism** (excessive salivation), which may be caused by the decrease in unconscious swallowing by the patient when nauseated or caused by stimulation of salivary glands by eating starchy food (Antony et al., 2017) (see Table 11.3 for further discussion of ptyalism).

Teeth. Oral health may be affected during pregnancy due to hormonal changes. There is an increased risk for gingivitis and periodontitis. Periodontitis has been associated with poor pregnancy outcomes, such as having a preterm birth or low-birth-weight baby (Government of Canada, 2019).

Esophagus, stomach, and intestines. Increased progesterone production causes decreased tone and motility of smooth muscles, resulting in esophageal regurgitation (reflux), slower emptying time of the stomach, and reverse peristalsis. As a result, the patient may experience "acid indigestion" or heartburn (**pyrosis**) beginning as early as the first trimester and intensifying through the third trimester. Pregnancy reduces the risk for peptic ulcer disease (Antony et al., 2017).

The incidence of hiatal hernia is increased during pregnancy as a result of the upward displacement of the stomach by the enlarging uterus, which causes a widening of the hiatus of the diaphragm. Hiatal hernia occurs more often in multiparas and older or obese patients.

In response to increased needs during pregnancy, iron is absorbed more readily in the small intestine. Even when the patient is deficient in iron, it will continue to be absorbed in sufficient amounts for the fetus to have a normal hemoglobin level.

Smooth muscle relaxation and reduced peristalsis caused by increased progesterone result in an increase in water absorption from the colon and may cause constipation. Constipation can also result from food choices linked to constipation, lack of fluids, iron supplementation, decreased activity level, abdominal distension by the pregnant uterus, and displacement and compression of the intestines. If the pregnant patient has hemorrhoids (Figure 10.15) and is constipated, the hemorrhoids can evert or bleed during straining at stool.

Fig. 10.15 Hemorrhoids. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

The maternal gut microbiome changes during pregnancy. The bacterial diversity within the gut seems to decrease as pregnancy progresses. By the third trimester, there is an overall increase in *Proteobacteria* and a decrease in *Faecalibacterium,* which creates a gut microbiome that is similar to proinflammatory and prodiabetogenic states (Antony et al., 2017). Gestational changes in vaginal and gut microbiomes seem to be adaptive responses that protect the fetus and contribute to establishing the microbiome of the newborn (Mueller et al., 2015).

Gallbladder and liver. The gallbladder is often distended because of its decreased muscle tone during pregnancy. Increased emptying time and thickening of bile caused by prolonged retention are typical changes. These features, together with slight hypercholesterolemia from increased progesterone levels, may account for the development of gallstones during pregnancy (Lee et al., 2019).

Minor changes in liver function develop. Liver size is unchanged during pregnancy. Serum albumin and total protein levels are reduced due to hemodilution. Serum alkaline phosphatase levels increase up to four times the nonpregnant level. Other liver function tests remain at nonpregnant levels (Antony et al., 2017).

Occasionally, intrahepatic cholestasis (retention and accumulation of bile in the liver caused by factors within the liver) occurs late in pregnancy in response to placental steroids. It can result in severe itching with or without jaundice (Rapini, 2019) (see Chapter 11).

Abdominal discomfort. Intra-abdominal alterations that can cause discomfort include pelvic heaviness or pressure, round ligament tension, flatulence, distension and bowel cramping, and uterine contractions. In addition to displacement of intestines, pressure from the expanding uterus causes an increase in venous pressure in the pelvic organs. Although most abdominal discomfort is a consequence of normal pregnancy alterations, the health care provider must be alert to the possibility of disorders such as bowel obstruction or an inflammatory process.

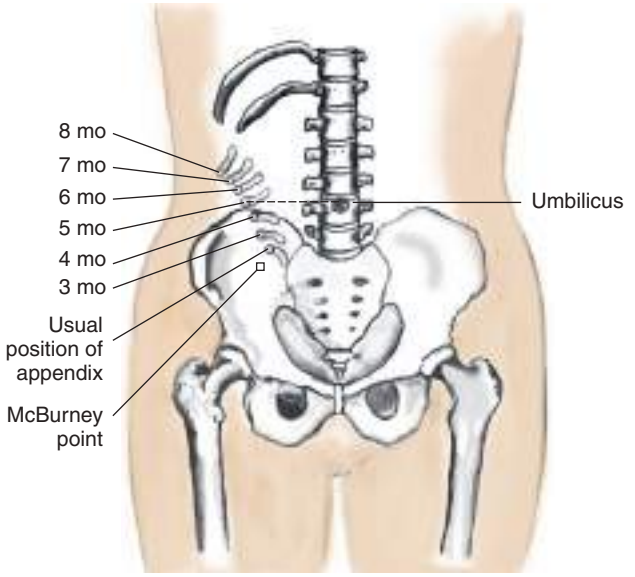

Fig. 10.16 Change in position of appendix in pregnancy. Note McBurney point.

Appendicitis may be difficult to diagnose in pregnancy because the appendix is displaced upward and laterally, high and to the right, away from McBurney point (Figure 10.16). (See further discussion in Chapter 14, section Appendicitis.)

Endocrine System. Profound endocrine changes are essential for pregnancy maintenance, normal fetal growth, and postpartum recovery. Hormones, their sources, and their effects on the pregnancy are presented in Table 10.6.

TABLE 10.6 Hormones and Effects of Changes During Pregnancy

Hormone	Source	Effects of Changes During Pregnancy
Human chorionic gonadotropin	Fertilized ovum and chorionic villi	Maintains corpus luteum production of estrogen and progesterone until placenta takes over the function
Progesterone	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; maintains pregnancy by relaxing smooth muscles, decreasing uterine contractility; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; decreases person's ability to use insulin
Estrogen	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; promotes enlargement of genitals, uterus, and breasts; increases vascularity; relaxes pelvic ligaments and joints; interferes with folic acid metabolism; increases level of total body proteins; promotes retention of sodium and water; decreases secretion of hydrochloric acid and pepsin; decreases mother's ability to use insulin
Serum prolactin	Anterior pituitary gland	Prepares breasts for lactation
Oxytocin	Posterior pituitary gland	Stimulates uterine contractions; stimulates milk ejection from breasts
Human placental lactogen (previously called chorionic somatomammotropin)	Placenta	Acts as a growth hormone; contributes to breast development; decreases maternal metabolism of glucose; increases amount of fatty acids for metabolic needs
Thyroxine-binding globulin, thyroxine, triiodothyronine	Thyroid gland	With adequate iodine intake, little or no enlargement of thyroid gland. Total T_3 and T_4 levels are slightly increased, peak by midpregnancy; by term are 10 to 15% lower than nonpregnant
Parathyroid	Parathyroid glands	Controls calcium and magnesium metabolism
Insulin	Pancreas	Increases production of insulin to compensate for insulin antagonism caused by placental hormones: effect of insulin antagonists is to decrease tissue sensitivity to insulin or ability to use insulin
Cortisol	Adrenal glands	Stimulates production of insulin; increases peripheral resistance to insulin
Aldosterone	Adrenal glands	Stimulates resorption of excess sodium from the renal tubules

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone.

KEY POINTS

- ELISA testing, with monoclonal antibody technology, is the most popular method of pregnancy testing and is the basis for most over-the-counter home pregnancy tests.
- The biochemical, physiological, and anatomical adaptations that occur during pregnancy are profound and most revert back to the nonpregnant state after birth and lactation.
- Adaptations in the pregnant person are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues.
- Adaptations to pregnancy protect the patient's normal physiological functioning, meet the metabolic demands that pregnancy imposes, and provide for fetal developmental and growth needs.
- Presumptive, probable, and positive signs of pregnancy aid in the diagnosis of pregnancy; only positive signs (identification of a fetal heart tone, verification of fetal movements, and visualization of the fetus) can establish the diagnosis of pregnancy.
- Although the pH of the pregnant patient's vaginal secretions is more acidic than in the nonpregnant state, they are more vulnerable to some vaginal infections, especially yeast infections.
- Increased vascularity and sensitivity of the vagina and other pelvic viscera may lead to a high degree of sexual interest and arousal.
- Some adaptations to pregnancy result in discomforts such as fatigue, urinary frequency, nausea, constipation, and breast sensitivity.
- Balance and coordination are affected by changes in joints and in the patient's centre of gravity as pregnancy progresses.

Nursing Care of the Family During Pregnancy

Nancy Watts

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the processes of confirming pregnancy and estimating the date of birth.
2. Summarize the physical, psychosocial, and behavioural changes that usually occur as the pregnant individual and family members adapt to pregnancy.
3. Discuss the benefits of prenatal care and challenges of accessibility for some people.
4. Outline the routine assessments of maternal and fetal health status at the initial and follow-up visits during pregnancy.
5. Conceptualize common nursing assessments, diagnoses, interventions, and methods of evaluation in providing care for the pregnant patient and family.
6. Plan education needed by pregnant patients related to physical discomforts of pregnancy and recognition of the signs and symptoms of potential complications.
7. Examine the effects of culture, age, parity, and number of fetuses on the response of the patient and family to the pregnancy and on the prenatal care provided.
8. Describe the available options for pregnant patients regarding health care providers and birth setting choices.
9. Determine the options and scope of childbirth and perinatal education in the community.

The prenatal period is a time of physical and psychological preparation for birth and parenthood. Becoming a parent is a major life event that brings challenges to the pregnant patient and their family (Denissen et al., 2019). It is a time of intense learning, psychological and social demands, as well as change for parents and those close to them. The prenatal period provides a unique opportunity for nurses and other members of the health care team to have a positive influence on the health of all family members. During this period, healthy people seek regular care and guidance, and many are motivated to change behaviours such as eating habits, based on their pregnancy. The perinatal nurse's health promotion interventions and routine prenatal care can affect the well-being of the patient, their unborn child, and the rest of their family as part of the continuum in a long-term primary care relationship with caregivers (Cline & Young, 2020).

Regular prenatal visits, ideally beginning soon after the first missed menstrual period, offer opportunities to provide information and ensure the health of the expectant parent and their newborn. Care is designed to monitor the growth and development of the fetus and identify abnormalities that may interfere with the course of a healthy regnancy. The pregnant patient and their family can seek support to reduce stress and learn parenting skills.

Pregnancy lasts about 40 weeks, or 280 days. It is often described in terms of **trimesters**. The first trimester covers weeks 1 through 13; the second, weeks 14 through 26; and the third, weeks 27 through term gestation. The focus of this chapter is on the health care needs of the expectant family over the course of pregnancy, which is known as the *prenatal period.*

CONFIRMATION OF PREGNANCY

Patients often suspect pregnancy when they miss a menstrual period. Many patients come to the first visit after a positive home pregnancy test. However, the clinical diagnosis of pregnancy before the second missed period may be challenging in some patients. Factors such as physical variations, lack of abdominal muscle relaxation, obesity, or presence of fibroids may confound even the experienced examiner. Accuracy in diagnosis is important because emotional, social, or medical consequences related to an inaccurate diagnosis, either positive or negative, can be extremely serious.

Signs and Symptoms

Much variability is possible in the subjective and objective symptoms of pregnancy. Therefore, the confirmation of pregnancy may be uncertain

for a time. It is based on signs and symptoms that are reported during history taking or found during physical examination. These signs and symptoms are classified as *presumptive, probable,* or *positive* (see Table 10.2, Signs of Pregnancy).

Estimating Date of Birth

When pregnancy is confirmed, the patient's first question usually is when they will give birth. This date is called the **estimated date of birth (EDB)**. Accurate dating of pregnancy is vital to promoting healthy outcomes for the patient and the fetus. A correct date for the first day of the last (normal) menstrual period (LMP), the date of intercourse, and a **basal body temperature (BBT)** record may be of great value in the accurate determination of pregnancy (see Chapter 8). An early ultrasound done in the first trimester is considered the gold standard for confirmation of pregnancy and dating (Butt & Lim, 2019). Accurate assignment of gestational age may decrease post-date induction and improve obstetrical care through optimal timing of interventions and avoidance of others, for example, prenatal screening tests. First-trimester crown–rump length is the best parameter for estimating gestational age and should be used if possible (Butt & Lim, 2019). If a patient is not able to get a first-trimester ultrasound for dating purposes, a second-trimester ultrasound that includes several parameters such as biparietal diameter, head circumference, and femur length can be used to provide accuracy (Butt & Lim, 2019).

Nägele's rule is a common method for calculating the EDB. It is based on the person's accurate recall of their last menstrual period (LMP). It assumes that the person has a 28-day cycle and that fertilization occurred on the 14th day. According to Nägele's rule, after determining the first day of the LMP, subtract 3 months, add 7 days and 1 year; or, alternatively, add 7 days to the LMP and count forward 9 months. For example, if the first day of the LMP was September 10, 2021, the EDB is June 17, 2022.

An adjustment is in order if the cycle is longer or shorter than 28 days. Only about 5% of pregnant women give birth spontaneously on the EDB as determined by Nägele's rule. Most women give birth during the period extending from 7 days before to 7 days after the EDB.

ADAPTATION TO PREGNANCY

Pregnancy affects all family members, and each family member needs to adapt to the pregnancy and interpret its meaning in light of their own needs and circumstances. This process of family adaptation to pregnancy takes place within a cultural environment influenced by societal trends and continues for usually at least 1 year past the birth. With the occurrence and greater awareness of cultural and demographic changes in Western society in recent years, the perinatal nurse must be prepared to support the diversity in family structure. Families are not limited to but may include lone parents, LGBTQ families, extended families, or surrogate families.

Much of the research around family dynamics during pregnancy has been done with White, middle-class nuclear families; thus findings may not apply to families who do not fit this model. It is important that the nurse adapt concepts and understanding to acknowledge family diversity and demonstrate cultural humility. It is helpful to ask the pregnant patient about their "family," which is whoever they may choose, and their relationship to them (see Chapter 2).

Maternal Adaptation

Pregnant patients of all ages use the months of pregnancy to adapt to the maternal role, a complex process of social and cognitive learning. With the perception of fetal movement in the second trimester, the patient turns their attention inward to their pregnancy and to relationships with their mother and other women who have been or who are pregnant.

Pregnancy is a maturational milestone that can be stressful but also rewarding as the person prepares for a new level of caring and responsibility. Their self-concept changes in readiness for parenthood as they anticipate their new role. They may move gradually from being self-contained and independent to being committed to a lifelong concern for another human being. This growth requires mastery of certain developmental tasks: accepting the pregnancy, identifying with the role of mother, reordering the relationships between themselves and their mother and between themselves and their partner, establishing a relationship with the unborn child, and preparing for the birth experience. The presence of the person's family and emotional support are important factors in their successful accomplishment of these developmental tasks. Single patients with limited support may have more difficulty making this adaptation.

Accepting the Pregnancy. The first step in adapting to the maternal role is accepting the idea of pregnancy and assimilating the pregnant state into the patient's way of life. Mercer (1995) described this process as *cognitive restructuring* and credited Rubin (1975, 1984) as the nurse theorist who pioneered our understanding of maternal role attainment.

The degree of acceptance is reflected in the patient's emotional responses. Initially, many patients are dismayed at finding themselves pregnant, especially if the pregnancy is unplanned or unintended. Eventual acceptance of pregnancy parallels the growing acceptance of the reality of a child. This has been described as "engagement," or giving of oneself both in time and emotional self to the fetus or child (Curran et al., 2017). However, nonacceptance of the pregnancy does not equate with rejection of the child, because a patient may dislike being pregnant but feel love for the child to be born.

Patients who are happy and pleased about their pregnancy usually have high self-esteem and tend to be confident about outcomes for themselves, their babies, and other family members. Despite a general feeling of well-being, many pregnant patients are surprised to experience *emotional lability*, that is, rapid and unpredictable changes in mood. These swings in emotions and increased sensitivity to others are disconcerting to the expectant mother and loved ones. Increased irritability, tears, and anger may alternate with feelings of great joy and cheerfulness. Profound hormonal changes that are part of the maternal responses to pregnancy may be responsible for these mood changes.

Many patients have ambivalent feelings during pregnancy, regardless of whether the pregnancy was intended. *Ambivalence*—having conflicting feelings at the same time—is considered a normal response for people preparing for a new role. For example, during pregnancy, individuals may feel great pleasure that they are fulfilling a lifelong dream, but they also may feel great regret with the changes that come with parenthood.

Even people who are pleased to be pregnant may, from time to time, experience feelings of hostility toward the pregnancy or the unborn child. Negative emotions may surface with chance remarks regarding another person's appearance or with missed employment possibilities on account of the pregnancy. Body sensations, feelings of dependence, or realization of the responsibilities of child care also can generate such feelings.

Intense feelings of ambivalence that persist through the third trimester may indicate an unresolved conflict with the motherhood role (Mercer, 1995). After the birth of a healthy child, memories of these ambivalent feelings usually are dismissed. If the child is born with a disability, a patient may look back at the times when they did not want the pregnancy and feel intense guilt. They may believe that their

ambivalence caused the birth defect. The patient will need emotional support and information regarding actual causes for the anomaly.

Identifying With the Mother Role. The process of identifying with the mother role begins early in each person's life, when being mothered as a child. Their cultural and social group's perception of what constitutes a woman's role can subsequently influence them in choosing between motherhood and a career, being married or single, being independent rather than interdependent, or being able to manage multiple roles. Practice roles such as playing with dolls, babysitting, and taking care of siblings may increase the person's understanding of what being a mother involves.

Many individuals have always wanted a baby; they like children and look forward to motherhood. Their high motivation to become a parent promotes acceptance of pregnancy and eventual prenatal and parental adaptation. Other people may not have considered in any detail what motherhood means to them. During pregnancy, these patients will need to resolve conflicts such as not wanting the pregnancy and child-related or career-related decisions.

Reordering Personal Relationships. Close relationships of the pregnant person generally undergo change as they prepare emotionally for the new role of mother. As family members learn their new roles, periods of tension and conflict may occur. Social support, aid, and affirmation are critical to the pregnant person and are most often provided by their social network, extended family, and partner. The friendship of other pregnant individuals or new mothers may also be important as their experience is valued. Information can be passed from one person to another that normalizes what one is feeling or doing as preparation for labour, birth, or parenting.

An understanding of the typical patterns of adjustment can help the nurse reassure the pregnant patient and explore issues related to social support. Promoting effective communication patterns between the expectant mother and their own mother and between the expectant mother and their partner are common nursing interventions provided during the prenatal visits.

The individual's relationship with their mother is significant in adapting to and feeling confidence in their pregnancy and motherhood. Important components in the pregnant patient's relationship with their mother are the mother's availability (past and present), their reactions to their child's pregnancy, respect for their child's autonomy, and the willingness to reminisce (Mercer, 1995).

The mother's positive reaction to their own child's pregnancy signifies their acceptance of the grandchild and of their offspring. If the mother is supportive, their child has an opportunity to discuss pregnancy and labour and their feelings of joy or ambivalence with a knowledgeable and accepting person who is close to them (Figure 11.1). Reminiscing about the pregnant person's early childhood and sharing the grandmother-to-be's account of their childbirth experience can help the pregnant person anticipate and prepare for labour and birth.

Although the pregnant person's relationship with their mother is significant in considering their adaptation in pregnancy, the most important person to the pregnant patient is usually their partner. Patients generally express two major needs within this relationship during pregnancy: feeling loved and valued, and having the child accepted by their partner.

In a committed relationship, the addition of a child changes forever the nature of the bond between partners. This can be a time when couples grow closer and the pregnancy has a maturing effect on the partners' relationship as they assume new roles and discover new aspects of one another. Partners who trust and support each other are able to share mutual dependency needs (Mercer, 1995).

Fig. 11.1 A pregnant woman and her mother enjoying a walk together. (Courtesy Michael S. Clement, MD.)

Sexual expression during pregnancy is highly individual. The sexual relationship is affected by physical, emotional, and interactional factors, as well as the couple's knowledge about sexual activity during pregnancy. As pregnancy progresses, changes in body shape, body image, and levels of discomfort influence both partners' desire for sexual expression. During the first trimester, the patient's sexual desire may decrease, especially if they have breast tenderness, nausea, or fatigue. As they progress into the second trimester, their sense of well-being, combined with the increased pelvic congestion that occurs at this time, may increase their desire for sexual release. In the third trimester, somatic discomforts and physical bulkiness may increase their physical discomfort and diminish their interest in sex. Partners need to feel free to discuss their sexual responses during pregnancy with each other and with their health care provider (see later discussion).

Establishing a Relationship With the Fetus. Emotional attachment—feelings of being connected through affection or love—begins during the prenatal period as patients fantasize and daydream in preparing themselves for motherhood (Rubin, 1975, 1984). They think of themselves as mothers and imagine maternal qualities they would like to possess. Expectant parents wish to be warm, loving, and close to their child. They try to anticipate changes the child will bring to their lives and wonder how they will react to noise, disorder, reduced freedom, and caregiving activities. The mother–child relationship progresses through pregnancy as a developmental process that tends to unfold over three phases.

In phase 1, the pregnant person accepts the biological fact of pregnancy. They need to be able to state, "I am pregnant." In phase 2, the person accepts the growing fetus as distinct from themselves and as a person to nurture. They can now say, "I am going to have a baby." Attachment of a mother to her child is enhanced by experiencing a planned pregnancy, and it increases when ultrasound examination and quickening (feeling movement) confirm the reality of the fetus. During phase 3, the pregnant person prepares realistically for the birth and parenting of the child. They express the thought, "I am going to be a mother," and define the nature and characteristics of the child. For example, they may speculate about the child's sex (if unknown) and personality traits based on patterns of fetal activity.

Although the mother alone experiences the child within, both parents and siblings may believe the unborn child responds in a very individualized, personal manner. Mothers and parents may create mental images about their unborn fetus that may promote prenatal caregiving. The frequent use of ultrasound in pregnancy in developed countries promotes these images of the fetus as "the baby" and cultivates a sense of maternal–fetal connection (Curran et al., 2017). Family members may interact with the unborn child by talking to the fetus and stroking the mother's abdomen, especially when the fetus shifts position. They may sing to, play music for, or read to the fetus. The fetus may have a nickname used by family members.

Preparing for Birth. Many patients actively prepare for birth. They read books, view films, search the Internet, attend childbirth classes, and talk to other individuals. They seek the caregiver with whom they feel most comfortable for advice, monitoring, and caring. The multipara has their own history of labour and birth, which influences their approach to preparation for this childbirth experience.

Some mothers may feel anxious about safe passage—for themselves and for their child during the birth process (Mercer, 1995; Rubin, 1975, 1984). This concern may not be expressed overtly but rather through making plans for care of the new baby and other children in case "anything should happen." The nurse needs to listen for such cues of a mother's concern. Many patients fear the pain of childbirth or fear mutilation; they do not understand anatomy and the birth process. Education offered by the perinatal nurse can alleviate many of these fears.

Toward the end of the third trimester, a pregnant person's breathing can be difficult and fetal movements become vigorous enough to disturb their sleep. Backaches, increased frequency and urgency of urination, constipation, and varicose veins can become troublesome. The bulkiness and awkwardness of their body may interfere with their ability to care for other children, perform routine work-related duties, and assume a comfortable position for sleep and rest. A strong desire to see the end of pregnancy, to be over and done with it, makes patients at this stage ready to move on to childbirth.

Paternal Adaptation

The same fears, questions, and concerns of the pregnant person may also affect their birth partner, whether the partner is a biological father or not. Birth partners need to be kept informed, supported, and included in all activities in which the mother desires the partner's participation. The nurse can do much to promote pregnancy and birth as a family experience. A partner who is supportive has a direct effect on the pregnant patient, with decreased anxiety, depression and smoking (Cheng et al., 2016).

Modern fatherhood is increasingly diverse, given the wide variety of family structures. The father's beliefs and feelings about ideal parenting roles and their cultural expectation of appropriate behaviour during pregnancy will affect their response to their partner's need for him. One partner may engage in nurturing behaviour; another may feel lonely and alienated as the pregnant person becomes physically and emotionally engrossed in the unborn child. The partner may seek comfort and understanding outside the home or become interested in a new hobby or involved with their work. Some partners view pregnancy as proof of their masculinity and their dominant role. To others, pregnancy has no meaning in terms of responsibility to either mother or child. However, for most partners, pregnancy is a time of preparation for the parental role, fantasizing about being in that role, great anticipation, and intense learning (Figure 11.2).

Accepting the Pregnancy. The ways in which fathers adjust to the parental role have been the subject of considerable research. In older societies, the man enacted the ritual couvades; that is, he behaved in specific ways and respected taboos associated with pregnancy and giving birth. In this way, the man's new status was recognized and endorsed. By contrast, some modern-day men experience pregnancy-like symptoms, such as nausea, weight gain, and other physical symptoms. This phenomenon is known as the **couvade syndrome**. Changing cultural and professional attitudes have encouraged fathers' participation in the birth experience; however, there are still many cultures in which pregnancy and childbirth are considered a female domain and men are not encouraged to be part of the labour and birth process. It is important that the nurse be aware and understanding of different cultural expectations.

Fig. 11.2 A prospective mother and father spending time together. Women respond positively to their partner's interest and concern. (iStock.com/ElenaNichizhenova)

The man's emotional response to becoming a father, his concerns, and his informational needs will change during the course of pregnancy. May (1982) described three phases characterizing the developmental tasks experienced by the expectant father:

- The *announcement phase* may last from a few hours to a few weeks. The developmental task is to accept the biological fact of pregnancy. Men react to the confirmation of pregnancy with joy or dismay, depending on whether the pregnancy is desired, unplanned, or unwanted. Ambivalence in the early stages of pregnancy is common. If pregnancy is unplanned or unwanted, some men find the alterations in life plans and lifestyles difficult to accept. Some men engage in extramarital affairs for the first time during their partner's pregnancy. Others may subject their partner to intimate partner violence for the first time or escalate the frequency of violent episodes.
- The second phase, the *moratorium phase,* is the period when the man adjusts to the reality of pregnancy. The developmental task is to accept the pregnancy. Some men appear to put conscious thought of the pregnancy aside for a time. They become more introspective and engage in many discussions about their philosophy of life, religion, childbearing, and child-rearing practices and their relationships with family members, particularly with their father. Depending on the man's readiness for the pregnancy, this phase may be relatively short or persist until the last trimester.
- The third phase, the *focusing phase,* begins in the last trimester and is characterized by the father's active involvement in both the pregnancy and his relationship with his child. The developmental task is to negotiate with his partner the role he is to play in labour and to prepare for parenthood. In this phase, the man concentrates on his experience of the pregnancy and begins to think of himself as a father.

These phases are not rigid, and various men will act them out to different degrees or may not go through them at all, but they can be used as a guideline.

Identifying With the Father Role. Each man brings to pregnancy attitudes that affect the way in which he adjusts to the pregnancy and parental role. His memories of the fathering he received from his own father, the experiences he has had with child care, and the perceptions of the male and father roles within his social group guide his selection of the tasks and responsibilities he will assume. Some men are highly motivated to nurture and love a child. They may be excited and pleased about the anticipated role of father. Others may be more detached or even hostile to the idea of fatherhood.

Reordering Personal Relationships. One of the partner's roles in pregnancy is to nurture and respond to the pregnant person's feelings of vulnerability. The partner also must deal with the reality of the pregnancy. The partner's support indicates involvement in the pregnancy and preparation for attachment to the child.

Some aspects of a partner's behaviour indicate rivalry. Direct rivalry with the fetus may be evident, especially during sexual activity. Men may protest that fetal movements prevent sexual gratification or that the fetus is watching them during sexual activity. Feelings of rivalry may be unconscious and not verbalized but expressed through subtle behaviours.

The pregnant patient's increased introspection may cause their partner to feel uneasy as they become preoccupied with thoughts of the child and of motherhood, with their growing dependence on their health care provider, and with their re-evaluation of the couple's relationship.

Establishing a Relationship With the Fetus. The father–child attachment can be as strong as the mother–child relationship, and fathers can be as competent as mothers in nurturing their infants. The father–child attachment also begins in pregnancy. A father may rub or kiss the maternal abdomen; try to listen, talk, or sing to the fetus; or play with the fetus as he notes fetal movement. Calling the unborn child by name or nickname helps to confirm the reality of pregnancy and promotes attachment.

Men prepare for fatherhood in many of the same ways that women prepare for motherhood (e.g., by reading and fantasizing about the baby). Daydreaming about their role as father is common in the last weeks before the birth; men rarely describe their thoughts unless they are reassured that such daydreams are normal.

Nurses can help fathers identify concerns and prepare for the role of being a father by asking questions such as the following:

- What does the word *father* mean to you?
- How do you envision life as a father or parent?
- How will you be involved in caring for your baby?
- What do you imagine your baby will look and act like?
- How will having a baby affect your relationship with your partner?

Some fathers may not wish to answer such questions when they are asked but may need time to think them through or discuss them with their partners.

As the birth day approaches, fathers may have more questions about fetal and newborn behaviours. Some fathers are shocked or amazed at the small size of the clothes and furniture for the baby. The nurse can tell the father about the unborn child's ability to respond to light, sound, and touch and encourage him to feel and talk to the fetus. Discussions with new fathers, as in childbirth classes, may be welcomed.

Preparing for Birth. The days and weeks immediately before the expected day of birth are characterized by anticipation and anxiety. Boredom and restlessness are common as the couple focuses on the birth process; however, during the last 2 months of pregnancy many expectant fathers experience a surge of creative energy at home and on the job. They can become dissatisfied with their present living space. They tend to act on the need to alter the environment (e.g., remodelling, painting). This activity can be overt evidence of their sharing in the childbearing experience. They are able to channel the anxiety and other feelings experienced during the final weeks before birth into productive activities. This behaviour generally earns recognition and compliments from friends, relatives, and their partner.

Major concerns for partners are getting the pregnant person to the birthing facility in time for the birth and not appearing ignorant. Many partners want to be able to recognize labour and determine when it is appropriate to leave for the hospital or call the physician or midwife. They may imagine different situations and plan what they will do in response to them; they may rehearse taking various routes to the hospital, timing each route at different times of the day.

Some prospective fathers have questions about the birthing suite's furniture, nursing staff, and location, as well as the availability of the health care provider and anaesthesiologist. Others want to know what is expected of them when their partner is in labour. A tour of the hospital may help alleviate some of these concerns. The man may have fears concerning the safety of his partner and about the possible mutilation or death of his partner or child. It is important that he be able to express these fears; otherwise he cannot help his partner deal with unspoken or overt apprehension.

With the exception of childbirth preparation classes, men have few opportunities to learn ways to be an involved and actively participate in this rite of passage into parenthood. The tensions and apprehensions of the unprepared, unsupportive father are readily transmitted to the mother and may increase the mother's own fears regarding childbirth and parenting.

Adaptation to Parenthood for the Nonpregnant Partner

The same fears, questions, and concerns can affect birth partners who are not the biological father or who are the nonpregnant partner in a same-sex couple. Much attention is paid to the needs of the pregnant patient, but the nonpregnant partner's needs receive less attention. Nonpregnant female partners, also referred to as *co-mothers*, can feel excluded by heterocentric maternity care service structures, but are likely to feel included by nursing staff (Cherguit et al., 2012). Nonpregnant partners will be better prepared for the changes that come with pregnancy and parenting if they are included in the process. In addition to dealing with their own feelings and the care of their partner, nonpregnant partners in a same-sex couple are often not acknowledged or accepted as a parent-to-be from within their own families and in society in general. Partners need to be kept informed, supported, and included in all activities in which the mother desires their participation. Nurses can do much to promote pregnancy and birth as a family experience by providing information about resources for same-sex parents such as community and online support groups.

Sibling Adaptation

Sharing the spotlight with a new brother or sister may be the first major crisis for a child. The older child often experiences a sense of loss or feels jealous at being "replaced" by the new baby. Some of the factors that influence the child's response are age, the parents' attitudes, the father's role, the length of separation from the mother, the hospital's visitation policy, and how the child has been prepared for the change.

The mother with other children needs to devote time and energy to reorganizing relationships with these children. The mother needs to prepare siblings for the birth of the baby (Figure 11.3) and begin the process of **role transition** in the family by including the children in the pregnancy and being sympathetic to older children's concerns about losing their place in the family hierarchy. No child willingly gives up a familiar position. See Family-Centred Care: Tips for Sibling Preparation.

FAMILY-CENTRED CARE

Tips for Sibling Preparation

Prenatal

Adjust the timing and content of information about an anticipated newborn to the age and understanding of the older child.

Take your child on a prenatal visit. Let the child listen to the fetal heartbeat and feel the baby move.

Involve the child in preparations for the baby, such as helping to decorate the baby's room.

Move the child to a bed (if still sleeping in a crib) at least 2 months before the baby is due or wait until a few months after the birth.

Read books, show videos, or take the child to sibling preparation classes (see figure), including a hospital tour.

Answer your child's questions about the coming birth and what babies are like, as well as any other questions factually and at the child's level of understanding.

Take your child to the homes of friends who have babies so that the child has realistic expectations of what babies are like.

Preschoolers in a sibling class learn about childbirth and infant care using dolls. (Courtesy Julie and Darren Nelson.)

During the Hospital Stay

Have someone bring the child to the hospital to visit you and the baby (unless you plan to have the child attend the birth).

Don't force interactions between the child and the baby. Often the child will be more interested in seeing you and being reassured of your love.

Help the child explore the infant by showing how and where to touch the baby.

Give the child a gift (from you or from you, the father, and the baby).

Going Home

Leave the child at home with a relative or babysitter.

Have someone else carry the baby from the car so that you can hug the child first.

Adjustment After the Baby Is Home

Arrange for a special time with the child alone with each parent.

Don't exclude the child during infant feeding times. The child can sit with you and the baby and feed a doll or drink juice or milk with you or sit quietly with a game. Encourage others to give gifts of nutritious snacks in little gift bags to eat when feeding the baby.

Prepare small gifts for the child so that, when the baby gets gifts, the sibling won't feel left out. Praise the child for acting age appropriately (so that being a baby does not seem better than being older).

Fig. 11.3 A young child likes to examine the pregnant abdomen of their mother. (iStock.com/FatCamera)

Sibling responses to pregnancy vary with age and dependency needs. The 1-year-old infant seems largely unaware of the process, but the 2-year-old child notices the change in their mother's appearance and may comment that "Mommy's fat." Toddlers' need for sameness in the environment makes children aware of any change. They can exhibit more clinging behaviour and sometimes regress in toilet training or eating.

By age 3 or 4 years, children like to be told the story of their own beginning and accept its being compared to the present pregnancy. They like to listen to heartbeats and feel the baby moving in utero (see Figure 11.3). Sometimes they worry about how the baby is being fed and what it wears.

School-age children take a more clinical interest in their mother's pregnancy. They may want to know in more detail "How did the baby get in there?" and "How will it get out?" Children in this age group notice pregnant people in stores, churches, and schools and sometimes seem shy if they need to approach a pregnant person directly. On the whole, they look forward to the new baby, see themselves as "mothers" or "fathers," and enjoy buying baby supplies and readying a place for the baby. Because they still think in concrete terms and base judgements on the here and now, they respond positively to their mother's current good health.

Early and middle adolescents preoccupied with the establishment of their own sexual identity may have difficulty accepting the overwhelming evidence of the sexual activity of their parents. They reason that if they are too young for such activity, certainly their parents are too old. They seem to take on a critical parental role and may ask, "What will people think?" or "How can you let yourself get so fat?" Many pregnant patients with teenage children confess that their teenagers are the most difficult factor in their current pregnancy.

Late adolescents do not appear to be unduly disturbed. They realize that they soon will be gone from home. Parents usually report that late adolescents are comforting and act more like other adults than children.

Grandparent Adaptation

Historically and currently, the roles of grandparents are affected by age, ability to nurture, culture, and expectations of themselves. Up to 8% of Canadian households have grandparents living with the nuclear family, which may increase support for the childbearing patient and family in many ways, including financial support, child-care information, cultural influences, physical caregiving, and emotional nurture (Vanier Institute, 2017). Many households of those born outside of Canada include members of several generations, who may provide assistance

Fig. 11.4 A grandmother relaxes with her grandson. (Courtesy Shannon Perry.)

for the new mother and family. For expectant grandparents, a first pregnancy in their child is evidence that they are aging, although with life expectancy increasing this may be received as positive news. Some individuals react negatively to the news that they will be grandparents, indicating that they are not ready for the new role.

Most grandparents are delighted with the prospect of a new baby in the family (Figure 11.4). It reawakens their feelings of their own youth, the excitement of giving birth, and their delight in the behaviour of the parents-to-be when they were infants. They set up a memory store of their child's first smiles, first words, and first steps that can be used later for "claiming" the newborn as a member of the family. Their satisfaction and that of the parents come with the realization that continuity between past and present is guaranteed.

The grandparent is the historian who transmits the family history, a resource person who shares knowledge based on experience, a role model, and a support person. The grandparent's presence and support can strengthen family systems by widening the circle of care and nurturance. Other sources of information cannot replace the unique contribution that grandparents make.

In some families, however, a grandparent may have a negative response, with stories of negative birth experiences or expressing of financial or time concerns around the coming of the new baby.

NURSING CARE

The goal of prenatal care is to promote a healthy pregnancy, labour, and birth, as well as to optimize the health and well-being of the pregnant patient, their fetus, the newborn, and the family (Heaman et al., 2018). Major emphasis is placed on preventive aspects of care, primarily to encourage the pregnant patient to practise healthy self-management and report unusual changes early so that any concerns can be minimized or prevented. In holistic care, nurses provide information and guidance about not only the physical changes but also the psychosocial impact of pregnancy on the patient and members of their family. Therefore, the goals of prenatal nursing care are to assess risk, promote healthy lifestyle behaviours, and identify and address medical and psychosocial issues that could affect the pregnancy and the ongoing health of the mother, child, and family (Gregory et al., 2019).

In Canada the majority of pregnant people (95%) receive care in the first trimester (Vanier Institute, 2017). Prenatal care is sought routinely by people of middle or high socioeconomic status. Lack of culturally sensitive care providers and barriers in communication caused by a lack of health care providers fluent in a population's language may be barriers in access to care. Immigrant patients from cultures in which prenatal care is provided on a different schedule or not emphasized may not know to seek routine prenatal care. Birth outcomes in populations with fewer prenatal visits or inconsistent care are less positive, with higher rates of maternal and fetal or newborn complications. In particular, newborns with low birth weight (LBW) (less than 2500 g) and infant mortality have been associated with inadequate prenatal care (Public Health Agency of Canada [PHAC], 2020a).

Barriers to obtaining health care during pregnancy include inadequate numbers of or access to health care providers, low income, education less than high school, social isolation, unpleasant clinic facilities or procedures, inconvenient clinic hours, great distance from health care facilities, lack of transportation, fragmentation of services, inadequate finances, and conflicting personal attitudes. The availability and accessibility of prenatal care may be improved by increasing the use of advanced practice nurses in collaborative practice with physicians or midwives or providing hours for clinics that accommodate working mothers (Heaman et al., 2018).

The traditional model for providing prenatal care has been used for more than a century. The initial visit usually occurs in the first trimester, with monthly visits occurring through week 28 of pregnancy. Thereafter, visits are scheduled every 2 weeks until week 36 and then every week until birth. This results in 7 to 11 prenatal visits during pregnancy. While this schedule may be appropriate for a low-risk pregnancy, patients with chronic conditions or with needs requiring closer assessment or monitoring or support should have their visits tailored to their needs (PHAC, 2020a). An increased rate of interventions such as induction of labour or Caesarean birth has been noted in low-risk patients who have an increased number (>10) of prenatal visits (Carter et al., 2016).

Group prenatal care is an alternative model to traditional care during pregnancy. In group prenatal care, authority is shifted from the provider to the patient and other pregnant patients who have similar due dates. The model creates an atmosphere that facilitates learning, encourages discussion, and develops mutual support. Centering Pregnancy (see Additional Resources at the end of the chapter) is a well-known model of group prenatal care that involves three components: health care assessment, education, and peer support. Most care takes place in the group setting after the initial visit and continues for ten 2-hour sessions that begin at about 16 weeks. At each meeting, the first 30 to 40 minutes consists of assessments (by the patient themselves and by the health care provider) and the remaining 60 to 75 minutes is spent in group discussion of specific issues such as discomforts of pregnancy, nutrition, and preparation for labour and birth. Families and partners are encouraged to participate. Benefits associated with group prenatal care include improved birth outcomes such as lower rates of preterm birth, decreased rates of infants who are small for gestational age, increased knowledge, improved satisfaction, higher rates of postpartum contraception, and higher breastfeeding initiation rates (Carter et al., 2017, PHAC, 2020a).

The South Community Birth Program (SCBP) in Vancouver, British Columbia, uses a Centering Pregnancy approach called Connecting Pregnancy. Low-risk pregnant patients in the underserved community of South Vancouver receive collaborative, interprofessional care from family physicians, midwives, physiotherapists, nutritionists, community health nurses, and doulas. This is the first such multidisciplinary program of its kind in Canada in which midwives and family physicians share the care of patients (see Additional Resources at end of the chapter).

Whether a traditional or group approach, prenatal care occurs in physician or midwifery offices, public health or hospital clinics, or in the patient's home. Optimal care is provided by an interprofessional team that includes the obstetrical care provider, nurses, and other health care providers and support groups (Gregory et al., 2019). Family physicians, nurse practitioners, public health nurses, registered dietitians, childbirth educators, maternal-fetal medicine specialists, and other health care providers may be part of the care team, based on the individual needs of the patient. Psychiatric care providers and social workers may be involved if the patient has mental health concerns, such as a history of depression. Collaboration among these individuals is necessary to provide holistic care. The case management model, which makes use of care maps and critical pathways, is one system that promotes comprehensive care with limited overlap in services. To emphasize the nursing role, care management for the initial visit and follow-up visits is organized around the central elements of the nursing process: assessment, analysis, plan of care and interventions, and evaluation.

In recent years, the concept of preconception care has been recognized as an important contributor to good pregnancy outcomes. If people can incorporate healthy lifestyle behaviours prior to conception—specifically, good nutrition, entering pregnancy with as healthy a weight as possible, adequate intake of folic acid, avoidance of alcohol and tobacco use, prevention of sexually transmitted infections (STIs) and other health hazards—a healthier pregnancy may result. Likewise, patients who have health concerns related to chronic diseases such as diabetes mellitus can be counselled about their special needs with the intent to minimize maternal and fetal complications. See Chapter 5 for further discussion of preconception care.

Initial Visit

Once the pregnancy is confirmed and the person's desire to continue the pregnancy has been validated, prenatal care is begun. The assessment process begins at the initial visit and is continued throughout the pregnancy. Assessment techniques include the interview, physical examination, and laboratory tests. Because the initial visit and follow-up visits are distinctly different in content and process, they are described here separately.

Interview. The therapeutic relationship between the nurse and the patient is established during the initial assessment interview (Figure 11.5). During this interview, the nurse must work to develop the patient's trust.

Fig. 11.5 Prenatal interview. (Courtesy Dee Lowdermilk.)

The pregnant patient and their partner or family members who may be present should be told that the first prenatal visit is longer and more detailed than future visits. The initial evaluation includes a comprehensive health history emphasizing the current pregnancy, previous pregnancies, the family, a psychosocial profile, a physical assessment, diagnostic testing, and an overall risk assessment.

With the patient's permission, persons accompanying them should be included in the initial prenatal interview. Observations and information about the patient's partner or family are then entered in the database. For example, if the patient is accompanied by small children, the nurse can ask about previous pregnancies and their plans for child care during the time of labour and birth. Any special needs should be noted at this time (e.g., wheelchair access, assistance in getting on and off the examining table, and cognitive deficits).

Current pregnancy. The presumptive signs of pregnancy, such as nausea and vomiting, can be of great concern to the patient. A review of symptoms they may be experiencing and how they are coping with them helps establish a database to develop a plan of care. Some early teaching may be provided at this time.

Childbearing and female reproductive system history. Data are gathered on the patient's age at menarche; menstrual history; contraceptive history; the nature of any infertility or gynecological conditions; history of any STIs; their sexual history; and a detailed history of all their pregnancies, including the present one, and their outcomes. The experience of a perinatal loss in a previous pregnancy may affect prenatal care and mental health in this pregnancy, so it is important to ask questions about what happened and how care can be structured this time to help alleviate anxiety associated with this history.

The date of the last Papanicolaou (Pap) test and the result are noted. The date of the LMP is obtained to assist in determining the EDB.

Health history. The health history includes those physical or surgical procedures that can affect the pregnancy or that can be affected by the pregnancy. For example, a pregnant patient who has diabetes, hypertension, or epilepsy requires special care. A careful history of any allergies and the type of reaction, medication use, and immunizations must be included. Because patients may be anxious during the initial interview, the nurse's reference to cues such as a MedicAlert bracelet can prompt the patient to explain allergies; chronic diseases; or medications being taken, such as cortisone, insulin, or anticonvulsants.

The patient is asked to list any previous surgical procedures. If a patient has had uterine surgery or extensive repair of the pelvic floor, a Caesarean birth may be necessary; previous appendectomy rules out appendicitis as a cause of right lower quadrant pain in pregnancy. Spinal surgery may contraindicate the use of spinal or epidural anaesthesia, or a referral to an anaesthesiologist during pregnancy may help determine what options are available. Breast augmentation or reduction procedures may affect the breastfeeding experience. Any injury involving the pelvis should be noted.

Currently, roughly 11% of the population has a physical disability, and increasingly these are being seen among the pregnant population. Patients who have chronic or disabling conditions often forget to mention them during the initial assessment because they have become so adapted to them. Special shoes or a limp may indicate the existence of a pelvic structural abnormality—an important consideration in pregnant patients. Nurses need to observe these special characteristics and sensitively inquire about them in order to obtain individualized data that will provide the basis for a comprehensive nursing care plan that can optimize pregnancy outcomes (Bekdache & Berndle, 2019). Observations of this nature are a vital component of the interview process because they prompt the nurse and the patient to focus on the specific needs of the patient and their family. For example, specific things like

increased falls or preparing for child care afterward will be critical to address during pregnancy.

Nutritional history. The nutritional status of a pregnant patient has a direct effect on the growth and development of the fetus. A dietary assessment can reveal special diet practices, food allergies, eating behaviours, the practice of **pica**, and other factors related to their nutritional status (see Box 12.5). Body mass index (BMI) should be calculated for all patients at the first prenatal visit to provide the basis for counselling about weight gain, physical activity, and healthy food choices. Pregnant patients are usually motivated to learn about good nutrition and respond well to nutritional advice generated by this assessment. Cultural influences on diet and food selection should also be considered (see Chapter 12).

It is essential that patients with obesity receive counselling about weight gain, nutrition, and food choices. They should also be advised about the risk for complications for themselves and increased risk for congenital abnormalities in the fetus. Patients with a history of bariatric surgery are nutritionally at risk and should be followed closely throughout pregnancy to ensure adequate caloric and micronutrient intake. Maternal weight gain and fetal growth should be closely monitored (Davies et al., 2018).

History of use of drugs and herbal preparation use. The prenatal history includes past and present use of drugs (legal over-the-counter [OTC] and prescription medications; vitamin supplements such as A, C, D, and E; herbal preparations; caffeine; alcohol; nicotine) and problematic substances (e.g., cannabis, opioids, cocaine). This is because many substances cross the placenta and can pose a risk to the developing fetus. Increasing numbers of individuals, including pregnant patients, are using herbal preparations. Therefore, it is important for health care providers to question prenatal patients regarding their use of herbal preparations and to document their responses.

It is especially important to form a relationship with patients who are being treated for a history of problematic substance use, such as those in a methadone program or those who are continuing to use substances during pregnancy that will be concerning for the fetus during pregnancy or the infant at birth. Providing information about care during pregnancy and in labour and birth that is honest and transparent will help foster the therapeutic relationship needed to empower the pregnant person and family to attend prenatal care and practise interventions required for a healthy pregnancy. Asking questions about substance use in a nonthreatening way as well as exploring the patient's story can facilitate this relationship (Mahoney et al., 2019). See Chapter 15 for discussion of substance use during pregnancy.

LEGAL TIP

Screening for Drug Use

Hospitals must obtain informed consent from a pregnant patient before they can be tested for drug use (Mahoney et al., 2019). Providing the patient information about how the test will be used to provide care for their infant will help them understand the reason for the test.

Family history. The family history provides information about the patient's immediate family, including parents, siblings, and children. These data can be used to identify familial or genetic disorders or conditions that could affect the health of the patient or their fetus.

Social, experiential, and occupational history. Situational factors such as the family's social support and socioeconomic status are assessed while the history is obtained. The following information may be gathered over several encounters. The patient's perception of this pregnancy is explored by asking them such questions as the following:

- Is this pregnancy wanted or not, planned or not, and is the timing helpful for your family?
- Is the pregnant person or couple pleased or displeased, accepting or nonaccepting?
- Will any changes related to family relationships, finances, career, or living accommodations occur as a result of the pregnancy?

The family support system is determined by asking the patient such questions as the following:

- What primary support is available to them?
- Are changes needed to promote adequate support?
- What are the existing relationships between the mother, father or partner, siblings, and expectant grandparents?
- What preparations are being made for their care and that of dependent family members during labour and for the care of the infant after birth?
- Is financial, educational, or other support needed from the community?
- What are the person's ideas about childbearing, their expectations of the infant's behaviour, and their outlook on life and the maternal role?

Other questions that should be asked include the following:

- What does the person think it will be like to have a baby in the home?
- How is their life going to change by having a baby?
- How prepared do they feel for becoming a parent?

During interviews throughout the pregnancy, the nurse should remain alert for the appearance of potential parenting issues such as depression, lack of family support, distance from family support, and inadequate living conditions.

Coping mechanisms and patterns of interacting should also be identified. Early in the pregnancy, the nurse should determine the patient's knowledge of pregnancy, maternal changes, fetal growth, self-management, and care of the newborn, including feeding. Before planning for nursing care, the nurse needs information about the patient's decision-making abilities and living habits (e.g., exercise, sleep, diet, diversional interests, personal hygiene). Common stressors during childbearing include the baby's welfare, the labour and birth process, the behaviours of the newborn, the relationship with the baby's father and her family, changes in body image, and physical symptoms.

Attitudes concerning the range of acceptable sexual behaviour during pregnancy can be explored by asking, for example, what the patient's family (partner, friends) have told them about sex during pregnancy. The patient's sexual self-concept can be addressed by asking such questions as: How do you feel about the changes in your appearance? How does your partner feel about your body now? How do you feel about wearing maternity clothes?

Patients should be questioned about their occupation, past and present, as this may adversely affect maternal and fetal health. For some patients, heavy lifting and exposure to chemicals and radiation may be part of their daily work, and these activities can negatively affect the pregnancy. For others, long hours of sitting at a desk working at a computer can contribute to carpal tunnel syndrome or circulatory stasis in the legs. Patients also should be asked about their exposure to children, such as at a day care centre or in a school, to assess the possibility of exposure to infectious diseases such as varicella or parvovirus.

Mental health screening. As part of routine prenatal care, all patients should be assessed and screened for mental health issues. Perinatal depression and anxiety are the most common complications of pregnancy and, if left untreated, can have serious adverse effects on the mother, the newborn, and the family. The American College of Obstetricians and Gynecologists (ACOG) recommends screening for depression and anxiety symptoms at least once during the perinatal

period using a standardized, validated instrument such as the Edinburgh Postnatal Depression Scale (EDPS) (ACOG, 2018). Appropriate follow-up and treatment, including referral to mental health care providers, is essential whenever there is a positive screen. Patients may be unlikely to initiate discussions with health care providers related to mental health concerns; they may be more willing to disclose issues and concerns when they are informed that the screening is part of routine prenatal care, when health care providers are interested and sensitive, and when patients are informed about the prevalence of mental health issues during the perinatal period (Kingston et al., 2015). When mental health issues are identified, appropriate referral and follow-up are needed. Risk factors for depression or anxiety during pregnancy include lack of support from their partner, inadequate social support, history of intimate partner violence, personal history of mental illness, family history of mental illness, unintended pregnancy, pregnancy complications or loss, and stressful life events (Biaggi et al., 2016).

Physical, sexual abuse and intimate partner violence. All patients should be assessed for a history or risk of physical or sexual abuse, particularly because the likelihood of intimate partner violence (IPV) increases during pregnancy (see Chapter 5 for a detailed discussion). A history of childhood sexual abuse also needs to be assessed, as this can have an impact on the patient's labour experience. It is essential that the screening be done in a safe, private setting with the patient alone. The nurse can ask the patient screening questions along with routine assessments during pregnancy. Examples of questions that might be asked include the following:

- Are you with a spouse or partner who threatens or physically hurts you? If yes, who?
- Within the past year or in this pregnancy, has anyone hit, slapped, kicked, or otherwise hurt you? If yes, who? Are you currently with that person?
- Has anyone forced you to have sexual activities that made you uncomfortable? If yes, who? Are you currently with that person?

IPV begins or escalates during pregnancy for a variety of reasons. Pregnancy tends to be a time of increased autonomy and self-awareness for pregnant patients. A patient's focus on their body, preoccupation with the fetus, and reduced physical and emotional availability can trigger jealous and possessive responses by the partner, especially if the pregnancy was unintended. After birth, the mother may be so physically and emotionally drained that they may have difficulty bonding with their infant; they have little time or energy to focus on the partner, which can trigger more violence. They may be at risk for becoming an abusive mother whether or not they remain in the abusive relationship (Campo, 2015).

Although visual cues from the patient's appearance or behaviour may suggest the possibility of abuse, routine screening is important, as no one profile of the person who experiences IPV exists. Identification of abuse and immediate clinical intervention that includes information about safety can result in increased safety for the person; intervention may involve taking steps to prevent future abuse, such as seeking shelter for themselves during pregnancy (Robinson et al., 2019). During pregnancy, the target body parts tend to change during abusive episodes. Patients report physical blows directed to the head, breasts, abdomen, and genitalia. Sexual assault is common.

IPV occurs more frequently in pregnant adolescents than in adult patients (Alhusen et al., 2015). Violence during pregnancy in teenagers constitutes a particularly difficult situation. Adolescents may be more trapped in the abusive relationship than adult patients because of their inexperience. They may ignore the violence because the jealous and controlling behaviour is interpreted as love and devotion. Routine screening for abuse and sexual assault is recommended for pregnant adolescents. Because pregnancy in young adolescent girls may be the result of sexual abuse, feelings about the pregnancy should be assessed.

Nurses should be aware that pregnant victims of **human trafficking** may be seen in prenatal settings (see Chapter 5: Human Trafficking). Approximately 25% of people involved in trafficking are in the childbearing years and could be pregnant (Collins & Skarparis, 2020). Nurses and other health care providers need to be supportive and provide care consistently in order to encourage return of the patient. Many do not seek prenatal care until late in pregnancy, so forming a therapeutic relationship quickly is important.

Review of systems. During the review of systems, the patient should be asked to identify and describe pre-existing or concurrent health concerns in any of the body systems. Their mental status also needs to be assessed. The patient is questioned about physical symptoms they have experienced, such as shortness of breath or pain. Pregnancy affects and is affected by all body systems; therefore, information on the present status of body systems is important in planning care. For each sign or symptom described, the following additional data should be obtained: body location, quality, quantity, chronology, aggravating or alleviating factors, and associated manifestations (onset, character, and course).

Physical Examination. The initial physical examination provides the baseline for assessing subsequent changes. The examiner should determine the patient's needs for basic information regarding reproductive anatomy and provide this information, along with a demonstration of the equipment that may be used during the examination and an explanation of the procedure itself. The interaction requires an unhurried, sensitive, and gentle approach with a matter-of-fact attitude.

The physical examination begins with assessment of vital signs, including blood pressure (BP), height, and weight (for calculation of BMI). The bladder should be empty before a pelvic examination is done, if required. The patient may be asked to provide a urine specimen at this time.

Each examiner develops a routine for proceeding with the physical examination; most choose the head-to-toe progression. Heart and lung sounds are evaluated and extremities examined. The skin is assessed for changes in pigmentation, rashes, and edema. Distribution, amount, and quality of body hair are of particular importance because the findings reflect nutritional status, endocrine function, and attention to hygiene. The thyroid gland is assessed carefully, as are the breasts and abdomen. The height of the fundus is noted if the first examination occurs after the first trimester of pregnancy. During the examination, the examiner must remain alert to the patient's cues that give direction to the remainder of the assessment and that indicate imminent untoward response, such as feeling light-headed or dizzy. See Chapter 6 for a detailed description of the physical examination.

Whenever a pelvic examination is performed, the tone of the pelvic musculature and the patient's knowledge of Kegel exercises should be assessed. Particular attention is paid to the size of the uterus because this is an indication of the duration of gestation. The nurse can prepare the patient prior to the examination about what they may feel and coach the patient in breathing and relaxation techniques as needed during the procedure. Vaginal examinations during pregnancy are not routinely done unless there is a medical reason or the patient requires a Pap screening.

Laboratory Tests. The data yielded through laboratory examination of specimens obtained during the examination add important information about the symptoms of pregnancy and the patient's health status.

Specimens are collected at the initial visit so that any abnormal findings can be treated then. Blood is drawn for a variety of tests (Table 11.1).

TABLE 11.1 Laboratory Tests in Prenatal Period

Laboratory Test	Purpose
Hemoglobin, hematocrit/WBC, differential	Detects anemia/detects infection
Hemoglobin electrophoresis	Identifies patients with hemoglobinopathies (e.g., sickle cell anemia, β-thalassemia)
Blood type, Rh, and presence of antibodies	Identifies fetuses at risk for developing erythroblastosis fetalis or hyperbilirubinemia in newborn period
Rubella, varicella, and parvovirus B19 titre	Determines immunity to rubella, chicken pox, and parvovirus (particularly in patients with a previous child or exposure to children in the workplace)
Tuberculin skin testing (depending on patient's history); chest film after 20 weeks of gestation in patients with reactive tuberculin tests	Screens for exposure to tuberculosis
Urinalysis, including microscopic examination of urinary sediment; pH, specific gravity, colour, glucose, albumin, protein, RBCs, WBCs, casts, acetone; hCG	Identifies patients with renal disease, hypertensive disease of pregnancy; infection; occult hematuria
Urine culture	Identifies patients with asymptomatic bacteriuria
Renal function tests: BUN, creatinine, electrolytes, creatinine clearance, total protein excretion	Evaluates level of possible renal compromise in patients with a history of diabetes, hypertension, or renal disease
Papanicolaou test	Screens for cervical intraepithelial neoplasia, herpes simplex type 2, and HPV
Vaginal or rectal smear for *Neisseria gonorrhoeae*, *Chlamydia,* HPV, GBS	Screens high-risk population for asymptomatic infection; GBS screening recommended at 35–37 weeks for all patients
RPR/VDRL/FTA-ABS	Identifies patients with untreated syphilis
HIV antibody,* hepatitis B surface antigen, toxoplasmosis	Screens for the specific infection
1-hour glucose tolerance	Screens for gestational diabetes; done at initial visit for patients with risk factors; recommended to be done at 26–28 weeks for all pregnant patients (earlier if risk factors)
2-hour glucose tolerance	Screens for diabetes in patients with elevated glucose level after 1-hour test; must have two elevated readings for diagnosis (see further discussion in Chapter 14)
Cardiac evaluation: ECG, chest X-ray film, and echocardiogram	Evaluates cardiac function in patients with a history of hypertension or cardiac disease

BUN, Blood urea nitrogen; *ECG,* electrocardiogram; *FTA-ABS,* fluorescent treponemal antibody absorption test; *GBS,* group B streptococcus; *hCG,* human chorionic gonadotropin; *HIV,* human immunodeficiency virus; *HPV,* human papilloma virus; *RBC,* red blood cell; *RPR,* rapid plasma reagin; *VDRL,* Venereal Disease Research Laboratories; *WBC,* white blood cell.
*With patient consent following pre- and post-counselling.

Patients should receive information about the various tests and the purpose for each test and be provided an opportunity to opt out of testing. A sickle cell screen is recommended for patients of African, Asian, or Middle Eastern descent. The folate level is measured when indicated. A urine specimen is collected for cultures and metabolic function tests. A purified protein derivative tuberculin test may be administered to assess exposure to tuberculosis. During the pelvic examination, cervical and vaginal smears can be obtained for cytological studies and for diagnosis of infection (e.g., chlamydia, gonorrhea). Recognition of risk factors during pregnancy may indicate the need to repeat some tests at other times.

STI screening in pregnancy. All pregnant patients should have screening for STIs done early in pregnancy as STIs may have negative effects on the mother and fetus. Careful assessment and thorough screening are essential.

Cervical cultures for chlamydia and gonorrhea should be obtained at the first prenatal visit. All patients should have serum testing for hepatitis B virus (HBV) and syphilis at the first prenatal visit and if they are considered to be high risk (see Box 7.4: Risk Factors for Sexually Transmitted Infections).

HIV in pregnancy. Testing for antibodies to the human immunodeficiency virus (HIV) is strongly recommended for all pregnant patients; this testing must be voluntary and without coercion (Keenan-Lindsay & Yudin, 2017) (Box 11.1). Testing should be done with the patient's understanding of the test and potential result, and documentation of the counselling and consent needs to be placed on their antenatal records. Transmission of HIV from mother to fetus can occur throughout the perinatal period. Exposure may occur to the fetus through the maternal circulation as early as the first trimester of pregnancy, to the newborn during labour and birth by inoculation or ingestion of maternal blood and other infected fluids, or to the infant through breast milk (Loutfy et al., 2018). With identification of HIV and prescribed antiretroviral medications, during pregnancy the patient can be provided with appropriate care to decrease the risk of transmission to the fetus and to the infant after birth to less than 1% (Loutfy et al., 2018).

Maternity nurses should be advocates for the fetus while accepting the pregnant patient's decision regarding testing, treatment, or both for HIV. Health care providers have an obligation to ensure that pregnant patients are well informed about HIV symptoms, testing, and methods of decreasing maternal–fetal transmission. However, mandatory HIV screening involves ethical issues related to privacy, discrimination, social stigma, and reproductive risks to the pregnant patient. See Chapter 15 for further discussion of HIV in pregnancy.

Other prenatal tests. From the initial interview, other tests may be ordered to ensure good outcomes for the pregnant patient and newborn. If the pregnant patient is a teacher or early childhood education worker, serum for parvovirus antibodies may be drawn. Conversely, depending on the patient's history and travel in the past year, a test to confirm the presence of Zika virus may be chosen. Depending on a patient's health at the time of presentation, swabs for influenzae or viruses related to travel may be determined to be appropriate.

BOX 11.1 HIV Screening In Pregnancy

All pregnant patients in Canada should be offered HIV screening, with appropriate pre- and post-test counselling. Testing of patients thought to be at higher risk should be offered in each trimester. Targeting only patients thought to be at high risk will fail to identify all HIV-positive patients, as some people do not perceive themselves to be at risk, nor do their health care providers. HIV testing must be voluntary and free from coercion. No patient should be tested without their knowledge. Nurses should be advocates for the fetus while being accepting of the pregnant patient's decision regarding testing or treatment for HIV.

Pregnant patients should receive oral or written information that includes an explanation of HIV infection, a description of interventions that can reduce HIV transmission from mother to infant, and the meaning of positive and negative test results. They should be offered an opportunity to ask questions and to decline testing. Patients should also be informed that all testing is confidential.

No additional process or written documentation of informed consent beyond that required for other routine prenatal tests should be required for HIV testing.

If a patient declines an HIV test, this decision should be documented in the medical record.

Timing of HIV Testing

Testing should be done as early as possible in pregnancy.

Rapid Testing During Labour

Any patient with undocumented HIV status at the time of labour should be screened with a rapid HIV test unless they decline. Reasons for declining a rapid test should be explored.

Immediate initiation of appropriate antiretroviral prophylaxis should be recommended to patients on the basis of a reactive rapid test result without waiting for the result of a confirmatory test.

Postpartum/Newborn Testing

When a patient's HIV status is still unknown at the time of birth, they should be screened with a rapid HIV test immediately after giving birth, unless they decline.

When the patient's HIV status is unknown, rapid testing of the newborn as soon as possible after birth is recommended so that antiretroviral prophylaxis can be offered to HIV-exposed infants and bottle feeding is chosen as the form of infant nutrition. Patients should be informed that identifying HIV antibodies in the newborn indicates that the mother is infected.

The benefits of newborn antiretroviral prophylaxis are best realized when it is initiated within 12 hours after birth.

Follow-up Visits

The timing of follow-up visits varies according to the model of care and the individual needs of the pregnant patient. The pattern of interviewing the patient first and then assessing physical changes and performing laboratory tests continues. Patient education is part of every prenatal visit.

Interview. Follow-up visits are less intensive than the initial prenatal visit. At each of these follow-up visits, the patient is asked to summarize relevant events that have occurred since the previous visit. They are asked about general emotional and physiological well-being, any concerns or problems, and questions they may have. Personal and family needs are identified and explored.

A patient's emotional state can affect their and their family's general well-being. Thus the nurse needs to ask whether the patient has had any mood swings, reactions to changes in body image, bad dreams, anxieties, or worries. Regular assessment for depression with a tool such as the EDPS is recommended (see discussion in Mental Health Screening section above). The reactions of family members to the pregnancy and the patient's emotional changes are also assessed and recorded.

Current family situations and their effect on the patient should be assessed (e.g., the response of partner, siblings, and grandparents to the pregnancy and the coming child). The nurse needs to assess the parents' understanding of the following: the warning signs that indicate emergencies such as bleeding and abdominal pain, the signs of preterm and term labour, the labour process and anxieties about labour, fetal development, and methods to assess fetal well-being. The nurse should ask if the patient is planning to attend childbirth preparation classes and what they know about the control of discomfort during labour.

A review of the patient's physical systems is appropriate at each prenatal visit, and any suspicious signs or symptoms are assessed in depth. This review of systems includes identifying any discomforts reflecting adaptations to pregnancy. The nurse needs to inquire about success with self-care measures as well as outcomes of prescribed therapy.

Physical Examination. Re-evaluation is a constant aspect of a pregnant patient's care. Each patient reacts differently to pregnancy. As a result, careful monitoring of the pregnancy and their reactions to care is vital. Physiological changes are documented as the pregnancy progresses and are reviewed for possible deviations from normal progress.

At each visit, physical parameters are measured. BP is taken at every visit using the same arm at the level of the heart and with the patient seated. Their weight is assessed, and the appropriateness of the weight gain is evaluated in relation to the patient's BMI. The presence and degree of edema are noted. For examination of the abdomen, the patient lies on their back with their arms by their side and head supported by a pillow; a small wedge should be placed under their right hip to prevent supine hypotension. Supine hypotension can occur when the patient lies on their back and the weight of the abdominal contents compresses the vena cava and aorta, causing a decrease in BP and a feeling of faintness (see Emergency box: Supine Hypotension). Abdominal inspection is followed by measurement of the height of the fundus (Figure 11.6).

EMERGENCY

Supine Hypotension

Signs and Symptoms

Pallor
Dizziness, faintness, breathlessness
Tachycardia
Nausea
Clammy (damp, cool) skin; sweating

Intervention

Position patient on their side until their signs and symptoms subside and vital signs stabilize within normal limits.

The information provided through the interview and physical examination reflect the status of maternal adaptations. When any of the findings is suspicious, an in-depth examination needs to be performed. For example, careful interpretation of BP is important in the risk-factor analysis of all pregnant patients. A systolic blood pressure (SBP) of 140 mm Hg or more and a diastolic blood pressure (DBP)

Fig. 11.6 Measurement of fundal height from symphysis to top of fundus. Note position of hands and measuring tape. (Courtesy Chris Rozales.)

of 90 mm Hg or more, based on the average of at least two measurements, suggest the presence of hypertension (Butalia et al., 2018). See Chapter 15 for an in-depth discussion of issues associated with hypertension. Signs and symptoms other than hypertension also can be present that indicate potential complications (Table 11.2).

Fetal Assessment. Toward the end of the first trimester, before the uterus is an abdominal organ, the fetal heart rate (FHR) can be heard with an ultrasound fetoscope or an ultrasound stethoscope. To hear the FHR, the instrument is placed in the midline just above the symphysis pubis and firm pressure is applied. The patient and their family should be offered the opportunity to listen to the fetal heart. The health status of the fetus is assessed at each visit for the remainder of the pregnancy.

Gestational age. In an uncomplicated pregnancy, fetal gestational age is estimated after the EDB is determined. Fetal gestational age is determined from the menstrual history, contraceptive history, pregnancy test results, and the following findings obtained from the clinical evaluation:

- First uterine evaluation: date, size
- Fetal heart first heard: date, method (Doppler stethoscope, fetoscope)
- Date of quickening
- Current fundal height, estimated fetal weight
- Current week of gestation by history of LMP or ultrasound examination (or both)
- Ultrasound examination: date, week of gestation, biparietal diameter (if done in the first trimester, this is the ideal determination of gestational age)

Quickening ("feeling life") refers to the mother's first perception of fetal movement. It usually occurs between weeks 16 and 20 of gestation and is initially experienced as a fluttering sensation. The mother's report should be recorded. Multiparas often perceive fetal movement earlier than primigravidas; sometimes this may occur as early as 14 weeks.

Routine ultrasound examination in early pregnancy is used to determine the EDB and is recommended for fetal screening (see Chapter 13). Ultrasound can detect a multiple gestation pregnancy and provide information about the well-being of the fetus or fetuses.

Fundal height. The size of the uterus palpated through pelvic or abdominal examination can be roughly correlated with gestational age. However, several factors can affect this measurement, such as the present of uterine fibroids or a patient's BMI. The uterus is approximately the size of a grapefruit at 10 to 12 weeks and is level with the umbilicus at week 20. The *fundal height*, or measurement of the height of the uterus above the symphysis pubis, is used as one indicator of fetal growth after 20 weeks.

From gestational weeks (GW) 18 to 32, the height of the fundus in centimetres is approximately the same as the number of weeks of gestation (±2 GW) if the patient's bladder is empty at the time of measurement (Butt & Lim, 2019). For example, the fundal height of a patient of 28 weeks of gestation with an empty bladder would measure from 26 to 30 cm. In addition, the fundal height measurement may aid in the identification of risk factors. A stable or decreased fundal height may indicate the presence of intrauterine growth restriction (IUGR); an excessive increase could indicate the presence of multifetal gestation (more than one fetus) or polyhydramnios (excessive amniotic fluid).

A disposable paper measuring tape is preferred for measuring fundal height. To increase the reliability of the measurement, the same person examines the pregnant patient at each of their prenatal visits, although often this is not possible. All clinicians who examine a particular pregnant patient should be consistent in their measurement technique (see Figure 11.6).

TABLE 11.2 Signs of Potential Complications During the First, Second, and Third Trimesters

Signs and Symptoms	Possible Causes
First Trimester	
Severe vomiting	Hyperemesis gravidarum
Chills, fever	Infection
Burning on urination	Infection
Diarrhea	Infection
Abdominal cramping; vaginal bleeding	Miscarriage, ectopic pregnancy
Second and Third Trimesters	
Persistent, severe vomiting	Hyperemesis gravidarum, hypertension, pre-eclampsia
Sudden discharge of fluid from vagina before 37 weeks	Premature rupture of membranes
Vaginal bleeding, severe abdominal pain	Miscarriage, placenta previa, placental abruption
Chills, fever, burning on urination, diarrhea	Infection
Severe backache or flank pain	Kidney infection or stones; preterm labour
Change in fetal movements: absence of fetal movements after quickening, any unusual change in pattern or amount	Fetal position or intrauterine fetal death
Uterine contractions; pressure; cramping before 37 weeks	Preterm labour
Visual disturbances: blurring, double vision, or spots	Hypertensive conditions, pre-eclampsia
Headaches: severe, frequent, or continuous	Hypertensive conditions, pre-eclampsia
Muscular irritability or convulsions	Hypertensive conditions, pre-eclampsia
Epigastric or abdominal pain (perceived as severe stomach ache)	Hypertensive conditions, pre-eclampsia, placental abruption
Glycosuria, positive glucose tolerance test reaction	Gestational diabetes mellitus

Fig. 11.7 Detecting fetal heartbeat. **A:** Doppler ultrasound stethoscope (fetal heartbeat detectable at 12 weeks). **B:** Father can listen to the fetal heart with a fetoscope (first detectable at 18 to 20 weeks with a fetoscope). (**A,** Courtesy Shannon Perry; **B,** Courtesy Dee Lowdermilk.)

Health status. The assessment of fetal health status includes consideration of fetal movement. The mother should be instructed to note the extent and timing of fetal movements and report immediately if the pattern changes or movement ceases. Regular movement has been found to be a reliable indicator of fetal health (Liston et al., 2018) (see Chapter 13).

The FHR is checked on routine visits once it has been heard (Figure 11.7). Late in the first trimester, the heartbeat may be heard with the Doppler device that transmits fetal heart tones through a speaker or attached earpieces (see Figure 11.7, *A*). As the uterus grows and becomes an abdominal organ, the fetal heartbeat can also be auscultated with a fetoscope (see Figure 11.7, *B*). Many practitioners use the Doppler device because it allows the mother and others who are present to easily hear the fetal heartbeat.

To detect the heartbeat before the fetal position can be palpated by Leopold manoeuvres (see Box 17.5), the scope is moved around the abdomen until the heartbeat is audible. The heartbeat is counted for 1 minute, and the quality and rhythm are noted. A normal rate and rhythm are other good indicators of fetal health. Once the heartbeat is noted, its absence is cause for immediate investigation.

Intensive investigation of fetal health status is initiated if any maternal or fetal complications arise (e.g., maternal hypertension, IUGR, premature rupture of membranes [PROM], irregular or absent FHR, absence of fetal movements after quickening). Careful, precise, and concise recording of patient responses and laboratory results is an essential part of the continuous supervision required to ensure well-being of the mother and fetus.

Laboratory Tests. The number of routine laboratory tests done during follow-up visits in pregnancy is limited. Urine specimens for culture and sensitivity, and blood samples are obtained only if signs and symptoms warrant this.

First-trimester screening for chromosomal abnormalities is offered as an option between 11 and 14 weeks. This multiple marker screen includes ultrasound evaluation of nuchal translucency (NT) and biochemical markers—pregnancy-associated placental protein (PAPP-A) and free beta-human chorionic gonadotropin (β-hCG). Between 15 and 20 weeks, maternal serum alpha-fetoprotein (MSAFP) screening, the QUAD test (alpha-fetoprotein, hCG, estriol, and inhibin A) can be done to screen for neural tube defects (NTDs) and other chromosomal abnormalities. This is recommended for patients who are obese or who do not have access to a good quality ultrasound to survey fetal anatomy at 18 to 22 weeks (Wilson & SOGC Genetics Committee, 2014). Further discussion regarding maternal screening testing is in Chapter 13.

STIs in pregnancy. STIs in pregnancy are responsible for significant morbidity and mortality. Some consequences of maternal infection, such as infertility and sterility, last a lifetime. Congenitally acquired infection may affect a child's length and quality of life. Table 11.3 describes the

TABLE 11.3 Pregnancy and Fetal Effects of Common Sexually Transmitted Infections

Infection	Maternal Effects	Fetal Effects
Chlamydia	Premature rupture of membranes* Preterm labour*	Conjunctivitis Pneumonia
Gonorrhea	Postpartum endometritis Postpartum sepsis	Ophthalmia neonatorum Systemic neonatal infection
Herpes simplex virus	Spontaneous abortion*	Congenital infection (rare) Newborn infection Preterm birth* Intrauterine growth restriction (IUGR)*
Human papillomavirus (HPV)	Excessive bleeding from lesions after birth	Recurrent respiratory papillomatosis (RRP) (rare)
Bacterial vaginosis	Premature rupture of membranes Preterm labour Postpartum endometritis	Preterm birth
Trichomoniasis	Premature rupture of the membranes Preterm labour	Low birth weight Preterm birth
Syphilis	Miscarriage Preterm labour	Preterm birth Stillbirth Congenital abnormalities Congenital infection

*Research is not convincing.

Data from Government of Canada. (2017). *Canadian guidelines on sexually transmitted infections – Specific populations – Pregnancy.* http://www.phac-aspc.gc.ca/std-mts/sti-its/cgsti-ldcits/section-6-4-eng.php.

effects of several common STIs on pregnancy and the fetus. It is difficult to predict these effects with certainty. Factors such as co-infection with other STIs and at what point in pregnancy the infection was treated can affect outcomes.

Testing for STIs should be repeated late in the third trimester (36 weeks) if the patient was previously positive or if they are younger than age 25, have a new sex partner, or have multiple sex partners (PHAC, 2013). Treatment of STIs is discussed in Table 7.3: Sexually Transmitted Infections and Drug Therapies.

During pregnancy, maternal infection with herpes simplex virus 2 (HSV-2) can have adverse effects on both the mother and fetus. During pregnancy, the use of acyclovir and valacyclovir after 36 weeks' gestation may reduce viral shedding and the risk of a lesion at the time of labour/birth and thus the need for a Caesarean birth; the use of medication has not been shown to reduce the risk of maternal–child transmission (Money et al., 2017). Because neonatal HSV infection is such a devastating disease, prevention is critical. (See Chapter 7 for further discussion of STIs.)

Group B streptococcus (GBS). GBS may be considered a normal vaginal flora in an individual who is not pregnant. It is present in 20 to 40% of healthy pregnant patients (Hughes et al., 2017). However, GBS infection is associated with severe, early-onset newborn infection resulting from vertical transmission from the birth canal of the infected mother to the newborn during birth.

To decrease the risk of neonatal GBS infection, it is recommended that all patients be screened at 35 to 37 weeks of gestation for GBS using a rectovaginal culture and that intravenous antibiotic prophylaxis (IAP) be offered to all who test positive. Patients with planned Caesarean birth should also be swabbed because of their risk of preterm or term labour or ruptured membranes earlier than the scheduled Caesarean birth. If a culture is not available at onset of labour or if risk factors are present, IAP is also offered. IAP is not recommended before a Caesarean birth if labour or rupture of membranes has not occurred. The recommended treatment is penicillin G, 5 million units in an intravenous loading dose, and then 2.5 to 3.0 million units intravenously every 4 hours during labour. Cefazolin or clindamycin may be used in patients who are allergic to penicillin (Money & Allen, 2016). If a labouring patient has had 4 hours of prophylaxis, the newborn is considered to have been treated and has minimal risk for the development of GBS infection (Hughes et al., 2017; Money & Allen, 2016).

Patients who have had a positive urine culture for GBS during pregnancy, preterm labour, or birth or had a previous infant with GBS infection or a high fever in labour are at high risk for GBS infection being passed to their infants (Hughes et al., 2017).

Other tests. Tests that are often repeated at 28 weeks include hemoglobin and hematocrit. In addition, at 28 weeks, an Rh type and screen for antibodies is performed. If the patient is Rh negative and unsensitized, they should receive 300 mcg of Rh immune globulin (RhIG) (see Medication Guide in Chapter 22). Hematocrit testing may be repeated at 36 weeks in patients with anemia and those at risk for peripartum hemorrhage (Gregory et al., 2019).

Other diagnostic tests are available to assess the health status of both the pregnant patient and the fetus and are described in Chapter 13.

Nursing Interventions

After obtaining information through the assessment process, the data are analyzed to identify the unique needs of the pregnant patient and their family. Care is optimized with a collaborative approach involving the physician or midwife, nurse, other relevant health care providers, the patient, their partner, and their family.

The nurse–patient relationship is critical in setting the tone for further interaction. The techniques of listening with an attentive expression, touching (if culturally appropriate), and using eye contact have their place, as does recognizing the patient's feelings and their right to express these feelings. The interaction may occur in various formal or informal settings. A clinical setting, home visits, or telephone conversations all provide opportunities for contact and can be used effectively.

Education About Maternal and Fetal Changes. Expectant parents typically are curious about the growth and development of the fetus, the consequent changes that occur in the mother's body, and how to cope with changes. Mothers may be more tolerant of the discomforts related to the continuing pregnancy if they understand the underlying causes. The nurse who is observant, listens, and knows typical concerns of expectant parents can anticipate what questions will be asked and prompt mothers and their partners to discuss what is on their minds. Printed literature can be given to supplement the individualized teaching the nurse provides. To be most effective, educational materials should be appropriate for the pregnant patient's or couple's ethnicity, culture, and literacy level and the agency's resources. Patients often avidly read books, pamphlets, and web information related to their own pregnancy experience. There are also many apps that allow a person to track the changes during their pregnancy. Nurses should be familiar with the educational materials that are distributed to expectant parents as well as popular web-based resources related to pregnancy. Nurses can direct pregnant patients and their families to reliable websites that contain accurate information.

Because family members are common sources for health information, it is also important to include them in health education endeavors during pregnancy. This can enhance their ability to be supportive of the pregnant patient as they progress through pregnancy.

Patients who receive conflicting advice or instruction are likely to grow frustrated with members of the health care team and the care provided. Several topics that may cause concern in pregnant patients are discussed in the following sections.

Nutrition. Good nutrition is important in the maintenance of maternal health during pregnancy and in the provision of adequate nutrients for embryonic and fetal development. Assessing a patient's nutritional status and weight gain and providing information on nutrition are part of the nurse's responsibilities in providing prenatal care. Education for pregnant patients includes recommendations about daily intake of nutrients, calories, vitamins, and minerals. Based on the person's BMI, the recommended weight gain during pregnancy is discussed. Additional information regarding nutrition during pregnancy may include foods high in iron, the importance of taking prenatal vitamins, and recommendations to avoid using alcohol and to limit caffeine intake. Pregnant patients are instructed in how to avoid food-borne illnesses such as listeriosis. In some settings, a dietitian counsels patients individually or conducts classes for pregnant patients about nutrition during pregnancy. Nurses can refer patients to a registered dietitian if a related need becomes apparent during the nursing assessment—for example, previous history of an eating disorder or nutritional deficiency. (For detailed information on maternal and fetal nutritional needs and related nursing care, see Chapter 12.)

Personal hygiene. During pregnancy, the sebaceous (sweat) glands are highly active because of hormonal influences, and patients often perspire freely. They may be reassured that the increase is normal and that their previous patterns of perspiration will return after the postpartum period. Baths and warm showers can be therapeutic because they relax tense, tired muscles; help counter insomnia; and make the pregnant patient feel better. Tub bathing is not restricted even in late pregnancy because little water enters the vagina unless under pressure. However, the temperature of the water should not be higher

than 39°C as this will increase the pregnant patient's core body temperature and can cause postural hypotension. Hot tubs should also be avoided for this reason. Late in pregnancy, when the patient's centre of gravity lowers, they are at risk for falling. Tub bathing after rupture of the membranes needs to be carefully monitored and may be contraindicated in some patients.

Preventing respiratory infections. Pregnant patients need to be aware they may be at risk of developing respiratory tract infections (e.g., SARS, COVID-19). In order to prevent this, people need to minimize their risk as much as possible by maintaining good hand hygiene, getting appropriate immunizations, isolating themselves if required, and avoiding travel if there is an increase in respiratory infections in the community. Pregnant patients who develop respiratory infections and are admitted to hospital will follow the hospital guidelines regarding personal protective equipment. It is important that if the patient goes into labour, they still require family-centred care and the presence of important support people.

Preventing urinary tract infection. Because of physiological changes that occur in the renal system during pregnancy (see Chapter 10), infections of the lower urinary tract (acute urethritis, acute cystitis) are common. *Escherichia coli (E. coli)* is the most common causative organism for urinary tract infection (UTI) in pregnant patients (Duff & Birsner, 2017). Although UTIs can be asymptomatic, typical symptoms include frequency, urgency, dysuria, dribbling, and hesitancy; gross hematuria may occur. Patients should be instructed to inform their health care provider if they experience these symptoms. UTIs pose a risk to the mother and fetus, mainly through increasing rates of preterm labour; thus their prevention or early treatment is essential. Oral antibiotics are commonly prescribed.

The nurse can assess the patient's understanding of appropriate hand hygiene techniques to use before and after urinating and the importance of wiping the perineum from front to back. Soft, absorbent toilet tissue, preferably white and unscented, should be used; harsh, scented, or printed toilet paper may cause irritation. Use of bubble bath or other bath oils should be avoided because these can irritate the urethra. Patients should wear underpants and panty hose with a cotton crotch and avoid wearing tight-fitting slacks or jeans for long periods. Anything that allows a buildup of heat and moisture in the genital area can foster bacterial growth.

Some patients do not consume enough fluid. After ascertaining the patient's fluid preferences, the nurse should advise the patient to drink at least 2 L (eight glasses) of liquid a day to maintain an adequate fluid intake that ensures frequent urination. Pregnant patients should not limit fluids in an effort to reduce the frequency of urination. Patients need to know that if urine looks dark (concentrated), they must increase their fluid intake.

The nurse should review healthy urination practices with the patient. Patients should be told not to ignore the urge to urinate, because holding urine lengthens the time bacteria are in the bladder and allows them to multiply. Patients should plan ahead when faced with situations that may normally require them to delay urination (e.g., a long car ride). They should always urinate before going to bed at night. Bacteria also can be introduced during intercourse. Therefore, patients are advised to urinate before and after intercourse and to then drink a large glass of water to promote additional urination. Consumption of cranberry juice has been considered preventive for UTI based on the acidity of the juice. There appears to be greater benefit from cranberry supplements than with cranberry juice. Recent evidence indicates that the value of using cranberry supplements is related to the component proanthocyanidins (PAC), which prevent adhesion of bacteria to the bladder wall. Cranberry capsules are the best source of PAC, although it has been shown that there is high variability in the amount of PAC in commercially available products (Chughtai et al., 2016).

Kegel exercises. **Kegel exercises**—deliberate contraction and relaxation of the pubococcygeus muscle—strengthen the muscles around the reproductive organs and improve muscle tone. Many patients are not aware of the muscles of the pelvic floor until it is pointed out that these are the muscles used during urination and sexual intercourse and that they can be consciously controlled. The pelvic floor muscles encircle the vaginal outlet, and they need to be exercised. An exercised muscle can stretch and contract readily at birth. Practice of pelvic muscle exercise during pregnancy also results in fewer concerns of urinary incontinence in late pregnancy and postpartum (see Chapter 5, Patient Teaching box: Kegel Exercise).

Preparation for breastfeeding the newborn. During the first prenatal visit, the nurse should ask if the patient is planning to breastfeed. Breast milk is the food of choice, in part because breastfeeding is associated with a decreased incidence in newborn morbidity and mortality. The Canadian Paediatric Society and the World Health Organization recommend exclusive breastfeeding for at least 6 months with continuation to 2 years or beyond. A person's decision about the method of infant feeding is usually made before pregnancy; thus it is essential to educate individuals of childbearing age about the benefits of breastfeeding. The patient and their partner are encouraged to decide which method of feeding is suitable for them; however, the benefits of breastfeeding should be emphasized. Once the couple has been given information about the advantages and disadvantages of breastfeeding and formula-feeding, they can make an informed choice. Most people who choose to breastfeed do so because they are aware of the numerous benefits (see Chapter 27). Lack of knowledge about the benefits of breastfeeding and perceived personal and social disadvantages to breastfeeding can influence a person not to breastfeed. Modesty issues, effect on the mother's figure, lack of support by the partner and family, incompatibility with lifestyle, and lack of confidence are among the reasons cited by patients who decide to formula-feed their infants (Lawrence & Lawrence, 2016). Education and support from health care providers will increase the number of patients who initiate and continue with breastfeeding as people who perceive their health care providers as supportive of breastfeeding are more likely to breastfeed than those who perceive them as neutral or favouring formula feeding. Also, the more often breastfeeding is mentioned during pregnancy, the more likely people will breastfeed (PHAC, 2021).

Assessment of breasts during the prenatal period may reveal potential concerns related to breastfeeding. Scars on the breast may indicate previous breast reduction surgery, which can affect milk production. Some patients may have breast implants; this may or may not affect successful breastfeeding. Examination of the breasts may reveal flat or inverted nipples, which can affect the baby's ability to successfully latch on to the breast. To determine if nipples are inverted, a patient can perform a test on their nipples to determine freedom of protrusion (Figure 11.8). The patient places their thumb and forefinger on their areola and presses inward gently. A normal nipple will evert or stand erect, whereas an inverted nipple will appear to withdraw (Lawrence & Lawrence, 2016).

Exercises to break the adhesions that cause the nipple to invert do not work and may cause uterine contractions. Some clinicians recommend the prenatal use of breast shells (Figure 11.9) during the last trimester for patients with flat or inverted nipples, although evidence to support their effectiveness is lacking (Lawrence & Lawrence, 2016). They can be uncomfortable and cause irritation to the nipple or areola. Breast stimulation is contraindicated in patients at risk for preterm labour; therefore the decision to suggest the use of breast shells to patients with flat or inverted nipples must be made judiciously (Lawrence & Lawrence, 2016).

There is no special preparation of the nipples or breasts for breastfeeding. The patient is taught to cleanse the nipples with warm water to

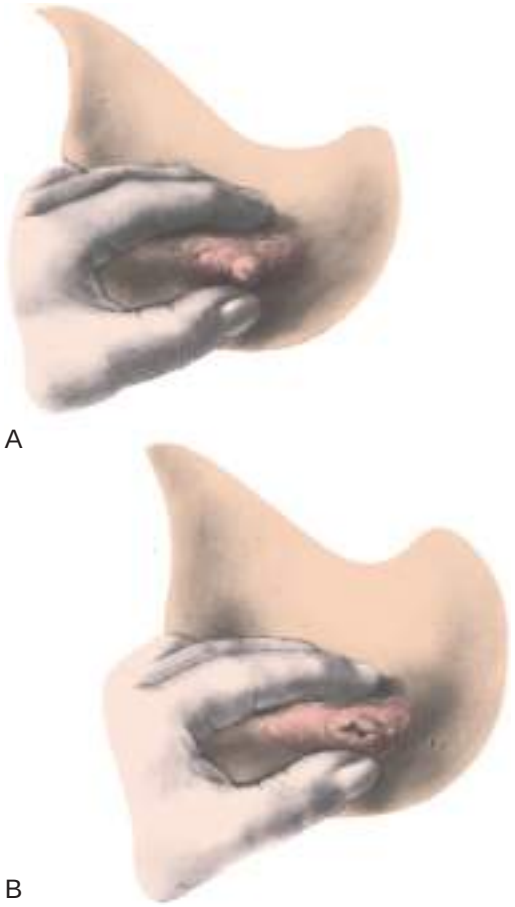

Fig. 11.8 Pinch test. **A:** Normal nipple everts with gentle pressure. **B:** Inverted nipple inverts with gentle pressure. (Modified from Lawrence, R. A., & Lawrence, R. M. [2011]. *Breastfeeding: A guide for the medical profession* [7th ed., p. 241]. Mosby.)

keep the ducts from being blocked with dried colostrum. Soap, ointments, alcohol, and tinctures should not be applied because they remove protective oils that keep the nipples supple. Use of breast pads with plastic liners should be avoided. Patients with nipple piercings should be instructed to remove the jewellery during pregnancy to allow the nipple to recover, which will help prevent infection (Lawrence & Lawrence, 2016).

A bra that fits well and provides support promotes comfort as breasts increase in size during pregnancy. The patient who plans to breastfeed may want to purchase a nursing bra that will accommodate their increased breast size during the last few months of pregnancy and during lactation. Some pregnant patients may leak **colostrum** during the pregnancy and some may not. Whether this occurs does not relate to how much breast milk a mother will produce after the birth of the baby.

The nurse needs to listen to the mother's questions and concerns related to breastfeeding and can recommend sources of information, including books and websites. The patient may appreciate a list of local breastfeeding resources that includes prenatal breastfeeding classes as well as lactation consultants and the services they provide, such as inpatient and outpatient consultations, home visits, and breast pump rentals.

Oral health. Oral health during pregnancy is especially important because it can affect maternal health and pregnancy outcomes (Government of Canada, 2021; Hartnett et al., 2016). There is an increased incidence of gingivitis (swelling and inflammation of the gums) and periodontitis (infection of gums that can cause damage to soft tissues and bone) during pregnancy. Studies have shown an association between periodontal disease and preterm birth, LBW, very low–birth weight (VLBW), pre-eclampsia, and gestational diabetes (Corbella et al., 2016; Parihar et al., 2015). Health care providers should assess oral health at the initial prenatal visit and at intervals throughout pregnancy (ACOG, 2013/2017). It only takes 1 minute to complete an oral examination, so it can easily be incorporated into routine care.

Fig. 11.9 Breast shell in place inside bra to evert nipple. (Courtesy Michael S. Clement, MD.)

Diagnosis and treatment of oral health issues, including necessary dental X-rays and the use of local anaesthetics or nitrous oxide–oxygen anaesthesia, are considered safe during pregnancy. Dental care and nonemergent procedures are best scheduled during the second trimester, when the patient is past the stage of feeling nauseated and can sit comfortably in the chair. Antibacterial therapy should be considered for prevention of sepsis, especially in pregnant patients who have had rheumatic heart disease or nephritis.

Nurses can teach pregnant patients about the importance of dental hygiene, including regular brushing and flossing. Patients who experience nausea and vomiting episodes can prevent erosion of tooth enamel by rinsing with a solution of baking soda after vomiting.

Physical activity. The benefits of physical activity during pregnancy are many and include the following (PHAC, 2020a):

- Avoiding excessive weight gain during pregnancy and maintaining a healthy weight after the birth
- Possibly reducing the risk of pregnancy complications such as pre-eclampsia, macrosomia, and gestational diabetes, as well as the length of labour
- Decreasing the risk of type 2 diabetes, obesity, and heart disease
- Enhancing physical comfort during labour, decreasing complications of labour and birth, and recovering more quickly following childbirth
- Achieving better mental health during and after pregnancy
- Alleviating some of the discomforts of pregnancy, including fatigue, poor sleep quality, back pain, and constipation

The Society of Obstetricians and Gynaecologists of Canada (SOGC) and the Canadian Society for Exercise Physiology (CSEP) recommend that pregnant patients engage in moderate activity for 150 minutes per week over at least 3 days per week, although daily activity is encouraged (Mottola et al., 2018). Patients who are highly active or engage in vigorous aerobic exercise can continue during pregnancy if they remain healthy and discuss with their health care provider adjusting activity over time as needed (Mottola et al., 2018). Individuals who have not

been active before pregnancy should be advised to start with mild activities such as walking and swimming, even for short periods of time, and gradually increase the duration of the exercise (PHAC, 2020a). Individuals should be assessed using the PARmed-X for PREGNANCY, which is a guideline for health screening prior to participation in a prenatal fitness class or other exercise. See Additional Resources at end of chapter for more information.

Patients should be advised that adverse pregnancy or newborn outcomes are not increased for exercising patients (Mottola et al., 2018). Detailed exercise tips for pregnancy are presented in the Patient Teaching box: Exercise Tips for Pregnancy.

Exercises that help relieve the low back pain that often arises during the second trimester because of the increased weight of the fetus are demonstrated in Figure 11.10. See Clinical Reasoning Case Study: Exercise in Pregnancy.

PATIENT TEACHING

Exercise Tips for Pregnancy

Participate in Aerobic and Strength-Conditioning Exercises
- You can do this as part of a healthy lifestyle during pregnancy as long as you are not considered high risk. When starting an aerobic exercise program, previously sedentary patients should begin with 15 minutes of continuous exercise three times a week, increasing gradually to 150 minutes of activity per week.

Maintain a Good Fitness Level Throughout Pregnancy
- Do this in moderation; do not try to reach peak fitness or train for an athletic competition. Elite athletes who continue to train during pregnancy require supervision by an obstetrical care provider with knowledge of the impact of strenuous exercise on maternal and fetal outcomes. For very fit, medically prescreened pregnant patients, the current target heart rate zones may not be appropriate and the PARmed-X for PREGNANCY should be consulted for appropriate target heart rate zones.

Perform Warm-Up and Cool-Down Exercises
- All aerobic activity should begin with a warm-up and cool-down of 5 to 10 minutes of lower intensity. After the fourth month of gestation, you should not perform exercises flat on your back.

Monitor the Intensity of Exercise
- You should be able to converse easily while exercising. If you cannot, you need to slow down.

Choose Activities That Will Minimize the Risk of Loss of Balance and Fetal Trauma
- Avoid doing risky activities.
- Activities such as surfing, mountain climbing, skydiving, and racquetball require precise balance and coordination and thus may be dangerous. Avoid doing activities that require holding your breath and bearing down (Valsalva manoeuvre). Jerky, bouncy motions also should be avoided. Stretches should be controlled.
- Avoid downhill snow skiing, because the centre of gravity changes and there is a risk of falls; contact sports such as ice hockey, soccer, and basketball; and scuba diving, because the pressure from the water could put the baby at risk for decompression sickness.

Avoid Becoming Overheated for Extended Periods of Time
- Avoid doing hot yoga and hot pilates.
- It is best not to exercise for more than 35 minutes, especially in hot, humid weather. As your body temperature rises, the heat is transmitted to your fetus.
- Do not use hot tubs and saunas.

Drink Two or Three 250-mL Glasses of Water After You Exercise
- After you exercise you need to replace the body fluids lost through perspiration. While exercising, drink water whenever you feel the need.

Take Your Time
- This is not the time to be competitive or train for activities requiring speed or long endurance.

Wear a Supportive Bra
- Your increased breast weight may cause changes in posture and put pressure on the ulnar nerve.

Wear Supportive Shoes
- As your uterus grows, your centre of gravity shifts, and you compensate for this by arching your back. These natural changes may make you feel off balance and more likely to fall.

Stop Exercising Immediately Upon Experiencing Warning Signs
- If you experience shortness of breath, chest pain, dizziness, painful uterine contraction, vaginal bleeding, or leakage of amniotic fluid, you should stop exercising immediately and consult your health care provider.

CLINICAL REASONING CASE STUDY

Exercise in Pregnancy

Lourdes is 16 weeks pregnant with her second child. She wants to avoid gaining extra weight during this pregnancy and would like to continue her exercise habits: walking and Zumba classes. What guidance can you give to Lourdes?

Questions
1. Evidence—Is the evidence sufficient to make a recommendation for or against exercising during pregnancy?
2. Assumptions—Describe the underlying assumptions for each of the following issues:
   a. Physiological changes in pregnancy that affect balance, movement, respiration, and cardiac function
   b. Maternal physiological response during exercise
   c. Benefits of exercise
3. What implications and priorities for nursing care can be drawn at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may be involved in caring for Lourdes.

Posture and body mechanics. Skeletal, musculature, and hormonal changes (relaxin) in pregnancy can predispose the patient to backache and possible injury. As pregnancy progresses, the pregnant patient's centre of gravity changes, pelvic joints soften and relax, and stress is placed on abdominal musculature. Poor posture and body mechanics contribute to the discomfort and potential for injury. To minimize these complications, patients can be taught good body posture and body mechanics (Figure 11.11). The activities described in the Patient Teaching box: Posture and Body Mechanics can also promote greater physical comfort.

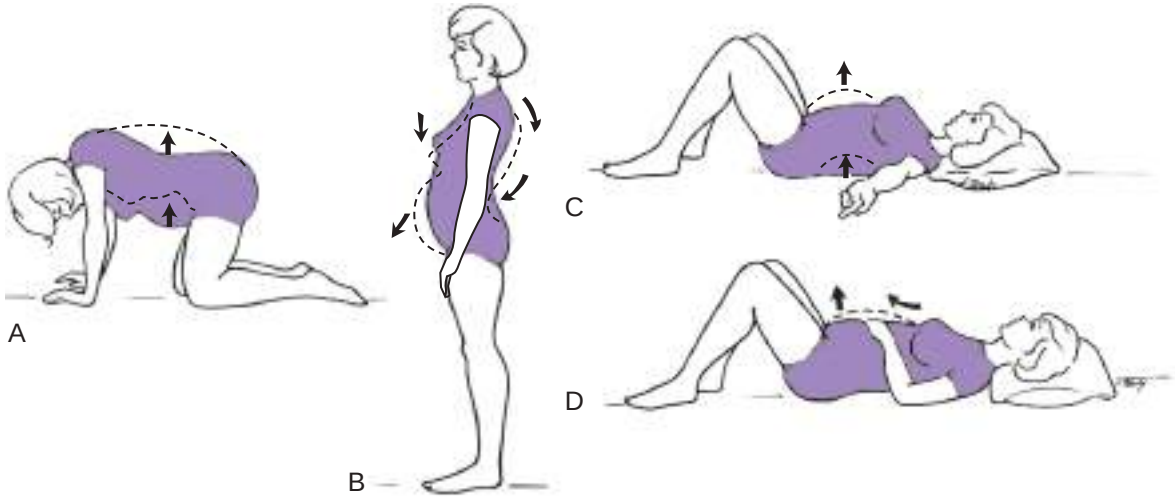

Fig. 11.10 Exercises. **A, B,** and **C:** Pelvic rocking relieves low backache (excellent for relief of menstrual cramps as well). **D:** Abdominal breathing aids relaxation and lifts the abdominal wall off the uterus.

Fig. 11.11 Correct body mechanics. **A:** Squatting. **B:** Lifting. (Courtesy Sandy Matos.)

PATIENT TEACHING

Posture and Body Mechanics

To Prevent or Relieve Backache

Do pelvic tilt:

- Pelvic tilt (rock) on hands and knees (see Figure 11.10, *A*) and while sitting in a straight-back chair.
- Pelvic tilt (rock) in standing position against a wall or lying on the floor (see Figure 11.10, *B* and *C*).
- Perform abdominal muscle contractions during pelvic tilt while standing, lying, or sitting to help strengthen rectus abdominis muscle (see Figure 11.10, *D*).
- Use good body mechanics.
- Use leg muscles to reach objects on or near the floor. Bend at the knees, not the back. Knees are bent to lower the body to squatting position. Keep feet shoulder-width apart to provide a solid base to maintain balance (see Figure 11.11, *A*).
- Lift with the legs. To lift a heavy object (e.g., young child), place one foot slightly in front of the other and keep it flat as you lower yourself onto one knee. Lift the weight, holding it close to your body and never higher than the chest. To stand up or sit down, place one leg slightly behind the other as you raise or lower yourself (see Figure 11.11, *B*).

To Restrict the Lumbar Curve

- For prolonged standing, place one foot on a low footstool or box; change positions often.
- Move the car seat forward so that knees are bent and higher than hips. If needed, use a small pillow to support the low back area.
- Sit in chairs low enough to allow both feet to be placed on the floor, preferably with knees higher than hips.
- Use a hot water bottle or ice packs intermittently on your back to relieve discomfort.

Rest and relaxation. The pregnant patient should be encouraged to plan regular rest periods, particularly as pregnancy advances. The side-lying position is recommended to promote uterine perfusion and feto-placental oxygenation by eliminating pressure on the ascending vena cava and descending aorta, which can lead to supine hypotension (Figure 11.12). Lying on the left side allows the most blood flow through the uterus, although patients should be taught that it is acceptable to rest on either side. The mother should also be shown the way to rise slowly from a side-lying position, to prevent placing strain on the back and minimize the orthostatic hypotension caused by changes in position common in the later part of pregnancy. To stretch and rest back muscles at home or at work, the pregnant person can do the following exercises:

- While standing behind a chair, support and balance themselves using the back of the chair (Figure 11.13). Squat for 30 seconds and then stand for 15 seconds. Repeat this six times, in several sets per day, as needed.
- While sitting in a chair, lower the head to the knees knees for 30 seconds and then raise the head. Repeat this six times, several times per day, as needed.

Conscious relaxation is the process of releasing tension from the mind and body through deliberate effort and practice. The ability to relax consciously and intentionally can be beneficial for the following reasons:

- To relieve the normal discomforts related to pregnancy
- To reduce stress and diminish pain perception during the childbearing cycle
- To heighten self-awareness and trust in one's own ability to control responses and functions
- To help cope with stress in everyday life situations, whether the person is pregnant or not

The techniques for conscious relaxation are numerous and varied. The guidelines given in Box 11.2 can be used by anyone.

Fig. 11.12 Side-lying position for rest and relaxation. (Courtesy Julie Perry Nelson.)

Fig. 11.13 Squatting for muscle relaxation and strengthening and for keeping leg and hip joints flexible. (Courtesy Sandy Matos.)

BOX 11.2 Conscious Relaxation Tips

Preparation—Loosen clothing, assume a comfortable sitting or side-lying position with all parts of the body well supported with pillows. The use of soothing music is optional.

Beginning—Allow yourself to feel warm and comfortable. Inhale and exhale slowly and imagine peaceful relaxation coming over each part of the body, starting with the neck and working down to the toes. People who learn conscious relaxation often speak of feeling relaxed even if some discomfort is present.

Maintenance—Use imagery (fantasy or daydream) to maintain the state of relaxation. Using active imagery, imagine yourself moving or doing some activity and experiencing its sensations. Using passive imagery, imagine yourself watching a scene such as a lovely sunset.

Awakening—Return to the wakeful state gradually. Slowly begin to take in stimuli from the surrounding environment.

Further retention and development of the skill—Practise regularly each day (e.g., at the same hour for 10 to 15 minutes each day) to feel refreshed, revitalized, and invigorated.

Employment. Pregnant patients' employment usually has no adverse effects on pregnancy outcomes. Job discrimination based solely on pregnancy is illegal. Unless complications occur, most patients can continue working until the onset of labour. However, some job environments pose potential risk to the fetus (e.g., dry cleaning plants, chemical laboratories, and parking garages). Excessive fatigue is usually the deciding factor in the termination of employment during pregnancy. Strategies to improve safety during pregnancy are described in the Patient Teaching box: Safety During Pregnancy.

Patients in sedentary jobs need to walk around at intervals to counter the sluggish circulation in the legs. They should neither sit nor stand in one position for long periods of time. They should avoid crossing their legs at the knees because this can foster the development of varices and thrombophlebitis. Standing for long periods also increases the risk of preterm labour. The pregnant patient's chair should provide adequate back support. Use of a footstool can prevent pressure on veins, relieve strain on varicosities, minimize swelling of feet, and prevent backache.

PATIENT TEACHING

Safety During Pregnancy

Changes in the body caused by pregnancy include relaxation of joints, alteration to the centre of gravity, faintness, and discomfort. Difficulties with coordination and balance are common. Therefore, the pregnant person should follow these guidelines:

- Use good body mechanics.
- Use safety features on tools and vehicles (safety seat belts, shoulder harnesses, headrests, goggles, helmets) as specified.
- Avoid doing activities that require coordination, balance, and concentration.
- Take rest periods; reschedule daily activities to meet rest and relaxation needs.

The developing embryo and fetus are vulnerable to environmental teratogens. Many potentially dangerous chemicals are present in the home, yard, and workplace, such as cleaning agents, paints, sprays, herbicides, and pesticides. The soil and water supply may be unsafe. Therefore, the person should follow these guidelines:

- Read all labels for ingredients and proper use of a product.
- Ensure adequate ventilation with clean air.
- Dispose of wastes appropriately.
- Wear gloves when handling chemicals.
- Change job assignments or workplace as necessary.

Clothing. Some pregnant individuals continue to wear their usual clothes during pregnancy as long as they fit and feel comfortable. If maternity clothing is needed, outfits may be purchased new or found in good condition at thrift shops or garage sales. Comfortable, loose clothing is best. Wearing tight bras and belts, stretch pants, garters, tight-top knee socks, body shapers, and other constrictive clothing should be avoided because tight clothing over the perineum encourages vaginitis and miliaria (heat rash), and impaired circulation in the legs can cause varicosities.

Maternity bras are constructed to accommodate the increased breast weight, chest circumference, and size of breast tail tissue (under the arm). These bras have drop-flaps over the nipples to facilitate breastfeeding. A good bra can help prevent neck ache and backache.

Maternity support (compression) hose give considerable comfort and promote greater venous emptying in patients with large varicose veins. Ideally, support stockings should be put on before the patient gets out of bed in the morning. Figure 11.14 demonstrates a position for resting the legs and reducing swelling.

Comfortable shoes that provide firm support and promote good posture and balance are advisable. Very high heels and platform shoes should not be worn because of the patient's changed centre of gravity, which can cause them to lose their balance. In addition, the patient's pelvis tilts forward in the third trimester, increasing the lumbar curve. The resulting leg aches and cramps will be aggravated by shoes that do not provide good support. Figure 11.15 shows exercises to relieve leg cramps.

Travel. Travel is not contraindicated for low-risk pregnant patients. Patients with high-risk pregnancies are advised to avoid long-distance travel after fetal viability has been reached, to avert the economic and psychological consequences of giving birth to a preterm infant far from home. Travel to areas where medical care is poor, water is untreated, and malaria, Zika, or other communicable diseases are prevalent should be avoided if possible. Patients who contemplate foreign travel should be aware that some provincial health insurance plans may not cover all expenses for birth in a foreign setting or even hospitalization for preterm labour. In addition, vaccinations for foreign travel may be contraindicated during pregnancy.

Pregnant patients who travel long distances should schedule periods of activity and rest. Prolonged periods of sitting during car or air travel increase the risk for venous stasis and thromboembolism. Six hours per day of sitting is the maximum amount of time for driving; the pregnant person should stop at least every 2 hours to walk around for 10 minutes (Gregory et al., 2019). While sitting, the individual can practice deep breathing, foot circling, and alternately contracting and relaxing different muscle groups. They should avoid becoming fatigued.

Fig. 11.14 Position for resting legs and reducing edema and varicosities. Encourage the patient with vulvar varicosities to include a pillow under their hips. (Courtesy Sandy Matos.)

Fig. 11.15 Relief of muscle spasm (leg cramps). Woman stands and leans forward, thereby dorsiflexing foot of the affected leg. (Courtesy Sandy Matos.)

A combination lap belt and shoulder harness is the most effective automobile restraint, and both should be used whether the pregnant person is a driver or passenger seated in the front or back. The lap belt should be worn low across the pelvic bones as snugly as is comfortable. The shoulder harness should be worn above the gravid uterus and below the neck to prevent chafing (Figure 11.16). The pregnant person should sit upright. The headrest should be used to prevent whiplash injury. Airbags, if present, should remain engaged, but the steering wheel should be tilted upward, away from the abdomen and the seat moved back away from the steering wheel as much as possible.

Air travel in large commercial jets usually poses little risk to the pregnant patient, although policies regarding flight by pregnant patients vary from airline to airline. The pregnant patient is advised to inquire about restrictions or recommendations from their carrier. Most health care providers allow air travel up to 36 weeks of gestation for patients without medical or pregnancy complications. It is

Fig. 11.16 Proper use of seat belt. (iStock.com/Ruslan Dashinsky)

recommended that pregnant patients avoid altitudes above 3 658 metres (12 000 feet). For high-risk pregnancies and patients in the late stages of pregnancy, altitudes should be limited to 2 500 metres (8 200 feet). Patients with pregnancy-related complications should avoid unnecessary high-altitude exposure (Government of Canada, 2019). Metal detectors used at airport security checkpoints emit low levels of radiation and should not pose an increased risk for harm to the fetus (Morof & Carroll, 2016). Exposure to cosmic radiation while in flight is below the dose that can cause harm at any stage of gestation (Health Physics Society, 2016). Pregnant individuals who fly frequently (e.g., flight attendants) should be aware of the increased exposure. The 8% humidity at which the cabins of commercial airlines are maintained can result in some water loss; hydration (with water) should therefore be maintained. The lower oxygen tension on commercial airliners does not create difficulties for patients with uncomplicated pregnancies; however, those with severe anemia, sickle cell disease, or pre-existing cardiovascular concerns may experience issues. Sitting in the cramped seat of an airliner for prolonged periods can increase the risk for superficial and deep vein thrombosis, therefore the person is encouraged to take a walk around the aircraft during each hour of travel and to wear graduated compression stockings to minimize this risk (Morof & Carroll, 2016).

Medications and herbal preparations. Although much has been learned in recent years about fetal drug toxicity, the possible teratogenicity of many medications, both prescription and OTC, is still unknown. This is especially true for new medications and combinations of medications. Moreover, certain subclinical errors or deficiencies in intermediate metabolism in the fetus may cause an otherwise harmless medication to be converted into a hazardous one. The greatest danger of medication-caused developmental defects in the fetus extends from the time of fertilization through the first trimester, a time when the person may not realize they are pregnant. Self-treatment must be discouraged. The use of all medications, including OTC medications, herbs, and vitamins, should be limited and a careful record kept of all therapeutic and nontherapeutic agents used.

The use of complementary and alternative medicine by pregnant patients is widespread and is based primarily on historical use and anecdotal information (Frawley et al., 2013). There is limited research evidence on the safety of herbal preparations, especially during pregnancy. While the use of complementary and alternative therapies is consistent with the holistic, person-centred approach to care, caution is warranted in their use because of the lack of evidence.

SAFETY ALERT

Although some complementary and alternative medicine (CAM) may benefit the patient during pregnancy, some practices should be avoided because they may increase their risk for complications. It is important to ask the patient about all medications they are taking, including OTC and herbal preparations.

Immunizations. Immunization with live or attenuated live virus or live bacterial vaccines is generally contraindicated during pregnancy because of potential teratogenicity. Live virus vaccines include those for measles (rubeola and rubella), chicken pox, mumps, and the Sabin (oral) poliomyelitis vaccine (no longer used in Canada). Human papilloma virus (HPV) vaccine is not recommended during pregnancy. Vaccines consisting of killed viruses that may be administered during pregnancy include tetanus, diphtheria, recombinant hepatitis B, rabies vaccines, and most influenza vaccines.

Reported cases of pertussis (whooping cough) have increased significantly in Canada in recent years. Pertussis can cause serious and life-threatening complications in mothers and infants. To provide maximal maternal antibody response and transfer passive immunity to the newborn, it is recommended that all pregnant patients be offered the diphtheria and tetanus toxoids and acellular pertussis (Tdap) vaccine during the second or third trimester, preferably between 27 and 32 weeks' gestation. Maternal antipertussis antibodies are short-lived, and antibody levels drop significantly during the first year after vaccination. It is unlikely that a Tdap vaccination in one pregnancy will transfer passive immunity from mother to infant in a subsequent pregnancy; therefore, Tdap should be given during every pregnancy, irrespective of the patient's immunization history (Castillo & Poliquin, 2018; Government of Canada, 2020).

All patients who are pregnant during the influenza season (November to March) should be offered an influenza vaccination for every pregnancy. The injectable inactivated influenza vaccine is safe throughout pregnancy. The intranasal influenza vaccine is contraindicated during pregnancy because it contains a live virus (Government of Canada, 2020). Patients who are pregnant or breastfeeding should be offered COVID-19 vaccination at any time during their pregnancy if they are eligible and no contraindications exist. The decision to get the vaccine is based on the patient's personal values and an understanding that the risk of infection or morbidity from COVID-19 outweighs the theorized and undescribed risk of being vaccinated during pregnancy or while breastfeeding (Poliquin et al., 2020/2021).

Rh Immune globulin. Testing to determine the pregnant patient's blood type is done at the first prenatal visit. Rh-negative patients will also have an antibody screen in the first and third trimester. Patients with Rh-negative (D-negative) blood type who are carrying an Rh-positive (D-positive) fetus can develop antibodies against the D antigen on the fetal red blood cell, causing lysis of the fetal red blood cells. This can lead to life-threatening hemolytic disease of the fetus and newborn (Aitken & Tichy, 2015).

Prophylactic RhIG can be administered to the Rh-negative (D-negative) pregnant patient to prevent formation of antibodies (alloimmunization) by destroying any fetal red blood cells in the maternal circulation before their immune system recognizes the D-positive antigen and begins to produce antibodies (Blackburn, 2018). A dose of 300 mcg RhIG is routinely administered at 26 to 30 weeks to all Rh-negative patients without evidence of anti-D alloimmunization. If they give birth to an Rh-positive infant, the dose of RhIG is repeated within 72 hours after birth (see Medication Guide: Rh Immune Globulin in Chapter 22). Other indications for administration of RhIG to Rh-negative patients during pregnancy include chorionic villus sampling, amniocentesis, spontaneous or therapeutic abortion, ectopic pregnancy, external cephalic version, and abdominal trauma (Moise, 2017).

Substance use. Any drug or environmental agent that enters the pregnant patient's bloodstream has the potential to cross the placenta and harm the fetus. The nurse needs to inquire about the use of any substances at the initial prenatal visit and at all subsequent visits.

One substance that is used by some people during pregnancy is alcohol. A safe level of alcohol consumption during pregnancy has not yet been established. Although the consumption of occasional alcoholic beverages may not be harmful to the mother or their developing embryo or fetus, complete abstinence is strongly advised (Carson et al., 2017).

The SOGC recommends that each pregnant patient be screened for alcohol use during pregnancy (Carson et al., 2017). Using a harm reduction approach, they recommend that screening involve a thorough history, motivational interviewing, specific questionnaires, and diagnostic testing, bearing in mind that the patient has a right to refuse laboratory testing. One or two interview questions about alcohol use is an effective way to screen patients and identify patients who require further education or intervention (Carson et al., 2017). Questions may include the following:

- When was the last time you had a drink?
- Do you ever enjoy a drink or two?
- Do you sometimes drink beer, wine, or other alcoholic beverages?
- Do you ever use alcohol?
- In the past month or two, have you ever enjoyed a drink or two?

Research has shown that brief interventions can be very useful in helping a pregnant patient who drinks low to moderate amounts of alcohol to reduce their alcohol intake during pregnancy. If a patient identifies that they require further intervention, a more in-depth assessment of drinking practices is necessary (Carson et al., 2017).

Smoking tobacco during pregnancy is associated with LBW, stillbirth, spontaneous abortion, decreased fetal growth, premature birth, placental abruption, and sudden infant death syndrome (SIDS) as well as many risks to the pregnant patient's health (PHAC, 2020a). Smoking rates vary across Canada among pregnant patients, with the highest rate being in the northern territories (59.3%) and lowest in Ontario (18.5%) (Cui et al., 2014). Smoking-cessation activities should be incorporated into routine prenatal care. All patients who smoke should be strongly encouraged to quit or at least reduce the number of cigarettes they smoke (see Clinical Reasoning Case Study). The Canadian Smoking Cessation Clinical Practice Guideline offers recommendations and strategies for pregnant patients giving up smoking cigarettes (see Chapter 5 for further discussion).

CLINICAL REASONING CASE STUDY

Smoking Cessation During Pregnancy

Doreen is a 25-year-old who is 8 weeks pregnant. At her first prenatal visit a history is taken; she reports that she smokes about half a pack of cigarettes a day. She says she knows that she should probably try to cut down, but she has been smoking since she was 15. She has tried to quit smoking before and has not been successful.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about what the nurse should say?
2. Assumptions—What assumptions can be made about the following issues?
   a. Effects of smoking on pregnancy
   b. Cessation interventions for pregnant patients
3. What implications and priorities for nursing care can be made at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may be involved in caring for Doreen.

Cannabis, opioids, and cocaine are other examples of substances that may be used by pregnant patients. Substance use in pregnancy is a major public health concern; comprehensive care of patients with substance use disorder can improve maternal and newborn outcomes with increasing numbers of facilities and providers available for treatment of these patients. See Chapters 5 and 15 for information on substance use during pregnancy.

Normal discomforts. Pregnant patients are confronted with symptoms that would be considered abnormal in the nonpregnant state. Some individuals who are pregnant for the first time have a greater need for explanations of the causes of associated discomforts and advice on ways to relieve them. Information about the physiology, prevention, and self-management of discomforts experienced during the three trimesters is given in Table 11.4. Nurses can do much to allay a first-time mother's anxiety about such symptoms by telling them about these discomforts in advance, using terminology that the patient (or couple) can understand. When the patient understands the rationale for treatment, they are more likely to participate in their own care. Interventions should be individualized, with attention given to the patient's lifestyle and culture.

Recognizing potential complications. One of the most important responsibilities of health care providers is to alert the pregnant patient to signs and symptoms that indicate a potential complication of pregnancy. The patient needs to know how and to whom such warning signs should be reported. It is difficult to remember specifics when stressed by a disturbing symptom. Therefore, it is important that the patient and family receive a printed form written at the appropriate literacy level listing the signs and symptoms that warrant an investigation and the phone numbers to call with questions or in an emergency.

The nurse must answer questions honestly as they arise during pregnancy. Pregnant patients often have difficulty deciding when to report signs and symptoms. The mother should be encouraged to refer to the printed list of potential complications and to listen to their body. If they sense that something is wrong, they should call their care provider immediately. Several signs and symptoms must be discussed more extensively. These include vaginal bleeding, alteration in fetal movements, symptoms of pre-eclampsia, rupture of membranes, and preterm labour (see Table 11.2).

TABLE 11.4 Discomforts Related to Pregnancy

Discomfort	Physiology	Education for Self-Care
First Trimester		
Breast changes, enlargement; pain, tingling, tenderness	Hypertrophy of mammary glandular tissue and increased vascularization, pigmentation, and size and prominence of nipples and areolae caused by hormonal stimulation	Wear supportive maternity bras with pads to absorb discharge (may be worn at night); wash with warm water and keep dry; breast tenderness may interfere with sexual expression and foreplay but is temporary
Urgency and frequency of urination	Vascular engorgement and altered bladder function caused by hormones; bladder capacity reduced by enlarging uterus and fetal presenting part	Empty bladder regularly; perform Kegel exercises; wear perineal pad; report pain or burning sensation to primary health care provider
Languor and malaise; fatigue (early pregnancy, most commonly)	Unexplained; may be caused by increasing levels of estrogen, progesterone, and hCG or by elevated BBT; psychological response to pregnancy and its required physical and psychological adaptations	Rest as needed; eat a well-balanced diet to prevent anemia
Nausea and vomiting, morning sickness—occurs in 50–80% of pregnant patients; starts between first and second missed periods and lasts until about fourth missed period; may occur any time during day; partners also may have symptoms	Cause is unknown; may result from hormonal changes, possibly hCG; may be partly emotional, related to ambivalence about pregnant state	Eat whatever pregnancy-safe food is appealing; make lifestyle changes that work for the person such as: Avoid empty or overloaded stomach (eat every 1 to 2 hours); try not to drink or eat too much at same time; don't wait to be too hungry or thirsty; do not skip meals; eat dry carbohydrate on awakening; remain in bed until feeling subsides or alternate dry carbohydrate 1 hour with fluids such as hot herbal decaffeinated tea, milk, or clear coffee the next hour until feeling subsides; ensure adequate fluids (minimum 2 L/day); try adding any source of protein to each meal and snack; eat bland, dry, or salty foods; minimize or avoid spicy, fried, and/or high-fat foods; reduce strong odours (sniff lemons or limes, or get fresh air); ginger supplementation, vitamin B_6, acupuncture, or acupressure may be beneficial (Campbell et al., 2017); consult primary health care provider if intractable vomiting occurs (medication may be prescribed), see Chapter 12 for further discussion
Ptyalism (excessive salivation) may occur starting 2–3 weeks after first missed period	Possibly caused by elevated estrogen levels; may be related to reluctance to swallow because of nausea	Use astringent mouthwash, chew gum, eat hard candy as comfort measures
Gingivitis and epulis (hyperemia, hypertrophy, bleeding, tenderness); condition disappears spontaneously 1–2 months after birth: often noted throughout pregnancy	Increased vascularity and proliferation of connective tissue from estrogen stimulation	Eat a well-balanced diet, with adequate protein and fresh fruits and vegetables; brush teeth gently and observe good dental hygiene; avoid infection; see dentist
Nasal stuffiness; epistaxis (nosebleed)	Hyperemia of mucous membranes related to high estrogen levels	Use humidifier; normal saline nose drops or spray may be used
Leukorrhea: often noted throughout pregnancy	Hormonally stimulated cervix becomes hypertrophic and hyperactive, producing abundant amount of mucus	Not preventable; do not douche; wear perineal pads; perform hygienic practices such as wiping front to back; report to primary health care provider if accompanied by pruritus, foul odour, or change in character or colour
Psychosocial dynamics, mood swings, mixed feelings; often noted throughout pregnancy	Hormonal and metabolic adaptations; feelings about female role, sexuality, timing of pregnancy, and resultant changes in life and lifestyle	Participate in pregnancy support group; communicate concerns to partner, family, and others; request referral for supportive services if needed (e.g., financial assistance)
Second Trimester		
Pigmentation deepens, acne, oily skin	Melanocyte-stimulating hormone (from anterior pituitary)	Not preventable; it usually resolves during puerperium

Continued

TABLE 11.4 Discomforts Related to Pregnancy—cont'd

Discomfort	Physiology	Education for Self-Care
Spider nevi (angiomas) appear over neck, thorax, face, and arms during second or third trimester	Focal networks of dilated arterioles (end-arteries) from increased concentration of estrogens	Not preventable; they fade slowly during late puerperium but rarely disappear completely
Pruritus (noninflammatory)	Unknown cause; various types as follows: nonpapular; closely aggregated pruritic papules Increased excretory function of skin and stretching of skin are possible factors	Keep fingernails short and clean; contact primary health care provider for diagnosis of cause Not preventable; use comfort measures for symptoms: distraction; tepid baths with sodium bicarbonate or oatmeal added to water; lotions and oils; change of soaps or reduction in use of soap; wear loose clothing; contact primary health care provider if it does not resolve with treatment
Palpitations	Unknown; should not be accompanied by persistent cardiac irregularity	Not preventable; contact primary health care provider if accompanied by symptoms of cardiac decompensation
Supine hypotension (vena cava syndrome) and bradycardia	Induced by pressure of gravid uterus on ascending vena cava when patient is supine; reduces uteroplacental and renal perfusion	Assume side-lying position or semisitting posture, with knees slightly flexed (see also Emergency box: Supine Hypotension)
Faintness and, rarely, syncope (orthostatic hypotension): may persist throughout pregnancy	Vasomotor lability or postural hypotension from hormones; in late pregnancy may be caused by venous stasis in lower extremities	Exercise moderately (deep breathing, vigorous leg movements); avoid sudden changes in position and warm crowded areas; move slowly and deliberately; keep environment cool; avoid hypoglycemia by eating five to six small meals per day; wear compression hose; sit as necessary; if symptoms are serious, contact primary health care provider
Food cravings	Cause unknown; craving determined by culture or geographic area	Not preventable; satisfy craving unless it interferes with well-balanced diet; report unusual cravings to primary health care provider
Heartburn (pyrosis or acid indigestion): burning sensation, occasionally with burping and regurgitation of a little sour-tasting fluid	Progesterone slows GI tract motility and digestion, reverses peristalsis, relaxes cardiac sphincter, and delays emptying time of stomach; stomach is displaced upward and compressed by enlarging uterus	Limit or avoid gas-producing or fatty foods and large meals; maintain good posture; drink hot herbal tea; primary health care provider may prescribe antacid between meals; contact primary health care provider for persistent symptoms
Constipation	GI tract motility slowed because of progesterone, resulting in increased reabsorption of water and drying of stool; intestines compressed by enlarging uterus; predisposition to constipation because of oral iron supplementation	Drink 2 L (eight glasses) of water per day; include fibre in diet; exercise moderately; maintain regular schedule for bowel movements; use relaxation techniques and deep breathing; do not take stool softener, laxatives, mineral oil, other medications, or enemas without first consulting primary health care provider
Flatulence with bloating and belching	Reduced GI motility because of hormones, allowing time for bacterial action that produces gas; swallowing air	Chew foods slowly and thoroughly; avoid gas-producing foods, fatty foods, large meals; exercise, maintain regular bowel habits
Varicose veins (varicosities): may be associated with aching legs and tenderness; may be present in legs and vulva; hemorrhoids are varicosities in perianal area	Hereditary predisposition; relaxation of smooth muscle walls of veins because of hormones causing tortuous dilated veins in legs and pelvic vasocongestion; condition aggravated by enlarging uterus, gravity, and bearing down for bowel movements; thrombi from leg varices are rare but may be produced by hemorrhoids	Avoid lengthy standing or sitting, wearing constrictive clothing, and constipation and bearing down with bowel movements; exercise moderately; rest with legs and hips elevated (see Figure 11.14); wear compression hose; thrombosed hemorrhoid may be evacuated; relieve swelling and pain with warm sitz baths; use local application of astringent compresses
Headaches (through week 26)	Emotional tension (more common than vascular migraine headache); eye strain (refractory errors); vascular engorgement and congestion of sinuses resulting from hormone stimulation	Conscious relaxation; rest, massage, application of heat or cold; OTC analgesics (check with provider); contact primary health care provider for constant "splitting" headache to assess for pre-eclampsia

Continued

TABLE 11.4 Discomforts Related to Pregnancy—cont'd

Discomfort	Physiology	Education for Self-Care
Carpal tunnel syndrome (involves thumb, second and third fingers, lateral side of little finger)	Compression of median nerve resulting from changes in surrounding tissues; pain, numbness, tingling, burning; loss of skilled movements (typing); dropping of objects	Not preventable; elevate affected arm; splinting of affected hand may help; regressive after pregnancy; surgery is curative
Periodic numbness, tingling of fingers (acrodysesthesia)	Brachial plexus traction syndrome resulting from drooping of shoulders during pregnancy (occurs especially at night and early morning)	Maintain good posture; wear supportive maternity bra; condition will disappear if lifting and carrying baby does not aggravate it
Round ligament pain (tenderness)	Stretching of ligament caused by enlarging uterus	Not preventable; rest, maintain good body mechanics to avoid overstretching ligament; relieve cramping by squatting or bringing knees to chest; sometimes heat helps
Joint pain, backache, and pelvic pressure; hypermobility of joints	Relaxation of symphyseal and sacroiliac joints because of hormones, resulting in unstable pelvis; exaggerated lumbar and cervicothoracic curves caused by change in centre of gravity resulting from enlarging abdomen	Maintain good posture and body mechanics; avoid fatigue; wear low-heeled shoes; abdominal supports may be useful; practise conscious relaxation; sleep on firm mattress; apply local heat or ice; get back rubs; do pelvic rock exercise (see Figure 11.10); physiotherapy; acupuncture; water gymnastics; rest; condition disappears 6–8 weeks after birth
Third Trimester		
Shortness of breath and dyspnea: occur in 60% of pregnant patients	Expansion of diaphragm limited by enlarging uterus; diaphragm elevated about 4 cm; some relief after lightening	Maintain good posture; sleep with extra pillows; avoid overloading stomach; stop smoking; contact primary health care provider if symptoms worsen, to rule out anemia, emphysema, and asthma
Insomnia (later weeks of pregnancy)	Fetal movements, muscle cramping, urinary frequency, shortness of breath, or other discomforts	Reassurance, conscious relaxation, back massage or effleurage, support of body parts with pillows, and warm milk or warm shower before bedtime
Psychosocial responses: mood swings, mixed feelings, increased anxiety	Hormonal and metabolic adaptations; feelings about impending labour, birth, and parenthood	Reassurance and support from partner and nurse, and improved communication with partner, family, and others
Urinary frequency and urgency return	Vascular engorgement and altered bladder function caused by hormones; bladder capacity is reduced by enlarging uterus and fetal presenting part	Empty bladder regularly, do Kegel exercises; reassurance is helpful; wear perineal pad; contact primary health care provider for pain or burning sensation
Perineal discomfort and pressure	Pressure from enlarging uterus, especially when standing or walking; multifetal gestation	Rest, conscious relaxation, and good posture are helpful; contact primary health care provider for assessment and treatment if pain is persistent
Leg cramps (gastrocnemius spasm), especially when reclining	Compression of nerves supplying lower extremities because of enlarging uterus; reduced level of diffusible serum calcium or elevation of serum phosphorus; aggravating factors: fatigue, poor peripheral circulation, pointing toes when stretching legs or when walking, drinking more than 1 L of milk per day	Dorsiflex foot until spasm relaxes; use massage if not reddened or increased temperature at site; stand on a cold surface; supplement orally with calcium carbonate or calcium lactate tablets; aluminum hydroxide gel, 30 mL, with each meal removes phosphorus by absorbing it (consult with primary health care provider before taking these remedies); avoid pointing toes
Ankle edema (nonpitting) to lower extremities	Edema aggravated by prolonged standing, sitting, poor posture, lack of exercise, constrictive clothing, or hot weather	Drink ample fluid for natural diuretic effect; put on compression stockings before arising; rest periodically with legs and hips elevated (see Figure 11.14); exercise moderately; contact primary health care provider if generalized edema develops; diuretics are contraindicated

BBT, Basal body temperature; *GI,* gastrointestinal; *hCG,* human chorionic gonadotropin; OTC, over-the-counter.

Recognizing preterm labour. Teaching each expectant mother to recognize preterm labour is necessary for early diagnosis and treatment. Preterm labour occurs after the twentieth week but before the thirty-seventh week of pregnancy. It consists of uterine contractions that, if untreated, cause the cervix to open earlier than normal, resulting in preterm birth.

If a patient knows the warning signs and symptoms of preterm labour and seeks care early enough, prevention of preterm birth may be possible, and if labour is not stopped, transport to an appropriate care facility may be planned. Warning signs and symptoms of preterm labour are given in the Patient Teaching box: How to Recognize Preterm Labour. See Chapter 20 for a comprehensive discussion of preterm labour.

PATIENT TEACHING

How to Recognize Preterm Labour

Because the onset of preterm labour is subtle and often hard to recognize, it is important to know how to feel your abdomen for uterine contractions. You can feel for contractions in the following way:

- While lying down, place your fingertips on the top of your uterus. A contraction is the periodic tightening or hardening of your uterus. If your uterus is contracting, you will actually feel your abdomen get tight or hard and then feel it relax or soften when the contraction is over.
- If you think you are having any signs and symptoms of preterm labour (see below), empty your bladder, drink three to four glasses of water for hydration, lie down tilted toward your side, and place a pillow at your back for support.
- Check for contractions for 1 hour. To tell how often contractions are occurring, check the minutes that elapse from the beginning of one contraction to the beginning of the next.
- It is not normal to have frequent uterine contractions (every 10 minutes or more often for 1 hour).
- Contractions of labour are regular, frequent, and hard. They also may be felt as a tightening of the abdomen, a menstrual-like cramp, or a backache. This type of contraction causes the cervix to efface and dilate. Preterm labour contractions may not feel uncomfortable.
- Call your doctor, midwife, or labour and birth unit or go to the hospital if any of the following signs occur:
  - You have uterine contractions every 10 minutes or more often for 1 hour *or*
  - You feel pelvic pressure that is not relieved
  - You have any bloody spotting or leaking of fluid from your vagina
  - You feel "something is not right"
- It is often difficult to identify preterm labour. Accurate diagnosis requires assessment by the health care provider, usually in the hospital or clinic.

Adapted from Best Start. (2020). *Preterm labour signs and symptoms.* https://resources.beststart.org/wp-content/uploads/2018/12/E06-E.pdf. Adapted with permission by the Best Start Resource Centre.

Sexuality. It is important to provide couples with information regarding sexuality during pregnancy, including countering misinformation, providing reassurance of normality, and suggesting alternative sexual behaviours. The uniqueness of each couple is considered within a biopsychosocial framework (see Patient Teaching Box: Sexuality in Pregnancy). Nurses can initiate discussion about sexual adaptations that must be made during pregnancy. They need a sound knowledge base about the physical, social, and emotional responses to sex during pregnancy. Not all perinatal nurses are comfortable discussing the sexual concerns of their patients with their patients. Nurses who are aware of their personal strengths and limitations in dealing with sexual content will be better prepared to make referrals, if necessary.

PATIENT TEACHING

Sexuality in Pregnancy

- Be aware that maternal physiological changes such as breast enlargement, nausea, fatigue, abdominal changes, perineal enlargement, leukorrhea, pelvic vasocongestion, and orgasmic responses may affect sexuality and sexual expression.
- Discuss responses to pregnancy with your partner.
- Keep in mind that cultural prescriptions (do's) and proscriptions (don'ts) may affect your responses.
- Although your libido may be depressed during the first trimester, it often increases during the second trimester.
- Discuss and explore the following with your partner:
  - Alternative behaviours (e.g., mutual masturbation, foot massage, cuddling).
  - Alternative positions (e.g., female superior, side-lying) for sexual intercourse.
- Intercourse is safe as long as it is not uncomfortable. There is no correlation between intercourse and miscarriage, but observe the following precautions:
  - Abstain from intercourse if you experience uterine cramping or vaginal bleeding; report the event to your health care provider as soon as possible.
  - Abstain from intercourse (or any activity that results in orgasm) if you have a history of premature dilation of the cervix until the problem is corrected or if your membranes are ruptured.
- Continue to use risk reduction behaviours. Patients at risk for acquiring or conveying sexually transmitted infections are encouraged to use condoms during sexual intercourse throughout pregnancy.

Many patients merely need permission to be sexually active during pregnancy. Others, however, need to be given information about the physiological changes that occur during pregnancy, have the myths that are associated with sex during pregnancy dispelled, and participate in open discussion of positions for intercourse that decrease pressure on the gravid abdomen (Figure 11.17). Such tasks are within the purview of

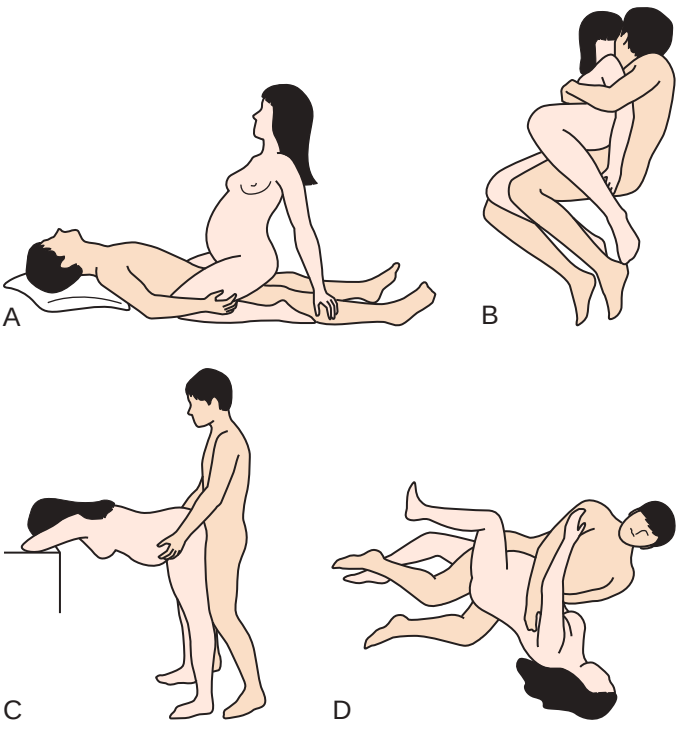

Fig. 11.17 Positions for sexual intercourse during pregnancy. **A:** Female superior. **B:** Side by side. **C:** Rear entry. **D:** Facing each other.

the perinatal nurse and should be an integral component of the health care provided.

Many myths and much of the misinformation related to sex and pregnancy are masked by seemingly unrelated issues. For example, a discussion about the baby's ability to hear and see in utero may be prompted by questions about the baby being an observer of lovemaking. The counsellor must be sensitive to the issues behind such questions when counselling in this highly charged emotional area.

Suggesting alternative behaviours. For most patients, there are no restrictions on sexual intercourse during pregnancy. However, pregnant patients should be aware that they are likely to experience alternations in sexual desire and comfort during sexual activity. Uterine activity can increase with sexual intercourse; this can be related to breast stimulation, orgasm, or prostaglandins in male ejaculate. For the majority of patients, this is not a concern. However, a history of more than one miscarriage; a threatened miscarriage in the first trimester; impending miscarriage in the second trimester; threatened or actual preterm labour; and PROM, bleeding, or abdominal pain during the third trimester may warrant caution regarding coitus and orgasm.

Solitary and mutual masturbation and oral–genital intercourse may be used by couples as alternatives to penile–vaginal intercourse. Partners who enjoy cunnilingus (oral stimulation of the clitoris or vagina) may feel "turned off" by the normal increase in amount and odour of vaginal discharge during pregnancy. Couples who practise cunnilingus should be cautioned against the blowing of air into the vagina, particularly during the last few weeks of pregnancy, when the cervix may be slightly open. An air embolism can occur if air is forced between the uterine wall and fetal membranes and enters the maternal vascular system through the placenta.

Showing the patient or couple illustrations of the possible variations of coital position can be helpful (see Figure 11.17). The female-superior, side-by-side, rear-entry, and facing-each-other positions are alternatives to the traditional male-superior position. The patient astride (superior position) allows them to control the angle and depth of penile penetration, as well as protect their breasts and abdomen. During the third trimester, the side-by-side position or any position that places less pressure on the pregnant abdomen and requires less energy may be preferred.

Multiparous patients sometimes have significant breast tenderness in the first trimester. A coital position that avoids direct pressure on the patient's breasts and decreased breast fondling during love play can be recommended to such couples. The patient should also be reassured that this condition is normal and temporary.

Some patients state that they have lower abdominal cramping and backache after orgasm during the first and third trimesters. A back rub can often relieve some of the discomfort and provide a pleasant experience. A tonic uterine contraction, often lasting up to a minute, replaces the rhythmic contractions of orgasm during the third trimester. Changes in FHR without fetal distress have also been reported.

The objective of risk reduction is to provide prophylaxis against the acquisition and transmission of STIs (e.g., HSV, HPV, and HIV). Because these diseases may be transmitted to the patient and the fetus, the use of condoms is recommended throughout pregnancy if the patient is at risk for acquiring an STI.

Well-informed nurses who are comfortable with their own sexuality and the sex-counselling needs of expectant couples can offer information and advice in this valuable but often neglected area. They can establish an open environment in which couples can feel free to introduce their concerns about sexual adjustment and seek support and guidance. This intervention is as important for lesbians and their partners as it is for women partnered with men.

Psychosocial Support. Respect, affection, trust, concern, consideration of cultural and religious responses, and listening are all components of the emotional support that nurses can give to the pregnant patient and the family. The patient's satisfaction with their relationships and support as well as their sense of competence and being in control are all important issues to be addressed. Other issues that can arise for the pregnant patient and couple include fear of pain, loss of control during labour, and possible birth of the infant before reaching the hospital. Parental concerns about the responsibilities and tasks of parenthood; the safety of the mother and unborn child; siblings and their acceptance of the new baby; social and economic responsibilities; and possible conflicts in cultural, religious, or personal value systems should all be addressed. The father's or partner's commitment to the pregnancy, the couple's relationship, and their concerns about sexuality and sexual expression can emerge as issues for many expectant parents.

By providing the prospective parents with opportunities to discuss their concerns and validating the normality of their responses, the perinatal nurse can help them feel more at ease with the pregnancy. Nurses must also recognize that men tend to feel more vulnerable during their partner's pregnancy. Female partners may also have these feelings. Anticipatory guidance and health promotion strategies can help partners cope with their concerns. Nursing interventions may help them to deal with such concerns either directly through counselling or indirectly through the education of the mothers. Health care providers can foster and encourage open dialogue between the couple.

Variations in Prenatal Care

The course of prenatal care described thus far can seem to suggest that the experiences of childbearing patients are similar and that nursing interventions are uniform across all populations. Although typical patterns of response to pregnancy are easily recognized and many aspects of prenatal care indeed are consistent, pregnant patients enter the health care system with individual concerns and needs. The nurse's ability to assess unique needs and tailor interventions to the individual is the hallmark of expertise in providing care. Factors that influence prenatal care and a patient's response to it include culture, age, and number of fetuses.

Cultural Influences. Prenatal care as we know it is a phenomenon of Western medicine. In the biomedical model of care, patients are encouraged to seek prenatal care as early as possible in their pregnancy by visiting a physician or midwife. This model is not only unfamiliar but may seem strange to many cultural groups.

Many cultural variations in prenatal care exist. Even if the prenatal care described is familiar to a patient, some practices may conflict with the beliefs and practices of a subculture group to which they belong. Because of these and other factors, such as lack of money, lack of transportation, fear of judgement, and language barriers, patients from diverse cultures may not keep prenatal appointments. The nurse may misinterpret their behaviour as uncaring, lazy, or ignorant.

A concern for modesty is a deterrent to many patients seeking prenatal care. For some women, exposing body parts, especially to a man, is considered a major violation of their modesty. For some patients, invasive procedures such as vaginal examination may be so threatening that they cannot be discussed even with their own partners. Many patients prefer a female health care provider. Too often, health care providers assume that people lose this modesty during pregnancy and labour, but most patients value and appreciate efforts to maintain their modesty.

Because pregnancy is considered a normal process and the person is in a state of health, many cultural groups regard care from a health care provider to be necessary only in times of illness. Therefore, the services of a clinician are considered inappropriate during pregnancy. Western medicine's view of health issues in pregnancy can differ from that of members of other cultural groups.

Although pregnancy is considered normal by many, certain practices are expected of patients of all cultures to ensure a good outcome. *Cultural prescriptions* tell people what to do, and *cultural proscriptions* establish taboos. The purposes of these practices are to prevent maternal illness caused by a pregnancy-induced imbalanced state and to protect the vulnerable fetus. Prescriptions and proscriptions regulate the person's emotional response, clothing, physical activity and rest, sexual activity, and dietary practices. Exploration of the individual's beliefs, perceptions of the meaning of childbearing, and health care practices may help health care providers foster their self-esteem, promote attainment of the maternal role, and positively influence the person's relationship with their partner.

To provide culturally safe care, the nurse must be knowledgeable about specific practices and customs. Although it is not possible to know all there is to know about every culture and subculture or the many lifestyles that exist, it is important to learn about the varied cultures in the setting in which a nurse practises. By exploring and becoming knowledgeable in the cultural beliefs and practices related to childbearing, the nurse can better support and nurture the beliefs that promote physical or emotional adaptation. The most important aspect of providing culturally safe care is to remember that all people are different; just because someone is of a particular culture does not mean they will respond in a particular way. Nurses must assess each patient individually (Box 11.3).

Emotional response. Virtually all cultures emphasize the importance of maintaining a socially harmonious and agreeable environment for the pregnant patient (see Community Focus box). A lifestyle with minimal stress is important in ensuring a successful outcome for the mother and baby. Harmony with other people must be fostered, and visits from extended family members may be required to demonstrate pleasant and noncontroversial relationships. If discord exists in a relationship, it is usually dealt with in culturally prescribed ways.

COMMUNITY FOCUS

Availability of Culturally Appropriate Childbirth Resources

Select a cultural group different from your own within your community and identify childbirth-related beliefs and practices that are unique to that group. Are there stores in the area that sell items that meet the needs of that group? Does the community centre have activities or classes that are directed toward that group? Are there outreach programs in the community that meet the cultural needs of the group? Are childbirth education programs available that provide essential information while incorporating cultural patterns? Are childbirth classes available in languages other than English? What written and online resources are available in the appropriate language and are they comprehensive? What could you, as a nurse, contribute to the community that would help meet the needs of that group?

Physical activity and rest. Norms that regulate physical activity of mothers during pregnancy vary tremendously. Many groups, including Indigenous groups as well as some Asian groups, encourage pregnant individuals to be active, to walk, and to engage in normal but not strenuous activities to ensure that the baby is healthy and not too large. Other groups, such as Filipinos, believe that any activity is dangerous, and others willingly take over the work of the pregnant person. Some Filipinos believe that this inactivity protects the mother and child. If health care providers do not know of this belief, they could misinterpret this behaviour as laziness or nonadherence to the desired prenatal health care regimen. It is important for the nurse to find out the way that each pregnant patient views activity and rest.

Nutrition. Nutritional information given by Western health care providers may be a source of conflict for many cultural groups. Such a conflict commonly is not discovered by health care providers unless they understand the dietary beliefs and practices of the particular people for whom they are caring. For example, some religious groups have strict regulations about the preparation of food and if meat cannot be prepared as prescribed, they may omit it from their diets. Some cultures permit pregnant people to eat only warm foods.

Age Differences. The age of the childbearing couple may have a significant influence on their physical and psychosocial adaptation to pregnancy. Normal developmental processes that occur in both very young and older mothers are interrupted by pregnancy and require a different type of adaptation to pregnancy than that of the person of typical childbearing age. Special needs of expectant mothers 15 years of age or younger or those 35 years of age or older are summarized here.

Adolescents. Overall, teenage pregnancy rates have decreased in Canada; in 2018, the rate of adolescent pregnancies was 1.8% of all births (Statistics Canada, 2021). Many of these pregnancies are unintended. Among Indigenous people, 45% of Inuit women, 28% of First Nations women living off reserve, and 20% of Métis women became mothers before the age of 20, compared with 6% of non-Indigenous women in the same age group (Boulet & Badet, 2017). Pregnancy rates are also higher among teens with lower educational levels and who are economically disadvantaged. Many of these young people do not have consistent support and may not be ready for the emotional, psychosocial, and financial responsibilities of parenthood.

When adolescents become pregnant and decide to give birth, they are much less likely than older patients to access adequate prenatal care. These young patients also are more likely to smoke and less likely to gain adequate weight during pregnancy. Newborns born to adolescents are at increased risk for LBW, VLBW, and infant death. Adolescents are at increased risk for maternal anemia, preterm birth, pre-eclampsia and/or HELLP syndrome, postpartum hemorrhage, and chorioamnionitis, but they do not have an increased likelihood of Caesarean birth (Kawakita et al., 2016).

BOX 11.3 Questions to Ask to Explore Cultural Expectations About Childbearing

1. What beliefs do you and your family have that may help you remain healthy during pregnancy?
2. Do you have any beliefs regarding things you should not do in order to improve your health and the health of your baby?
3. Tell me about any special dietary needs or foods that you cannot eat during pregnancy or any foods that you are encouraged to eat.
4. Does your culture or religion guide any of your beliefs about pregnancy, birthing, and the period after birth that would be important for your health care providers to know?
5. What are your expectations for your hospitalization for childbirth?
6. Who do you want with you during your labour?
7. What actions are important for you and your family to take after the baby's birth? How can the nurse support this?
8. How can the health care team help you achieve a healthy pregnancy and birth?
9. How will family members participate in your pregnancy, childbirth, and parenting?

Delayed entry into prenatal care may be the result of late recognition of pregnancy, denial of pregnancy, or confusion about the services that are available. Such a delay in care may leave inadequate time before birth to attend to correctable problems. The very young pregnant adolescent is at higher risk for each of the confounding variables associated with poor pregnancy outcomes (e.g., socioeconomic factors) and for the conditions associated with a first pregnancy, regardless of age (e.g., gestational hypertension). However, when prenatal care is initiated early and consistently and confounding variables are controlled, very young pregnant adolescents are at no greater risk (nor are their infants) for an adverse outcome than older pregnant patients. Thus the role of the nurse in reducing the risks and consequences of adolescent pregnancy is to encourage early and continued prenatal care; to provide early and ongoing education about pregnancy, birth, and parenting; and to refer the adolescent, if necessary, for appropriate social support services, which can help reverse the effects of a negative socioeconomic environment (Figure 11.18; see Nursing Care Plan on Adolescent Pregnancy on Evolve).

Late maternal age (older than 35 years). Two groups of older parents have emerged in the population of individuals having a child late in their childbearing years. One group consists of people who have many children and who have an additional child during the menopausal period. The other group consists of individuals who have deliberately delayed childbearing until their late 30s or early 40s and those who previously were unable to conceive due to fertility issues and became pregnant through assisted human reproduction (AHR). Current statistics show that approximately 26% of patients giving birth in Canada are 35 years of age or more (Statistics Canada, 2021).

As maternal age advances, there is a greater chance of pre-existing conditions such as hypertension and diabetes (Gregory et al., 2019). In addition, in patients ages 35 years or older, there is an increased risk for maternal mortality from hemorrhage, infection, embolisms, hypertensive disorders of pregnancy, cardiomyopathy, and strokes. The rate of stillbirth is also higher for many reasons, such as comorbidities and higher rates of hypertension and diabetes, so patients over 35 are recommended to have the option of induction at 39 weeks' gestation (Walker et al., 2016).

Multiparous older patients. For some multiparous patients older than 35 years of age, pregnancy is desired, such as with a new marriage or partner. For others, it may be unplanned. Some multiparous patients have never used contraceptives because of personal choice or lack of knowledge concerning contraceptives. Others may have used contraceptives successfully during the childbearing years, but as menopause approaches they cease menstruating regularly or stop using contraceptives and consequently become pregnant.

Fig. 11.18 Pregnant adolescents review fetal development. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

Pregnancy can bring feelings of joy as patients consider continuing the maternal role and expanding the family. For some older multiparas, pregnancy can evoke feelings of isolation. The person may feel that pregnancy separates them from their peer group and that age is a hindrance to close associations with young mothers.

Primiparous older patients. The number of first-time pregnancies in patients between ages 35 and 40 has increased significantly over the last two decades. Currently, the average age of first-time mothers is 30.2 years of age, which is the oldest ever recorded (Statistics Canada, 2018). Seeing patients in their late 30s or 40s during their first pregnancy is no longer unusual for health care providers. Reasons for delaying pregnancy include a desire to obtain advanced education, career priorities, and use of effective contraceptive measures. As stated earlier, patients with infertility issues may not delay pregnancy deliberately but may become pregnant at a later age through the use of AHR. There is evidence of increased risk for preterm labour and pre-eclampsia for patients older than 40 years of age who conceive through assisted reproductive technology and oocyte donation (Gregory et al., 2019).

Many primigravidas older than 35 years of age deliberately choose parenthood. They often are successfully established in a career and a lifestyle with a partner that includes time for self-attention, the establishment of a home with accumulated possessions, and freedom to travel. When asked the reason they chose pregnancy later in life, many reply, "Because time is running out."

The dilemma of choice includes recognition that being a parent will have both positive and negative consequences. Couples need to discuss the consequences of childbearing and child-rearing before committing themselves to this lifelong venture. Partners in this group seem to share the preparation for parenthood, the planning for a family-centred birth, and the desire to be loving and competent parents. However, the reality of child care may prove difficult for them.

First-time mothers older than 35 years select the "right time" for pregnancy; this time is influenced by their awareness of the increasing possibility of infertility or of genetic defects in the infants of older patients. Such patients often seek information about pregnancy from the Internet, books, family, and friends. They may seek preconception care that includes genetic testing, assessment of blood pressure, weight, updating immunizations, cervical and breast cancer screening, as well as mental health care. They may identify sources of stress in their lives. They may have concerns about having enough energy and stamina to meet the demands of parenting and their new roles and relationships.

If older patients become pregnant after treatment for infertility, they may suddenly have negative or ambivalent feelings about the pregnancy. They may experience a multifetal pregnancy that may create emotional and physical challenges. Adjusting to parenting two or more infants requires adaptability and additional resources.

During pregnancy, parents explore the possibilities and responsibilities of changing identities and new roles. They must prepare a safe and nurturing environment during pregnancy and after birth. They must integrate the child into an established family system and negotiate new roles (parent, sibling, and grandparent roles) for family members.

Adverse perinatal outcomes are more common in older primiparas than in younger patients, even when they receive good prenatal care. Patients 35 years of age and older are more likely to have an early loss or ectopic pregnancy. They are also more at risk than younger primiparas to have infants with chromosomal abnormalities, LBW infants, preterm birth, placental abruption, and multiple gestation (Dillon

et al., 2019; Johnson & Tough, 2017). The incidence of malpresentation also is more common in older primiparas, and they are more likely to have a Caesarean birth. The occurrence of these complications can be quite stressful for the new parents, thus nursing interventions that provide information and psychosocial support in addition to care for physical needs are important.

Multifetal Pregnancy. With the increased use of AHR, the incidence of multifetal pregnancy has risen. The rate of twin births was 3.0% in 2016, with higher percentages in older patients over the age of 35 (Provencher et al., 2018).

A multifetal pregnancy, or pregnancy with more than one fetus, places the mother and fetuses at increased risk for adverse outcomes. Maternal physiological adaptation to pregnancy is more dramatic with multiple fetuses. Levels of pregnancy hormones such as human chorionic gonadotropin are significantly increased over a singleton pregnancy; this increases the risk for hyperemesis gravidarum. The maternal blood volume is increased, resulting in an increased strain on the maternal cardiovascular system. Anemia often develops because of a greater demand for iron by the fetuses. Marked uterine distention, increased pressure on the adjacent viscera and pelvic vasculature, and diastasis of the rectus abdominis muscles can occur. Multifetal gestation increases the risk for many pregnancy complications, including spontaneous abortion, gestational diabetes, hypertension, preeclampsia, placenta previa, and postpartum hemorrhage. Preterm birth is more likely with multifetal gestation; the risk rises as the number of fetuses increases. Intrauterine growth restriction or discordant growth, LBW, VLBW, congenital abnormalities, newborn death, and cerebral palsy are more common in multifetal gestation. There can be local shunting of blood between placentas (twin-to-twin transfusion); this causes the recipient twin to be larger and the donor twin to be small, pallid, dehydrated, malnourished, and hypovolemic. However, the larger twin can develop congestive heart failure during the first 24 hours after birth. The risk for death of one or more fetuses increases significantly with higher-order multiples (Newman & Unal, 2017).

If the presence of more than three fetuses is diagnosed, parents may receive counselling regarding selective reduction to reduce the incidence of premature birth and improve the opportunities for the remaining fetuses to grow to term gestation (ACOG, 2013). This situation poses an ethical dilemma for many couples, especially those who have worked hard to overcome difficulties with infertility and have strong values regarding right to life. Nurses can initiate discussions with couples to help them identify resources (e.g., a minister, priest, rabbi, or mental health counsellor) to aid in the decision-making process.

The likelihood of a multifetal pregnancy is increased if, during a careful assessment, any one or a combination of the following factors is noted:

- History of dizygotic twins in the female lineage
- Use of fertility medications
- More rapid uterine growth for the number of weeks of gestation
- Polyhydramnios
- Palpation of more than the expected number of small or large parts
- Asynchronous fetal heartbeats or more than one fetal electrocardiographic tracing
- Ultrasound evidence of more than one fetus

The diagnosis of multifetal pregnancy can come as a shock to many expectant parents, and they may need additional support and education to help them cope with the changes they face.

The prenatal care for patients with multifetal pregnancies includes changes in the pattern of care and modifications in other aspects. Prenatal visits are scheduled more frequently. Frequent ultrasound examinations, nonstress tests, and FHR monitoring may be performed. The pregnant patient needs information related to self-management of a multifetal pregnancy because guidelines differ from those for a singleton pregnancy. Specific instruction should be provided regarding nutrition so that they consume a well-balanced diet with adequate caloric intake and gain weight appropriately. The recommended weight gain in twin gestations is 17 to 25 kg (37.4 to 55 lb) (Alberta Health Services, 2019). Iron and vitamin supplements are desirable. Since pre-eclampsia and eclampsia occur more commonly during multifetal pregnancies, the health care team needs to work aggressively to prevent, identify, and treat these complications of pregnancy.

Other pertinent information includes maternal adaptations during pregnancy, management of discomforts, and the risk for preterm labour and birth, including warning signs and when to call the provider. The uterine distention associated with multifetal pregnancy can cause the backache commonly experienced by pregnant patients to be even worse. Support hose may be worn to control leg varicosities. Limiting activity may be recommended beginning at 20 weeks for patients carrying multiple fetuses, to prevent preterm labour. Prolonged bedrest is not recommended as it does not prevent preterm labour and causes other complications. If birth is delayed until after the thirty-sixth week, the risk of morbidity and mortality decreases for the newborns.

Multiple newborns may likely place a strain on finances, space, workload, and the mother's and family's coping abilities. Lifestyle changes may be necessary. Parents may need assistance in making realistic plans for the care of the babies (e.g., how to breastfeed and whether to raise them as "alike" or as separate individuals). Parents can be referred to national organizations such as Multiple Births Canada and the La Leche League for further support.

PERINATAL CARE CHOICES

Patients have the option to choose from a variety of health care providers; this may include physicians, nurses, midwives, doulas, childbirth educators, and various others who may help with physical or social needs. Those caring for patients during pregnancy, birth, and the early parenting period must work together to provide appropriate care for patients and their families. Often the first decision the patient makes is who will be their primary health care provider for the pregnancy and birth. This decision is doubly important because it usually affects where the birth will take place. In Canada, the options for primary care during pregnancy are a physician or, in most provinces, a registered midwife. The nurse can provide information about the different types of health care providers and what kind of care to expect from each type. Patients need to be provided information about choices and encouraged to ask potential care providers the following questions to ensure that they feel comfortable with the choices they make:

- Who can be with me during labour and birth?
- What happens during a normal labour and birth in your setting?
- How do you allow for differences in culture and beliefs?
- Can I walk and move around during labour? What position do you suggest for birth?
- What things do you normally do to a patient in labour?
- How do you help mothers stay as comfortable as they can be? Besides medications, how do you help relieve the pain of labour?
- What if my baby is born early or has special problems?
- What support do you have for breastfeeding mothers?

Physicians

While specific statistics on the number of births attended by physicians are not presently collected, it is estimated that physicians (obstetricians and family practice physicians) attended approximately 90% of births in Canada in 2018 (PHAC, 2020b). Physicians see both low-risk and high-risk patients. In general, family practice physicians provide care for primarily low-risk pregnant patients and refer high-risk patients

to obstetricians. Obstetricians provide care for low-risk and high-risk pregnant patients. High-risk pregnant patients are often referred to maternal-fetal medicine specialists for part or all of their care. Almost all physicians manage births in a hospital setting. A patient may see one doctor for the entire pregnancy and birth or, more commonly, they may be cared for in a group practice setting, seeing multiple physicians and having the physician who is on call present at the birth.

Midwives

Registered midwives in Canada are educated through a university program as a profession distinct from nursing. Throughout history, midwives have held a holistic view of childbirth. Midwives care for low-risk obstetrical patients. Care is often noninterventionist, and the patient and their family are encouraged to be active participants in the care. See Box 4.4 for a discussion of the principles of midwifery care. Patients are often cared for by one or two midwives who provide care throughout the pregnancy, birth, and postpartum period. Many patients appreciate the continuity of care that this model of care provides. Midwives refer patients with complications to physicians. Births may be managed in a hospital setting, in a birth centre, or at home.

Patients who are seeing a midwife may have some of their visits with the midwife at their home. The midwife will typically have one prenatal visit and several postpartum visits at the patient's home. This reduces stress on the new mother, who may find it difficult in the first few weeks after birth to get out with the baby.

In Canada, midwives are regulated by the Canadian Association of Midwives, although currently, not all provinces and territories have legislation regarding the practice of midwives. While approximately 10% of all births in Canada are attended by a midwife, this number is increasing with the greater number of available midwives (PHAC, 2020b). See Chapter 4 for further discussion on midwifery in Canada.

Doula

A **doula** provides labour support, including physical, emotional, and informational support, to the mother and their partner before, during, and just after birth, or provides emotional and practical support during the postpartum period alongside other health care providers. The doula does not become involved with clinical tasks. Birth doulas provide support during labour, and postpartum doulas provide assistance after the birth; both are part of the health care team. Some doulas are certified by Doulas of North America (DONA) International or Childbirth and Postpartum Professional Association (CAPPA), while others provide care without having any certification. Doulas usually work on a fee-for-service basis, and many will offer a sliding scale for families who cannot afford to pay for their services.

Currently, many couples employ a doula for labour support. Research has found that patients who had continuous labour support like that provided by doulas were more likely to have a spontaneous vaginal birth and less likely to have intrapartum analgesia or to report dissatisfaction with birth. In addition, their labours were shorter, they were less likely to have a Caesarean or instrumental vaginal birth, or a baby with a low 5-minute Apgar score. There was no apparent impact on other intrapartum interventions, maternal or newborn complications, or breastfeeding (Howard & Low, 2020). Continuous support seemed to be most effective when the provider was neither part of the hospital staff nor the patient's social network and in settings in which epidural analgesia was not routinely available.

A doula typically meets with the mother and their partner before labour to ascertain their expectations and desires for the birth experience. With this information as a guide during labour and birth, the doula works collaboratively with other health care providers and the patient's support people and focuses on assisting the patient and couple to achieve their goals. Doulas who are also trained medical interpreters can enhance the care of patients with limited English proficiency (Howard & Low, 2020).

Doulas may be found through community contacts, other health care providers, or childbirth educators; a number of organizations offer information or referral services. It is important that the expectant mother be comfortable with the doula who will be attending her. See Box 11.4 for a list of questions to ask when arranging for a doula.

Birth Setting Choices

With careful thought, the concept of family- or person-centred maternity care can be implemented in any setting. Currently, the three primary options for birth settings are the hospital, birth centre, and home, depending on the province or territory in which a patient lives. Patients consider several factors in choosing a setting for childbirth, including where the care provider has privileges and the characteristics of the birthing unit. The majority of births in Canada take place in a hospital setting, although the provinces of Ontario and British Columbia have higher rates of home births (PHAC, 2020b).

Hospitals. The types of labour and birth services in hospitals vary greatly, from the traditional labour and birth rooms with separate postpartum and newborn units to in-hospital birthing centres where all or almost all care takes place in a single unit.

Labour, birth, and recovery (LBR) and labour, birth, recovery, and postpartum (LBRP) rooms offer families a comfortable, private space for childbirth (Figure 11.19). Patients admitted to LBR units go through labour and give birth there and spend the first 1 to 2 hours postpartum there for immediate recovery, to have time with their families to bond with their newborns. After this period of recovery, the mothers and newborns are usually transferred to a mother–baby unit for the duration of their stay. In most hospitals in Canada, the same nurse provides care for both mothers and newborns (mother–baby or couplet care).

In LBRP units, total care is provided, from admission for labour through postpartum discharge, in the same room and usually by the same nursing staff. The patient and their family may stay in this unit for 6 to 48 hours after giving birth. The units are furnished in a

BOX 11.4 Questions to Ask When Choosing a Doula

To discover the specific training, experience, and services offered by anyone who provides labour support, potential patients should ask the following questions of that person:

- What training have you had?
- Tell me about your experience with birth, personally and as a doula.
- What is your philosophy about childbirth and supporting women and their partners through labour?
- May we meet to discuss our birth plans and the role you will play in supporting me and my partner through childbirth?
- May we call you with questions or concerns before and after the birth?
- When do you try to join women in labour? Do you come to our home or meet us at the hospital?
- Do you meet with us after the birth to review the labour and answer questions?
- Do you work with one or more backup doulas for times when you are not available? May we meet them?
- What is your fee and refund policy?

From DONA International. (2016). *Position paper: The birth doula's role in maternity care.* https://www.dona.org/wp-content/uploads/2020/02/DONA-Birth-Position-Paper-FINAL.pdf

Fig. 11.19 Labour, birth, recovery, and postpartum unit. (Courtesy Mercy Hospital.)

homelike atmosphere, similar to LBR units, but have accommodations for family members to stay overnight.

Both LBR and LBRP units are equipped with fetal monitors, emergency resuscitation equipment for mother and newborn, and heated cribs or warming units for the newborn. Often this equipment is out of sight in cabinets or closets when it is not being used.

Birth Centres. Free-standing birth centres are usually built in locations separate from the hospital but may be located nearby, in case transfer of the patient or newborn is needed. These birth centres are intended to offer families a safe alternative to hospital or home birth. The centres are usually staffed by nurses, midwives, or physicians who also have privileges at the local hospital. Only patients considered low risk are admitted for care.

The Toronto Birth Centre is an example of a birth centre that focuses on the promotion of cultural safe care with a large Indigenous population in the Toronto area.

Birth centres typically have homelike accommodations, including a double bed for the couple and a crib for the newborn (Figure 11.20). Emergency equipment and medications are available but stored out of view. Private bathroom facilities are incorporated into each birth unit. There may be an early labour lounge or a living room and small kitchen. The family is admitted to the birth centre for labour and birth and will remain there until discharge, which often takes place within 6 hours of the birth. An emergency plan needs to be considered for the mother and family as needed when complications arise, such as with emergency medical services and hospital transfer.

Home Birth. In developing countries, hospitals or adequate facilities often are unavailable to most pregnant patients, and home birth is a necessity, whereas in Canada it is a choice of the pregnant patient and family. Research supports the safety of planned home birth for healthy, low-risk patients who are attended by registered midwives and when there is a system in place for transfer to a hospital facility.

With a home birth, the family is in control of the experience, and the birth may be more physiologically natural in familiar surroundings (see Community Focus box). The mother may be more relaxed than she would be in the hospital environment. The family can assist in and be a part of the birth, and the mother–father or partner–infant (and sibling–infant) contact is immediate and sustained. Serious infection may be less likely (assuming aseptic principles are followed) because it is common for people to be relatively immune to the bacteria in their own home.

COMMUNITY FOCUS

Deciding About a Home Birth

Maxine, a 37-year-old primiparous patient, is interested in having a home birth. She is currently 14 weeks pregnant, and her pregnancy is progressing normally. According to an ultrasound examination she has one fetus of appropriate size for gestational age with no detectable anomalies. She would like to pursue midwifery care with plans for a home birth. Explore the options for home birth in your province that are available for Maxine. What are the guidelines for midwifery care in your area? What patients are eligible for midwifery care? How many women have home births in your area and how many have hospital births? Are midwife-led birth centres available? What provisions are needed for a home birth?

Fig. 11.20 Birth centre. Note double bed, baby crib, and birthing stool. (Ian Hooton/Science Source.)

PRENATAL EDUCATION

The goal of prenatal education is to assist individuals and their family members to make informed, safe decisions about pregnancy, birth, and early parenthood. It is also to assist them in comprehending the long-lasting effects that empowering birth experiences have on people and the impact of early experiences on the development of children and the family.

Pregnant patients consider maternity care providers and childbirth education classes as the most valuable sources of information about pregnancy and birth. However, time with providers for education during prenatal visits is limited, and only about half of pregnant patients report having ever attended a childbirth education class. Attendance at formal childbirth classes has declined in recent years. Patients are turning to electronic media for information. A majority of individuals seek information from online resources such as pregnancy websites, blogs, emails, apps, and social media, as well as television shows about labour and birth (Declercq et al., 2013). Yet, patients do not typically discuss information they have retrieved from these sources with their health care providers. Many patients are unable to differentiate between commercially sponsored and not-for-profit websites; they cannot assess the accuracy of the information they are reading or hearing. Nurses can help to fill the education gap by talking with pregnant patients about the sources and types of information they are finding through the Internet and other technology-based resources. Nurses can also offer to answer questions and direct patients to sites that present current, accurate information about pregnancy, birth, newborn care, breastfeeding, parenting, and other issues of interest (Demirci et al., 2016).

Childbirth Education Classes

Contemporary prenatal education programs may consist of a menu of class series and activities, from preconception through pregnancy, childbirth, and the early months of parenting. The prenatal curriculum may include many topics (Box 11.5). Optimally, these classes help patients trust their bodies and offer them a way to take full advantage of the opportunities presented by a prepared-for and well-supported childbirth experience. Creating an environment of safety where patients and their partners can ask questions as well as have the opportunity to look at fears and concerns is important for their learning during pregnancy and preparing for parenthood.

All health-promoting education should be provided in a context that emphasizes the ability of a healthy body to adapt to the changes that accompany pregnancy. Without this context of health, routine care and testing for risks may foster a mindset in families that pregnancy is a pathological condition and not a healthy mind–body–spirit event.

Most childbirth education classes are attended by the pregnant individual and their partner, although a friend, teenage daughter, sister, or parent may be the designated support person. Classes may also be held for grandparents and siblings to prepare them for their attendance at birth or the arrival of the baby. Siblings often see a film about birth and learn ways they can help welcome the baby. They also learn to cope with changes, including a reduction in parental time and attention. Grandparents learn about current child-care practices and how to help their adult children in a supportive way to adapt to parenting.

BOX 11.5 Childbirth Education Topics

- Physical and emotional changes during pregnancy
- Breastfeeding/Infant feeding
- Nutrition during pregnancy
- Working during pregnancy
- Pain management strategies during labour—pharmacological and nonpharmacological
- Labour and birth process
- Becoming a parent
- Transition to parenting
- Newborn care

Although traditional face-to-face classes are often the preferred mode of learning, many couples are unable to commit to attending regular classes because of conflicting work schedules and long commutes. Other couples prefer to obtain their prenatal information online. To meet the needs of today's childbearing families, many health departments have begun to offer eLearning prenatal classes. This is an excellent way of reaching pregnant patients and their partners who would not have attended face-to-face prenatal classes.

When pregnant patients are prepared for childbirth and are well supported, childbirth can present a unique and powerful opportunity for patients to find their core strength in a manner that forever changes their self-perception. In providing the requisite childbirth education, it is important to remember that expectant parents and their families have different interests and information needs as the pregnancy progresses. Parents may select a variety of classes, such as the following:

- Early pregnancy ("early bird") classes provide fundamental information. Classes are developed around the following areas: (1) early fetal development, (2) physiological and emotional changes of pregnancy, (3) human sexuality, and (4) the nutritional needs of the mother and fetus. Environmental and workplace hazards may be addressed. Exercises, nutrition, warning signs, drug use, and self-medication are topics of interest and concern.
- Midpregnancy classes emphasize the patient's participation in self-management. Classes provide information on preparing for newborn feeding; infant care; basic hygiene; common discomforts and simple, safe remedies; infant health; parenting; and updating and refining of the birth plans.
- Late pregnancy classes address labour and birth. Different methods of coping with labour and birth have been developed and are often the basis for various prenatal classes. A hospital tour may be included.
- Refresher classes for parents with children not only review coping techniques for labour and birth and address any concerns from their previous birth but also help couples prepare for sibling reactions and adjustments to a new baby.
- Caesarean birth classes are offered for couples who have this kind of birth scheduled because of breech position or other risk factors.
- Other classes focus on vaginal birth after Caesarean (VBAC), as many patients successfully give birth vaginally after a previous Caesarean birth.

Throughout the series of classes, it is important to identify support systems that people can use during pregnancy and after birth. Such support systems help parents function independently and effectively. During all the classes, members should be encouraged to openly express their feelings and concerns about any aspect of pregnancy, birth, and parenting.

Methods of Childbirth Education. There are many different methods of childbirth education, and most educators use a combination of many techniques. The Dick-Read method focuses on the idea that pain in childbirth is socially conditioned and caused by a fear–tension–pain syndrome (see Figure 18.3). Another option is HypnoBirthing, where pregnant patients (couples) learn how the birthing muscles work when the patient is in a state of relaxation. The aim is for the patient to be relaxed and in control. The Bradley Method (see Additional Resources at end of the chapter) uses partner-coached

childbirth, breath control, abdominal breathing, and general body relaxation. Working in harmony with the body is emphasized. Bradley's technique emphasizes environmental variables such as darkness, solitude, and quiet to make childbirth a more natural experience. Birthing From Within mentors (teachers) believe that childbirth is not a medical event but a profound rite of passage. Parents are taught the power of birthing-in-awareness. Mentors create a safe, nurturing class experience and help parents find their personal strength and wisdom. Birth is taught from four perspectives: mother, partner, baby, and culture. Parents are assisted in developing a pain-coping mindset. Birthing From Within advocates that parents deserve support for whatever birth option they choose.

The Childbirth and Postpartum Professional Association (CAPPA) is a nonprofit international organization that provides professional membership and training to antepartum doulas, childbirth educators, labour doulas, postpartum doulas, and lactation educators. They are proponents of evidence-informed practice in childbirth education.

Lamaze International also certifies childbirth educators. The core values, which have become an ideal for many childbirth education organizations, include that care for normal pregnancy and birth should be removed from total control of doctors, be based on the use of appropriate technology (as opposed to overuse), and be evidence informed, regionalized, multidisciplinary, holistic, family-centred, and culturally appropriate. Patients should be involved in decision making, and their privacy, dignity, and confidentiality should be respected. They should feel empowered to make the choices that seem right for them. Lamaze has as its foundation six care principles modified from the World Health Organization (WHO) recommendations that are based on good research evidence (see Box 17.1).

Components of Perinatal Education Programs. A variety of approaches to perinatal education that go beyond preparation for birth have evolved as educators attempt to meet the learning and support needs of expectant parents and to capitalize on their openness to learning. For example, prenatal and new-mother weekly exercise classes can offer both physiological and social support for a mixture of expectant and new mothers who may also elect to stay connected by email for support between weekly classes. However, it is important that a focus on preparation for birth not become lost in all the topics that could be offered to expectant parents.

Birth Plans

The **birth plan** is a natural evolution of a contemporary wellness-oriented lifestyle in which patients assume a level of responsibility for their own health. The birth plan is a tool with which parents can explore their childbirth options and use their plan or guide as a communication tool with their care provider to discuss their choices and preferences. Birth plans need to be seen as collaborative, flexible documents in order to be both a positive and useful tool for individuals and those that provide care for them. The purpose of the birth plan is not to focus on a particular outcome or process but rather to have a tool to improve communication between a patient and their partner and with their care providers in order to work together to create a positive and safe birth experience (PHAC, 2020a). Information to include in a birth plan may include the following (PHAC, 2020a):

- Information about where a person wishes to give birth
- Who will be at the birth
- What forms of pain relief a labouring person wishes
- What types of medical interventions and practices they welcome and do not welcome
- What the person would like to have happen immediately after the birth with the baby

It is useful for the nurse in a prenatal practice setting to initiate a discussion of choices and birth planning during the first and second prenatal visits. An early introduction to the idea of a birth plan allows the couple time to think about events or situations that could make their childbearing experience more meaningful and those they would prefer to avoid. The nurse can think of a birth plan as a "living will" or an opportunity to express the patient's or couple's wishes about normal life events such as birthing (Duvall et al., 2017).

Some health care providers provide birth plan templates, and there are numerous interactive programs on the Internet that will assist couples in creating their birth plans. Childbirth educators may provide a list of helpful websites during classes as well as topics to consider. It is important that the childbirth educator thoroughly review all resources given to potential new parents to ensure the information is appropriate and evidence-informed. If patients have an opportunity to communicate their wishes using their plan and have choices based on their expressed wishes, they tend to be more satisfied with their experience (than those not having this opportunity) and have no increased rate of obstetrical complications, such as Caesarean birth (Duvall et al., 2017). However, patients also need to know that it is difficult to "plan" birth and that it is important to try to be flexible with the birth experience when circumstances change.

KEY POINTS

- The prenatal period is a preparatory one—physically, emotionally, and psychologically.
- Psychosocial aspects of care may affect pregnancy, childbirth, and the adjustment of the new family.
- The pregnant individual's readiness to learn is at a high level, making this an excellent time to help them expand their self-management skills.
- Maternal physical and familial adaptations to pregnancy generate needs that the nurse can anticipate and meet.
- Parent–child, sibling–child, and grandparent–child relationships are affected by pregnancy.
- Even with a healthy pregnancy, the nurse must remain alert to hazards such as supine hypotension, warning signs and symptoms, and signs of a family having difficulty coping with the pregnancy.
- Patients need to have appropriate care and screening provided throughout the pregnancy to ensure a healthy outcome.
- Each pregnant patient needs to know how to recognize and report preterm labour.
- Cultural prescriptions and proscriptions influence responses to pregnancy and to the health care delivery system.
- Childbirth education helps patients feel confident that their bodies are able to give birth and provides coping strategies that enhance their ability to give birth.
- Childbirth education is a process designed to help parents make the transition from the role of expectant parents to the role and responsibilities of parents of a new baby.

Maternal Nutrition

Jennifer Buccino
Originating US Chapter by *Ellen F. Olshansky*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explain the importance of good nutrition during the preconception and prenatal periods for the health of the pregnant patient and fetus.
2. Explain recommended weight gain during pregnancy.
3. Compare the recommended levels of intake of energy (calories), protein, and key vitamins and minerals during pregnancy.
4. Give examples of foods that provide the nutrients required for optimal maternal nutrition during pregnancy.
5. Examine the role of nutrition supplements during pregnancy.
6. List nutrition risk factors during pregnancy.
7. Compare the nutrient needs of pregnant adolescents with those of adult pregnant patients.
8. Assess nutrition status during pregnancy.
9. Give strategies to assist with nutrition-related discomforts.

As discussed in previous chapters, the determinants of health are important social and individual factors that influence the health of Canadians (see Box 1.1). Many of the determinants of health have an impact on the quality and amount of food that patients have access to, which can ultimately influence pregnancy outcomes (Figure. 12.1). Nutrition status of pregnant patients is a significant factor because it is potentially alterable and because good nutrition before and during pregnancy can help prevent a variety of health concerns. Inadequate nutrition in the patient can lead to an increase in the number of low-birth-weight (LBW) infants (birth weight of 2500 g or less) and preterm infants that are born. Evidence is growing that a mother's nutrition and lifestyle affect the long-term health of their children. Thus the importance of good nutrition must be emphasized to all patients of childbearing potential. Key components of nutrition care during the preconception period and pregnancy include the following:

- Nutrition assessment that includes appropriate weight for height (body mass index [BMI]), and adequacy and quality of food and eating habits
- Diagnosis of issues or risk factors, such as diabetes, phenylketonuria (PKU), and obesity, that require nutrition intervention
- Intervention based on an individual's dietary requirements and plan to promote appropriate weight gain, ingestion of a variety of healthy foods, appropriate use of dietary supplements, and physical activity
- Evaluation as an integral part of the nursing care provided to patients during the preconception period and pregnancy, with referral to a dietitian as necessary

PRECONCEPTION NUTRITION

A healthy diet before conception is the best way to ensure that adequate nutrients are available for the developing fetus. Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight when pregnancy begins. Ideally, all patients would achieve their desirable body weight before conception (Davies et al., 2018).

Folate or folic acid intake is of particular concern in the preconceptual period. Folate is the form in which this vitamin is found naturally in foods, and folic acid is the form used in the fortification of grain products and other foods and in vitamin supplements. *Neural tube defects* (NTD) (failure in closure of the neural tube) are more common in infants of mothers with poor folic acid intake (Government of Canada, 2018). In Canada, the rate of children born with a neural tube defect has declined, mainly due to folic acid fortification of food, and in 2014 was 5.7 per 10 000 births (Public Health Agency of Canada [PHAC], 2019). Proper closure of the neural tube is required for normal formation of the spinal cord. The neural tube begins to close within the first month of gestation, often before the patient realizes they are pregnant. Thus all individuals capable of becoming pregnant, regardless of whether or not they are considering pregnancy, should be advised during medical wellness visits (birth control renewal, Pap testing, gynecological examination) about the benefits of folic acid in a multivitamin supplement (Wilson & Genetics Committee, 2015). Patients should be advised to maintain a healthy folate-rich diet (Box 12.1). In addition,

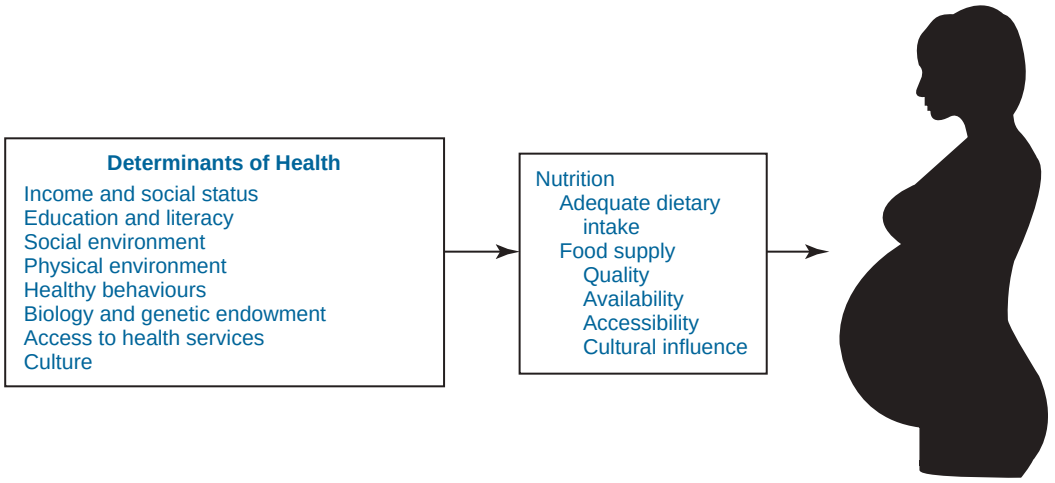

Fig. 12.1 Determinants of health that influence nutritional status.

BOX 12.1 Food Sources of Folate*

Foods Providing 500 mcg or More per Serving
- Liver: chicken, turkey, goose; cooked (75 g)

Foods Providing 200 mcg or More per Serving
- Liver: lamb, veal; cooked (75 g)
- Lentils, cooked (175 mL)
- Beans, cranberry/roman, cooked (175 mL)
- Yeast extract spread (Vegemite or Marmite) (30 mL)
- Edamame (125mL)

Foods Providing 100 mcg or More per Serving
- Liver: beef, pork; cooked (75 g)
- Legumes, cooked (125 mL)
- Peas: black-eyed, chickpea, garbanzo (125 mL)
- Beans: black, kidney, pinto, red, navy, white, great northern (125 mL)
- Vegetables: edamame, okra (cooked), spinach (125 mL)
- Pasta, egg noodles, white, enriched (125 mL)
- Bagel, plain (½, 45 g)
- Sunflower seeds, without shell (60 mL)
- Soy burger/vegetarian patty (75 g)

Foods Providing 50 mcg or More per Serving
- Vegetables (125 mL): artichoke, turnip greens, collards, broccoli, asparagus, Brussels sprouts, beets
- Vegetables (250 mL): lettuce (Romaine, mesclun, escarole, endive), spinach
- Potato, with skin
- Fruits: avocado, papaya (½)
- Orange or orange juice (125 mL)
- Bread, white 1 slice (35 g)

Foods Providing 20 mcg or More per Serving
- Egg (1 large)
- Corn (125 mL)

*Amounts of folate listed in food are in mcg. The amount required daily is 0.4 to 1.0 mg.
Amounts are approximate based on Government of Canada. (2015). *The Canadian nutrient file.* https://www.canada.ca/en/health-canada/services/food-nutrition/healthy-eating/nutrient-data/canadian-nutrient-file-about-us.html.

folic acid/multivitamin supplementation may be needed to achieve the red blood cell (RBC) folate levels associated with maximal protection against NTD (Health Canada, 2019b; Wilson & Genetics Committee, 2015). The amount of folic acid required depends on the risk for NTDs in the patient and their partner (Box 12.2).

NUTRIENT NEEDS DURING PREGNANCY

Nutrient needs are determined, at least in part, by the stage of gestation. The amount of fetal growth varies during the different stages of pregnancy. During the first trimester, the synthesis of fetal tissues places relatively few demands on maternal nutrition. Therefore, during the first trimester, when the embryo or fetus is very small, the needs are only slightly increased over those before pregnancy. In contrast, the last trimester is a period of noticeable fetal growth when most of the fetal stores of energy sources and minerals are deposited. Thus, as fetal growth progresses during the second and third trimesters, the pregnant patient's need for some nutrients increases greatly.

The Institute of Medicine, in partnership with Health Canada, publishes recommendations for **Dietary Reference Intakes (DRIs)** for the people of Canada and the United States that are updated regularly. The DRIs consist of **Recommended Dietary Allowances (RDAs)**, Adequate Intakes (AIs), and Upper Limits (ULs) (i.e., guidelines for avoiding excessive intakes of nutrients that may be toxic if consumed in excess). RDAs are recommendations for daily nutrient intakes that meet the needs of almost all (97 to 98%) healthy members of the population. The DRIs include a wide variety of nutrients and food components; they are divided into age, sex, and life-stage categories (e.g., infancy, pregnancy, and lactation). They can be used as goals in planning the diets of individuals (Table 12.1).

Energy Needs

Energy (**kilocalories**, or kcal) needs are met by carbohydrate, fat, and protein in the diet. No specific recommendations exist for the amount of carbohydrate and fat in the diet of pregnant patients. However, intake of these nutrients should be adequate to support the recommended weight gain. Although protein can be used to supply energy, its primary role is to provide amino acids for the synthesis of new tissues (see discussion later in this chapter). The estimated energy expenditure for the first trimester is the same as in the prepregnant state;

BOX 12.2 Folic Acid Recommendations During Pregnancy

Low Risk

0.4 mg daily for at least 2 to 3 months prior to pregnancy, throughout pregnancy, and during the postpartum period if breastfeeding

Moderate Risk (diabetes, epilepsy, obesity, or first- or second-degree relative with history of NTDs)

1.0 mg daily for the 3 months prior to pregnancy and during the first trimester
Decrease dose to 0.4 mg after first trimester

Increased or High Risk for NTD (partner or self who has had an NTD or a previous pregnancy with NTD)

4 mg/day at least 3 months prior to conception and through the first trimester of pregnancy, after which time can decrease intake to 0.4 to 1.0 mg daily

NTD, Neural tube defect.

SOGC clinical practice guideline: Canadian consensus on female nutrition: Adolescence, reproduction, menopause, and beyond. *Journal of Obstetrics & Gynecology of Canada, 38*(6), 508e554; Wilson, R. D., & Genetics Committee. (2015). Pre-conception folic acid and multivitamin supplementation for the primary and secondary prevention of neural tube defects and other folic acid-sensitive congenital anomalies. *Journal of Obstetrics & Gynaecology Canada, 37*(6), 534–549.

during the second **trimester** the RDA is 340 kcal greater than prepregnancy needs, and during the third trimester it is 452 kcal more than prepregnancy needs (Health Canada, 2014). These recommendations are for a singleton pregnancy and will need to be adjusted for multiple gestation. Longitudinal assessment of weight gain during pregnancy is the best way to determine whether the kilocalorie intake is adequate; very underweight or active individuals may require more than the recommended increase in kilocalories to sustain the desired rate of weight gain (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Nutrition and the Pregnant Patient

Nina, age 22, is a Cree patient who lives on a remote reserve in Northern Saskatchewan. She is 6 weeks pregnant and comes to her initial appointment for diagnosis and care. When her pregnancy is confirmed, you are asked to plan a diet with Nina that meets the minimum daily requirements and allows for growth of the fetus. You know that it is important to include consideration of personal preferences and cultural factors in your plan. Nina is lactose intolerant and has a BMI of 22. Develop a plan with Nina that can assist her to achieve her nutrition needs.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about an appropriate nutrition plan, taking into consideration finances, food security, availability of food sources, healthy eating, and cultural factors?
2. Assumptions—What assumptions can be made about the following factors?
   a. Dietary Reference Intakes for pregnancy
   b. Possible barriers to adequate nutrition
   c. Daily food recommendations for pregnancy
   d. Sources of calcium for patients who are lactose intolerant
3. What implications and priorities for nursing care can be drawn at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Nina.

TABLE 12.1 Recommendations for Daily Intakes of Selected Nutrients During Pregnancy and Lactation

Nutrient (Units)	Recommendation for Nonpregnant Woman	Recommendation for Pregnancy*	Recommendation for Lactation*	Role in Relation to Pregnancy and Lactation	Food Sources
Energy (kilocalories [kcal])	Variable	First trimester, same as nonpregnant; second trimester, nonpregnant needs + 340 kcal; third trimester, nonpregnant needs + 452 kcal	First 6 months, nonpregnant needs + 330 kcal; second 6 months, nonpregnant needs + 400 kcal	Growth of fetal and maternal tissues; milk production	Carbohydrate, fat, and protein
Protein (g)	46	First trimester, second and third trimesters, nonpregnant needs + 25 g‡	Nonpregnant needs + 25 g	Synthesis of the products of conception; growth of maternal tissue and expansion of blood volume; secretion of milk protein during lactation	Meats, eggs, cheese, yogurt, legumes (dry beans and peas, peanuts), nuts, grains
Water (L)	2.7 total	3 total	3.8 total	Expansion of blood volume, excretion of wastes; milk secretion	Water and beverages made with water, milk, juices; all foods, especially frozen desserts, fruits, lettuce, and other fresh vegetables
Fibre (g)	25	28	29	Promotes regular bowel elimination; reduces long-term risk of heart disease, diverticulosis, and diabetes	Whole grains, bran, vegetables, fruits, nuts and seeds

Continued

TABLE 12.1 Recommendations for Daily Intakes of Selected Nutrients During Pregnancy and Lactation—cont'd

Nutrient (Units)	Recommendation for Nonpregnant Woman	Recommendation for Pregnancy	Recommendation for Lactation	Role in Relation to Pregnancy and Lactation	Food Sources
Minerals					
Calcium (mg)	1 300/1 000	1 300/1 000	1 300/1 000	Fetal skeleton and tooth formation; maintenance of maternal bone and tooth mineralization	Milk, cheese, yogurt, sardines, or other fish eaten with bones left in; deep green leafy vegetables except spinach or Swiss chard; calcium-set tofu, baked beans, tortillas
Iodine (mcg)	150	220	290	Increased maternal metabolic rate	Iodized salt, seafood, milk and milk products, commercial yeast breads, rolls, and doughnuts
Iron (mg)	15/18	27	10/9	Maternal hemoglobin formation; fetal liver iron storage	Liver§, meats, whole-grain or enriched breads and cereals, deep green leafy vegetables, legumes, dried fruits
Magnesium (mg)	360/310–320	400/350–360	360/310–320	Involved in energy and protein metabolism, tissue growth, muscle action	Nuts, legumes, cocoa, meats, whole grains
Zinc (mg)	9/8	12/11	13/12	Component of numerous enzyme systems; possibly important in preventing congenital malformations	Liver§, shellfish, meats, whole grains, milk
Fat-Soluble Vitamins					
A (mcg)	700	750/770	1 200/1 300	Essential for cell development, tooth bud formation, bone growth	Deep green leafy vegetables, dark yellow vegetables, fruits, chili peppers, liver§, fortified margarine and butter
D (mcg)	15 (600 IU)	15 (600 IU)	15 (600 IU)	Involved in absorption of calcium and phosphorus; improves mineralization	Fortified milk and margarine, egg yolk, butter, liver§, seafood
E (mg)	15	15	19	Antioxidant (protects cell membranes from damage), especially important for preventing breakdown of RBCs	Vegetable oils, green leafy vegetables, whole grains, liver§, nuts and seeds, cheese, fish
K (mcg)	75/90	75 (14- to 18-year-old) 90 (19- to 50-year-old)	75 (14- to 18-year-old) 90 (19- to 50-year-old)	Involved in synthesis of protein, blood coagulation, and bone metabolism	Green leafy vegetables, plant oils, margarine, soybeans, lentils
Water-Soluble Vitamins					
B_6 or pyridoxine (mg)	1.2/1.3	1.9	2	Involved in protein metabolism	Meats, liver§, deep green vegetables, whole grains
B_{12} (mcg)	2.4	2.6	2.8	Production of nucleic acids and proteins; especially important in formation of RBCs and neural functioning	Milk and milk products, eggs, meats, liver§, fortified soy milk

TABLE 12.1 Recommendations for Daily Intakes of Selected Nutrients During Pregnancy and Lactation—cont'd

Nutrient (Units)	Recommendation for Nonpregnant Woman	Recommendation for Pregnancy	Recommendation for Lactation	Role in Relation to Pregnancy and Lactation	Food Sources
C (mg)	65/75	80/85	115/120	Tissue formation and integrity, formation of connective tissue; enhancement of iron absorption	Citrus fruits, strawberries, melons, broccoli, tomatoes, peppers, raw deep green leafy vegetable
Folate (mcg)	400	600	500	Prevention of neural tube defects, support for increased maternal RBC formation	Fortified ready-to-eat cereals and other grain products, green leafy vegetables, oranges, broccoli, asparagus, artichokes, liver§

RBC, Red blood cell.
*When two values appear, separated by a diagonal slash, the first is for females younger than 19 years, and the second is for those 19 to 50 years of age.
‡Add an additional 25 g in twin pregnancies.
§Pregnant patients should not eat liver because of a high concentration of vitamin A.
Source: Health Canada. (2010). *Dietary reference intakes tables.* http://www.hc-sc.gc.ca/fn-an/alt_formats/hpfb-dgpsa/pdf/nutrition/dri_tables-eng.pdf.

Protein

Protein, with its essential element nitrogen, is the nutrient that is basic to growth. Adequate protein intake is essential to meet increasing physiological demands in pregnancy. These demands arise from:

- The rapid growth of the fetus
- The enlargement of the uterus and its supporting structures, the mammary glands, and the placenta
- The increase in maternal circulating blood volume and subsequent demand for increased amounts of plasma protein to maintain colloidal osmotic pressure
- The formation of amniotic fluid

Animal sources of protein (e.g., milk, meat, eggs, and cheese) are considered complete-protein foods with a high biological value. Complete-protein foods contain all the essential amino acids. Legumes (dried beans and peas), whole grains, and nuts are also valuable sources of protein. These sources are incomplete proteins; however, when consumed in a healthy diet and with other protein sources, all essential amino acids are provided. In addition, protein-rich foods can be sources of other nutrients such as calcium, iron, and B vitamins and of dietary fibre. *Canada's Food Guide* recommends eating a variety of foods each day that includes protein foods. Plant and animal sources can provide adequate protein in the diet (see Appendix A). Pregnant adolescents and adults adhering to vegan or highly restrictive vegetarian diets (e.g., macrobiotic diet) may need extra teaching to ensure that protein intake is adequate. Animal sources of protein (e.g., meat, eggs, fish) can be more expensive, so patients with lower income may need assistance in finding appropriate food sources. High-protein supplements are not recommended because of the potentially harmful effects on the fetus.

Fluids

Water is the main substance of cells, blood, lymph, amniotic fluid, and other vital body fluids. It is essential during the exchange of nutrients and waste products across cell membranes. It also aids in maintaining body temperature. A good fluid intake promotes regular bowel function; without it, constipation can become a concern, especially during pregnancy. The recommended daily intake of fluid is 2.2 litres (9 cups). Water, milk, decaffeinated tea, and juices are good sources, although pregnant patients should limit their intake of fruit juice, as it can be high in calories and therefore lead to extra weight gain. Foods in the diet should supply an additional 700 mL or more of fluid. Dehydration may increase the risk of cramping, contractions, hyperemesis gravidarum, and preterm labour.

Energy drinks claim to give people extra physical and mental energy. They are highly caffeinated beverages that also contain sugar, artificial sweeteners, amino acids, vitamins, and herbs and thus should be avoided during pregnancy (HealthLinkBC, 2020).

SAFETY ALERT

Energy drinks are not recommended for children or for pregnant or breastfeeding patients. Energy drinks contain high levels of caffeine and added vitamins, minerals, amino acids, and herbs. Some of the caffeine in energy drinks may come from herbs, such as guarana and yerba maté. The label on these energy drinks will list the herbs as ingredients, but the caffeine in the herbs may not be listed as a separate ingredient. Therefore, it is possible to unintentionally consume more caffeine than is listed on the label (HealthLinkBC, 2020).

Omega-3 Fatty Acids

Omega-3 fatty acids are important for overall health, providing benefits such as lowering the risk of heart disease. They are transferred across the placenta and play an important role in the growth and development of the fetus. The long-chain polyunsaturated fatty acids (LC-PUFAs) docosahexaenoic acid (DHA) and arachidonic acid (AA) are considered essential to fetal brain development and neurological function. Supplementation of omega-3 (n-3) LC-PUFA during pregnancy has been associated with reduced risk for preterm birth and improved neurological and visual development in the offspring. These fatty acids are primarily found in fish, shellfish, fish oil supplements, and omega-3-enriched eggs. Pregnant patients should be advised to consume 150 g (or 5 ounces) of cooked fish each week to meet the requirement for omega-3 fatty acid (Health Canada, 2009).

Pregnant and nursing patients should be especially careful when choosing fish to select those that are low in mercury. Larger fish that eat smaller fish are usually higher in mercury content.

! NURSING ALERT

High levels of mercury can harm the developing nervous system of the fetus or young child. Certain fish are especially high in mercury content. Patients who may become pregnant, patients who are pregnant or nursing, and young children need to follow some precautions: Limit consumption of fresh or frozen tuna, shark, swordfish, escolar, marlin, and orange roughy to 150 g/month, and eat as much as 75 g/week of a variety of commercially caught fish and shellfish low in mercury such as shrimp, salmon, pollock, catfish, and canned light tuna (but limit intake of albacore or "white" tuna and tuna steaks, which contain more mercury, to 300 g/week) (Health Canada, 2019a).

Minerals, Vitamins, and Electrolytes

In general, the nutrient needs of pregnant patients, except perhaps the need for folate and iron, can be met through dietary sources. Counselling about the importance of a varied diet rich in vitamins and minerals should be a part of every pregnant patient's early prenatal care and should be reinforced throughout pregnancy.

Supplements of certain nutrients are recommended when the pregnant patient's diet is nutritionally poor or when significant nutritional risk factors are present (Box 12.3). It is important that the patient understand that the use of a vitamin-mineral supplement does not lessen the need to consume a nutritious, well-balanced diet.

Iron. Iron is needed both to allow the transfer of adequate iron to the fetus and to permit expansion of the maternal RBC mass. Iron-deficiency anemia is relatively common among patients in the childbearing years. Anemic patients may be unable to tolerate a hemorrhage if it occurs at the time of birth. In addition, patients who have iron-deficiency anemia during early pregnancy are at increased risk for preterm birth and LBW infants. Iron deficiency during the third trimester apparently does not carry the same risk. In Canada, anemia is a common condition in approximately 25% of childbearing-aged patients. It may be caused by low intake of iron, poor absorption of iron, or blood loss. Iron-deficiency anemia is more prevalent in isolated Indigenous communities and in teenage girls of South Asian descent (British Columbia Ministry of Health, 2019).

The RDA of iron during pregnancy is 27 mg/day. Health Canada recommends that all pregnant patients take a daily multivitamin with 16 to 20 mg of iron (Health Canada, 2009). Pregnant patients who eat a plant-based diet may need an increased amount of iron. This dose is well below the level of iron supplementation that has been linked to adverse effects (reduced zinc absorption and gastrointestinal symptoms) (Health Canada, 2009). Iron supplements may be poorly tolerated if a patient has significant nausea in the first trimester and may need to be started after week 12. Iron supplementation of patients with iron deficiency can improve maternal hematological indices and appears to reduce the rate of LBW births. If maternal iron-deficiency anemia is present (preferably diagnosed by measurement of serum ferritin, a storage form of iron), increased dosages (60 to 120 mg daily) are recommended. Certain foods taken with an iron supplement can promote or inhibit absorption of iron from the supplement (e.g., tea or coffee close to meals can inhibit absorption). See the Patient Teaching box: Iron Supplementation regarding intake of iron and supplementation. Even when a patient is taking an iron supplement, they should include good food sources of iron in their daily diet (see Table 12.1).

BOX 12.3 Indicators of Nutritional Risk in Pregnancy

- Adolescence or less than 2 years postmenarche
- Frequent pregnancies: three within 2 years
- Poor fetal outcome in a previous pregnancy
- Poverty or food insecurity
- Poor eating habits with resistance to change
- Use of tobacco, alcohol, or drugs
- Weight at conception significantly under or over normal weight
- Any weight loss
- Weight gain of less than 1 kg/month after the first trimester
- Weight gain of more than 1 kg/week after the first trimester
- Multifetal pregnancy
- Low hemoglobin or hematocrit values (or both)
- Diabetes
- Chronic illness, including an eating disorder that affects intake, absorption, or metabolism of nutrients

PATIENT TEACHING

Iron Supplementation

- Vitamin C (in citrus fruits, tomatoes, peppers, melons, and strawberries) increases the absorption of iron; therefore, eat these foods with iron food sources.
- Heme iron (found in meats) is better absorbed than non-heme sources of iron (vegetable sources)
- Bran, tea, coffee, milk, oxalates (in spinach and Swiss chard), and egg yolk decrease iron absorption. Avoid consuming them at the same time as an iron source.
- Iron supplements are absorbed best if taken when the stomach is empty (i.e., take it between meals with a beverage other than tea, coffee, or milk).
- Iron supplements can be taken at bedtime if abdominal discomfort occurs when it is taken between meals.
- If an iron dose is missed, take it as soon as it is remembered if that is within 13 hours of the scheduled dose. Do not double up on the dose.
- Keep iron supplements in a childproof container and out of reach of children in the household.
- Iron may cause stools to be black or dark green.
- Constipation is common with iron supplementation. A diet high in fibre with adequate fluid intake is recommended.

Calcium. There is no increase in the DRI of calcium during pregnancy and lactation over that recommended for the nonpregnant patient (see Table 12.1). The DRI (1 000 mg daily for patients 19 years and older and 1 300 mg for those younger than 19 years) appears to provide sufficient calcium for fetal bone and tooth development to proceed while maintaining maternal bone mass.t

Milk and yogurt are rich sources of calcium, providing approximately 300 mg per 240 mL serving. Nevertheless, many patients either do not consume these foods or do not consume adequate amounts to provide the recommended intake of calcium. One condition that can interfere with milk consumption is **lactose intolerance**, the inability to digest milk sugar (lactose) caused by the lack of the lactase enzyme in the small intestine. Lactose intolerance is more common among people of African, Asian, and Latin American descent and Indigenous people. Milk consumption can cause abdominal cramping, bloating, and diarrhea in individuals with lactose intolerance, although many of these individuals can tolerate small amounts of milk without symptoms. Yogurt, sweet acidophilus milk, buttermilk, cheese, chocolate milk, and cocoa may be tolerated even when liquid milk is not. Commercial lactase supplements (e.g., Lactaid) are widely available to consume with milk. Many grocery stores stock lactase-treated milk. The lactase in

BOX 12.4 Sources of Calcium

Each of the following provides approximately the same amount of calcium as 240 mL (1 cup) of milk:

Fish
90 g (3-oz) can of sardines
150 g (4 ½–oz) can of salmon (if bones are eaten)

Beans and Legumes
750 mL (3 cups) of cooked dried beans
625 mL (2 ½ cups) of refried beans
500 mL (2 cups) of baked beans with molasses
240 mL (1 cup) of tofu (calcium is added in processing)

Greens
240 mL (1 cup) of collards
365 mL (1 ½ cups) of kale or turnip greens

Baked Products
3 pieces of cornbread
3 English muffins
4 slices of French toast
2 waffles (15 cm in diameter)

Fruits
11 dried figs
270 mL (1 ⅛ cups) of orange juice with calcium added

Sauces
90 mL (3 oz) of pesto sauce
150 g (5 oz) of cheese sauce

these products hydrolyzes, or digests, the lactose in milk, making it possible for people with lactose intolerance to drink milk.

In some cultures it is uncommon for adults to drink milk. Pregnant patients from these cultures may need to consume nondairy sources of calcium (Box 12.4). Vegetarian diets may also be deficient in calcium. If calcium intake appears low, a daily supplement containing 600 mg of elemental calcium may be needed.

SAFETY ALERT

Bone meal, which is sometimes used as a calcium source by pregnant patients, is frequently contaminated with lead. Lead freely crosses the placenta; thus regular maternal intake of bone meal may result in high levels of lead in the fetus.

Vitamin D. Vitamin D plays an important role in the absorption and metabolism of calcium. Food sources of vitamin D include enriched or fortified foods such as cow's milk and soy beverage, fortified juices, yogurts, fatty fish (e.g., salmon), and egg yolks. Vitamin D is also produced in the skin by the action of ultraviolet light (in sunlight). Severe deficiency may lead to newborn hypocalcemia and tetany, as well as to hypoplasia of the tooth enamel. Patients with lactose intolerance and those who do not include milk in their diet are at risk for vitamin D deficiency. Other risk factors for low vitamin D status include being overweight or obese, living at northern (north of 37°N) latitudes during the winter, having darker pigmented skin, wearing clothing that covers the body and thus prevents exposure to sunlight, or having limited exposure to direct sunlight.

Use of recommended amounts of sunscreen with a sun protection factor (SPF) rating of 15 or greater reduces skin vitamin D production by as much as 99%, thus regular intake of fortified foods or a supplement may be needed. All pregnant patients should be ensure that their multivitamin contains 400 IU of vitamin D. Some Canadians living at a higher latitude may require more vitamin D, but this would be determined on an individual basis with the obstetrical health care provider.

Magnesium. Magnesium is necessary for bone and tissue growth. Diets of patients in the childbearing years are likely to be low in magnesium, and as many as half of pregnant and lactating patients may have inadequate intake. Adolescents and low-income patients are especially at risk. Dairy products, nuts, whole grains, and green leafy vegetables are good sources of magnesium.

Sodium. During pregnancy the need for sodium increases slightly, primarily because the body water is expanding (e.g., the expanding blood volume). Sodium is essential for maintaining body water balance. In the past, dietary sodium was routinely restricted in an effort to control the peripheral edema that commonly occurs during pregnancy. It is now recognized that moderate peripheral edema is normal in pregnancy, occurring as a response to the fluid-retaining effects of elevated levels of estrogen. Sodium is not routinely restricted in pregnancy, and restriction has not proved effective in reducing the rates of preeclampsia. Severe sodium restriction may make it difficult for pregnant patients to achieve an adequate diet. In addition, sodium restriction may stress the adrenal glands and the kidneys as they attempt to retain adequate sodium. In general, sodium restriction is necessary only if the patient has a medical condition such as renal or liver failure or hypertension that warrants such a restriction.

Excessive intake of sodium is discouraged during pregnancy, because it may contribute to the development of hypertension in salt-sensitive individuals. An adequate sodium intake for pregnant and lactating patients, as well as nonpregnant patients in the childbearing years, is estimated to be 1.5 g/day, with a recommended upper limit of intake of 2.3 g/day. Table salt (sodium chloride) is the richest source of sodium, with approximately 2.3 g of sodium contained in 5 g (1 tsp) of salt. Most canned foods contain added salt unless the label states otherwise. Large amounts of sodium are also found in many processed foods, including meats (e.g., smoked or cured meats, cold cuts, and corned beef), frozen entrées and meals, baked goods, mixes for casseroles or grain products, soups, and condiments. Products low in nutrient value and excessively high in sodium include pretzels, potato and other chips (except salt-free), pickles, ketchup, prepared mustard, steak and Worcestershire sauces, some soft drinks, and bouillon. A moderate sodium intake can usually be achieved by salting food lightly during cooking; adding no additional salt at the table; and avoiding low-nutrient, high-sodium foods.

Potassium. Diets with adequate intake of potassium are associated with a reduced risk of hypertension. Eating fresh fruits and vegetables daily along with moderate amounts of low-fat meats and dairy products has been effective in providing adequate amounts of potassium and reducing sodium intake while.

Zinc. Zinc is a constituent of numerous enzymes involved in major metabolic pathways. Zinc deficiency is associated with malformations of the central nervous system in infants. When large amounts of iron and folic acid are consumed, the absorption of zinc is inhibited, and serum zinc levels are reduced as a result. Because iron and folic acid supplements are commonly prescribed during pregnancy, pregnant

patients should be encouraged to consume recommended sources of zinc daily (see Table 12.1). Patients with anemia who receive high-dose iron supplements also need supplements of zinc and copper.

Fluoride. There is no evidence that prenatal fluoride supplementation reduces the child's likelihood of tooth decay during the preschool years. No increase in fluoride intake over the nonpregnant RDAs is currently recommended during pregnancy.

Fat-Soluble Vitamins. Fat-soluble vitamins—A, D, E, and K—are stored in the body tissues. These are of special concern during pregnancy because vitamin E intake is among the nutrients most likely to be lacking in the diets of patients of childbearing age, and intake of vitamins A and D is also low in the diets of some patients. With chronic overdoses these vitamins can reach toxic levels. Because of the high potential for toxicity, pregnant patients are advised to take fat-soluble vitamin supplements only as prescribed. Vitamin D is discussed above with calcium.

Adequate intake of vitamin A is needed so that sufficient amounts of the vitamin can be stored in the fetus. A healthy diet including adequate amounts of deep yellow and dark green vegetables and fruits such as leafy greens, broccoli, carrots, cantaloupe, and apricots provides sufficient amounts of carotenes that can be converted in the body to vitamin A. Congenital malformations have occurred in infants of mothers who took excessive amounts of preformed vitamin A (from supplements) during pregnancy; thus supplements are not recommended for pregnant patients. Liver contains large amounts of vitamin A and is not recommended during pregnancy.

! NURSING ALERT

Vitamin A analogues such as isotretinoin (Accutane), which are prescribed for the treatment of cystic acne, are of special concern. Isotretinoin use during early pregnancy has been associated with an increased incidence of heart malformations, facial abnormalities, cleft palate, hydrocephalus, and deafness and blindness in the infant, as well as an increased risk of miscarriage. Topical agents such as tretinoin (Retin-A, Avita) do not appear to enter the circulation in any substantial amounts, but their safety in pregnancy has not been confirmed.

Vitamin E is an antioxidant and therefore needed for protection against oxidative stress, and pregnancy is associated with increased oxidative stress. Oxidative stress above that usually associated with pregnancy has been proposed as an etiology of pre-eclampsia, although supplementation with vitamin E has not been effective in reducing rates of pre-eclampsia. Vegetable oils and nuts are especially good sources of vitamin E, and whole grains and green leafy vegetables are moderately good sources.

Vitamin K is involved in the synthesis of proteins needed for blood coagulation and bone metabolism. The RDA for women is 90 mcg/day. The classic sign of vitamin K deficiency is an increase in prothrombin time; severe cases result in hemorrhage. Food sources are green leafy vegetables, plant oils and margarine, and soybeans and lentils.

Water-Soluble Vitamins. Water soluble vitamins include ascorbic acid (vitamin C), thiamin (B_1), riboflavin (B_2), niacin (B_3), vitamin B_6 (pyridoxine, pyridoxal, and pyridoxamine), vitamin B_{12}, biotin, pantothenic acid, and folic acid/folate (see discussion above: Preconception Nutrition). Body stores of water-soluble vitamins are much smaller than those of fat-soluble vitamins. In contrast to fat-soluble vitamins, water-soluble vitamins are readily excreted in the urine. Therefore, recommended sources of these vitamins must be consumed regularly. Toxicity with overdose is less likely than with fat-soluble vitamins.

Vitamin B_6 (pyridoxine). Pyridoxine, or vitamin B_6, is essential for carbohydrate, protein, and fat metabolism and is involved in the synthesis of RBCs, antibodies, and neurotransmitters. Although the recommended intake during pregnancy is 1.9 mg/day, there is evidence that larger doses are effective for some pregnant patients in reducing nausea and vomiting (West et al., 2017).

Vitamin C (ascorbic acid). Vitamin C, or ascorbic acid, plays an important role in tissue formation and enhances the absorption of iron. The vitamin C needs of most pregnant patients are readily met by a diet that includes at least one daily serving of citrus fruit or juice or another good source of the vitamin (see Table 12.1), but individuals who smoke need an extra 35 mg/day above their age and sex recommendations.

Vitamin B_{12} (cobalamin). Vitamin B_{12} is involved in the production of nucleic acids and proteins; it is especially important in the formation of RBCs and neural functioning. It is found in milk and milk products, eggs, meats, liver, and fortified soy milk. Vitamin B_{12} is only found in animal food sources; therefore, patients following a fully plant-based diet will need to ensure that their multivitamin supplement contains B_{12}. Vitamin B_{12} deficiency can result in megaloblastic anemia, glossitis (inflamed red tongue), and neurological deficits in the mother. Infants born to affected mothers are likely to have megaloblastic anemia and exhibit neurodevelopmental delays.

Weight Gain

The recommended weight gain during pregnancy varies among patients. The primary factor to consider in making a weight-gain recommendation is the prepregnancy weight for the patient's height—that is, whether the patient's weight was normal before pregnancy or whether they were underweight or overweight (Table 12.2). Whenever possible, the patient should achieve a weight in the normal range for

TABLE 12.2 Recommended Rate of Weight Gain in Pregnancy

	MEAN* RATE OF WEIGHT GAIN IN SECOND AND THIRD TRIMESTER		RECOMMENDED RANGE OF TOTAL WEIGHT GAIN	
Prepregnancy BMI Category	kg/ week	lb/ week	kg	lb
BMI <18.5 Underweight	0.5	1.0	12.5–18	28–40
BMI 18.5–24.9 Normal weight	0.4	1.0	11.5–16	25–35
BMI 25.0–29.9 Overweight	0.3	0.6	7–11.5	15–25
BMI ≥30† Obese	0.2	0.5	5–9	11–20

BMI, body mass index.
*Rounded values.
†A narrower range of weight gain may be advised for patients with a prepregnancy BMI of 35 or greater. Individualized advice is recommended for these patients.
Source: © All rights reserved. *Prenatal nutrition guidelines for health professionals: Gestational weight gain.* Health Canada, 2014. Adapted and reproduced with permission from the Minister of Health, 2016. http://www.hc-sc.gc.ca/fn-an/nutrition/prenatal/ewba-mbsa-eng.php.

their height before pregnancy. Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight before pregnancy and when weight gain during pregnancy is either too low or too high. Underweight patients (BMI <18.5) are more likely to have preterm birth, small-for-gestational-age (SGA) babies, and an increased risk of spontaneous miscarriage (O'Connor et al., 2016). Women with a low prepregnancy BMI may reduce these risks by gaining the recommended amount of gestational weight described in Table 12.2. Both normal-weight and underweight patients with inadequate weight gain have an increased risk for giving birth to an infant with **intrauterine growth restriction (IUGR)**. Greater-than-expected weight gain during pregnancy may occur for many reasons, including multiple gestation, edema, gestational hypertension, and overeating. When obesity is present (either pre-existing obesity or obesity that develops during pregnancy), there is an increased likelihood of macrosomia and fetopelvic disproportion; operative vaginal birth; emergency Caesarean birth; postpartum hemorrhage; wound, genital tract, or urinary tract infection; birth trauma; and late fetal death. Patients with obesity are more likely to have pre-eclampsia and gestational diabetes. See Chapter 15 for a more complete discussion of complications of obesity and pregnancy.

A commonly used method of evaluating the appropriateness of weight for height is the body mass index (BMI). The BMI is calculated with the following formula:

$$\text{BMI} = \text{Weight} \div \text{Height}^2$$

where the weight is in kilograms and height is in metres. Thus, for a patient who weighed 51 kg before pregnancy and is 1.57 m tall:

$$\text{BMI} = 51\ \text{kg} \div (1.57\ \text{m})^2 = 20.7$$

Prepregnant BMI can be classified into the following categories:

- less than 18.5, underweight or low;
- 18.5 to 24.9, normal;
- 25 to 29.9, overweight or high; and
- greater than 30, obese.

At the first health care visit, the pregnant patient should be helped to establish a weight-gain goal for pregnancy that is suited to their prepregnancy weight. Progress toward this goal should be monitored regularly. The pregnancy weight gain calculator from Health Canada is a good resource for pregnancy patients (see Additional Resources at end of the chapter). It is not always realistic to achieve a body weight within the BMI range, and BMI is only one indicator of health. A complete assessment by a dietitian would be valuable to assess risk and lifestyle factors.

Pattern of Weight Gain. Weight gain should take place throughout pregnancy. The optimal rate of weight gain depends on the stage of pregnancy. During the first and second trimesters, growth takes place primarily in maternal tissues; during the third trimester, growth occurs primarily in fetal tissues. During the first trimester of a singleton pregnancy, the average total weight gain is only 1 to 2 kg. Thereafter the recommended weight gain depends on the pregnant patient's BMI (see Table 12.2).

The recommended energy (kcal) intake corresponds to the recommended pattern of weight gain. During the second and third trimesters, pregnant patients require slightly more calories each day to support the growth of the fetus, and this can be achieved by eating an extra snack or small meal (PHAC, 2021). *Canada's Food Guide* is the foundation of healthy eating (based on the DRIs) that offers meal planning tips and recipes for Canadians to help them achieve positive health outcomes (see Appendix A).

In multiple gestations, weight gain during the first half of pregnancy is important; overall weight gain should be 17 to 25 kg (Health Canada, 2014). Patients who are pregnant with multiples should be referred to a dietitian for nutrition counselling to assist with appropriate food intake and weight gain.

The reasons for an inadequate weight gain (less than 1 kg per month for normal-weight patients or less than 0.5 kg per month for patients with obesity during the last two trimesters) or excessive weight gain (more than 3 kg per month) should be evaluated thoroughly. Possible reasons for deviations from the expected rate of weight gain, besides inadequate or excessive dietary intake, include measurement or recording errors, differences in weight of clothing, time of day, and accumulation of fluids. An exceptionally high gain is likely to be caused by an accumulation of fluids; a gain of more than 3 kg in a month, especially after the twentieth week of gestation, may indicate the development of pre-eclampsia.

Hazards of Restricting Adequate Weight Gain. An obsession with thinness and dieting pervades the North American culture. Figure-conscious patients may find it difficult to make the transition from guarding against weight gain before pregnancy to valuing weight gain during pregnancy. In counselling these patients, the nurse can emphasize both the positive effects of good nutrition and the adverse effects of malnutrition (manifested by poor weight gain) on infant growth and development. This counselling should include information on the components of weight gain during pregnancy (Figure 12.2) and the amount of this weight that will be lost at birth. Because lactation can

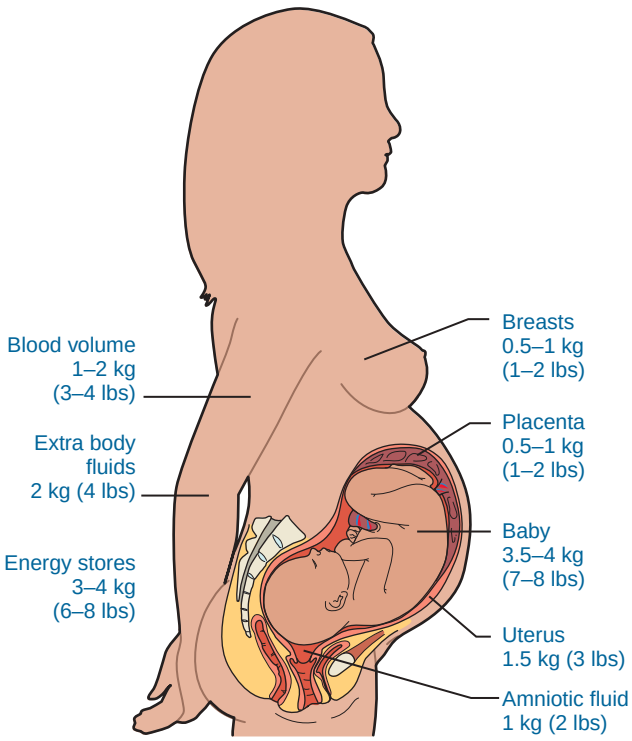

Fig. 12.2 Distribution of weight gain in pregnancy. The numbers represent an average for a person with a normal BMI; variation among patients is considerable. The component with the greatest fluctuation is the weight increase attributed to extravascular fluids (edema) and maternal reserves of fat. (Adapted from Health Canada. [2018]. *Prenatal nutrition guidelines for professionals: Pregnancy weight gain calculator.* http://www.hc-sc.gc.ca/fn-an/nutrition/prenatal/bmi/index-eng.php).

help reduce maternal energy stores gradually, this could be an incentive for patients to breastfeed their infants and thus be an opportunity for the nurse to promote breastfeeding.

Obesity and Pregnancy. Patients with obesity have an increased risk of pregnancy and labour complications; these are discussed in Chapter 15. However, pregnancy is not a time for weight reduction. Even pregnant patients with overweight or obesity need to gain at least enough weight to equal the weight of the products of conception (fetus, placenta, and amniotic fluid). Limiting energy intake to prevent weight gain may also excessively limit intake of important nutrients. Moreover, dietary restriction results in catabolism of fat stores, which in turn augments the production of ketones. While the long-term effects of mild ketonemia during pregnancy are not known, ketonuria has been found to be associated with preterm labour. It should be stressed to all pregnant patients that the quality of the food is important, with emphasis placed on the consumption of nutrient-dense foods and the avoidance of empty-calorie foods.

Excessive Weight Gain. Weight gain is important, but excessive weight gain can be detrimental. The pregnant patient should place an emphasis on the quality of their food intake as they consider their needs and those of the fetus. Excessive weight gained during pregnancy may be difficult to lose after pregnancy, contributing to chronic overweight or obesity, an etiological factor in a host of chronic diseases, including hypertension, diabetes mellitus, and arteriosclerotic heart disease. The patient who gains 18 kg or more during pregnancy is especially at risk. When counselling the patient, it is best not to focus unduly on weight gain because this could result in feelings of stress and guilt in the patient who does not follow the preferred pattern of gain.

Nutritional Concerns During Pregnancy

Caffeine Consumption. Caffeine in moderate amounts has not been proven to cause adverse effects during pregnancy. However, patients who consume more than 300 mg of caffeine daily (equivalent to a little more than 2 cups of coffee) may be at increased risk of miscarriage and giving birth to infants with IUGR. The ill effects of caffeine are thought to result from vasoconstriction of the blood vessels supplying the uterus or from interference with cell division in the developing fetus. Consequently, caffeine-containing products such as caffeinated coffee, tea, soft drinks, and cocoa beverages should be consumed only in limited quantities (maximum 300 mg daily) (Government of Canada, 2020). Energy drinks are high in caffeine and should not be consumed by pregnant patients. See Box 12.5 regarding the safety of herbal teas.

Artificial Sweeteners. Artificial sweeteners commonly used in low- or no-calorie beverages and low-calorie food products have not been found to have adverse effects on the normal mother or fetus and thus are approved by Health Canada for use during pregnancy.

BOX 12.5 Herbal Teas During Pregnancy

Safe (if taken in moderation, two to three cups per day): citrus peel, ginger, lemon balm, orange peel, rose hip, linden flower, and peppermint

Teas to avoid: chamomile, aloe, coltsfoot, juniper berries, pennyroyal, buckthorn bark, comfrey, Labrador tea, sassafras, duck roots, lobelia, and senna leaves

Source: Public Health Agency of Canada. (2020). *Caffeine and pregnancy.* https://www.canada.ca/en/public-health/services/pregnancy/caffeine.html.

Fig. 12.3 Nonfood substances consumed in pica: red clay, Nzu from Eastern Nigeria, baking powder, corn starch, baking soda, laundry starch, and ice. Some individuals practise poly-pica (consuming more than one of these substances). (Courtesy Shannon Perry.)

These include Aspartame (NutraSweet, Equal), acesulfame potassium (Ace K), sucralose (Splenda), and stevioside (Stevia). It is recommended that pregnant patients use artificial sweeteners in moderate amounts only. Aspartame, which contains phenylalanine, should be avoided by pregnant patients with PKU (Health Canada, 2008).

Pica and Food Cravings. Pica is an eating disorder characterized by the consumption of nonfood substances (e.g., clay, dirt, chalk, soap, and laundry starch) or excessive amounts of foodstuffs low in nutritional value (e.g., cornstarch, ice or freezer frost, baking powder, and baking soda). Pica has been associated with mineral deficiencies (e.g., iron deficiency) (Figure 12.3). Regular and heavy consumption of low-nutrient products may cause more nutritious foods to be displaced from the diet, and the items consumed may interfere with the absorption of nutrients, especially minerals.

Moreover, there is a risk that nonfood items are contaminated with heavy metals or other toxic substances. Lead contamination of soils and soil-based products has caused high levels of lead in both pregnant patients and their newborns. The possibility of pica must be considered when pregnant patients are found to be anemic, and the nurse should provide counselling about the health risks associated with pica. The existence of pica and details of the types and amounts of products ingested are likely to be discovered only by the sensitive interviewer who has developed a relationship of trust with the patient.

Many patients experience food cravings during pregnancy. In general, consuming foods to satisfy the cravings is not harmful. However, there is some concern that it can lead to dietary imbalances, especially if the cravings involve pica. The nurse can suggest choosing healthy alternatives for cravings, eating small amounts of the craved foods (buying single servings), eating regularly and including healthy snacks to avoid drops in blood glucose levels, and using distraction to curb the craving (taking a walk or making a call to a friend).

Adolescent Pregnancy Needs. Pregnant adolescents and their infants are at increased risk of complications during pregnancy and postpartum. Dietary survey findings indicate that adolescent girls have inadequate intakes of vitamins (folate, vitamin A, D, B_6), minerals (calcium, magnesium, iron, zinc), and fibre, as well as excessive intakes of total fat, saturated fat, sodium, and cholesterol (Health Canada, 2012).

Failure to consume an adequate diet during the adolescent period can result in delayed sexual maturation and can stop or slow linear growth.

Growth of the pelvis is delayed in comparison with growth in stature, which helps to explain why cephalopelvic disproportion and other mechanical issues associated with labour may be more common among young adolescents. Competition for nutrients between the growing adolescent and the fetus may also contribute to some of the poor outcomes apparent in teen pregnancies. Recommended weight-gain goals are not different from those of adult patients. Pregnant adolescents should be encouraged to choose a weight-gain goal at the upper end of the range for their BMI. Adolescent females who have given birth have greater percentages of total fat and visceral fat (associated with the metabolic syndrome and cardiovascular disease) than those who have never given birth (Chang et al., 2013); thus the adolescent mother needs careful teaching regarding nutritional intake and physical activity to control body weight in the postpartum period.

Adolescents may not have adequate knowledge of nutrition, and their "present-focused" orientation may inhibit them from easily understanding how their current behaviours relate to later outcomes. Efforts to improve the nutritional health of pregnant adolescents focus on the following:

- Assessment of individual dietary preferences and what the person may be willing to change
- Improving their nutrition knowledge, meal planning, and food selection and preparation skills
- Promoting access to prenatal care
- Developing nutrition interventions and educational programs that are effective with adolescents
- Striving to understand the factors that create barriers to change in the adolescent population

Pregnancy and Breastfeeding. Patients who are breastfeeding and become pregnant can continue to breastfeed. Caloric requirements are higher when breastfeeding than in pregnancy. Pregnant patients who are breastfeeding should be counselled to eat a healthy diet with a few extra snacks during the day and to ensure they are drinking fluids regularly. See Chapter 27 for further information on nutritional needs during lactation.

Nursing Care

During pregnancy, nutrition plays a key role in achieving an optimal outcome for the mother and their unborn baby. Motivation to learn about nutrition is usually higher during pregnancy as parents strive to "do what's right for the baby." Optimal nutrition cannot eliminate all concerns that may arise during pregnancy, but it does establish a good foundation for supporting the needs of the mother and fetus.

Assessment. Ideally, a nutrition assessment is performed before conception so that any recommended changes in diet and lifestyle can be undertaken before the patient becomes pregnant. Information on nutrition and diet is obtained through an interview and review of the patient's health records, physical examination, and laboratory results.

Obstetrical and gynecological effects on nutrition. Nutrition reserves may be depleted in the multiparous patient or one who has had frequent pregnancies (especially three pregnancies within 2 years). A history of preterm birth or the birth of an LBW or SGA infant may indicate inadequate dietary intake. Birth of a large-for-gestational-age (LGA) infant often indicates the existence of maternal diabetes mellitus. Contraceptive methods may also affect reproductive health. Increased menstrual blood loss often occurs during the first 3 to 6 months after placement of an intrauterine contraceptive device; consequently, the user may have low iron stores or even iron-deficiency anemia. Oral contraceptive agents are associated with decreased menstrual losses and increased iron stores; however, oral contraceptives may interfere with folic acid metabolism.

Health history. Chronic maternal illnesses such as diabetes mellitus, renal disease, liver disease, cystic fibrosis or other malabsorptive disorders, seizure disorders and the use of anticonvulsant agents, hypertension, and PKU may affect a patient's nutritional status and dietary needs. In patients with illnesses that have resulted in nutrition deficits or that require dietary treatment (e.g., diabetes mellitus, PKU), it is extremely important that nutritional care be started and the condition be optimally controlled before conception. A registered dietitian can provide in-depth counselling for the patient who requires medical nutrition therapy during pregnancy and lactation.

Usual maternal diet. A history that includes the patient's usual food and beverage intake, any dietary modifications, food allergies and intolerances, cultural dietary requirements, all medications and nutrition supplements, and the adequacy of income and other resources to meet their nutrition needs should be ascertained. In addition, the presence and severity of nutrition-related discomforts of pregnancy such as morning sickness, constipation, and heartburn (pyrosis) should be determined (for management see Chapter 11). The nurse should be alert to any evidence of eating disorders such as anorexia nervosa, bulimia, pica, or frequent and rigorous dieting before or during pregnancy.

The effect of food allergies and intolerances on nutrition status ranges from very important to almost nil. Lactose intolerance is of special concern in pregnant and lactating patients as patients restricting dairy products may be at risk for calcium deficiency. If a patient has lactose intolerance, the nurse should explore their intake of other calcium sources (see Box 12.4).

Diet quality tends to improve with increasing socioeconomic status and educational level, therefore the nursing assessment must include an evaluation of the patient's financial status and their knowledge of healthy eating. Patients with a lower socioeconomic status may not have access to adequate refrigeration and cooking facilities and may find it difficult to obtain adequate nutritious food. Pregnancy rates can be high among homeless individuals, and prenatal nutrition programs may assist patients in obtaining healthy food (see Community Focus box).

COMMUNITY FOCUS

Canada Prenatal Nutrition Program

The Canada Prenatal Nutrition Program (CPNP) funds community groups to develop or enhance programs for vulnerable pregnant patients. Through a community development approach, the CPNP aims to reduce the incidence of unhealthy birth weights, improve the health of both infant and mother, and encourage breastfeeding.

Look for a Canada Prenatal Nutrition Program in your area. Contact the program and, if possible, visit the clinic. What services are offered by the program? Who are the clients that use this service? How difficult is it to access the services provided by the program? Does the clinic employ a registered dietitian? Are there materials and services provided in a variety of languages? Identify strengths and weaknesses of nutrition education in that setting. How do patients get access to the services provided by CPNP?

Source: Government of Canada. (2020). *Canada prenatal nutrition program (CPNP).* http://www.phac-aspc.gc.ca/hp-ps/dca-dea/prog-ini/cpnp-pcnp/index-eng.php.

BOX 12.6 Food Intake Questionnaire

Do you regularly consume each of the following and, if so, how much?
Beer, wine, other alcoholic drinks _____
Tea _____
Coffee _____
Water _____
Fruit juices _____
Fruit drinks (e.g., fruit punch) _____
Soda/pop _____
Whole fruit___
Grains:
Whole grains _____
White/processed foods (e.g., white bread, white pasta)____
Dairy _____ (what fat content?) _____
Meat, poultry, eggs _____
Fish/seafood _____
Nuts, seeds, soy _____
Legumes (beans and peas) _____
Dark green vegetables _____
All other vegetables _____
Candy/chocolate/desserts? _____
Do you add salt to your food? _____
Do you eat canned soups or fast food? _____
Fats:
Do you use butter? _____
Do you eat deep-fried food? _____
Do you take any supplements? _____
Are you often bothered by any of the following? (Circle all that apply.)
Nausea Vomiting Heartburn Constipation
Are you on a special diet? No _____ Yes _____ If yes, what kind? _____
Do you try to limit the amount or kind of food you eat to control your weight?
No ___ Yes ___
Do you avoid any foods for health or religious reasons? No _____ Yes _____
If yes, what foods? _____
Do you take any prescribed medications? No _____ Yes _____
If yes, what are they? _____
Do you take any over-the-counter medications (such as Aspirin, cold medicines, pain relievers)? No _____ Yes _____
If yes, what are they? _____
Do you take any herbal supplements? No _____ Yes _____
If yes, what are they? ____
Do you ever have trouble affording the food you need? No _____ Yes _____
Do you have any help getting the food you need? No _____ Yes _____
If yes, circle all that apply.
Prenatal Nutrition Program
School lunch or breakfast
Food from a food pantry, soup kitchen, or food bank

Adapted from National Collaborative on Childhood Obesity Research. (2015). *The healthy eating index, 2015*. https://www.nccor.org/wp-content/uploads/2019/06/HEI-2015-Factsheet.pdf.

Box 12.6 provides a simple tool for obtaining diet history information. When potential concerns are identified, they should be followed up with a careful interview.

Physical examination. **Anthropometric (body) measurements** provide short- and long-term information on a patient's nutrition status and are thus essential to the assessment. At a minimum, the patient's height and weight must be determined at their first prenatal visit, and their weight should be measured on a regular basis (see earlier discussion of BMI).

A careful physical examination can reveal objective signs of poor nutrition (Table 12.3). However, it is important to note that some of these signs are nonspecific and that the physiological changes of pregnancy may complicate the interpretation of physical findings. For example, lower extremity edema often occurs in calorie and protein deficiency, but it may also be a normal finding in the third trimester of pregnancy. Interpretation of physical findings is made easier by taking a thorough health history and conducting laboratory testing, if indicated.

Laboratory testing. The only nutrition-related laboratory testing needed by most pregnant patients is a hematocrit or hemoglobin measurement to screen for the presence of anemia. Because of the **physiological anemia of pregnancy**, the reference values for hemoglobin and hematocrit must be adjusted during pregnancy. The lower limit of the normal range for hemoglobin during pregnancy is 110 g/L (compared with 120 g/L in the nonpregnant state). The lower limit of the normal range for hematocrit is 0.33 (compared with 0.37 in the nonpregnant state). Cut-off values for anemia are higher in patients who smoke or live at high altitudes because the decreased oxygen-carrying capacity of their RBCs causes them to produce more RBCs than other patients.

A pregnant patient's history or physical findings may indicate the need for additional testing. These tests might include a complete blood cell count with a differential to identify megaloblastic (vitamin B_{12} deficiency) or macrocytic anemia and measurement of levels of specific vitamins or minerals believed to be lacking in the diet.

Nutrition Care and Teaching. For many patients with uncomplicated pregnancies, the nurse can serve as the primary source of nutrition education during pregnancy (see Nursing Care Plan on Nutrition during Pregnancy on Evolve). A registered dietitian who has specialized training in evaluating diets, planning nutrition needs during illness, recognizing ethnic and cultural food patterns, and translating nutrient needs into food patterns frequently serves as a consultant. Pregnant patients with serious nutrition concerns, those with intervening illnesses such as diabetes (either pre-existing or gestational), and those with any other conditions requiring in-depth dietary counselling should be referred to the dietitian.

Nutrition teaching can take place in a one-on-one interview or in a group setting. In either case, teaching should emphasize the importance of choosing a varied diet using *Canada's Food Guide*, composed of readily available foods rather than specialized diet supplements. The importance of consuming adequate amounts of healthy foods that will meet specific nutrient requirements (e.g., calcium) must be emphasized, especially for adolescents younger than 18 years of age, who are still actively adding calcium to their skeletons. Good nutrition practices (and avoidance of poor practices such as smoking and alcohol or drug use) are essential content for prenatal classes designed for patients in early pregnancy.

Canada's Food Guide can be used as a guide to making daily food choices during pregnancy (see Appendix A). *Canada's Food Guide* snapshot is translated into over 25 different languages including 9 Indigenous languages. See Additional Resources listed at the end of the chapter.

TABLE 12.3 Physical Assessment of Nutritional Status

Signs of Good Nutrition	Signs of Poor Nutrition
General Appearance	
Alert, responsive, energetic, good endurance	Listless, apathetic, cachectic, easily fatigued, looks tired
Muscles	
Well developed, firm, good tone, some fat under skin	Flaccid, poor tone, undeveloped, tender, "wasted" appearance
Nervous System Function	
Normal attention span, not irritable or restless, normal reflexes, psychological stability	Inattentive, irritable, confused, burning and tingling of hands and feet, loss of position and vibratory sense, weakness and tenderness of muscles, decrease or loss of ankle and knee reflexes
Gastrointestinal Function	
Good appetite and digestion, normal regular elimination, no palpable organs or masses	Anorexia, indigestion, constipation or diarrhea, liver or spleen enlargement
Cardiovascular Function	
Normal heart rate and rhythm, no murmurs, normal blood pressure for age	Rapid heart rate, enlarged heart, abnormal rhythm, elevated blood pressure
Hair	
Shiny, lustrous, firm, not easily plucked, healthy scalp	Stringy, dull, brittle, dry, thin and sparse, depigmented, can be easily plucked
Skin (General)	
Smooth, slightly moist, normal colour	Rough, dry, scaly, pale, pigmented, irritated, easily bruised, petechiae
Face and Neck	
Skin colour uniform, smooth, pink, healthy appearance; no enlargement of thyroid gland; lips not chapped or swollen	Scaly, swollen, skin dark over cheeks and under eyes; lumpiness or flakiness of skin around nose and mouth; thyroid enlarged; lips swollen; angular lesions or fissures at corners of mouth
Oral Cavity	
Reddish pink mucous membranes and gums; no swelling or bleeding of gums; tongue healthy pink or deep red in appearance, not swollen or smooth, surface papillae present; teeth bright and clean, no cavities, no pain, no discoloration	Gums spongy, bleed easily, inflamed or receding; tongue swollen, scarlet and raw, magenta colour, beefy, hyperemic and hypertrophic papillae, atrophic papillae; teeth with unfilled caries, absent teeth, worn surfaces, mottled
Eyes	
Bright, clear, shiny, no sores at corners of eyelids, membranes moist and healthy pink colour, no prominent blood vessels or mound of tissue (Bitot's spots) on sclera, no fatigue circles beneath	Eye membranes pale, redness of membrane, dryness, signs of infection, Bitot's spots, redness and fissuring of eyelid corners, dryness of eye membrane, dull appearance of cornea, soft cornea, blue sclera

Continued

TABLE 12.3 Physical Assessment of Nutritional Status—cont'd

Signs of Good Nutrition	Signs of Poor Nutrition
Extremities	
No tenderness, weakness, or swelling; nails firm and pink	Edema, tender calves, tingling, weakness; nails spoon-shaped, brittle
Skeleton	
No malformations	Bowlegs, knock-knees, chest deformity at diaphragm, beaded ribs, prominent scapulas

Safe food preparation. Pregnant patients and their unborn or newborn children are at an increased risk for foodborne illnesses because they have a weaker immune system. For example, pregnant patients are about 20 times more likely to get listeriosis than other healthy adults. Listeriosis is a rare but serious infection caused by consuming a type of bacterium called *Listeria monocytogenes* (commonly called *Listeria*) that is sometimes found in food, water, and soil. If a pregnant patient develops listeriosis during the first 3 months of pregnancy they may experience a miscarriage. Up to 2 weeks before a miscarriage, pregnant patients may experience a mild flulike illness with chills, fatigue, headache, as well as muscular and joint pain. Listeriosis later on in the pregnancy can result in a stillbirth or the birth of an acutely ill child (Government of Canada, 2016).

For safe preparation of food and to decrease the risk of contracting listeriosis or other foodborne illnesses see Patient Teaching box Prevention of Foodborne Illness.

PATIENT TEACHING

Prevention of Foodborne Illness

- Follow all food instructions on the label of the package.
- Cleanse hands frequently.
- Clean and sanitize all food preparation surfaces, knives, and utensils with a kitchen sanitizer or using a 5-mL ratio of household bleach to 750 mL of water followed by a water rinse. This is particularly important when preparing raw fish or meat.
- Clean all fruits and vegetables carefully before eating.
- Refrigerate any perishable or prepared foods at 4°C or below. The warmer the refrigerator, the higher the bacterial count will be. Keep leftovers for only 2 to 3 days and reheat to an internal temperature of 74°C.
- Defrost frozen foods in the refrigerator, in cold water, or in the microwave, but never defrost at room temperature.
- Wash and disinfect the refrigerator on a frequent basis, which decreases the risk of bacteria in food being transferred to uncontaminated food stuff.
- Avoid contact between raw meat, fish, or poultry and other foods that will not be cooked before consumption.
- Cook foods to a proper internal cooking temperature.
- Avoid consumption of unpasteurized milk or products made with unpasteurized milk, including soft cheeses (Brie, Camembert); patés and meat spreads; raw eggs; raw sprouts (bean, mung); smoked seafood (unless cooked); and raw seafood. Hot dogs, luncheon meats, bologna, and non-dried deli meats should be eaten only if they have been reheated to steaming hot.

Sources: Government of Canada. (2016). *Listeriosis (Listeria).* https://www.canada.ca/en/public-health/services/diseases/listeriosis.html; Government of Canada. (2019). *Food safety for pregnant women.* https://www.canada.ca/en/health-canada/services/food-safety-vulnerable-populations/food-safety-pregnant-women.html.

SAFETY ALERT

Pregnant patients who contract listeriosis, a disease resulting from infection with the bacteria *Listeria,* are at increased risk for miscarriage, premature birth, and stillbirth. During pregnancy, patients should not consume unpasteurized milk or products made with unpasteurized milk, including soft cheeses such as Brie and Camembert. Hot dogs, luncheon meats, bologna, and deli meats should be eaten only if they have been reheated to be steaming hot.

Medical Nutrition Therapy. During pregnancy, the meal plan for patients requiring medical nutrition therapy may have to be modified. A registered dietitian can instruct these patients about their diets and assist them in meal planning. However, the nurse should understand the basic principles of the diet and be able to reinforce the diet teaching.

The nurse should be especially aware of the dietary modifications necessary for patients with diabetes mellitus (either gestational or pre-existing). This disease is relatively common, and fetal morbidity and mortality occur more often in pregnancies complicated by **hyperglycemia** or **hypoglycemia** (see discussion of diabetes in Chapter 15). Every effort should be made to maintain blood glucose levels in the normal range throughout pregnancy. The meal plan of the patient with diabetes usually includes three moderate-sized meals and two or more snacks (one of which should be at bedtime) (Feig et al., 2018). The complex carbohydrates—fibres and starches—should be well represented in the diet. To maintain strict control of the blood glucose level, self–blood glucose monitoring is essential.

Gluten-Free Diet. Many people eat gluten-free diets because of *celiac disease* (an autoimmune disease in which the small intestine is damaged by eating foods that contain gluten), nonceliac gluten sensitivity, or personal choice. *Gluten* is a type of protein found in wheat, barley, and rye grains. A patient consuming a gluten-free diet can obtain all the necessary nutrients required for pregnancy, although some modifications may be required. Gluten-free foods can be deficient in some vitamins and minerals as the flours and starches are not fortified. Gluten-free diets can be low in fibre, iron, and B vitamins (Case, 2019). Pregnant patients should consume 28 g of fibre per day, and 16 to 20 mg of iron. See Table 12.1 for examples of foods with fibre and iron.

Vegetarian Diets. Vegetarian diets provide many health benefits and, if planned well, are nutritionally adequate and appropriate during pregnancy (see Clinical Reasoning Case Study). Patients who consume vegetarian diets may require extra counselling to ensure that nutrient needs are met. Foods basic to almost all vegetarian diets are vegetables, fruits, legumes, nuts, seeds, and grains, but with many variations. Strict vegetarians, or **vegans**, consume only plant products (Melina et al., 2016). The diet should be carefully planned to include adequate protein, vitamins, and minerals. As discussed in the protein section, plant proteins are "incomplete" in that they lack one or more amino acids required for growth and the maintenance of body tissues. However, the daily consumption of a variety of different plant proteins—grains, dried beans and peas, nuts, and seeds—can provide all of the **essential amino acids** needed for a growing fetus. Additionally, because vitamin B_{12} is found only in foods of animal origin, vegan diets are deficient in vitamin B_{12}, thus regularly consumed vitamin B_{12}–fortified foods (e.g., soy milk) or a supplement is essential. Iron and zinc may also not be as well absorbed from plant foods as they are from meats, and calcium intake can be low if milk products are not included in the diet.

CLINICAL REASONING CASE STUDY

Vegetarian Diet in Pregnancy

Naomi is a 29-year-old patient who is pregnant with her first baby. Upon her initial visit she shares with the nurse that she has been successfully following a vegan diet since she was 16. She is curious about the nutrients that she needs during her pregnancy and for after birth when she will be breastfeeding.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about what nutrients Naomi might be lacking that are essential for a healthy pregnancy?
2. What implications and priorities for nursing care can be drawn at this time?
3. Develop a teaching plan for Naomi to ensure that she is getting all the nutrients she needs during her pregnancy and during the postpartum period.
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Naomi.

Cultural Influences. Consideration of a pregnant patient's cultural food preferences enhances the nurse's communication with the patient and provides a greater opportunity for the patient to follow necessary nutrient requirements. Patients of all cultures are encouraged to eat a diet typical for them. The nurse needs to be aware of what constitutes a typical diet for each cultural or ethnic group in the patient population. However, because several variations may occur within one cultural group, a careful exploration of individual preferences is needed. Food cravings during pregnancy are considered normal by many cultures, but the kinds of cravings often are culturally specific. In most cultures, patients crave acceptable foods, such as chicken, fish, and greens.

Coping with Nutrition-Related Discomforts of Pregnancy. The most common nutrition-related discomforts of pregnancy are nausea and vomiting (or "morning sickness"), constipation, and heartburn.

Nausea and vomiting. Nausea and vomiting of pregnancy (NVP) is most common during the first trimester in 85% of patients, and although NVP usually cause only mild to moderate nutrition issues, it may be a source of substantial discomfort. Antiemetic medications, vitamin B_6, ginger, and pericardium 6 acupressure (Figure 12.4) may be effective in reducing the severity of nausea, although the evidence

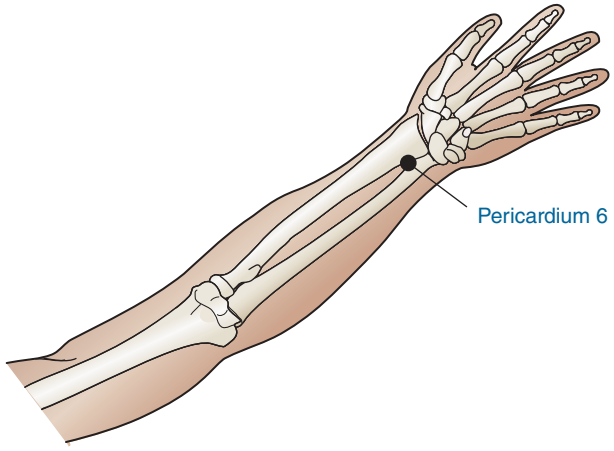

Fig. 12.4 Pericardium 6 (P6) acupressure/acupuncture point for nausea.

is not strong. A single drug combination of pyridoxine and doxylamine (Diclectin) may also be prescribed. The pregnant patient may find the suggestions in the Patient Teaching box: Managing Nausea and Vomiting During Pregnancy helpful in alleviating the discomfort.

PATIENT TEACHING

Managing Nausea and Vomiting During Pregnancy

- Consider discontinuing iron-containing prenatal vitamins during the first trimester and substitute them with folic acid or adult or children's vitamins low in iron.
- Eat small amounts of food every 1 to 2 hours, as this will help balance blood sugar levels, and do not eat or drink too much at one time.
- Try not to mix food and drinks. Drink liquids 20 to 30 minutes before or after you eat. Do not drink alcohol at all.
- Do not skip meals.
- Eat pregnancy-safe foods that are appealing.
- Avoid strong odours.
- Avoid making sudden movements. Get out of bed slowly and eat soon after getting out of bed.
- Try salty and tart foods (e.g., potato chips and lemonade). Sucking a lemon slice may help.
- Breathe fresh air. Keep the environment well ventilated (e.g., open a window), go for a walk outside, or decrease cooking odours by using an exhaust fan.
- Eat foods served at room or cool temperatures and foods that give off little aroma.
- Try candies, gums, and lozenges to help minimize the metallic taste in your mouth.
- Avoid brushing your teeth immediately after eating.

Alternative Therapies

- Herbal teas such as those made with mint, ginger, or orange have also been used for morning sickness (see Box 12.5: Herbal Teas).
- Ginger (up to 1 000 mg/day)
- Vitamin B_6 (up to 200 mg/day
- Acupuncture or acupressure
- Mindfulness-based cognitive therapy as an adjunct to medication

Adapted from Campbell, K., Rowe, H., Azzam, H., et al. (2016). The management of nausea and vomiting of pregnancy. *Journal of Obstetrics and Gynaecology Canada, 38*(12), 1127–1137.

Hyperemesis gravidarum, or severe and persistent vomiting causing weight loss, dehydration, and electrolyte imbalances, occurs in about 1% of pregnant patients. Intravenous fluid and electrolyte replacement, enteral tube feeding, and in some instances total parenteral nutrition have been used to nourish patients with hyperemesis gravidarum. See Chapter 14: Hyperemesis Gravidarum, for discussion on this condition.

Constipation. Improved bowel function generally results from increasing the intake of fibre (e.g., wheat bran and whole-wheat products, popcorn, and raw or lightly steamed vegetables) in the diet. Fibre helps retain water, creating a bulky stool that stimulates intestinal peristalsis. The recommendation for pregnant patients for fibre is 28 g/day. An adequate fluid intake (at least 2.2 L/day) helps hydrate the fibre and increase the bulk of the stool. Warm or hot fluids may increase peristalsis more than cold fluids. Making a habit of regular exercise that uses large muscle groups (walking, swimming, cycling) also helps stimulate bowel motility. Laxatives should not be taken unless first discussed with a health care provider.

Heartburn. Heartburn, or **pyrosis**, is usually caused by reflux of gastric contents into the esophagus. This condition is common in 40 to 85% of pregnant patients (HealthLinkBC, 2019). This condition can be minimized by using the following strategies:

- Eat small, frequent meals, rather than two or three larger meals, daily.
- Add a source of protein to each snack.
- Avoid drinking fluids with a meal as fluids increase the distension of the stomach.
- Avoid eating foods that are high in fat, spicy foods, acidic foods, as well as chocolate and mint.
- Avoid lying down immediately after eating.

Occasionally, patients may take antacids to help with heartburn. Not all antacids are safe; thus patients should check with their health care provider prior to taking this medication.

KEY POINTS

- A patient's nutrition status before, during, and after pregnancy contributes significantly to their well-being and that of their newborn.
- A healthy diet can affect the health of the mother and fetus, and different factors can influence the ability of a pregnant patient to access a healthy diet.
- Many physiological changes occurring during pregnancy influence the need for additional nutrients and the efficiency with which the body uses them.
- Both the total maternal weight gain and the pattern of weight gain are important determinants of the outcome of pregnancy.
- Recommended weight gain during pregnancy is influenced by the patient's prepregnancy weight for height (BMI).
- Nutrition risk factors include adolescent pregnancy, nicotine use, alcohol or drug use, food restrictions, a low weight for height, and frequent pregnancies.
- Iron supplementation is usually recommended during pregnancy. Other supplements may be warranted when nutrition risk factors are present.
- The nurse and the patient are influenced by cultural and personal values and beliefs that the nurse needs to take into account during nutrition counselling.
- Pregnancy complications that may be nutrition related include anemia, gestational hypertension, gestational diabetes, and intrauterine growth restriction (IUGR).
- Diet modifications can be an effective intervention for some of the common discomforts of pregnancy, including nausea and vomiting, constipation, and heartburn.

Pregnancy Risk Factors and Assessment

Nancy Watts

Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explore biophysical, psychosocial, sociodemographic, and environmental influences on high-risk pregnancy.
2. Identify the determinants of health that influence pregnancy outcomes.
3. Examine risk factors identified through history taking, physical examination, and diagnostic techniques.
4. Differentiate among screening and diagnostic techniques, including when they are used in pregnancy and for what purpose.
5. Discuss psychological considerations associated with a high-risk pregnancy diagnosis.
6. Develop a teaching plan to explain screening and diagnostic techniques and the implications of findings to pregnant patients and their families.

Although most pregnancies and births are considered low risk, there are pregnancies categorized as high risk because of maternal or fetal complications. Identification of the risks, together with appropriate and timely intervention during the perinatal period, can prevent morbidity and mortality among mothers and infants.

Using current Canadian demographic information, patients and families can be identified as at risk on the basis of factors other than biophysical criteria. High-risk pregnancies are considered to be a major public health challenge, and it is important to address the needs of these patients and families (Badakhsh et al., 2020). The increasing numbers of pregnant patients who have limited access to prenatal care during any stage of pregnancy, as well as behaviours and lifestyles that pose a risk to the health of the mother and fetus, contribute to the increasing incidence of high-risk pregnancies. An increasing number of patients are identifying mood disorders in pregnancy (15% in Canada in 2016), with another 13% describing a lack of support for this important time in their lives (Public Health Agency of Canada, 2016). Access to prenatal care may be challenged by language barriers, past negative experiences with health care providers, lack of transportation, and limited health care facilities available in remote or rural communities.

Care of high-risk patients requires the collaborative efforts of various health care providers. In this chapter, care of the high-risk patient and the factors associated with a diagnosis of high risk are discussed. Diagnostic techniques used to monitor the maternal–fetal unit are also outlined. Finally, psychological considerations of care of the patient experiencing a high-risk pregnancy are addressed.

DEFINITION AND SCOPE OF HIGH-RISK PREGNANCY

A *high-risk pregnancy* is one in which the life or health of the mother or newborn is jeopardized by a disorder or medical, social or environmental factors coincident with or unique to pregnancy (Badakhsh et al., 2020). For the mother, the high-risk status arbitrarily extends through the puerperium (approximately 6 weeks after childbirth). Postbirth maternal complications related to the pregnancy usually are resolved within 1 month of birth, but perinatal morbidity may continue for months or years. Ongoing medical challenges present before the pregnancy may have been improved or worsened during pregnancy and may take 3 to 6 months to return to prepregnancy stability.

High-risk pregnancy is a critical and growing concern for modern medical and nursing care. Globally, more than 20 million patients are at risk of a high risk pregnancy and more than 99% occur in developing countries, more frequently among adolescents and patients who live in rural locations (Badakhsh et al., 2020). The current social emphasis on quality of life and the wanted child has resulted in a reduction of family size and the number of unwanted pregnancies. At the same time, technological advances have facilitated pregnancies in previously infertile couples. As a consequence, emphasis is on the safe birth of healthy newborns who can develop to their potential. Scientific and technological advances have allowed perinatal health care to reach a level far beyond that previously available.

The diagnosis of high risk imposes a situational crisis on the family. These crises include, for example, loss of pregnancy before the

anticipated date and a fetal or maternal diagnosis that requires decision making about whether to continue or interrupt the pregnancy or birth of a newborn who does not meet cultural, societal, or familial norms and expectations. Management of pregnancy complications or a high risk pregnancy can involve activity restriction or extended hospital stays until birth. Pregnant patients experience fear and anxiety of the unknown as they await the birth of their child. This heightened anxiety can contribute to preterm birth in some patients and may influence parental attitude toward the infant (Schlegel et al., 2016).

Determinants of Health as Risk Factors

There are many factors that contribute to high-risk pregnancies; an analysis of the determinants of health (see Box 1.1) provides a more comprehensive approach to providing care. Social and individual factors associated with high-risk child-bearing include income and social status, social support networks, education, employment and working conditions, physical environment, personal health practices and coping skills, biology and genetics, availability of health services, and culture. Some personal health practices and lack of coping skills can place the mother and fetus at risk. Examples include problematic substance use, lack of prenatal care, inadequate nutritional status or dental hygiene, and psychosocial stressors (Box 13.1). Social factors can affect the body on a physiological level as complex interwoven stressors such as poverty, unsafe living conditions, food insecurity, racism and oppression. These factors contribute to chronic stress which has been shown to lead to preterm birth and hypertension (Lathrop, 2020). Alternatively, in qualitative research done with Aboriginal patients, they were able to identify social determinants of health which contributed to their resilience and strength such as cultural information, mothering by their mothers and strong family support (Shahram et al., 2017). Nurses who work together with pregnant patients to identify their stressors and strengths can individualize their care to promote their health and parenting skills (Lathrop, 2020). Box 13.2 provides questions that can be asked to assess how the determinants of health impact someone's life.

The determinants of health are interrelated and cumulative in their effects on health outcomes. A comprehensive database for pregnancy risk assessment can help ensure that appropriate resources are available. In Canada, the Canadian Perinatal Surveillance System (CPSS) provides this database (see Chapter 4; Perinatal Health Indicators: The Canadian Perinatal Surveillance System). The CPSS reports on more than 50 maternal, fetal, and infant health determinants and outcomes. The view is that health status is influenced by a range of factors; thus it is important to monitor not only health outcomes but also factors—such as behaviours, physical and social environments, and health services—that may affect those outcomes.

Regionalization of Health Care Services

Early and ongoing risk assessment is a crucial component of perinatal care. Conditions that are associated with perinatal morbidity and mortality can be prevented or treated by general perinatal health services, or they may require referral to more specialized health care providers. Factors to consider when determining a patient's risk status include resources available locally to treat the condition, availability of appropriate facilities for transport if needed, and determination of the best health care match for the patient's needs.

It is neither feasible nor reasonable for each hospital to develop and maintain the full spectrum of services required for treating high-risk perinatal patients. Consequently, health care has become regionalized, creating a system of coordinated care in which facilities within a geographic region are organized to provide different levels of care. This system also applies to preconception and ambulatory prenatal care services (see Community Focus box).

COMMUNITY FOCUS

Resources for Patients Experiencing a High-Risk Pregnancy

Contact the nearest high-risk pregnancy unit to assess the resources available for patients (e.g., pamphlets, websites for high-risk pregnancies) and to learn what screening is recommended during pregnancy to identify concerns. For what health issues is the screening conducted? What information or resources are available in your community for the concerns identified? Are there specialized clinics for different populations—for example, bariatric clinics, mental health obstetrical clinics, or those for patients with high-risk fetal diagnoses? How can pregnant patients access the resources that are available? What geographic area does this unit serve? What determinants of health are influencing these patients' lives? What is the role of the nurse in this unit?

ASSESSMENT OF RISK FACTORS

The leading causes of maternal death attributable to pregnancy differ throughout the world. In general, the major causes of maternal deaths worldwide are: hemorrhage, infection, hypertensive disorders, complications from the birth, and unsafe abortion (World Health Organization, 2019). In Canada today, the leading causes of maternal mortality are hypertensive disorders, pulmonary and amniotic embolism, hemorrhage, and other causes, such as mental illness. Factors strongly related to maternal death include age (younger than 20 years or 35 years or older), lack of prenatal care, and low education level. Box 13.3 lists common risk factors for several pregnancy-related complications.

In Canada in 2018, the annual **maternal mortality rate** (number of maternal deaths per 100 000 live births) was 8.3 (Statistics Canada, 2019). Although the overall number of maternal deaths is small, maternal mortality remains a significant concern because a high proportion of these deaths are preventable, primarily through improving access to and use of prenatal care services. While the number of adolescents becoming pregnant is decreasing, the number of patients who are greater than 35 years of age is increasing and their risk is higher (Aoyama et al., 2019). Nurses can be instrumental in educating the public about the importance of obtaining early and regular care during pregnancy.

Mental Health Concerns

Mental health issues may develop during the antepartum period, or they may already be present prior to pregnancy. Dollberg et al. (2016) found in a literature review that depression in mothers may have detrimental effects on perinatal outcome, such as preterm labour and lower rates of breastfeeding initiation. Depression during pregnancy is also related to decreased maternal self-care, smoking, and intrauterine growth restriction (IUGR), all of which may have a direct impact on the infant's health (Tsakiridis et al., 2018). Early education for prenatal patients and families about depression is an essential part of health promotion. Interprofessional collaboration and appropriate referrals are important interventions for the nurse to initiate when concerns regarding depression are identified. Interventions for both parents may be useful, as depression in the mother may extend to their relationship to their partner. The partner may also be depressed about the circumstances of the high-risk pregnancy, thus treatment may be beneficial to both parents during pregnancy rather than later, during the postpartum period (Dollberg et al., 2016; Tsakiridis et al., 2018).

British Columbia Mental Health Program and Perinatal Services British Columbia have developed guiding principles for the care of pregnant patients with mental health issues (BC Reproductive

BOX 13.1 Influence of Determinants of Health on Maternal and Newborn Outcomes

Biology and Genetic Factors

Genetic Considerations

Genetic risks include heritable factors that originate within the mother or fetus and affect the development or functioning of either or both. Genetic factors may interfere with healthy fetal or newborn development, result in congenital anomalies, or create difficulties for the mother. These factors include altered genes, transmittable inherited disorders, chromosome anomalies, multiple pregnancy, large fetal size, and ABO incompatibility. A genetic risk assessment should be done to determine the family's risk (see Chapter 9).

Demographic Characteristics

Availability of Health Care

The availability and quality of prenatal care vary greatly with geographic region. Pregnant patients in urban areas tend to have more prenatal visits than patients in remote and rural areas, who have fewer opportunities for specialized care because of the distance they have to travel to get to it. Patients in lower socioeconomic situations are also less likely to see a specialist and more likely to wait longer for an appointment. Patients who are recent immigrants to Canada may experience challenges accessing health care because they lack knowledge of the prenatal care visit schedule or have difficulty obtaining a health care provider, particularly one that is culturally competent or can provide care in their language of origin. Other patients may struggle with the cost of new prescriptions if they do not have a drug plan.

Physical Environment

There may be unsafe soil and water conditions and environmental exposure to pollutants, such as paint with lead content. Many Indigenous communities have boil-water alerts to ensure that they are drinking safe water. Another example is the consumption of mercury-contaminated fish, which may pose health risks to a developing fetus.

Income and Social Status

Income may be the most important determinant of health because of its influence on living conditions, level of education, quality of diet, and extent of physical activity (Mikkonen & Raphael, 2010; Shahram et al., 2017). A lower income level is associated with an increased risk for medical complications of pregnancy. A patient with a lower income may not have as many support people to ask for assistance or to arrange for transportation to appointments or for child care. For young Indigenous patients, trying to meet the challenges of a pregnancy is a source of "pride." Working with patients to sort out their appointments can be helpful to them (Shahram et al., 2017).

Education

A patient's level of education can reflect their knowledge of the importance of prenatal care and awareness of where to receive it. Having a higher education level can increase pregnant patients' confidence in asking questions and making choices and has been associated with fewer adverse outcomes in pregnancy and postpartum.

Social Support Networks

The increased mortality and morbidity rates for single patients, including a greater risk for pre-eclampsia, are often related to inadequate prenatal care, lower socioeconomic status, lower level of education, and younger childbearing age. The availability of social networks and close community ties have been shown to alleviate barriers related to lower income and less education.

Culture

Infant mortality rates are higher among Indigenous people. Indigenous patients have described encounters with health care providers that include judgement of their lifestyle choices, racism, and discrimination. Many factors influence whether they attend prenatal care visits, including lack of transportation, complex life situations, and whether they have had experience with child protection services. Patients have described their willingness to seek health care for their children but a reluctance to seek their own health care because of past negative experiences (Denison et al., 2014; Di Lallo, 2014).

Among other cultural groups there may be cultural beliefs that do not support the prenatal care schedule used in Canada; for example, there are differences across countries as to when to initiate care. There may also be discrimination against members of marginalized communities or language barriers to receiving culturally competent prenatal care (UN Development Program, 2011).

Employment/Working Hazards

Occupational hazards can be grouped into chemical, physical, biological, and psychological hazards. The risk to the fetus depends on the timing of the exposure, the dose, and fetal and maternal susceptibility. Patients who work at highly physically demanding jobs or are exposed to hazards such as industrial fumes or do shift work have higher pregnancy risks.

Personal Health Practices and Coping Skills

Substance Use

Smoking is associated with intrauterine growth restriction, preterm birth, and low birth weight. Alcohol consumption has adverse effects on the fetus, resulting in fetal alcohol spectrum disorders, which include fetal alcohol syndrome, alcohol-related neurodevelopmental disorder, and alcohol-related birth defects. Recreational or prescribed medication misuse can be teratogenic, cause metabolic disturbances, produce chemical effects, or cause depression or alteration of central nervous system function.

Nutritional Status

Adequate nutrition is one of the most important determinants of pregnancy outcome, for without it, fetal growth and development cannot proceed normally (see Figure 12.1). Dietary deficiencies are more common among households with children that have a lone parent, are Indigenous, and are receiving social assistance (Mikkonen & Raphael, 2010). Conditions that influence nutritional status include the following: young age of the mother; three pregnancies in the previous 2 years; tobacco, alcohol, or problematic substance use; inadequate dietary intake because of chronic illness or food fads; and inadequate or excessive weight gain (see Chapter 12).

Dental Hygiene

Periodontal disease increases the risk for preterm birth and low birth weight. Patients may not have adequate finances or information about the need for ongoing dental hygiene and health promotion during pregnancy.

Psychosocial Stressors

Childbearing triggers profound and complex physiological, psychological, and social changes; evidence suggests a relationship between emotional distress and birth complications. This risk factor includes conditions such as specific intrapsychic disturbances and addictive lifestyles; a history of child abuse or intimate partner violence (see discussion later in chapter); inadequate support systems; family disruption or dissolution; and maternal role changes or conflicts.

BOX 13.2 Assessing the Impact of Determinants of Health

Housing

Are you worried or concerned that in the next 2 months you may not have stable housing that you own, rent, or stay in as a part of a household? Yes ☐ No ☐

Think about the place where you live. Do you have problems with any of the following? (check all that apply)

Bug infestation ☐
Mould ☐
Lead paint or pipes ☐
Inadequate heat ☐
Oven or stove not working ☐
No or not working smoke detectors ☐
Water leaks ☐
None of the above ☐

Food

Within the past 12 months, you worried that your food would run out before you got money to buy more.

Often true ☐
Sometimes true ☐
Never true ☐

Within the past 12 months, the food you bought just didn't last and you didn't have money to get more.

Often true ☐
Sometimes true ☐
Never true ☐

Transportation

Do you put off or neglect going to the doctor because of distance or transportation? Yes ☐ No ☐

Utilities (Water, gas, electricity, oil)

In the past 12 months has the electric, gas, oil, or water company threatened to shut off services in your home? Yes ☐ No ☐ Already shut off ☐

Child Care

Do problems getting child care make it difficult for you to work or study? Yes ☐ No ☐

Employment

Do you have a job? Yes ☐ No ☐

Education

Do you have a high school diploma? Yes ☐ No ☐

Finances

How often does this describe you? I don't have enough money to pay my bills:

Never ☐
Rarely ☐
Sometimes ☐
Often ☐
Always ☐

Personal Safety

A value greater than 10, when the numerical values for answers to the following questions are summed, indicates a positive screen for personal safety.

How often does anyone, including family, physically hurt you?

Never (1) ☐
Rarely (2) ☐
Sometimes (3) ☐
Fairly often (4) ☐
Frequently (5) ☐

How often does anyone, including family, insult or talk down to you?

Never (1) ☐
Rarely (2) ☐
Sometimes (3) ☐
Fairly often (4) ☐
Frequently (5) ☐

Mental Health Program & Perinatal Services BC, 2014). The guiding principles include the following:

- All patients from a variety of backgrounds (social, economic, racial, cultural) are at risk for mental health issues (as many as one in five patients in the perinatal period).
- Providing services that preserve the mother–infant dyad is optimal.
- Care needs to be provided in a humane, supportive, caring environment so that patients feel strengthened and supported while being treated. These patients will often present in an acute state of distress, have fragile self-esteem, and experience multiple complex stressors.
- A collaborative team approach is optimal.
- Every effort should be made within communities to link services to provide support to patients.

Newborns are sensitive to the emotional states of their mothers. If the mother is distressed or has a mental health issue, this can lead to difficulty bonding. Therefore, it is important that mothers with mental health concerns be identified and treated during pregnancy or in the postpartum period. The use of a screening tool, for example, the Edinburgh Postnatal Depression Scale (EPDS), anytime during the perinatal period is helpful in identifying patients at risk for mental health issues. The Registered Nurses' Association of Ontario (RNAO) and Perinatal Services BC have a number of guidelines concerning reproductive mental health issues, including specific guidelines for screening and care for various disorders, such as anxiety and bipolar (see Additional Resources at the end of the chapter).

Intimate Partner Violence (IPV) During Pregnancy

Violence against women is a global public health issue, with current estimates at one in three women experiencing an abusive romantic relationship in her lifetime (Robinson et al., 2019). IPV is known to

BOX 13.3 Specific Pregnancy Conditions and Related Risk Factors

Polyhydramnios
Poorly controlled diabetes mellitus
Fetomaternal hemorrhage
Fetal congenital anomalies (e.g., gastrointestinal obstruction, central nervous system abnormalities)
Genetic disorders
Twin-twin transfusion syndrome

Intrauterine Growth Restriction
Maternal Causes
Hypertensive disorders
Pregestational diabetes
Cyanotic heart disease
Autoimmune disease
Restrictive pulmonary disease
Multifetal gestation
Malabsorption disease/malnutrition
Living at a high altitude
Tobacco or substance use

Fetal Causes
Genetic disorders
Teratogenic exposure
Fetal infection

Oligohydramnios
Renal agenesis (Potter syndrome)
Premature rupture of membranes
Prolonged pregnancy
Uteroplacental insufficiency
Severe intrauterine growth restriction (IUGR)
Maternal hypertensive disorders
Maternal dehydration/hypovolemia

Chromosomal Abnormalities
Advanced maternal age
Parental chromosomal rearrangements
Previous pregnancy with autosomal trisomy
Abnormal ultrasound findings during the current pregnancy (e.g., fetal structural anomalies, IUGR, amniotic fluid volume abnormalities)
Increased risk, as calculated from noninvasive screening results (e.g., nuchal translucency and maternal serum analytes)

Data from Baschat, A. A, & Galan, H. L. (2017). Intrauterine growth restriction. In S. G. Gabbe, J. R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier; Driscoll, D. A., Simpson, J. L., Holzgreve, W., et al. (2017). Genetic screening and prenatal genetic diagnosis. In S. G. Gabbe, J. R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier; Gilbert, W. M. (2017). Amniotic fluid disorders. In S. G. Gabbe, J. R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

increase risks to patients' health, particularly during pregnancy. Abuse during pregnancy increases the risk for placental abruption, preterm birth, low-birth-weight infants, and infections from nonconsensual sex. Patients who experience violence use health and mental health services more frequently but delay initiation of regular prenatal care. During pregnancy, the perinatal nurse should assess for abuse at each prenatal visit and on admission in labour (see Box 6.2). For further discussion of IPV see Chapter 5.

Abuse is about control of one person over another. In health care situations, many patients can feel this same type of power imbalance with health care providers. When providing care to the patient who is a victim of IPV, it is important to give them support as well as information that can enable them to make their own decisions and have control over their decisions. Patients have also identified that the fetus is aware and could suffer during abusive episodes from their movements and behaviour. Providing information on fetal development can be a specific source of support for patients in these situations (Robinson et al., 2019).

Reducing Infant Morbidity and Mortality

The leading causes of newborn morbidity and mortality are preterm and multiple birth rates. Other causes of newborn death include disorders relating to low birth weight, respiratory distress syndrome, the effects of maternal complications, and sudden infant death. Despite universal health care in Canada, the infant death rate is higher if the mother is of a lower socioeconomic status. Increased rates of survival during the newborn period have resulted largely from high-quality prenatal care and the improvement in perinatal services, including technological advances in neonatal intensive care and obstetrics.

Reducing infant mortality rates requires the removal of various barriers to care, including financial, educational, sociocultural, and logistical barriers, so that pregnant patients can seek and receive appropriate health services. Commitment in this area is required at the national, provincial/territorial, and local levels. Ultimately, barriers to care must be removed and perinatal services modified to meet contemporary health care needs.

ANTEPARTUM TESTING IN THE FIRST AND SECOND TRIMESTER

The major expected outcome of antepartum testing is the detection of potential fetal compromise. Ideally, the technique used will identify fetal compromise before intrauterine asphyxia of the fetus occurs so that the health care provider can take measures to prevent or minimize adverse perinatal outcomes. No single test can provide this information. Assessment tests should be selected on the basis of their effectiveness, and the results must be interpreted in light of the complete clinical picture. Box 13.4 lists common maternal and fetal indications for antepartum testing that are supported by currently available evidence (Miller et al., 2017).

Prenatal Screening

First-trimester pregnancy screening for fetal aneuploidy and second-trimester ultrasound examination to detect fetal anomalies should be offered to all pregnant patients. *Aneuploidy* is defined as having one or more extra or missing chromosomes in the 23 pairs each individual normally possesses. Chromosomal aneuploidies that are compatible with life but cause significant morbidity affect 0.67% of all births (Shea, 2020). The most common type is Down syndrome, which affects 0.15% of all live births (Shea, 2020). Previously, patients over the age of 35 were offered invasive testing, but this has been found to miss many cases of fetal anomalies. With recent advances in maternal screening and ultrasound techniques, it is possible to offer all pregnant patients a noninvasive method of screening. If the screening test is above a set cut-off level or if a patient is 40 years old at the time of the birth,

BOX 13.4 Common Maternal and Fetal Indications for Antepartum Testing

- Diabetes
- Pre-existing hypertension
- Pre-eclampsia
- Systemic lupus erythematosus
- Renal disease
- Cholestasis of pregnancy
- Multiple gestation
- Oligohydramnios
- Preterm premature rupture of membranes
- Postdate or post-term gestation
- Previous stillbirth
- Fetal growth restriction
- Decreased fetal movement

From Miller, L. A., Miller, D. A., & Tucker, S. M. (2013). *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* (7th ed.). Mosby.

invasive testing should be offered (amniocentesis or chorionic villus sampling; see discussion later in this chapter). There are regional differences across the country as to what screening tests are available, based on cost and the availability of trained ultrasound technicians. There are presently four options available for noninvasive screening, discussed next.

Enhanced First-Trimester Screening (eFTS). Enhanced first-trimester screening (eFTS) involves an ultrasound examination for nuchal translucency, combined with assessment of maternal serum biochemical markers done between 11 and 14 weeks' gestation. In *nuchal translucency* (NT) screening, ultrasound measurement of fluid in the nape of the fetal neck is used to identify possible fetal abnormalities (Figure 13.1). A finding of fluid collection that is greater than 3 mm is highly indicative of genetic disorders or physical anomalies. It is then appropriate to offer the option of further diagnostic testing. A finding of 3.5 or greater increases the risk of a congenital heart defect, and a fetal echocardiogram would be recommended in the second trimester.

First-trimester maternal serum biochemical markers are pregnancy-associated plasma protein-A (PAPP-A) and free beta-human chorionic gonadotropin (ß-hCG). PAPP-A is lower in Down syndrome pregnancies and free ß-hCG is higher. eFTS using all the criteria will detect 78 to 91% cases of Down syndrome, and 91 to 96% of trisomy 18 with a 5% false-positive rate (Audibert et al., 2017; Wilson et al., 2014). It is also recommended that the patient be screened for open neural tube defects (NTDs) at an 18- to 22-week ultrasound examination. A limitation of eFTS is its lack of availability in some centres.

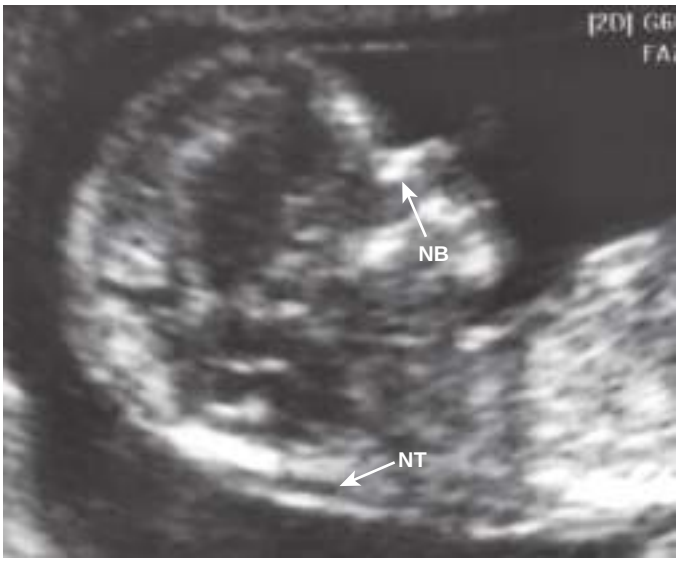

Fig. 13.1 Midsagittal view of a 12-week fetus showing the nuchal translucency *(NT)* and nasal bone *(NB)*.

Second-Trimester Serum Screening. Maternal serum alpha-fetoprotein (MSAFP) levels are used as a screening tool for NTD in pregnancy. Through this technique, approximately 71 to 90% of all open NTDs and open abdominal wall defects can be detected early in pregnancy, although the Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends that the primary use of MSAFP for screening for open or closed NTDs be discontinued unless there is a barrier to good-quality ultrasound examination at 18 to 22 weeks' gestation (Audibert et al., 2017). A detailed second-trimester ultrasound screen is better able to detect anomalies. MSAFP may also be used if someone presents too late in prenatal care to have first-trimester screening.

AFP is produced by the fetal liver and is detectable in increasing quantities in the serum of pregnant patients at 14 to 34 weeks' gestation. Although amniotic fluid AFP is diagnostic for NTD, MSAFP is a screening tool only and identifies candidates for the more definitive procedures of amniocentesis and ultrasound examination. MSAFP screening can be done with reasonable reliability any time between 15 and 20 weeks of gestation (Driscoll et al., 2017). Elevated levels are associated with other conditions such as fetal skin disorders, abdominal wall defects, fetal demise, and pregnancies at risk for placenta-related adverse events. Down syndrome—and probably other autosomal trisomies—is associated with lower than normal levels of MSAFP and amniotic fluid AFP.

Cell-Free DNA Screening. The newest screening test for aneuploidy, **cell-free DNA (cfDNA)**, is performed using a sample of maternal blood. The cfDNA screening test is an example of noninvasive prenatal testing (NIPT). Maternal plasma contains small fragments of cfDNA, resulting from the breakdown of both maternal and fetal cells (Driscoll et al., 2017; Latendresse & Deneris, 2015). Normal amounts of cfDNA, which vary throughout pregnancy, are known and compared with those obtained from the maternal sample. The test cannot actually distinguish fetal from maternal DNA, but it can accurately predict the fetal status by measuring the amount of cfDNA circulating in maternal blood and comparing it with known standards. If the fetus has a normal karyotype, the amount of DNA is consistent with the known standard for the normal amount. However, if more than the expected amount of chromosome 21 DNA is detected, it can then be assumed that the fetus is contributing the extra amount and therefore has trisomy 21. The same is true for trisomy 13 and 18. The test has a detection rate of more than 99% for trisomies 21 and 18 but a lower rate (approximately 80%) for trisomy 13 (Latendresse & Deneris, 2015). Patients should understand that although the cfDNA screen results nearly match those of diagnostic tests, cfDNA is still a screening test. Therefore, patients with positive cfDNA results are referred for amniocentesis or chorionic villus sampling (CVS) to confirm the findings (Harraway, 2017).

The accuracy of the test depends on the proportion of fetal-to-maternal DNA in the maternal plasma, which must be at least 4%.

As pregnancy progresses, the fetal contribution to the amount of cfDNA in maternal circulation increases. cfDNA screening for the detection of fetal chromosomal abnormalities is optimally performed at 10 to 12 weeks of gestation, by which time the average fetal DNA fraction should have reached approximately 10% of the maternal DNA (Driscoll et al., 2017; Latendresse & Deneris, 2015). The test is offered to patients considered to be at risk for chromosomal abnormalities (i.e., aneuploidies), including those with advanced maternal age, screen-positive maternal serum screens, or ultrasound abnormalities. Patients who have previously given birth to a child with a chromosomal abnormality are also candidates for the screening (Harraway, 2017; Latendresse & Deneris, 2015; Murdoch et al., 2017). The cfDNA test is simple to perform; a sample of maternal blood is obtained by venipuncture and sent to a commercial laboratory. Results are usually available in about 10 days. The test is less sensitive in women who are obese. Currently, cfDNA testing is not recommended for use in multifetal pregnancies (Latendresse & Deneris, 2015). Available results early in pregnancy either provide reassurance to the patient and family or assist in determining next steps in testing prior to decision making about this pregnancy.

At this time, the cost of this test is covered only upon consultation with a genetic counsellor or obstetrician and on the basis of risk factors such as a previous history of congenital anomaly or concerning test results in this pregnancy. Alternatively, patients can choose to pay for this test themselves if they wish to have these results (Audibert et al., 2017; Harraway, 2017).

Nurses play a role in ensuring that patients receive the information they need to make decisions about genetic testing in pregnancy. Use of infographics and translators to ensure that pregnant patients understand testing they are being offered is important to informed decision making (Shea, 2020).

Ultrasound. Diagnostic ultrasonography is an important, safe technique in antepartum fetal surveillance. It is considered by many to be the most valuable diagnostic tool used in obstetrics (Richards, 2017). It provides critical information to health care providers regarding fetal activity and **gestational age**, normal versus abnormal fetal growth curves, visual assistance with which invasive tests may be performed more safely, and fetal and placental anatomy early in pregnancy. Ultrasound examination done later during pregnancy is used to assess fetal well-being, and is discussed later in the chapter.

Sound is a form of wave energy that causes small particles in a medium to oscillate. The *frequency* of sound, which refers to the number of peaks or waves that move over a given point per unit of time, is expressed in hertz (Hz). Sound with a frequency of one cycle, or one peak per second, has a frequency of 1 Hz. When directional beams of sound strike an object, an echo is returned. The time delay between the emission of the sound and the return of the echo and the direction of the echo are noted. From these data, the distance and location of an object can be calculated. **Ultrasound** is sound frequency higher than that detectable by humans (greater than 20 000 Hz). Ultrasound images are a reflection of the strength of the sending beam, the strength of the returning echo, and the density of the medium (e.g., muscle [uterus], bone, tissue [placenta], fluid, or blood) through which the beam is sent and returned.

Ultrasound examination can be done abdominally or transvaginally during pregnancy. Ultrasound scans produce a two- or three-dimensional view of the area being examined and can be used to create pictorial images (Figure 13.2, *A* and *B*). Abdominal ultrasonography is more useful after the first trimester when the pregnant uterus becomes an abdominal organ.

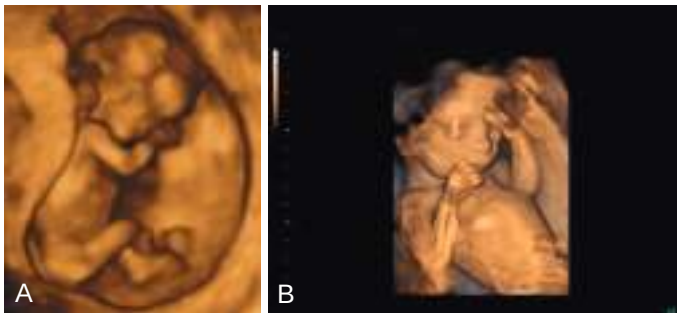

Fig. 13.2 Fetus seen on three-dimensional ultrasound. **A:** Full body view of fetus at 11 weeks and 6 days of gestation. **B:** Close-up view of fetal face later in pregnancy. (**A,** Courtesy Shannon Perry; **B,** Courtesy Margaret Spann.)

For the procedure, the patient is usually required to have a full bladder to push the uterus up in order to get a better image of the fetus. Transmission gel is applied to the abdomen before a transducer is moved over the skin to enhance transmission and reception of the sound waves. The patient is positioned with small pillows under their head and knees. The display panel is positioned so that the patient and their partner can observe the images on the screen if they so desire.

Transvaginal ultrasound, in which the probe is inserted into the vagina, allows pelvic anatomy to be evaluated in greater detail and enables earlier diagnosis of intrauterine pregnancy. It is used in the first trimester to detect ectopic pregnancies, monitor the developing embryo, help identify abnormalities, and help establish gestational age. In some instances it may be used as an adjunct to abdominal scanning to evaluate preterm labour, by assessing the cervical length, in second- and third-trimester pregnancies. A transvaginal ultrasound examination is well tolerated by most patients because it alleviates the need for a full bladder. It is especially useful in obese patients, whose thick abdominal layers cannot be penetrated adequately with an abdominal approach.

A transvaginal ultrasound examination may be performed either with the patient in a lithotomy position or with their pelvis elevated by towels, cushions, or a folded pillow. This pelvic tilt is optimal to image the pelvic structures. A protective cover such as a condom, the finger of a clean rubber surgical glove, or a special cover provided by the manufacturer is used to cover the probe. The probe is lubricated with a water-soluble gel and placed in the vagina either by the examiner or by the patient themselves. During the examination, the position of the probe or the tilt of the examining table may be changed to view the complete pelvis. The procedure is not physically painful, although the patient will feel pressure as the probe is moved.

Indications for use. Major indications for the use of obstetrical ultrasound are shown by trimester in Box 13.5. Ultrasonography can lead to earlier diagnoses, allowing therapy to be instituted early in pregnancy and thus in many cases decreasing the severity and duration of morbidity, both physical and emotional, for the family. For example, early diagnosis of a fetal anomaly gives the family choices, such as (1) preparation for the care of a newborn with a disorder, (2) intrauterine surgery or other therapy for the fetus, or (3) termination of the pregnancy.

Fetal heart activity. Fetal heart activity can be demonstrated by about 6 weeks of gestation using transvaginal ultrasound. When the fetus is in a favourable position, good views of the fetal cardiac anatomy are possible in most patients at 13 weeks of gestation (Richards, 2017).

BOX 13.5 Major Uses of Ultrasonography During Pregnancy

First Trimester
Confirm pregnancy
Confirm viability
Determine gestational age
Rule out ectopic pregnancy
Detect multiple gestation
Determine cause of vaginal bleeding
Use for visualization during chorionic villus sampling
Detect maternal abnormalities such as bicornuate uterus, ovarian cysts, fibroids
Assess nuchal translucency

Second Trimester
Assess fetal anatomy
Establish or confirm dates
Confirm viability
Detect polyhydramnios, oligohydramnios
Detect congenital anomalies, including neural tube defects
Detect intrauterine growth restriction (IUGR)
Assess placental placement and abnormal implantation
Assess cervical length
Use for visualization during amniocentesis

Third Trimester
Confirm viability
Detect macrosomia
Detect congenital anomalies
Detect IUGR
Determine fetal position
Detect placenta previa or placental abruption
Use for visualization during amniocentesis, external version
Biophysical profile
Assess amniotic fluid volume
Doppler flow studies
Detect placental maturity
Detect presenting part in labour, i.e., vertex or other fetal presentation

Fetal death can be confirmed by lack of heart motion; the presence of fetal scalp edema, and maceration; and overlap of the cranial bones.

Gestational age. Gestational dating by ultrasonography is indicated for conditions such as the following: (1) uncertain dates for the last normal menstrual period, (2) recent discontinuation of oral contraceptives, (3) bleeding during the first trimester, (4) uterine size that does not agree with dates, and (5) other high-risk conditions.

During the first 20 weeks of gestation, ultrasonography provides an accurate assessment of gestational age because most healthy fetuses grow at the same rate. With increased fetal age, the accuracy of gestational-age estimates using ultrasound decreases, as fetuses grow at different rates. First-trimester dating by crown–rump length has an accuracy of plus or minus 3 to 5 days for estimating gestational age, compared to the 7-day window for 18- to 22-week ultrasound, and should be used whenever possible for determining gestational age (Butt & Lim, 2019). A standard set of measurements has been accepted as being most useful for determining gestational age: the crown–rump length in the first trimester, and in the second and third trimesters, a combination of biparietal diameter, head circumference, abdominal circumference, and femur length (Butt & Lim, 2019) (Figure 13.3).

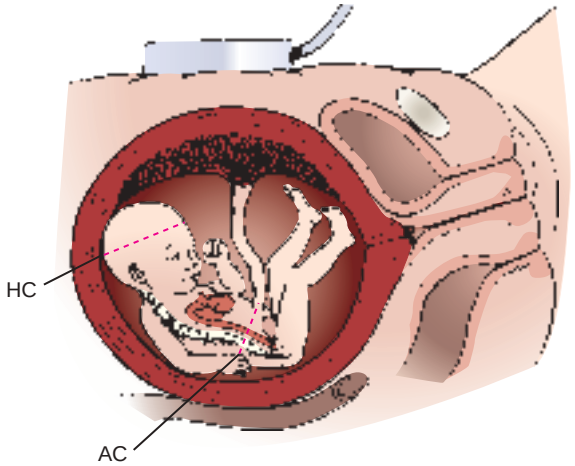

Fig. 13.3 Appropriate planes of sections *(dotted lines)* for head circumference *(HC)* and abdominal circumference *(AC)*.

Fetal growth. Fetal growth is determined by intrinsic growth potential and environmental factors that may enhance or inhibit that growth. Conditions that indicate the need for ultrasound assessment of fetal growth include slow maternal weight gain or pattern of weight gain, previous pregnancy with IUGR, chronic infections, ingestion of drugs (tobacco, alcohol, over-the-counter medications, and street drugs), maternal diabetes, hypertension, multifetal pregnancy, and other medical or surgical complications.

Serial evaluations of biparietal diameter (BPD), head circumference, limb length, and abdominal circumference can differentiate among size discrepancy resulting from inaccurate dates, true IUGR, and macrosomia. IUGR may be symmetrical (the fetus is small in all parameters) or asymmetrical (head and body growth vary). Symmetrical IUGR implies a chronic or long-standing insult and may be caused by low genetic growth potential, intrauterine infection, undernutrition, heavy smoking, or chromosome aberration. Asymmetrical growth reflects an acute or late-occurring deprivation such as placental insufficiency resulting from hypertension, renal disease, or cardiovascular disease. Reduced fetal growth is still one of the most frequent conditions associated with stillbirth.

Macrosomic newborns (those weighing 4 000 g or more) are at increased risk for dystocia, traumatic injury, and asphyxia during birth. Macrosomia in the infant of a mother with diabetes is asymmetrical and characterized by increases in fat and muscle in the abdomen and shoulders; head circumference remains normal. Macrosomia in an infant whose mother is obese without glucose intolerance results in symmetrical changes (i.e., excessive growth of abdominal and head circumferences).

Fetal anatomy. Depending on the gestational age, the following structures can be identified on ultrasound scans: head (including ventricles and blood vessels), neck, spine, heart, stomach, small bowel, liver, kidneys, bladder, limbs, and umbilical cord. The SOGC recommends that all patients be offered a routine second-trimester ultrasound examination between 18 and 22 weeks. Second-trimester ultrasonography is used for the detection of fetal anomalies including NTDs, assessment for multiple fetuses, location of placenta, and gestational age, and a complete anatomical scan should be performed. The SOGC recommends that second-trimester ultrasound be the primary screening tool for fetal structural abnormalities including open and

closed NTDs (anencephaly, encephalocele, and spina bifida) (Cargill & Morin, 2017). The presence of an anomaly may influence decisions regarding where the birth takes place, whether a specialist or multidisciplinary team is needed for the rest of the pregnancy (e.g., a subspecialty centre instead of a basic care centre), and the method of birth (vaginal versus Caesarean) to optimize newborn outcomes.

Placental position and function. One of the major advantages of ultrasound is its ability to diagnose serious complications related to placental location in a timely manner. Between 18 and 23 weeks of gestation, the edge of the placenta extends to or covers the internal os of the cervix in about 2% of pregnancies. However, most cases of placenta previa diagnosed during the second trimester resolve by term, primarily because of the elongation of the lower uterine segment as pregnancy advances. Therefore, if placenta previa is diagnosed during the second trimester, repeated ultrasounds should be performed as pregnancy progresses until the placenta moves well away from the cervical os or it becomes clear that the previa will persist (Richards, 2017).

Another use for ultrasound is assessment of placental appearance. Many changes observed in the placenta are related to calcification, fibrosis, and infarction. These changes tend to become more apparent as pregnancy progresses, but their clinical significance is not clear. It has recently been recognized that a "globular" placenta, with a narrow base in comparison to height, is associated with an increased rate of IUGR, fetal death, and other complications (Richards, 2017).

Nursing role. The main role of nurses in obstetrical ultrasound examination is in counselling and educating patients about ultrasound scans. Providing accurate information about the procedure is imperative to allay the mother's anxiety. Although ultrasound scanning has become a widely used diagnostic tool, recommendations for the procedure are based on expectations of a fetal anomaly and thus may cause concern. Unlike many diagnostic tests, most patients look forward to and enjoy their prenatal ultrasound. Exposure to diagnostic ultrasonography during pregnancy appears to be safe for the fetus. Nevertheless, because there is the possibility that unrecognized harm exists, ultrasound should be used only by qualified health providers, to offer medical benefit to patients (Richards, 2017).

Nonmedical use of ultrasonography during pregnancy. The use of three- and four-dimensional ultrasonography for nonmedical purposes has become increasingly popular with pregnant patients and their families. Although insurance does not cover the cost, patients can make appointments to have ultrasound images made of the fetus, just as professional photographs are often taken of infants and children. The SOGC and Canadian Association of Radiologists state that although ultrasonography is considered safe, exposure of the fetus to high-frequency sound waves without a clear medical indication for doing so should be avoided (Salem et al., 2019). In addition, casual ultrasonography performed by people who are not qualified health care providers could give false reassurance to patients or result in the discovery of abnormalities in settings that are not conducive to discussion and follow-up of findings. This technology should not be used for the sole purpose of determining fetal gender without a medical indication for that scan (Salem et al., 2019).

Biochemical Assessment

Biochemical assessment involves biological examination (e.g., chromosomes in exfoliated cells) and chemical determinations (e.g., lecithin/sphingomyelin [L/S] ratio and bilirubin level) (Table 13.1). Procedures used to obtain the specimens for study include amniocentesis, percutaneous umbilical blood sampling (PUBS), CVS, and maternal sampling.

TABLE 13.1 Summary of Biochemical Monitoring Techniques

Test	Possible Findings	Clinical Significance
Maternal Blood		
Coombs' test	Titre of 1:8 and rising	Significant Rh incompatibility
Cell-free DNA screening	Greater than normal amount of DNA from specific chromosomes	Fetus with trisomy 13, 18, or 21
Amniotic Fluid Analysis		
Lung profile		
L/S ratio	2:1	Fetal lung maturity
Phosphatidylglycerol	Present	Fetal lung maturity
Creatinine	>150 mcmol/L	Gestational age >36 weeks
Bilirubin (ΔOD 450 nm)*	<0.015	Gestational age >36 weeks, normal pregnancy
	High levels	Fetal hemolytic disease in Rh-isoimmunized pregnancies
Lipid cells	>10%	Gestational age >35 weeks
AFP	High levels after 15 weeks of gestation	Open neural tube or other defect
Osmolality	Decline after 20 weeks of gestation	Advancing gestational age
Genetic disorders Sex-linked Chromosomal Metabolic	Dependent on cultured cells for karyotype and enzymatic activity	Counselling possibly required

AFP, Alpha-fetoprotein; *L/S,* lecithin/sphingomyelin.
*The presence of bilirubin changes the colour of amniotic fluid. The change in optical density (ΔOD) is a measure of the amount of bilirubin in the amniotic fluid.

Coombs' Test. The indirect Coombs' test is a screening tool for Rh incompatibility. If the maternal titre for Rh antibodies is greater than 1:8, amniocentesis for determination of bilirubin in amniotic fluid is indicated to establish the severity of fetal hemolytic anemia. However, middle cerebral artery Doppler studies to determine the degree of fetal hemolysis have almost entirely replaced serial amniocentesis (Moise, 2017). The Coombs' test can also detect other antibodies that may place the fetus at risk for incompatibility with maternal antigens.

Amniocentesis. Amniocentesis is performed to obtain amniotic fluid, which contains fetal cells. Under direct ultrasound visualization, a needle is inserted transabdominally into the uterus, amniotic fluid is withdrawn into a syringe, and various assessments are performed on the fluid sample (Figure 13.4). Amniocentesis is possible after week 14 of pregnancy, when the uterus becomes an abdominal organ and sufficient amniotic fluid is available for testing (see Table 13.1). Indications for the procedure include prenatal diagnosis of genetic disorders or congenital anomalies (NTDs in particular), assessment of pulmonary maturity, and, rarely, diagnosis of fetal hemolytic disease.

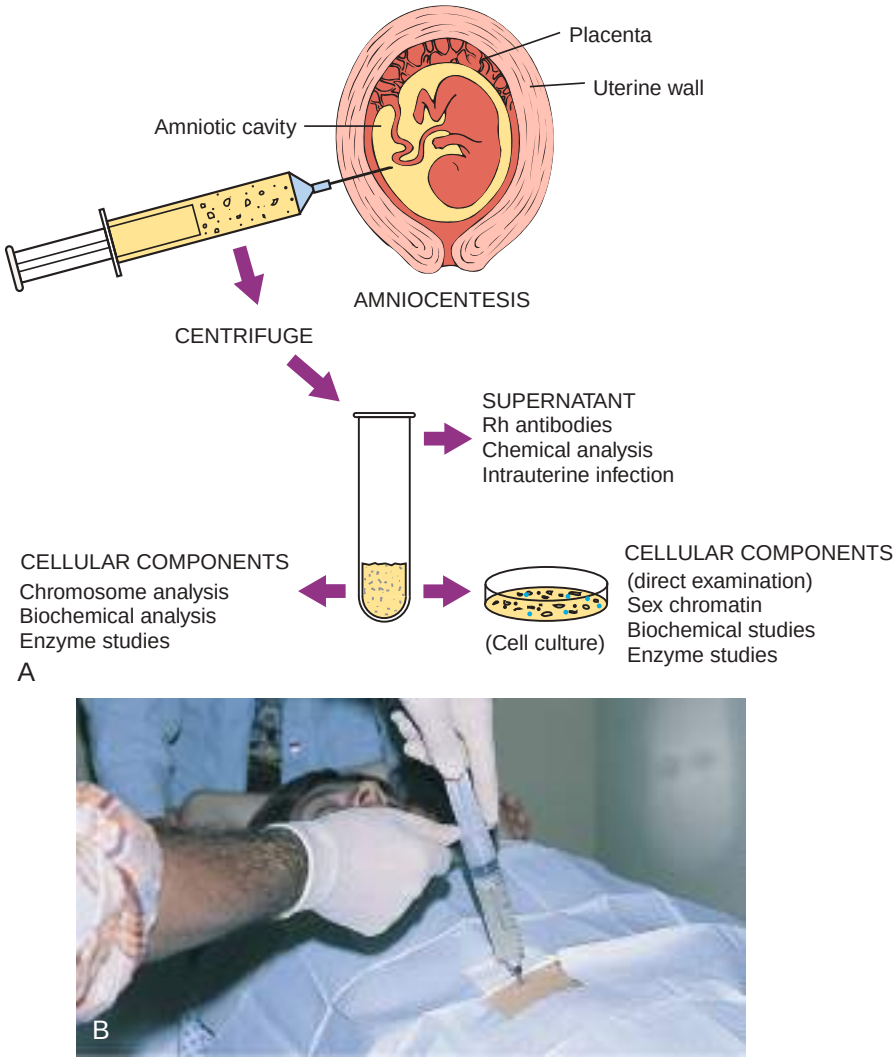

Fig. 13.4 **A:** Amniocentesis and laboratory use of amniotic fluid aspirant. **B:** Transabdominal amniocentesis. (**B,** Courtesy Marjorie Pyle, RNC, Lifecircle.)

Complications in the mother and fetus occur in less than 1% of cases and include the following:

Maternal—Leakage of amniotic fluid, hemorrhage, fetomaternal hemorrhage with possible maternal Rh isoimmunization, infection, labour, placental abruption, inadvertent damage to the intestines or bladder, and amniotic fluid embolism (anaphylactoid syndrome of pregnancy)

Fetal—Death, hemorrhage, infection (amnionitis), direct injury from the needle

Many of these complications have been minimized or eliminated by using ultrasound scanning to determine the exact position of the fetus, placenta, and pockets of amniotic fluid.

SAFETY ALERT

Because of the possibility of fetomaternal hemorrhage, administering RhoD immunoglobulin to the patient who is Rh negative is standard practice after an amniocentesis.

Indications for use.

Genetic concerns. The incidence of genetic disorders is increased in pregnant patients older than 35 years, those with a previous child with a chromosome abnormality, or those with a family history of chromosome anomalies. Nonetheless, the SOGC has stated that screening based on maternal age should be abandoned, except for patients over the age of 40 at the time of birth, and that all patients should be offered noninvasive screening for Down syndrome or trisomy 18. Older patients should have the option of going automatically to CVS or amniocentesis, as should patients who screen above a set risk cut-off level (Audibert et al., 2017).

Fetal cells can be cultured for **karyotyping** of chromosomes (see Chapter 9). Karyotyping also permits determination of fetal gender, which is important if a sex-linked disorder (occurring almost always in a male fetus) is suspected.

Biochemical analysis of enzymes in amniotic fluid can be used to detect inborn errors of metabolism or fetal structural anomalies. For example, AFP levels in amniotic fluid are assessed as a follow-up for elevated levels in maternal serum. High AFP levels in amniotic fluid help confirm the diagnosis of an open NTD, such as spina bifida or anencephaly, or an open abdominal wall defect, such as omphalocele. The elevation results from the increased leakage of cerebrospinal fluid into the amniotic fluid through the closure defect. AFP levels also may be elevated in a normal multifetal pregnancy and with intestinal atresia, presumably caused by lack of fetal swallowing.

Fetal maturity. Late in pregnancy, accurate assessment of fetal lung maturity is possible by examining amniotic fluid for the presence of phosphatidylglycerol (PG) or determination of the L/S ratio (see Table 13.1). However, because both of these tests require considerable time, technical expertise, and cost to perform, they are generally used as primary tests only in special clinical circumstances. They may also be used as secondary tests if simpler and less expensive automated tests indicate lung immaturity.

Fetal hemolytic disease. In the past, amniocentesis was used for identification and follow-up of fetal hemolytic disease in cases of isoimmunization. Amniocentesis is now only performed for this reason in rare circumstances because of the availability of noninvasive testing. Doppler velocimetry of the fetal middle cerebral artery is now the method of choice to monitor accurately and noninvasively for fetal anemia in isoimmunized pregnancies (Moise, 2017).

Chorionic Villus Sampling. The combined advantages of earlier diagnosis and rapid results have made **chorionic villus sampling (CVS)** a popular technique for genetic studies in the first trimester. Indications for CVS are similar to those for amniocentesis, although CVS cannot be used for maternal serum marker screening because no fluid is obtained. CVS performed in the second trimester carries no greater risk for pregnancy loss than amniocentesis and is considered equal to amniocentesis in diagnostic accuracy. When performed after the first trimester, the procedure is better known as *late CVS* or *placental biopsy* (Driscoll et al., 2017).

CVS can be performed in the first or second trimester, ideally between 10 and 13 weeks of gestation, and involves the removal of a small tissue specimen from the fetal portion of the placenta (Driscoll et al., 2017). Because chorionic villi originate in the zygote, this tissue reflects the genetic makeup of the fetus.

CVS procedures can be accomplished either transcervically or transabdominally. In transcervical sampling, a sterile catheter is introduced through the cervical canal toward the placenta under continuous ultrasonographic guidance, and a small portion of the chorionic villi is aspirated with a syringe (Figure 13.5) (Driscoll et al., 2017). The aspiration cannula and obturator must be placed at a suitable site, and rupture of the amniotic sac must be avoided. The transcervical procedure is contraindicated if a cervical infection such as chlamydia or herpes is present.

If the abdominal approach (Figure 13.6) is used, an 18-gauge spinal needle with stylet is inserted under sterile conditions through the abdominal wall into the chorion frondosum under ultrasonographic guidance. The stylet is then withdrawn, and the chorionic tissue is aspirated into a syringe.

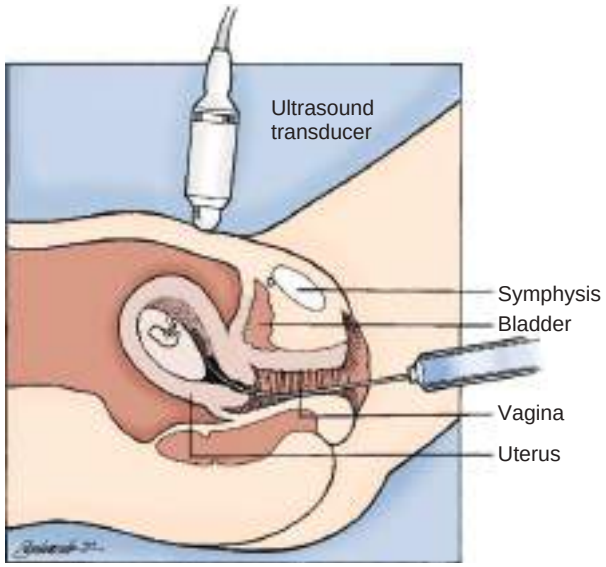

Fig. 13.5 Transcervical chorionic villi sampling. (From Gabbe, S., Niebyl, J., Simpson, J., et al. [Eds.]. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Saunders.)

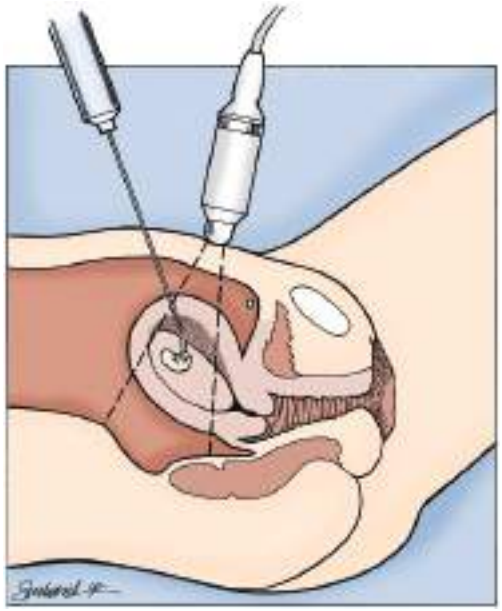

Fig. 13.6 Transabdominal chorionic villus sampling. (From Gabbe, S., Niebyl, J., Simpson, J., et al. [Eds.]. [2012]. *Obstetrics: Normal and problem pregnancies* [6th ed.]. Saunders.)

CVS is a relatively safe procedure. The incidence of IUGR, placental abruption, and preterm birth is no higher in patients undergoing CVS than would be expected in the general population. In the early 1990s there was controversy concerning an increased risk for fetal limb reduction defects associated with CVS. However, the consensus of further studies is that, when CVS is performed after 9 completed weeks of gestation, the risk for limb reduction defects is no higher than it is in the general population (Driscoll et al., 2017). See Box 13.6 regarding related fetal rights. Because of the possibility of fetomaternal hemorrhage, pregnant patients who are Rh negative should receive Rh immune globulin to avoid isoimmunization.

Because amniocentesis and CVS are invasive tests, their use is associated with a small but concerning risk for pregnancy loss and infection. Noninvasive diagnostic tests may someday replace them. These tests are able to isolate and analyze fetal DNA in maternal serum to diagnose multiple disorders such as single-gene disorders and chromosomal aberrations, in addition to trisomies (Latendresse & Deneris, 2015).

Percutaneous Umbilical Blood Sampling. Direct access to the fetal circulation during the second and third trimesters is possible through PUBS (also called *cordocentesis*). PUBS can be used for fetal blood sampling and transfusion. However, PUBS has been replaced in many centres by placental biopsy because it is a safer, easier, and faster alternative. Also, improvements in cytogenetic and molecular diagnostic testing have decreased the need for fetal blood samples.

BOX 13.6 Fetal Rights

Amniocentesis, percutaneous umbilical blood sampling, and chorionic villus sampling are prenatal tests used for diagnosing fetal defects in pregnancy. They are invasive and carry risks to the mother and fetus. A consideration of elective abortion is linked to the performance of these tests because there is no treatment for genetically affected fetuses. Thus, the issue of fetal rights is a key ethical concern in prenatal testing for fetal defects.

Many tests that were once performed using fetal blood can now be done using DNA-based analysis of chorionic villi (Driscoll et al., 2017).

PUBS involves the insertion of a needle directly into a fetal umbilical vessel, preferably the vein, under ultrasound guidance (Figures 13.7 and 13.8). Puncture of the umbilical cord near its insertion into the placenta is technically easier but is associated with a higher risk for contamination with maternal blood. Alternatively, free loops of umbilical cord or the intrahepatic vein may be used as puncture sites instead. Generally, a small amount of blood is removed and tested immediately to ensure that it is fetal in origin (Driscoll et al., 2017). The most common genetic indication for the use of PUBS is evaluation of mosaic results found on amniocentesis or CVS, when a sample of fetal blood is required to determine the specific mutation. PUBS is also used to assess for fetal anemia, infection, and thrombocytopenia (Wapner, 2019). Bleeding from the cord puncture site is the most common complication of the procedure. Transient fetal bradycardia can also occur. Maternal complications are rare but include amnionitis and transplacental hemorrhage (Driscoll et al., 2017).

THIRD-TRIMESTER ASSESSMENT FOR FETAL WELL-BEING

Assessment during the first and second trimesters is directed primarily at the diagnosis of fetal anomalies. The goal of third-trimester testing is to determine whether the intrauterine environment continues to be supportive to the fetus. The testing is often used to determine the timing of childbirth for patients at risk for uteroplacental insufficiency. Gradual loss of placental function results first in inadequate nutrient delivery to the fetus, leading to IUGR. Subsequently, respiratory function is compromised, resulting in fetal hypoxia. Indications for increased fetal surveillance in the third trimester, which includes fetal movement counting, nonstress test (NST), contraction stress test (CST), biophysical profile (BPP), and other ultrasound tests, are listed in Box 13.7. There is presently no evidence to suggest the use of antenatal fetal testing in uncomplicated pregnancies less than 41 weeks' gestation (Liston et al., 2018).

BOX 13.7 Indications Associated With Increased Perinatal Morbidity or Mortality When Antenatal Fetal Surveillance May Be Beneficial

Previous Obstetrical History

Maternal	Hypertensive disorder of pregnancy
	Placental abruption
Fetal	Intrauterine growth restriction
	Stillbirth

Current Pregnancy

Maternal	Late-term pregnancy (>294 days, >41 weeks)
	Hypertensive disorders of pregnancy
	Pregestational diabetes
	Insulin requiring gestational diabetes
	Preterm premature rupture of membranes
	Chronic (stable) abruption
	Isoimmunization
	Abnormal maternal serum screen in absence of confirmed fetal anomaly
	Motor vehicle accident during pregnancy
	Vaginal bleeding
	Morbid obesity
	Advanced maternal age
	Assisted reproductive technologies
Fetal	Decreased fetal movement
	Intrauterine growth restriction
	Suspected oligohydramnios/polyhydramnios
	Multiple pregnancy
	Preterm labour

Fetal Movement Counting

Assessment of fetal activity by the mother is a simple yet valuable method for monitoring the condition of the fetus. All patients should be taught to become aware of fetal movements in the third trimester, and only if they perceive decreased movement or have risk factors should they begin daily monitoring or counting of fetal movements. Fetal movement counting (also called "kick counts") can be done at home, is simple to understand, is noninvasive, and usually does not interfere with a daily routine. The presence of movements is generally a reassuring sign of fetal health. Decreased fetal movement can be related to decreased placental perfusion and fetal acidemia.

Patients should be taught the significance of the presence or absence of fetal movements, the procedure to use for counting, and when to notify their health care provider. For fetal movement counting the patient concentrates on the movements in a reclined (not supine) position. The recommended technique is to count six movements. If six movements are not felt within 2 hours, further evaluation of maternal and fetal status is required (Liston et al., 2018). This would initially include an NST or BPP (Figure 13.9).

! NURSING ALERT

In assessing fetal movements it is important to remember that they are usually not present during the fetal sleep cycle; they may be temporarily reduced if the patient is taking depressant medication, drinking alcohol, or smoking a cigarette. They do not decrease as the patient nears term. Obesity and an anterior placenta decrease perception of fetal movement and, consequently, the ability of the mother to count fetal movements.

Antepartum Assessment Using Electronic Fetal Monitoring

Electronic fetal heart monitoring is the most common method of fetal assessment (O'Brien-Abel, 2020). Observable fetal responses to hypoxia or asphyxia are the clinical basis for antepartum testing with electronic fetal monitoring (EFM). Hypoxia or asphyxia elicits a number of responses in the fetus. There is a redistribution of blood flow to certain vital organs. This series of responses, including redistribution of blood flow favouring vital organs, decreased total oxygen consumption, and a switch to anaerobic glycolysis, is a temporary mechanism that enables

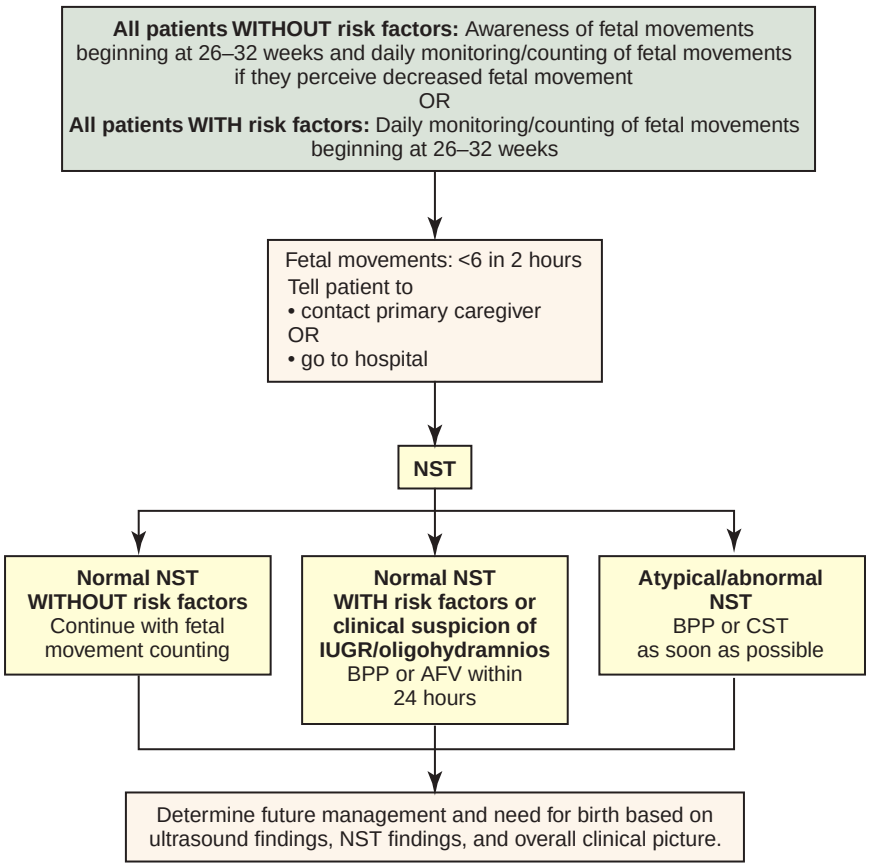

Fig. 13.9 Fetal movement algorithm. *AFV*, Amniotic fluid volume; *BPP*, biophysical profile; *CST*, contraction stress test; *IUGR*, intrauterine growth restriction; *NST*, nonstress test. (From Liston, R., Sawchuck, D., Young, D., et al. [2018]. Copyright 2007, with permission from Elsevier.)

the fetus to survive up to 30 minutes with limited oxygen supply without decompensation of vital organs. However, during more severe asphyxia or sustained hypoxemia, these compensatory responses are no longer maintained and a decrease in the cardiac output, arterial blood pressure, and blood flow to the brain and heart occurs (O'Brien-Abel, 2020), with characteristic fetal heart rate (FHR) patterns reflecting these changes.

Considerable evidence supports the clinical belief that FHR variability indicates an intact nervous pathway through the cerebral cortex, midbrain, vagus nerve, and cardiac conduction system. With 98% accuracy in predicting fetal well-being, the presence of normal FHR variability is an indicator of normal function. Input from various areas of the brain decreases after cerebral asphyxia, leading to a decrease in variability after failure of the fetal hemodynamic compensatory mechanisms to maintain cerebral oxygenation (O'Brien-Abel, 2020). As a rule, normal patterns with the NST or negative results with the CST are associated with favourable outcomes.

Nonstress Test. The **nonstress test (NST)** is the most widely applied technique for antepartum evaluation of the fetus, although there is poor evidence that use of NSTs decreases perinatal morbidity or mortality. The basis for the NST is that the normal fetus produces characteristic heart rate patterns in response to fetal movement. In the healthy fetus with an intact central nervous system, 85% of gross fetal body movements are associated with FHR accelerations. The acceleration with movement response may be blunted by hypoxia, acidosis, medications (analgesics, barbiturates, and β-blockers), fetal sleep, and some congenital anomalies (Greenberg, & Druzin, 2017).

The NST can be performed easily and quickly in an outpatient setting; it is noninvasive and has no known contraindications. Disadvantages centre on the high rate of false-positive results for atypical or abnormal tracings as a result of fetal sleep cycles, chronic tobacco smoking, medications, and fetal immaturity. The test is slightly less sensitive in detecting fetal compromise than the CST or BPP. No clinical contraindications exist for the NST, but results may be inconclusive if gestation is 26 weeks or less.

Procedure. The pregnant patient should have an empty bladder and be seated in a reclining chair (or in a semi-Fowler position) with a slight left tilt, to optimize uterine perfusion and avoid supine hypotension. The FHR is recorded with a Doppler transducer, and a tocodynamometer is applied to detect uterine contractions or fetal movements. The tracing is observed for signs of fetal activity and a concurrent acceleration of FHR. If evidence of fetal movement is not apparent on the tracing, the patient may be asked to depress a button on a handheld event marker connected to the monitor when they feel fetal movement. The movement is then noted on the tracing. Because almost all accelerations are accompanied by fetal movements, the movements need not be recorded for the test to be considered reactive. The test usually is completed in 20 minutes but should continue for up to 80 minutes if the response is not normal.

Administering glucose to the mother or stimulating the abdomen to encourage fetal movement is not recommended, as research has not proven either technique to be effective (Liston et al., 2018). Only **vibroacoustic stimulation** has had some impact on stimulating fetal movement, although it is not recommended because research has not concluded that this is safe or reliable (Liston et al., 2018).

Interpretation. NST results are either normal, atypical, or abnormal. Figure 13.10 and Table 13.2 list criteria for the results for a term and a preterm fetus.

Fig. 13.10 Normal nonstress test. Fetal heart rate accelerations with fetal movement. (From Miller L. A., Miller D. A., & Tucker, S. M. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. Mosby.)

An abnormal tracing persistently lacks accelerations after 80 minutes or contains significant abnormality of baseline heart rate or variability or shows evidence of significant decelerations (Figure 13.11 and see Table 13.2). In this case, further assessments are needed with a BPP. In most cases, a normal NST is predictive of a good perinatal outcome for 1 week as long as there are no changes to the clinical picture, except in patients with insulin-dependent diabetes or postdates pregnancy. In these patients, NSTs should be done twice weekly (Liston et al., 2018).

Contraction Stress Test. The **contraction stress test (CST)** or **oxytocin challenge test (OCT)** was the first widely used electronic fetal assessment test. Its purpose is to evaluate the response of the fetus to induced contractions and to thus identify poor placental function (Liston et al., 2018). Uterine contractions decrease uterine blood flow and placental perfusion. If this decrease is sufficient to produce hypoxia in the fetus, a deceleration in FHR results.

The CST provides an earlier warning of fetal compromise than the NST and produces fewer false-positive results. Like most methods of antepartum fetal surveillance, however, it cannot predict acute fetal compromise (e.g., umbilical cord accidents, placental abruption, or rapid deterioration of glucose control in a patient with diabetes). The CST is more time-consuming to perform than the NST. It is also an invasive procedure if oxytocin stimulation is required. In general, the CST cannot be performed on patients who should not give birth vaginally at the time the test is done. Absolute contraindications for the CST are the following: preterm labour, placenta previa, vasa previa, cervical insufficiency, multiple gestation, and previous classic uterine incision for Caesarean birth (Greenberg & Druzin, 2017; Miller et al., 2017). Because of these disadvantages, the CST is used much less frequently now, as uteroplacental function can be assessed using BPP or vascular flow measurements.

! NURSING ALERT

In a healthy fetoplacental unit, uterine contractions usually do not produce late decelerations; when there is underlying uteroplacental insufficiency, contractions produce late decelerations.

Procedure. The patient is placed in a semi-Fowler position or sits in a reclining chair with a slight lateral tilt, to optimize uterine perfusion and avoid supine hypotension. They are monitored electronically with

TABLE 13.2 Antepartum Classification

Nonstress Test

Parameter	Normal NST	Atypical NST	Abnormal NST
Baseline	• 110–160 bpm	• 110–160 bpm • >160 bpm <30 min • Rising baseline	• Bradycardia <100 bpm • Tachycardia >160 for >30 min • Erratic baseline
Variability	• 6–25 bpm (moderate) (see Figure 13.10) • ≤5 bpm (absent or minimal) for <40 min	• ≤5 bpm (absent or minimal) for 40–80 min (see Figure 13.11)	• ≤5 bpm for ≥80 min • ≥25 bpm >10 min • Sinusoidal
Decelerations	• None or occasional variable <30 sec	• Variable decelerations 30–60 sec duration	• Variable decelerations >60 sec duration • Late decelerations
Accelerations term fetus	• 2 accelerations with acme of ≥15 bpm, lasting 15 sec <40 min of testing	• ≤2 accelerations with acme of ≥15 bpm, lasting 15 sec in 40–80 min	• ≤2 accelerations with acme of ≥15 bpm, lasting 15 sec in >80 min
Preterm fetus (<32 weeks)	• ≥2 accelerations with acme of ≥10 bpm, lasting 10 sec <40 min of testing	• ≤2 accelerations with acme of ≧10 bpm, lasting 10 sec in 40–80 min	• ≤2 accelerations with acme of ≥10 bpm, lasting 10 sec in >80 min
Action	Further assessment optional, based on total clinical picture	Further assessment required	URGENT ACTION REQUIRED An overall assessment of the situation and further investigation with ultrasonography or BPP is required. Some situations will require delivery.

bpm, Beats per minute; *BPP*, biophysical profile; *NST*, nonstress test.

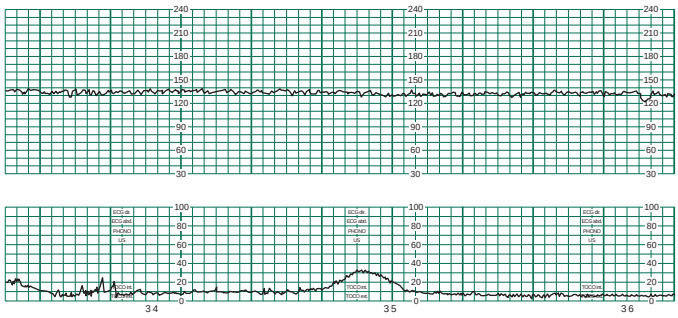

Fig. 13.11 Atypical or abnormal nonstress test (no fetal heart rate accelerations). (From Miller, L. A., Miller, D. A., & Tucker, S. M. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. Mosby.)

the fetal ultrasound transducer and uterine tocodynamometer. The tracing is observed for 10 to 20 minutes for baseline rate, variability, and the possible occurrence of spontaneous contractions. The goal of a CST is to induce three contractions, each lasting 1 minute within a 10-minute period so that the fetal heart response to the contractions can be evaluated (Liston et al., 2018). The CST can be done using maternal nipple stimulation or with an oxytocin infusion. Negative results for a CST are associated with favourable results.

Nipple-stimulated contraction test. Massaging the nipples causes a release of oxytocin from the posterior pituitary. The patient is instructed to stimulate one nipple through their clothing with the palmar surface of the fingers rapidly, but gently for 2 minutes, rest for 5 minutes, and repeat the cycles of massage and rest as necessary to achieve adequate uterine activity. Bilateral nipple stimulation may be considered when unable to achieve contractions while stimulating only one nipple. When adequate contractions or hyperstimulation occurs, stimulation should be stopped (Liston et al., 2018). Nipple stimulation has a shorter testing time than oxytocin infusion, although if nipple stimulation does not work, then oxytocin infusion should be considered.

Oxytocin-stimulated contraction test. Exogenous oxytocin can also be used to stimulate uterine contractions. An intravenous (IV) infusion is started and an oxytocin infusion initiated through a piggyback port into the tubing of the main IV device. An infusion pump is used to ensure accurate dosage. The oxytocin infusion usually is begun at 0.5 to 1.0 mU/minute and increased by 1.0 mU/minute at 15- to 30-minute intervals until three uterine contractions of good quality are observed within a 10-minute period. Hyperstimulation is a risk, so slowly increasing the rate of oxytocin is recommended.

Interpretation. If a normal baseline FHR tracing and no late decelerations are observed with the contractions, the findings are considered to be negative (Figure 13.12). A CST is positive if repetitive late decelerations occur with the induced contractions (Figure 13.13 and Table 13.3).

After interpretation of the FHR pattern, the oxytocin infusion is discontinued, and the maintenance IV solution is infused until the uterine activity has returned to the prestimulation level. If the CST is negative, the IV device is removed, and the fetal monitor is disconnected. If the CST is positive, continued monitoring and further evaluation of fetal well-being are indicated. While the use of CSTs has decreased because it has been replaced by other technologies, one indication for the use of CST is to determine if a fetus that has other abnormal testing results could tolerate a vaginal birth rather than requiring a Caesarean birth. A fetus demonstrating an atypical or abnormal NST and a positive CST is less likely to tolerate labour (Liston et al., 2018).

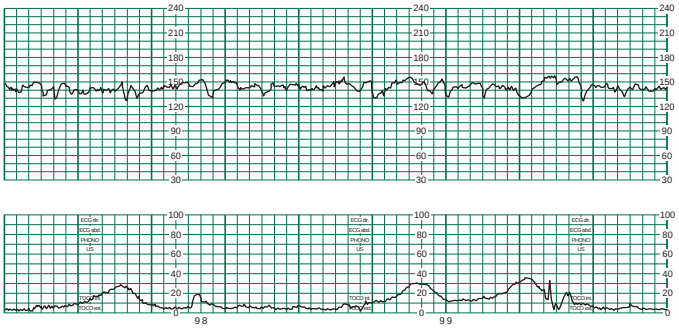

Fig. 13.12 Negative contraction stress test (normal external fetal heart rate tracing). (From Miller, L. A., Miller, D. A., & Tucker, S. M. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. Mosby.)

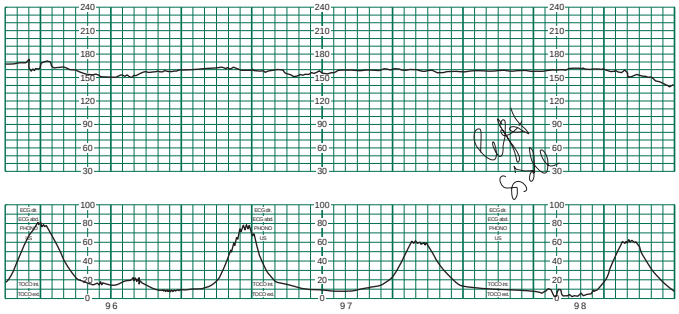

Fig. 13.13 Positive contraction stress test (late decelerations with uterine contractions). (From Miller, L. A., Miller, D. A., & Tucker, S. M. [2013]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [7th ed.]. Mosby.)

Ultrasound for Fetal Well-Being

Physiological parameters of the fetus that can be assessed with ultrasound scanning include amniotic fluid volume (AFV), vascular waveforms from the fetal circulation, heart motion, fetal breathing movements, fetal urine production, and fetal limb and head movements. Assessment of these parameters, singly or in combination, yields a fairly reliable picture of fetal well-being. The significance of these findings is discussed in the following sections.

Biophysical Profile. Real-time ultrasound imaging enables detailed assessment of the physical and physiological characteristics of the developing fetus to such an extent that it is possible to examine the fetus in detail and to catalogue normal and abnormal biophysical responses to stimuli. The **biophysical profile (BPP)** is a noninvasive dynamic assessment of a fetus that is based on the assessment of acute and chronic markers of fetal disease. The BPP is used to assess current fetal well-being by observing fetal breathing movements, fetal movements, fetal tone, and AFV.

The BPP may be considered a physical examination of the fetus, including determination of vital signs. The fetus responds to central hypoxia through alteration in movement, muscle tone, breathing, and heart rate patterns. The presence of normal fetal biophysical activities indicates that the central nervous system is functional; therefore, the fetus is not hypoxemic. BPP variables and scoring and management are detailed in Tables 13.4 and 13.5. The BPP is done with or without an NST. If done with the NST, the score is out of 10, and if done without the NST, the score is out of 8.

TABLE 13.3 Interpretation of the Contraction Stress Test

Interpretation	Clinical Significance
Negative	
No late decelerations, with minimum of three uterine contractions within 10-min period (see Figure 13.12)	Reassurance that the fetus is likely to survive labour should it occur within 1 week; more frequent testing may be indicated by clinical situation
Positive	
Late decelerations occurring with at least 50% or more of contractions, even if there are fewer than three contractions in 10 min (see Figure 13.13)	Management lies between use of other tools of fetal assessment, such as BPP, and termination of pregnancy; positive test result indicates that fetus is at increased risk for perinatal morbidity and mortality; physician may perform expeditious vaginal birth after successful induction or may proceed directly to Caesarean birth; decision to intervene is determined by fetal monitoring and presence of FHR reactivity
Atypical	
Prolonged, variable, or late decelerations occurring with less than 50% of the contractions	NST and CST should be repeated within 24 hr; if interpretable data cannot be achieved, other methods of fetal assessment must be used*
Equivocal–Tachysystole	
Decelerations that occur in the presence of contractions more frequent than every 2 min or lasting longer than 90 sec	Repeat test next day
Unsatisfactory	
Failure to produce three contractions within a 10-min window or inability to trace FHR	Repeat test next day

BPP, Biophysical profile; *CST,* contraction stress test; *FHR,* fetal heart rate; *NST,* nonstress test.

*Applies to results noted as suspicious, hyperstimulation, or unsatisfactory.

The BPP is an evaluation of current fetal well-being (Liston et al., 2018). Fetal acidosis can be diagnosed early with an abnormal NST and absent fetal breathing movements. A BPP score of less than 6, or a score of 6 along with **oligohydramnios**, indicates that labour should be induced (see Table 13.5). The BPP identifies a pocket of amniotic fluid of less than 2 cm by 2 cm as oligohydramnios. Fetal infection in patients whose membranes rupture prematurely (at less than 37 weeks of gestation) can be diagnosed early by changes in biophysical activities that precede the clinical signs of infection and indicate the necessity for immediate birth. When the BPP score is normal

TABLE 13.4 Scoring the Biophysical Profile

Variables	Normal (Score = 2)	Abnormal (Score = 0)
Fetal breathing movements	One or more episodes in 30 min, each lasting ≥30 sec	Episodes absent or no episode ≥30 sec in 30 min
Fetal movements	At least three trunk or limb movements in 30 min	Fewer than three episodes of body or limb movements in 30 min
Fetal tone	At least one episode of active extension with return to flexion of fetal limb or trunk; opening and closing of hand is considered normal tone	Absence of movement or slow extension/flexion
Amniotic fluid index	At least one cord and limb-free fluid pocket that is 2 cm by 2 cm in two measurements at right angles	No single pocket of fluid that is 2 cm by 2 cm
Nonstress test—may or may not be done	Normal	Abnormal Atypical

TABLE 13.5 Biophysical Profile Score Interpretation and Management

Score	Interpretation	Management
8–10	Normal; low risk for chronic asphyxia	Repeat testing as required based on risk factors
6 (normal fluid)	Equivocal test	Repeat testing within 24 hr
6 (abnormal fluid)	Suspect chronic asphyxia	Birth of term fetus. In fetus <34 weeks, intensive surveillance may be used and birth considered
<6	Abnormal; suspect chronic asphyxia	Deliver for fetal indications

Source: Liston, R., Sawchuck, D., Young, D., et al. (2018). SOGC clinical practice guideline: Fetal health surveillance: Antepartum and intrapartum consensus guideline. *Journal of Obstetrics and Gynaecology Canada, 29*(9), Suppl 4, S1–S56. Copyright 2007, with permission from Elsevier.

and the risk of fetal death low, intervention is indicated only for obstetrical or maternal factors.

Amniotic Fluid Volume. The volume of amniotic fluid in the second half of pregnancy is mostly a balance between fetal urine output and fetal swallowing. As pregnancy continues, amniotic fluid also includes lung secretions and gastrointestinal fluids. Normal maternal physiological processes (fluid intake, activity/rest, positions) affect AFV. Changes in AFV are usually gradual and accurate quantification of fluid by ultrasound is challenging (Lim et al., 2017).

Abnormalities in AFV are frequently associated with fetal disorders. Subjective determinants of oligohydramnios (decreased fluid) include the absence of fluid pockets in the uterine cavity and the impression of crowding of fetal small parts. Measurement of the single deepest pocket of fluid at 2 cm or less is considered a measurement of oligohydramnios (Lim et al., 2017). Increased amniotic fluid is called *polyhydramnios* or sometimes just *hydramnios*. Subjective criteria for polyhydramnios include multiple large pockets of fluid, the impression of a floating fetus, and free movement of fetal limbs. Hydramnios is usually defined as a single pocket of amniotic fluid measuring more than 8 cm (Lim et al., 2017).

The total AFV can be evaluated through a method in which the depths (in centimetres) of amniotic fluid in all four quadrants surrounding the maternal umbilicus are totalled, resulting in an amniotic fluid index (AFI). An AFI of less than 5 cm indicates oligohydramnios. With polyhydramnios, the AFI is 25 cm or more (Miller et al., 2017). Oligohydramnios is associated with congenital anomalies (e.g., renal agenesis [Potter syndrome]) and premature rupture of membranes. Polyhydramnios is associated with gastrointestinal and central nervous system abnormalities, multiple fetuses, and fetal hydrops (Gilbert, 2017). Oligohydramnios is associated with rupture of the membranes and congenital anomalies (such as renal agenesis), IUGR, and fetal distress in labour. Polyhydramnios is associated with NTDs, obstruction of the fetal gastrointestinal tract, multiple fetuses, and fetal hydrops.

Doppler Blood Flow Analysis. One of the major advances in perinatal medicine is the ability to study blood flow noninvasively in the mother, fetus, and placenta using ultrasound. **Doppler blood flow analysis** involves use of systolic/diastolic flow ratios and resistance indices to estimate blood flow in various arteries. Thus, it provides an indication of fetal adaptation and reserve. The vessels most often studied are the fetal umbilical and middle cerebral arteries and the maternal uterine arteries. Severe restriction of umbilical artery blood flow as indicated by absent or reversed flow during diastole has been associated with IUGR (Figure 13.14) (Miller et al., 2017). Doppler ultrasound has been demonstrated to be of value in reducing perinatal mortality and unnecessary obstetrical interventions in fetuses with IUGR (Greenberg & Druzin, 2017). Significantly increased peak systolic velocity in the middle cerebral artery has been found to predict moderate to severe fetal anemia. Abnormal maternal uterine artery Doppler waveforms have been used to predict fetal growth restriction (Miller et al., 2017).

NURSING ROLE IN ANTENATAL ASSESSMENT FOR RISK

The nurse's role is that of educator and support person when the patient is undergoing examinations such as ultrasonography, magnetic resonance imaging (MRI), CVS, PUBS, and amniocentesis. In some instances the nurse may assist the health care provider with the procedure. In many settings, nurses perform NSTs, CSTs, and BPPs; conduct an initial assessment; and begin necessary interventions for abnormal patterns. These nursing procedures are accomplished after additional education and training, under guidance of established protocols, and in collaboration with obstetrical providers. Patient teaching, which is an integral component of this role, involves preparing the pregnant patient for the procedure, interpreting the findings, and providing psychosocial support when needed.

Psychological Considerations

All patients who undergo antenatal assessments are at risk for real and potential health concerns and may be anxious. In most instances, the tests are ordered because of suspected fetal compromise, deterioration of a maternal condition, or both. In one study, high-risk patients who have multiple ultrasounds felt the testing facilitated their feelings of

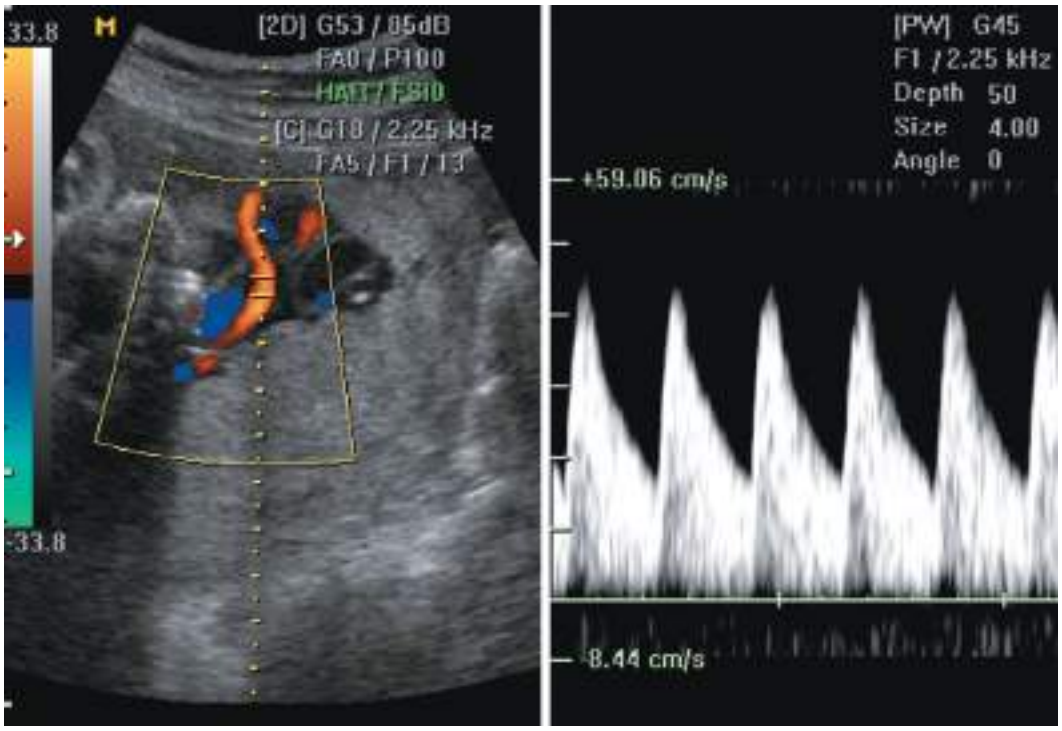

Fig. 13.14 Colour and spectral Doppler evaluation of the umbilical artery. In the **left** panel the coiling arteries and vein are shown. *Red* indicates flow toward the transducer, and *blue* is flow away. The sample gate for the pulse Doppler is superimposed. On the **right** is the result of the pulse Doppler, depicting a normal flow velocity waveform.

maternal–fetal connection and "babyfication" of the fetus (Curran et al., 2017). As pregnant patients came to understand the ultrasound pictures based on the health care provider's information, they were able to understand the growth and development of the baby and imagined themselves more easily as mothers during the pregnancy (Curran et al., 2017). In the third trimester, pregnant patients are most concerned about protecting themselves and their fetuses and consider themselves most vulnerable to outside influences. The label of "high risk" increases this sense of vulnerability.

When a patient is diagnosed with a high-risk pregnancy, the person and their family may experience stress related to the diagnosis. The patient may exhibit various psychological responses, including anxiety, low self-esteem, guilt, frustration, sense of failure, and inability to function. They may also think about their maternal identity as involving sacrificing themselves for the sake of their infant (Curran et al., 2017). Their perception of risk may be in the context of previous life experiences, coping strategies, and weight attached to the information provided from various sources. The development of a high-risk pregnancy also can affect parental attachment, accomplishment of the tasks of pregnancy, and family adaptation to the pregnancy.

The patient may be fearful for their own well-being, and they may feel a high degree of concern for this infant as well (Jain, 2019). This may cause them to feel some ambivalence about the pregnancy and they may not make regular attendance at prenatal care a priority. They may not be able to complete preparations for the baby or go to childbirth classes if hospitalized during the pregnancy. They may also be aware of the expectations of others about them and their pregnancy that may include judgement if they are not behaving in ways perceived to reduce risks, such as continuing to smoke during pregnancy. Nurses should assist patients in exploring their understanding of the risk associated with this pregnancy, as it is often different from that of their health care provider. Nurses should also help the patient understand that they are part of a team, and help them and their family to understand that they are all working together for the health of mother and baby to alleviate some of the worry and concern (Curran et al., 2017). Helping a patient maintain some of their identity outside of the hospital may also help them to focus on other aspects of their life (e.g., hobbies, maintaining contact with friends and family with email or group sessions) (Curran et al., 2017).

Antepartum hospitalization is an added stressor for the high-risk pregnant patient and their family. The patient may be lonely because they are separated from their home and family. They may feel powerless and unable to make decisions for themselves because their care is out of their control, including preparation for the birth process. Also, the longer the hospitalization, the greater the possibility that the mother–infant attachment process will be affected. Unexpected procedures and care for the patient or fetus may take priority over the usual birth plan and may not allow choices that would have been selected if the pregnancy had been low risk.

The nurse can help the patient and their family by encouraging their social support system to visit as frequently as possible and to maintain communication. Obtaining detailed information about the patient's care and the health of the fetus is also extremely important. Patients have reported that receiving frank information about their baby's health is helpful; it is also important to then have consistent support when they have questions (Harvey et al., 2019). While in hospital the patient may be encouraged to take part in group therapy to gain social support from others experiencing similar feelings and concerns. Providing support and encouragement, as well as opportunities for the patient to make as many choices as possible, can be helpful to this patient's care.

KEY POINTS

- A high-risk pregnancy is one in which the life or well-being of the mother or fetus is jeopardized by a biophysical or psychosocial disorder coincident with or unique to pregnancy.
- The pregnancy, fetus, or newborn can be placed at risk through the influence of many of the determinants of health.
- Psychosocial indicators that may increase risk include characteristics of the parents, the fetus, the newborn, their support systems, and family circumstances.
- Intimate partner violence has a negative impact on pregnancy outcomes.
- The mortality rate decreases when risks are identified early and intensive care is applied.
- In the first and second trimester, antepartum testing is done to screen for fetal abnormalities, assess for gestational age, ensure appropriate growth, and assess placenta position.
- Biophysical assessment techniques include fetal movement counts and ultrasonography.
- Biochemical monitoring techniques include amniocentesis, PUBS, and CVS.
- Normal NSTs and negative CSTs suggest fetal well-being.
- Assessment tests may have some degree of risk for the mother and fetus and usually cause some anxiety for the patient and their family.

Pregnancy at Risk: Gestational Conditions

Melanie Basso

Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter, the reader will be able to:

1. Differentiate gestational hypertension, chronic hypertension, and other hypertension.
2. Compare the care management strategies for patients with nonsevere hypertension and severe hypertension.
3. Describe the etiological theories and pathophysiology of pre-eclampsia.
4. Describe HELLP syndrome, including appropriate nursing actions.
5. Understand the screening and care of a patient with gestational diabetes mellitus.
6. Explain the effects of hyperemesis gravidarum on the pregnant patient as well as fetal well-being.
7. Differentiate among causes, signs and symptoms, possible complications, and management of spontaneous abortion, ectopic pregnancy, cervical insufficiency, and hydatidiform mole.
8. Compare and contrast placenta previa and placental abruption in regard to signs and symptoms, complications, and management.
9. Discuss the diagnosis and management of disseminated intravascular coagulation (DIC).
10. Discuss signs and symptoms, effects on pregnancy, and management of urinary tract infections.
11. Explain the basic principles of care for a pregnant patient undergoing abdominal surgery.
12. Discuss implications of trauma on the pregnant patient and fetus.
13. Identify priorities in assessment and stabilization measures for the pregnant trauma victim.

Providing safe and effective care for a pregnant patient with high-risk conditions requires an interprofessional team working alongside the patient and their family. Each team member contributes unique knowledge and skills toward providing optimum outcomes for the patient and infant. This chapter discusses a wide range of disorders that can develop during pregnancy and place the patient and fetus at risk. Hypertensive disorders in pregnancy, gestational diabetes mellitus (GDM), hyperemesis gravidarum, hemorrhagic complications of early and late pregnancy, surgery during pregnancy, and trauma are discussed. For most conditions, management throughout the entire perinatal period (antepartum, intrapartum, and postpartum) is included; thus all information for each condition is located in one place in the text.

HYPERTENSIVE DISORDERS IN PREGNANCY

Significance and Incidence

Hypertensive disorders in pregnancy are an increasingly common and leading cause of maternal and perinatal morbidity and mortality worldwide (Magee et al., 2014). In Canada, approximately 7% of pregnancies are complicated by hypertensive disorders of pregnancy (Butalia et al., 2018). The three most common types of hypertensive disorders occurring in pregnancy are chronic hypertension, gestational hypertension, and pre-eclampsia/eclampsia.

Definition of Hypertensive Disorder of Pregnancy

Hypertension in pregnancy (HDP) is determined by an assessed blood pressure (BP) measure of systolic blood pressure (SBP) of 140 mm Hg or greater and/or diastolic blood pressure (DBP) of 90 mm Hg or greater, taken at two separate measurements and at least 15 minutes apart. This is defined as *nonsevere hypertension*. Treatment with antihypertensive medication is indicated to attain a target DBP level of 85 mm Hg to reduce the risk of developing severe hypertension and the complications that may be associated (Table 14.1) (Butalia et al., 2018; Magee et al., 2014). Ongoing blood work and assessment for changes in BP are indicated to monitor for the development of increasingly severe disease. This level of BP is associated with higher adverse perinatal outcomes.

Severe hypertension is defined as an SBP of 160 mm Hg or greater or a DBP of 110 mm Hg, based on at least two measurements taken at least 15 minutes apart (Butalia et al., 2018; Magee et al., 2014). It is

TABLE 14.1 Differentiation Between Nonsevere and Severe Hypertension

Patient Effects	Nonsevere Hypertension	Severe Hypertension
Blood pressure (BP)	BP reading of ≥140/90 mm Hg × two readings 15 minutes apart	Rise to ≥160/110 mm Hg on two separate readings 15 minutes apart
Mean arterial pressure	>105 mm Hg	>105 mm Hg
Fetal Effects		
Fetal heart rate (FHR)	May be abnormal	May be abnormal
Placental perfusion	Reduced, oligohydramnios may be present	Decreased perfusion expressing as IUGR in fetus; FHR may show late decelerations in labour
Premature placental aging	Not apparent	At birth, placenta appearing smaller than normal for duration of pregnancy; premature aging apparent with numerous areas of ischemic necroses (white infarcts); numerous, intervillous fibrin deposition (red infarcts)

IUGR, Intrauterine growth restriction.
Adapted from Magee, L. A., Pels, A., Helewa, M., et al. (2014). SOGC clinical practice guideline: Diagnosis, evaluation and management of hypertensive disorders of pregnancy: Executive summary. *Journal of Obstetrics and Gynaecology Canada, 36*(5), 416–438.

considered to be an obstetrical emergency that requires immediate treatment to reduce the risk of severe complications (see Table 14.1).

Morbidity and Mortality

Complications from significant hypertension in pregnancy include death, acute renal failure, pulmonary edema, HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets; see later discussion), and cerebral edema with seizures (Mehrabadi et al., 2014). Deaths of pregnant patients associated with severe hypertension result primarily from complications of hepatic rupture, placental abruption, and eclampsia (generalized tonic-clonic seizures) (Sibai, 2017). Infants born at full term to a parent with hypertensive disorders of pregnancy have higher rates of newborn mortality than do newborns of a parent who was not hypertensive (Sibai, 2017). The unborn fetus of the pre-eclamptic patient is at increased risk from placental abruption, preterm birth, intrauterine growth restriction (IUGR), and acute hypoxia. Bellini et al. (2016) noted an increased prevalence of congenital malformations in infants born to a parent who was hypertensive. Clinical care goals focus on the optimal management of hypertensive disorders of pregnancy.

Classification

Hypertensive disorders of pregnancy represent a broad range of conditions including chronic hypertension (i.e., prepregnancy hypertension) that is present prior to 20 weeks of gestation, gestational hypertension (i.e., hypertension that develops after 20 weeks' gestation), and/or pre-eclampsia/eclampsia (gestational hypertension with proteinuria and/or other target organ involvement). Pre-eclampsia can occur with either chronic hypertension or gestational hypertension. Three categories of other hypertensive definitions have been identified: transient hypertension, white-coat hypertension, and masked hypertension (Butalia et al., 2018; Magee et al., 2014). Table 14.2 presents details of the criteria for each classification.

Chronic Hypertension. *Chronic hypertension* is present before pregnancy or becomes evident prior to 20 weeks of gestation. Patients with chronic (or prepregnancy) hypertension may also be at risk of developing superimposed pre-eclampsia (Butalia et al., 2018; Magee et al., 2014). Most pregnant patients with chronic hypertension experience uncomplicated pregnancies; however, there is an increased risk of poor fetal growth and fetal stillbirth. Preconception counselling is recommended for these patients (Magee et al., 2014).

Chronic hypertension with superimposed pre-eclampsia. Approximately 25% of pregnant patients with chronic hypertension develop pre-eclampsia or eclampsia. This disorder is associated with severe maternal and fetal complications. Chronic hypertension with superimposed pre-eclampsia is defined in the presence of the following findings:

- Hypertension before 20 weeks of gestation, with new onset of proteinuria
- Both hypertension and proteinuria before 20 weeks of gestation
- Thrombocytopenia
- Elevated liver enzymes

Gestational Hypertension. *Gestational hypertension* is hypertension that develops after 20 weeks gestation in the absence of proteinuria and without changes in blood work (Brown et al., 2018). It is not usually associated with fetal growth restriction. Most patients will experience few pregnancy complications, although up to 25% of patients will go on to develop pre-eclampsia.

Pre-Eclampsia. *Pre-eclampsia* is a hypertensive disorder accompanied by new-onset proteinuria and, potentially, other end-organ dysfunction. Treatment of pre-eclampsia occurs in hospital to reduce the risks of complications to the pregnant patient or intrauterine fetal morbidity and mortality due to uteroplacental insufficiency and placental abruption. It is a multisystem, vasospastic disease process of reduced organ perfusion characterized by the presence of hypertension and proteinuria, with a clinical continuum from mild to severe (see Table 14.1). It affects a myriad of the patient's and fetal systems and, if not controlled, results in poor perinatal outcomes. Rates of development of pre-eclampsia are higher for pregnant patients with strong clinical risk factors such as prior pre-eclampsia, chronic hypertension, or pregestational diabetes (Brown et al., 2018) (Box 14.1).

The two key components to the diagnosis of pre-eclampsia are gestational or chronic hypertension and new-onset proteinuria. Additional patient organ dysfunction may be present, including acute kidney or liver dysfunction; neurological complications, such as seizures, blindness, stroke, or severe headaches; as well as hematological complications, such as thrombocytopenia, disseminated intravascular coagulation (DIC), or hemolysis (Brown et al., 2018) (Table 14.3).

Research has resulted in the development of a clinical predictive model known as the PIERS model (Ukah et al., 2019). Assessment data are collected from a patient in the first 48 hours following admission to hospital with a diagnosis of pre-eclampsia, and the information is entered into the model calculator to determine the risk of severe adverse maternal outcome. The following risk factors variables are entered: gestational age, presence of chest pain or dyspnea, oxygen saturation, platelet count, serum creatinine, and aspartate aminotransferase (AST) (Ukah et al., 2019). The model may be a used as an adjunct tool in the care of patients with pre-eclampsia.

TABLE 14.2 Classification of Hypertensive Disorders of Pregnancy

Disorder	Comments
Chronic hypertension	Predates the pregnancy or appears before 20 weeks
A) With comorbid conditions	Comorbid conditions (pregestational type 1 or 2 diabetes mellitus or kidney disease) require tighter BP control outside of pregnancy because of their association with heightened cardiovascular risk
B) With evidence of pre-eclampsia (onset after 20 weeks' gestation)	Also known as superimposed pre-eclampsia. One or more symptoms must be present: • Resistant hypertension (defined as need for three antihypertensive medications) or • New-onset proteinuria or • One or more adverse conditions or • One or more severe complications
Gestational hypertension	Hypertension that appears for the first time at or beyond 20 weeks' gestation
A) With comorbid conditions	Comorbid conditions (pregestational type 1 or 2 diabetes mellitus or kidney disease) require tighter BP control outside of pregnancy because of their association with heightened cardiovascular risk
B) With evidence of pre-eclampsia (after 20 weeks' gestation)	Defined as gestational hypertension with one or more of the following symptoms: • New-onset proteinuria or • One or more adverse conditions or • One or more severe complications
Pre-eclampsia	May arise without previous symptoms. Defined as gestational hypertension with one or more of the following: • New-onset proteinuria or • One or more adverse conditions or • One or more severe complications
Other Hypertensive Effects	
Transient hypertension	Elevated BP may be due to environmental stimuli
White coat hypertension	BP that is elevated in the clinician's office (≥140/90) but is consistently normal outside of it (<135/85)
Masked hypertension	BP that is consistently normal in the clinician's office (<140/90) but is consistently higher outside of it (≥135/85)

BOX 14.1 Risk Factors for Pre-eclampsia

- Nulliparity
- Age >40 years
- Pregnancy with assisted reproductive technology
- Interpregnancy interval >7 years
- Family history of pre-eclampsia
- Patient born small for gestational age
- Obesity/gestational diabetes mellitus
- Multifetal gestation
- Pre-eclampsia in previous pregnancy
- Poor outcome in previous pregnancy
- Pre-existing medical/genetic conditions
- Chronic hypertension
- Renal disease
- Type 1 (insulin-dependent) diabetes mellitus
- Antiphospholipid antibody syndrome
- Factor V Leiden mutation

From Sibai, B. (2017). Pre-eclampsia and hypertensive disorders. In S. G. Gabbe, J. R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

Proteinuria. *Proteinuria* is defined as a concentration of 0.03 g/L or more in at least two random urine specimens collected at least 6 hours apart where there is no evidence of urinary tract infection (UTI). In a 24-hour specimen, *proteinuria* is defined as a concentration of greater than 0.3 g/L per 24 hours (Box 14.2). The diagnosis of proteinuria should be based on the use of the urinary protein-to-creatinine ratio or 24-hour

TABLE 14.3 Adverse Conditions and Severe Complications of Pre-eclampsia

Organ System Identified	Adverse Conditions (That Increase Risk of Severe Complications)	Severe Complications (That Warrant Birth)
Central nervous system	Headache/visual disturbances	Eclampsia/PRES Cortical blindness or retinal detachment GCS <13 Stroke or TIA
Cardiorespiratory	Chest pain/dyspnea	Uncontrolled severe hypertension >12 hours, despite use of three antihypertensive agents
	Oxygen saturation <97%	O_2 saturation <90, need for 50% O_2 for 1 hour, intubation, pulmonary edema Positive inotropic support Myocardial ischemia or infarction
Hematological	Elevated WBC Elevated INR or aPTT Low platelets	Platelet count <50 Transfusion of any blood product
Renal	Elevated serum creatinine Elevated serum uric acid	Acute kidney injury New indication for dialysis

Continued

TABLE 14.3 Adverse Conditions and Severe Complications of Pre-eclampsia—cont'd

Organ System Identified	Adverse Conditions (That Increase Risk of Severe Complications)	Severe Complications (That Warrant Birth)
Hepatic	Nausea or vomiting RUQ or epigastric pain Elevated serum AST, ALT, LDH, or bilirubin Low plasma albumin	Hepatic dysfunction Hepatic hematoma or rupture
Fetoplacental	Abnormal FHR IUGR Oligohydramnios Absent or reversed end-diastolic flow by Doppler velocimetry	Abruption with evidence of maternal or fetal compromise Reverse ductus venosus A wave Stillbirth

ALT, Alanine aminotransferase; *aPTT*, activated partial thromboplastin time; *AST*, aspartate aminotransferase; *FHR*, fetal heart rate; *GCS*, Glasgow Coma Scale; *INR*, international normalized ratio; *IUGR*, intrauterine growth restriction; *LDH*, lactate dehydrogenase; *PRES*, posterior reversible leukoencephalopathy syndrome; *RUQ*, right upper quadrant; *TIA*, transient ischemic attack; *WBC*, white blood cell.
Adapted from Magee, L. A., Pels, A., Helewa, M., et al. (2014). SOGC clinical practice guideline: Diagnosis, evaluation and management of hypertensive disorders of pregnancy: Executive summary. *Journal of Obstetrics and Gynaecology Canada, 36*(5), 416–438. Copyright 2014, with permission from Elsevier.

BOX 14.2 Urine Protein Values

Protein readings are designated as follows:
0—negative
Trace—trace
+1—0.3 g/L
+2—1.0 g/L (this result strongly suggests 0.3 g/day)
+3—3.0 g/L
+4—more than 10.0 g/L

urine collection (Butalia et al., 2018; Magee et al., 2014). Use of a dipstick to screen for the presence of protein is determined to be positive at +2 and should then be further quantified by laboratory testing.

Eclampsia. Eclampsia, characterized by seizures from profound cerebral effects of pre-eclampsia, is the major maternal risk. As a rule, maternal and perinatal morbidity and mortality rates are highest when eclampsia is seen early in gestation (before 28 weeks), maternal age is greater than 30 years, the patient has had no prenatal care, the patient is a multigravida, and chronic hypertension or renal disease is present (Sibai, 2017). Over the past 20 years, a marked reduction in the incidence of eclampsia has occurred, particularly in developed countries, and is probably related to prevention of cases of eclampsia in patients with a classic presentation (Sibai, 2017). The fetus of the eclamptic patient is at increased risk for placental abruption, preterm birth, IUGR, and acute hypoxia. Eclamptic seizures can occur before, during, or after birth. The frequency of postpartum eclampsia has ranged from 11 to 44%. Although most cases of postpartum eclampsia occur within the first 48 hours, some cases can develop beyond 48 hours postpartum and have been reported as late as 23 days postpartum (Sibai, 2017).

Etiology. The etiology of pre-eclampsia is theorized to include various possibilities: abnormal prostaglandin action, endothelial cell dysfunction, coagulation abnormalities, vasoconstrictor tone, and dietary

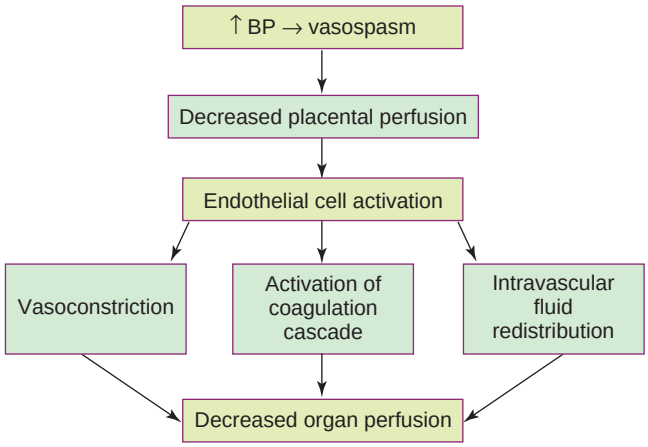

Fig. 14.1 Etiology of pre-eclampsia. *BP*, Blood pressure.

deficiencies or excesses (Figure 14.1). Immunological factors and genetic disposition may also play an important role (Sibai, 2017). Animal studies have suggested that abnormalities of the placenta are the cause of pre-eclampsia. The trophoblast cells of the placenta usually alter the spiral arteries in the uterus to accommodate increased blood flow.

In pre-eclampsia, the vessels are abnormally thick-walled and muscular and have higher resistance. The condition also results in a distinctive lesion called *acute atherosis*, and there is greater occurrence of placental infarcts. Placental perfusion is decreased, resulting in hypoxia; this in turn causes several pathophysiological abnormalities, especially endothelial damage. Many of these pathophysiological changes of pre-eclampsia occur before clinical symptoms develop (Sibai, 2017).

Since the etiology of pre-eclampsia is unknown, various clinical trials have attempted to correct theoretical abnormalities present in pre-eclampsia as a means of preventing pre-eclampsia. Some methods used to prevent pre-eclampsia are listed in Box 14.3.

BOX 14.3 Recommendations for Prevention of Pre-Eclampsia and Improvement of Pregnancy Outcomes in Patients at Low Risk of Developing Pre-Eclampsia

- Abstention from alcohol
- Smoking cessation
- Multivitamin supplementation containing folate (also to prevent neural tube defects)
- Calcium supplementation (at least 1 g/day orally) for patients with low dietary intake of calcium
- Regular exercise

The following are **NOT** recommended for prevention of pre-eclampsia in low-risk patients (due to insufficient evidence):

- Supplementation with magnesium or zinc
- Prostaglandin precursors such as fish and evening primrose oil
- High-protein and low-salt diet
- Calorie restriction for overweight patients
- Low-dose aspirin (recommended for patients at increased risk of pre-eclampsia)
- Vitamins C and E
- Thiazide diuretics
- Antihypertensive therapy (does not prevent pre-eclampsia)

Adapted from Magee, L. A., Pels, A., Helewa, M., et al., and Society of Obstetricians and Gynaecologists of Canada. (2014). SOGC clinical practice guideline: Diagnosis, evaluation and management of hypertensive disorders of pregnancy: Executive summary. *Journal of Obstetrics and Gynaecology Canada, 36*(5), 416–438.

Pathophysiology. Pre-eclampsia presents a significant risk to both the pregnant patient and the fetus. The diagnosis of pre-eclampsia in pregnancy is further classified into pre-eclampsia with or without severe features, which highlights the seriousness of the disease (American College of Obstetricians and Gynecologists [ACOG], 2019; Brown et al., 2018). The pathophysiology of pre-eclampsia reflects alterations in the normal adaptations of pregnancy. Normal physiological adaptations to pregnancy include increased blood plasma volume, vasodilation, decreased systemic vascular resistance, elevated cardiac output, and decreased colloid osmotic pressure. The main pathogenic factor is not an increase in BP but poor perfusion as a result of vasospasm. Arteriolar vasospasm diminishes the diameter of blood vessels, which impedes blood flow to all organs and increases BP (Magee et al., 2014; Sibai, 2017). Function in organs such as the placenta, kidneys, liver, and brain is depressed by as much as 40 to 60%. The pathophysiological sequelae are shown in Figure 14.2.

HELLP syndrome. HELLP syndrome is severe pre-eclampsia accompanied by a constellation of abnormalities in laboratory blood results, including hemolysis (*H*), elevated liver enzymes (*EL*), and low platelets (*LP*) (ACOG, 2019; Brown et al., 2018; Magee et al., 2014; Sibai, 2017). HELLP syndrome can be difficult to diagnose. Its symptoms are sometimes mistaken for gastritis, flu, acute hepatitis, gall bladder disease, or other conditions. The mortality rate of HELLP syndrome has been reported to be as high as 25%. It is critical for care providers to be aware of the condition and its symptoms so they can provide early diagnosis and treatment.

To establish a diagnosis of HELLP syndrome, the platelet count must be less than 100×10^9/L and the liver enzyme levels (AST and alanine aminotransferase [ALT]) must be elevated. A unique form of coagulopathy (not DIC) occurs with HELLP syndrome. The platelet count is low, but coagulation factor assays, prothrombin time (PT), partial thromboplastin time (PTT), and bleeding time remain normal. Patients who present with this constellation of abnormalities including hemolysis, elevated liver enzymes, and thrombocytopenia are considered to have pre-eclampsia (Brown et al., 2018).

The pathophysiological changes of HELLP syndrome occur as a result of arteriolar vasospasm, endothelial cell dysfunction with fibrin deposits, and adherence of platelets in blood vessels. Red blood cells are damaged as they pass through narrowed blood vessels and become hemolyzed, resulting in a decreased red blood cell and platelet count and hyperbilirubinemia. Endothelial damage and fibrin deposits in the liver lead to impaired liver function and can cause hemorrhagic necrosis. Liver enzymes are elevated when hepatic tissue is damaged.

HELLP syndrome appears in approximately 20% of patients with severe pre-eclampsia (ACOG, 2019). Most commonly, HELLP

Copyright 2014, with permission from Elsevier.)

syndrome is seen in older, White, multiparous patients (Harper et al., 2019). About 90% of patients report a history of malaise for several days. Many patients experience epigastric or right upper quadrant abdominal pain (possibly related to hepatic ischemia), and approximately half develop nausea and vomiting. Recognition of the clinical and laboratory findings associated with HELLP syndrome is important if early, aggressive therapy is to be initiated to prevent poor maternal and newborn outcomes. Complications reported with HELLP syndrome include renal failure, pulmonary edema, ruptured liver hematoma, DIC, and placental abruption (Brown et al., 2018; Sibai, 2017).

Numerous clinical trials have examined various interventions to prevent pre-eclampsia, including protein or salt restriction; zinc, magnesium, fish oil, or vitamins C and E supplementation; use of diuretics or other antihypertensive medications; and use of heparin or low-dose aspirin. It is recommended that all patients with risk factors for pre-eclampsia be started on low-dose aspirin (81 mg), ideally prior to 16 weeks of pregnancy (Brown et al., 2018; Sibai, 2017). Patients at risk for pre-eclampsia with low intake of calcium should also take 1.2–2.5 g/day (Brown et al., 2018).

No reliable test that can be used as a routine screening tool for predicting pre-eclampsia has yet been developed. An abnormal uterine artery Doppler velocimetry in the first or second trimester of pregnancy has been suggested as a good screening test to determine patients at risk for pre-eclampsia and who may benefit from low-dose aspirin therapy (Brown et al., 2018).

Although research offers future promise, much work remains before a screening test for pre-eclampsia is available for widespread clinical use. Nurses should be aware of the strategies that are being studied and use the most valid results so they can counsel pregnant patients about interventions that are evidence-informed. Meanwhile, the best pre-eclampsia prevention methods include early prenatal care for the identification of patients at risk and early detection of the disease (see Home Care box).

FAMILY-CENTRED CARE

Care of Patients With Gestational or Chronic Hypertension

Patients with gestational or chronic hypertension are managed at home and are taught to assess and report clinical signs of pre-eclampsia.

Report Immediately Any Clinical Signs
- Report any increase in blood pressure, protein in urine, or decreased fetal movement.*

Take Blood Pressure With Consistency
- Take blood pressure on the same arm with the patient in a sitting position (no dangling legs) each time for consistent and accurate readings. Support the arm on a table in a horizontal position at heart level.

Dipstick Test Clean-Catch Urine Sample
- This is done to assess proteinuria; report frequency or burning on urination. Report any presence of proteinuria.

Assess Fetal Activity Daily
- Decreased activity (five or fewer movements in 2 hours) may indicate fetal compromise.

Keep Scheduled Prenatal Appointments
- Regular appointments need to be kept so that any changes in condition of the patient or fetus can be detected immediately.

Keep a Daily Log or Diary
- Keep a log of assessments and bring it to prenatal visits.

*Thresholds for blood pressure, fetal movement counts, and proteinuria are set by the primary health care provider or institutional protocol.

Nursing Care

Blood Pressure Assessment. Accurate and consistent assessment of BP is important for establishing a baseline and for monitoring subtle changes throughout the pregnancy. BP readings are affected by position of the patient and measurement techniques, thus consistency must be ensured. Normally, the DBP drops an average of 10 mm Hg below nonpregnant values by midgestation and then slowly reaches nonpregnant levels in the third trimester. Evaluation of BP is focused on trends, not on a single reading (ACOG, 2019). Box 14.4 presents recommendations for standardizing this procedure.

Deep Tendon Reflexes. Deep tendon reflexes (DTRs) are evaluated at baseline and then throughout the pregnancy to detect any changes. The biceps and patellar reflexes and ankle clonus are assessed and the findings recorded (Figure 14.3 and Table 14.4). The evaluation of DTRs is especially important if the patient is being treated with magnesium sulphate. Decreased or absent DTRs may be an indication of magnesium toxicity.

To elicit the biceps reflex, a downward blow is struck over the thumb, which is placed over the biceps tendon. Normal response is flexion of the arm at the elbow, described as a 2+ response (see Figure 14.3, *A*, and Table 14.4).

The patellar reflex is elicited with the patient's legs hanging freely over the end of the examining table or with the patient lying on their side with the knee slightly flexed. A blow with a percussion hammer is dealt directly to the patellar tendon, inferior to the patella. Normal response is extension or kicking out of the leg, which is recorded as 2+ (see Figure 14.3, *B*, and Table 14.4).

To assess for hyperactive reflexes (clonus) at the ankle joint, the examiner supports the leg with the knee flexed. With one hand, the examiner sharply dorsiflexes the foot, maintains the position for a moment, and then releases the foot (see Figure 14.3, *C*). A normal (negative clonus) response is elicited when no rhythmic oscillations (jerks) are felt while the foot is held in dorsiflexion. When the foot is released, no oscillations are seen as the foot drops to the plantar-flexed position. An abnormal (positive clonus) response is indicated by rhythmic oscillations of one or more beats felt when the foot is in dorsiflexion and seen as the foot drops to the plantar-flexed position.

Fetal Health Surveillance. Uteroplacental perfusion can be decreased in patients with pre-eclampsia. Fetal health surveillance, by means of such methods as the nonstress test (NST), contraction

BOX 14.4 Protocol for Blood Pressure Measurement

- Blood pressure (BP) should be measured with the patient in a sitting position with the arm at the level of the heart.
- Use the proper-size cuff (cuff should cover 1.5 times the circumference of the arm).
- Use Korotkoff phase V for the diastolic reading.
- If BP is consistently higher in one arm, the arm with the higher values should be used.
- Use manual sphygmomanometer, or an automated BP device that has been validated for use in pre-eclampsia.
- Patients must be instructed in proper BP measurement if they are performing home BP monitoring.

TABLE 14.4 Assessing Deep Tendon Reflexes

Grade	Deep Tendon Reflex Response
0	No response
1+	Sluggish or diminished
2+	Active or expected response
3+	More brisk than expected; slightly hyperactive
4+	Brisk, hyperactive, with intermittent or transient clonus

From Seidel, H. M., Ball, J. W., Dains, J. E., et al. (2011). *Mosby's guide to physical examination* (7th ed.). Mosby.

stress test (CST), biophysical profile (BPP), and serial ultrasonography, is used to assess fetal status during pregnancy. The fetal heart rate (FHR) is assessed for baseline rate, variability, and presence of accelerations. Abnormal baseline rate, decreased or absent variability, or late decelerations are indications of fetal stress in the intrauterine environment. Since the patient with pre-eclampsia is at risk for placental abruption, it is important to assess uterine tone and tenderness and check for the presence of vaginal bleeding. Doppler flow velocimetry studies can be used to evaluate uteroplacental perfusion (see Chapter 13).

! NURSING ALERT

Uterine tenderness along with increasing tone may be the earliest finding of an abruption. Idiopathic preterm contractions also may be an early sign.

An evaluation of fetal growth by ultrasonography should be obtained at diagnosis and repeated every 2 weeks. Fetal movements are counted daily (see Chapter 13, Fetal Movement Counting). Fetal compromise evidenced by slowed growth, atypical or abnormal FHR surveillance, or a concerning finding during testing may necessitate immediate birth, depending on gestational age (labour induction or Caesarean birth) (ACOG, 2019; Harper et al., 2019; Magee et al., 2014).

Activity Restriction. Pregnant patients with chronic or gestational hypertension without pre-eclampsia may benefit from care in hospital to provide ongoing monitoring and assessment in an attempt to detect any progression to severe hypertension and preterm birth. For patients with pre-eclampsia who are hospitalized, strict bed rest is NOT recommended, but some reduced activity may be beneficial in decreasing BP and promoting fetal growth as well as improving amniotic fluid levels. There is no evidence that bed rest alone improves pregnancy outcomes (Magee et al., 2014). Adverse physiological outcomes related to bed rest include cardiovascular deconditioning; diuresis with accompanying fluid, electrolyte, and weight loss; muscle atrophy; and psychological stress (see Box 20.4). These changes may begin as early as the first day of bed rest and continue for the duration of therapy. Prolonged bed rest is known to increase the risk of thrombophlebitis. Thus, strict bed rest is not recommended because of potential harmful physical, psychosocial, and financial outcomes (Magee et al., 2014).

Patients with pre-eclampsia without severe features feel reasonably well, so they often find the need for increased monitoring of their condition in hospital to be stressful. Assistance from family and friends with activities of daily living, such as grocery shopping and child care, for the family at home can be helpful. Relaxation techniques can help reduce stress associated with the high-risk condition and prepare the patient for labour and the birth.

Diet. Diet and fluid recommendations are much the same as those for healthy pregnant patients. Diets high in protein and low in salt are not recommended to prevent pre-eclampsia (Magee et al., 2014). The exception may be the patient with chronic hypertension that had been successfully controlled with a low-salt diet before the pregnancy. Adequate fluid intake helps maintain optimum fluid volume and aids in renal perfusion and bowel function (see Guidelines box).

GUIDELINES

Nutrition for Patients With Pre-Eclampsia

- Eat a nutritious, balanced diet according to *Canada's Food Guide* (Appendix A). Consult with a registered dietitian on the diet best suited to the individual.
- There is no sodium restriction; however, consider limiting excessively salty foods (pretzels, potato chips, pickles, sauerkraut).
- Eat foods with fibre (whole grains, raw fruits, and vegetables).
- Drink a minimum of six to eight 250-mL glasses of water per day.
- Avoid drinking alcohol and limit caffeine intake.

Pre-Eclampsia or HELLP Syndrome.

Hospital care. The patient with pre-eclampsia or HELLP syndrome should receive appropriate treatment in a tertiary care centre from a perinatology team, including maternal–fetal medicine specialists, high-risk obstetrical nurses, internal medicine, if available, as well as anaesthesiology (see Nursing Care Plan, Severe Pre-eclampsia on Evolve). The need for tertiary care may result in the patient being transferred from their home community to a larger centre. The patient may be admitted to a high-risk antepartum or a labour and birth unit, depending on the hospital. If the patient's condition requires intensive monitoring, they may require care in a critical care unit for hemodynamic monitoring. If pre-eclampsia with severe features is diagnosed, birth is warranted regardless of gestational age (Brown et al., 2018; Butalia at al., 2018; Magee et al., 2014). Vaginal birth is the preferred type of birth, and Caesarean birth should only be performed for obstetrical indications. For pregnant patients at risk of giving birth prior to 35 weeks' gestation, corticosteroids (betamethasone) should be given to promote fetal lung maturation. The dose is 12 mg intramuscularly, repeated in 24 hours. It is ideal if the birth can be delayed for 48 hours, to provide the time for administration of steroids (Magee et al., 2014; Skoll et al., 2018) (see Chapter 20, Medication Guide: Antenatal Glucocorticoid Therapy With Betamethasone or Dexamethasone).

Recognition of the clinical and laboratory findings of pre-eclampsia with severe features or HELLP syndrome is important in order to prevent maternal and perinatal mortality. Patients with pre-eclampsia or HELLP syndrome have multisystem involvement, and nursing care must focus on the care of both the pregnant patient and the fetus. Patient and fetal surveillance, education of the patient and their family regarding the disease process, and supportive measures should be initiated. Assessments include review of the central nervous, cardiovascular, pulmonary, and renal systems. Breath sounds are auscultated for crackles or diminished breath sounds, which may indicate pulmonary edema. An in-dwelling urinary catheter may be inserted to measure urinary output. An in-dwelling urinary catheter facilitates monitoring of renal function and effectiveness of therapy; however, the risk of UTI should be considered in the stable antepartum patient. Hemoglobin oxygen saturation can be assessed with a pulse oximeter. Baseline laboratory assessments include metabolic studies for liver enzyme (AST, ALT, lactate dehydrogenase [LDH], and bilirubin) determination, complete blood count (CBC) with platelets, coagulation profile (including fibrinogen) to assess for DIC, and electrolyte studies to establish renal functioning (ACOG, 2019; Harper et al., 2019; Magee et al., 2014).

If there is uterine activity, vaginal examination may be done to assess for cervical changes. Abdominal palpation, uterine tonicity, and fetal size, activity, and position can be used to determine fetal well-being. Fetal health surveillance (e.g., NST, BPP) should be ordered because of the potential for hypoxia related to uteroplacental insufficiency. Electronic fetal monitoring to determine fetal status is initiated at least once a day with pre-eclampsia.

The nurse's skill in implementing these techniques can be reassuring to the patient and their family. The patient's room should be located close to staff and emergency medications, supplies, and equipment. Seizure precautions need to be taken (Box 14.5). The patient is at risk for thromboembolism due to restricted activity, so they may wear SCD (sequential compression device) boots while in bed or may be administered prophylactic anticoagulation with low- molecular-weight heparin (LMWH). The dose must be withheld if birth is imminent, to enable the provision of neuraxial analgesia.

Intrapartum nursing care of the patient with pre-eclampsia or HELLP syndrome involves continuous patient and fetal assessments as labour progresses. Arterial line insertion may be useful when continuous BP monitoring is desired, in the instance of poor BP control. Central venous pressure monitoring is not routinely used, but it may be used to monitor trends over time and not absolute values (Magee et al., 2014). Invasive hemodynamic monitoring with a pulmonary artery catheter (Swan-Ganz catheter) may be required for accurate intravascular fluid volume measurement in the presence of pulmonary edema or acute renal failure (ACOG, 2019; Magee et al., 2014).

BOX 14.5 Hospital Precautionary Measures for Seizures

- Environment
  - Quiet
  - Nonstimulating
  - Lighting subdued
  - Seizure precautions (have magnesium sulphate available)
  - Suction equipment tested and ready to use
  - Oxygen administration equipment tested and ready to use
  - Call button within easy reach
- Support for patients who may be separated from family and other children during their hospitalization
- Emergency medication tray immediately accessible
- Antihypertensive medication (labetalol, nifedipine, hydralazine) immediately available
- Calcium gluconate immediately available (if receiving magnesium sulphate)
- Emergency birth pack accessible

Magnesium sulphate. An important goal of care for the patient with pre-eclampsia is to prevent or control convulsions (eclamptic seizures). Magnesium sulphate is the medication of choice in the prevention and treatment of convulsions caused by pre-eclampsia or eclampsia. It is administered as a secondary infusion ("piggyback") to the main intravenous (IV) line by volumetric infusion pump. An initial loading dose of 4 g diluted in at least 100 mL of IV fluid per protocol or physician's order is infused over 20 to 30 minutes. This dose is followed by a maintenance dosage of magnesium sulphate diluted in an IV solution per physician's order (e.g., 20 g of magnesium sulphate in 500 mL of normal saline) and administered by infusion pump at 1 to 2 g/hr (Magee et al., 2014). There is no need to draw routine serial serum magnesium levels. After the loading dose, there may be a transient lowering of the arterial BP secondary to relaxation of smooth muscle.

! NURSING ALERT

The patient's BP, pulse, and respiratory rate should be monitored closely (every 5 minutes) while the loading dose of magnesium sulphate is being administered intravenously. Oxygen saturation and electronic fetal monitoring, including uterine activity, should be monitored continuously during the loading dose. Vital signs, including oxygen saturation, should be monitored a minimum of hourly during the maintenance infusion or even more frequently depending on the stability of the patient's condition. Electronic fetal monitoring and uterine activity should be continuous throughout the administration of magnesium sulphate infusion.

Magnesium sulphate is rarely given intramuscularly because the absorption rate cannot be controlled, injections are painful, and tissue necrosis can occur. The intramuscular (IM) route may be used, however, with some patients who are being transported to a tertiary care centre. The IM dose is 5 g given in the ventral gluteal muscle (one on each side), for a total of 10 g (1% procaine may be ordered as an

addition to the solution to reduce injection pain) and can be repeated at 4-hour intervals. Z-track technique should be used for the deep IM injection, followed by gentle massage at the site.

Magnesium sulphate interferes with the release of acetylcholine at the synapses, resulting in decreased neuromuscular irritability, depressed cardiac conduction, and decreased central nervous system (CNS) irritability. Because magnesium circulates free and unbound to protein and is excreted in the urine, accurate recordings of maternal kidney function and urine output must be maintained.

Diuresis within 24 to 48 hours is an excellent prognostic sign; it is considered evidence that perfusion of the kidneys has improved as a result of relaxation of arteriolar spasm. With improved perfusion, fluid moves from interstitial spaces to the intravascular bed, and edema is reduced. Diuresis results in weight loss. Although diuresis generally indicates overall improvement, in the presence of worsening clinical status, it may indicate impending renal failure. As renal function declines and serum creatinine levels rise, renal filtration is compromised. In this situation, the patient can excrete large volumes of urine (greater than 200 mL/hr) but does not excrete magnesium sulphate.

Because magnesium sulphate is a CNS depressant, the nurse needs to assess for signs and symptoms of magnesium toxicity. This is rare with the 1 g/hr maintenance dose, and serum magnesium levels are only obtained when signs of toxicity are present. Adverse effects that are frequently experienced with magnesium sulphate include lethargy, feeling of heat or warmth, headache, or nausea (Gilbert, 2011). Early signs of toxicity include vomiting, respiratory distress, hypotension, flushing, muscle weakness, decreased reflexes, and slurred speech. Magnesium sulphate is excreted by the kidneys. A decrease in urine output is a risk factor for magnesium sulphate toxicity. Serum creatinine levels should be assessed following a health care provider's order.

! NURSING ALERT

Loss of patellar reflexes, respiratory and muscular depression, oliguria, and a decreased level of consciousness are signs of magnesium toxicity. If magnesium toxicity is suspected, the infusion should be discontinued immediately. Calcium gluconate, the antidote for magnesium sulphate, may also be ordered (10 mL of a 10% solution, or 1 g) and given by slow IV push (usually given by the physician) over at least 3 minutes to avoid undesirable reactions such as dysrhythmias, bradycardia, and ventricular fibrillation, or may be given as a minibag infusion over 15 to 30 minutes by the nurse.

Magnesium sulphate seems to have a small negative effect on the FHR, variability, and accelerative pattern but is not sufficient clinically to warrant medical intervention (Nensi et al., 2014). Newborn serum magnesium levels approximate those of the mother. Doses of magnesium sulphate that prevent seizures in the patient have been determined to be safe for the fetus. There is no evidence that the newborn is affected at birth. However it is important that the neonatal team attend the birth to provide resuscitation measures as needed.

! NURSING ALERT

High serum levels of magnesium can cause relaxation of smooth muscle, such as the uterus. However, when administered as a 4 g loading dose followed by a 1 g/hr maintenance dose, magnesium sulphate has not been shown to increase the need for oxytocin stimulation of labour. Other than a brief period of uterine muscle relaxation during and immediately after administration of the loading dose, no evidence of decreased uterine contractility has been observed (Cunningham et al., 2018).

MEDICATION ALERT

Magnesium sulphate is considered a high-alert medication because it can cause patient harm when administered incorrectly. Measures to improve the safe use of this medication include developing detailed policies, procedures, protocols, and standing orders and thorough assessment and documentation. Never abbreviate magnesium sulphate as $MgSO_4$ anywhere in the medical record (Institute for Safe Medication Practices [ISMP], 2018).

Control of blood pressure. Initiation of antihypertensive therapy reduces maternal morbidity and mortality rates associated with left ventricular failure and cerebral hemorrhage; therefore, antihypertensive medications may be ordered to lower BP. Antihypertensive therapy must not decrease the arterial pressure too much or too rapidly as it will impact uteroplacental perfusion. Outcomes of the CHIPS (Control of Hypertension in Pregnancy Study) found that tight control (target DBP of >85 mm Hg) versus less tight control of BP (target DBP >100 mm Hg) resulted in no significant differences in overall major adverse perinatal outcomes. Patients in the study who were in the less tight control arm had higher rates of severe hypertension (Magee et al., 2014, 2015).

Labetalol administered intravenously is the antihypertensive drug of choice for the treatment of hypertension. Nifedipine; methyldopa; other beta blockers such as acebutolol, metoprolol, pindolol, and propranolol; and hydralazine are also used (Table 14.5) (Harper et al., 2019; Magee et al., 2014). The choice of medication used depends on the patient's response and physician preference.

! NURSING ALERT

When administering antihypertensive therapy, the nurse must remember that the medication effects depend on intravascular volume. Because pre-eclampsia is associated with contracted intravascular volume, initial doses should be given with caution and maternal response monitored closely.

Eclampsia. Eclampsia is usually preceded by premonitory signs and symptoms, including persistent headache, blurred vision, photophobia, severe epigastric or right upper quadrant abdominal pain, and altered mental status. However, seizures can appear suddenly and without warning in a seemingly stable patient with only minimal BP elevations (Sibai, 2017). Eclamptic seizures are frightening to observe. Tonic contraction of all body muscles (seen as arms flexed, hands clenched, legs inverted) precedes the tonic-clonic convulsion (Figure 14.4). During this stage muscles alternately relax and contract. Respirations are halted and then begin again with long, deep, stertorous inhalations. Hypotension follows; and muscular twitching, disorientation, and amnesia persist for a while after the seizure. The patient may also vomit or be incontinent of urine or stool. Subsequent seizures may recur within minutes of the first convulsion, or the patient may never have another. During the seizure, the pregnant patient and fetus are not receiving oxygen; thus eclamptic seizures produce a marked metabolic insult to both the patient and the fetus (Cunningham et al., 2018).

Immediate care. The immediate goal of care during a seizure is to ensure a patent airway (see Emergency box). Time, duration, and a description of the convulsions are recorded, and any urinary or fecal incontinence is noted. Administration of magnesium sulphate is recommended to prevent recurrent seizures. Phenytoin and benzodiazepines may be used for eclampsia prophylaxis or treatment when magnesium sulphate is contraindicated (Magee et al., 2014). If possible, the fetus should be monitored for adverse effects; however, this task

TABLE 14.5 Pharmacological Control of Hypertension in Pregnancy

Action	Target Tissue	ADVERSE EFFECTS: Maternal	ADVERSE EFFECTS: Fetal	Nursing Actions
Hydralazine (Apresoline)				
Arteriolar vasodilator	Peripheral arterioles: to decrease muscle tone, decrease peripheral resistance; hypothalamus and medullary vasomotor centre for minor decrease in sympathetic tone	Headache, flushing, palpitation, tachycardia, some decrease in uteroplacental blood flow, increase in heart rate and cardiac output, increase in oxygen consumption, nausea and vomiting	Tachycardia; late decelerations and bradycardia if maternal diastolic pressure >90 mm Hg	Assess for effects of medications, alert patient (family) to expected effects of medications, assess blood pressure frequently because precipitous decrease can lead to shock and perhaps placental abruption; assess urinary output; maintain bed rest in a lateral position with side rails up; use with caution in presence of maternal tachycardia
Labetalol Hydrochloride				
β-Blocking agent causing vasodilation without significant change in cardiac output	Peripheral arterioles (see hydralazine)	Minimal: flushing, tremulousness; minimal change in pulse rate	Minimal, if any	See hydralazine; less likely to cause excessive hypotension and tachycardia; less rebound hypertension than hydralazine
Methyldopa (Aldomet)				
Maintenance therapy if needed: 250–500 mg orally every 8 hr (β_2-receptor agonist)	Postganglionic nerve endings: interferes with chemical neurotransmission to reduce peripheral vascular resistance, causes CNS sedation	Sleepiness, postural hypotension, constipation; rare: medication-induced fever in 1% of patients and positive Coombs' test result in 20%	After 4 months' maternal therapy, positive Coombs' test result in infant	See hydralazine
Nifedipine				
Calcium channel blocker	Arterioles: to reduce systemic vascular resistance by relaxation of arterial smooth muscle	Headache, flushing; possible potentiation of effects on CNS if administered concurrently with magnesium sulphate, may interfere with labour	Minimal	See hydralazine; use caution if patient also receiving magnesium sulphate

CNS, Central nervous system.

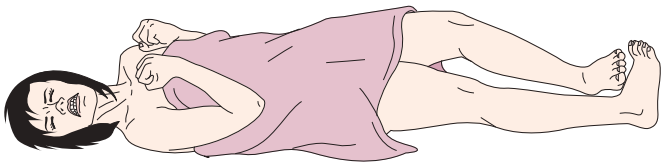

Fig. 14.4 Eclampsia (convulsion or seizure).

should not take precedence over other stabilizing care measures. Transient fetal bradycardia and decreased FHR variability are common. If the patient has been incontinent of urine and stool, or the membranes have ruptured during the convulsion, they will need assistance with hygiene and a change of gown. Oral care with a soft toothbrush may be of comfort.

EMERGENCY

Eclampsia

Tonic–Clonic Seizure Signs

- Stage of invasion—2 to 3 seconds: eyes are fixed; twitching of facial muscles occurs
- Stage of contraction—15 to 20 seconds: eyes protrude and are bloodshot; all body muscles are in tonic contraction
- Stage of seizure—Muscles relax and contract alternately (clonic); respirations are halted and then begin again with long, deep, stertorous inhalation; coma ensues

Intervention

- Keep airway patent: turn head to one side, place pillow under one shoulder or back if possible.
- Call for assistance. Do not leave bedside.
- Protect patient from injury during seizure by having padded side rails raised and safely locked.
- Observe and record convulsion activity.

After Convulsion or Seizure

- Do not leave patient unattended until they are fully alert.
- Observe for postconvulsion coma, incontinence.
- Use suction as needed.
- Administer oxygen via face mask at 10 L/min.
- Start intravenous fluids and monitor intake.
- Administer magnesium sulphate or anticonvulsant medication as ordered.
- Insert in-dwelling urinary catheter and monitor hourly output.
- Monitor blood pressure.
- Monitor fetal and uterine status.
- Expedite laboratory work as ordered to monitor kidney function, liver function, coagulation system, and medication levels.
- Provide hygiene and a quiet environment.
- Support patient and family and keep them informed.
- Be prepared to assist with birth as needed.

A rapid assessment of uterine activity, cervical status, and fetal status should be performed after a seizure. During the seizure, membranes can rupture, and the cervix can dilate because the uterus becomes hypercontractile and hypertonic; birth may be imminent. If birth is not imminent, once a patient's seizure activity and BP are controlled, an assessment is performed to determine if birth needs to occur immediately, regardless of gestational age. Since birth is the definitive cure for the disease, the more serious the condition of the patient, the greater the need to proceed to the birth following the cessation of seizure activity. The means of birth (i.e., induction of labour versus Caesarean birth) depends on the pregnant patient and fetal condition, fetal gestational age, presence of labour, and the cervical Bishop score. If fetal lungs are not mature and the birth can be delayed for 48 hours, steroids such as betamethasone can be given (Magee et al., 2014; Skoll et al., 2018).

NURSING ALERT

Immediately after a seizure, the patient may be confused and can be combative. Pad the side rails to prevent injury, and maintain a quiet, darkened environment. It may take several hours for the patient to regain their usual level of mental functioning. They should not be left alone. Provide emotional support to the family and discuss the management of seizures and the patient's progress with them.

Aspiration is a leading cause of maternal morbidity and mortality after an eclamptic seizure. After initial stabilization and airway management, the nurse should anticipate orders for a chest X-ray film and possibly arterial blood gases to determine whether aspiration occurred.

Postpartum Nursing Care. The nursing care of the patient with hypertensive disease differs in a number of ways from that required in the usual postpartum period. After birth, the symptoms of pre-eclampsia or eclampsia resolve quickly, usually within 48 hours. However, hypertension may persist, and the postpartum patient should be monitored from days 3 to 6 after giving birth. Resolution of the disease process is manifested by diuresis, which usually occurs within 24 to 48 hours after the birth. The hematopoietic and hepatic complications of HELLP syndrome may persist longer. Usually an abrupt decrease in platelet count occurs with a concomitant increase in LDH and AST levels after a trend toward normalization of values has begun. Generally, the laboratory abnormalities seen with HELLP syndrome resolve in 72 to 96 hours.

The patient will need careful assessment of their vital signs, intake and output, reflexes, level of consciousness, uterine tone, and lochia flow throughout the postpartum period. The magnesium sulphate infusion is continued 24 hours for ongoing seizure prophylaxis. Even if no convulsions occurred before the birth, they may occur during the postpartum period. The same assessments should continue until the medication is discontinued.

NURSING ALERT

The postpartum patient is at risk for a boggy uterus and a large lochia flow as a result of the muscle-relaxant effects of magnesium sulphate therapy. Administration of an oxytocin infusion is recommended. Uterine tone and lochial flow must be monitored closely.

The pre-eclamptic patient is usually hemoconcentrated and unable to tolerate excessive postpartum blood loss. Oxytocin or prostaglandin products are used to control bleeding. Ergot products (e.g., ergonovine and methylergonovine) are contraindicated because they increase BP. The patient should be advised to report symptoms such as headaches and blurred vision. The nurse will need to assess affect, level of consciousness, BP, pulse, and respiratory status before an analgesic is given for headache. Magnesium sulphate potentiates the action of narcotics and CNS depressants; thus these medications must be administered with caution. Patients who were receiving antihypertensive medication in pregnancy are recommended to resume the medications in the postpartum period (Brown et al., 2018).

Postpartum recovery may be prolonged as a result of the physiological consequences of the hypertensive disease processes. The nurse should accompany the patient when they ambulate after birth and assess for weakness, dizziness, shortness of breath, and muscle soreness. Postpartum thromboprophylaxis with LMWH should be considered for patients with hypertension or pre-eclampsia. A combination of other risks, including Caesarean birth or postpartum hemorrhage greater than 1 litre, should also be considered (Chan et al., 2014).

The patient's and family's responses to the birth itself and the newborn should be monitored. Interactions and involvement in the care of the newborn can be encouraged as much as the patient and their family desire. The infant may be premature and in the neonatal intensive care nursery. The patient and family may be worried about their newborn's survival, and the day-to-day fluctuations in the newborn's status can be emotionally draining. In addition, the patient and their family need opportunities to discuss their emotional response to the experience of having a pregnancy with complications. The primary care provider can provide information concerning the prognosis, with support from the nurses. If the outcome for the patient or baby is unfavourable, the family should be assisted in coping with their loss and grief.

Future Health Care. The recurrence risk for hypertensive disorders in subsequent pregnancy is 20.7% for pre-eclampsia, 13.8% for gestational hypertension, and 0.2% for HELLP syndrome (van Oostwaard et al., 2015). Patients can be somewhat reassured that when

hypertension in pregnancy does recur, it tends toward a milder response. The risk of subsequent pre-eclampsia is especially likely in patients who initially developed it earlier (during the second trimester) in pregnancy. Even if these patients remain normotensive in a subsequent pregnancy, they may have a greater likelihood of an adverse pregnancy outcome such as preterm birth, small-for-gestational-age infant, and perinatal death (Sibai, 2017).

Ideally, patients who have had pre-eclampsia in a previous pregnancy should receive counselling during a preconception visit before the next planned pregnancy. At this visit, the previous pregnancy history should be reviewed and the prognosis for the upcoming pregnancy discussed. Potential lifestyle modifications such as weight loss and increased physical activity should be encouraged. The current status of any chronic medical conditions, such as diabetes or chronic hypertension, should be assessed so that they are brought into the best control possible before the upcoming pregnancy. Current medications should be reviewed and their administration modified if necessary for the upcoming pregnancy. The use of low-dose aspirin during the upcoming pregnancy will likely be recommended, especially if an adverse outcome accompanied the previous pregnancy complicated by pre-eclampsia (ACOG, 2019).

Patients with pre-eclampsia also have an increased risk of developing chronic hypertension and cardiovascular disease later in life and need medical follow-up (Brown et al., 2018). It is believed that pre-eclampsia does not cause cardiovascular disease but rather that pre-eclampsia and cardiovascular disease share common risk factors. Further research is needed to determine how to take advantage of this information relating pre-eclampsia to cardiovascular disease later in life. For now, patients of childbearing age should be educated about lifestyle changes (maintaining a healthy weight, increasing physical activity, and avoiding smoking) that may decrease the risk for developing future health issues (ACOG, 2019; Sibai, 2017).

GESTATIONAL DIABETES MELLITUS

Gestational diabetes mellitus (GDM) is defined as elevated glucose levels that are first recognized during pregnancy. In the first trimester of pregnancy, uncontrolled hyperglycemia can affect fetal development, resulting in malformations (Feig et al., 2018). The incidence of GDM is increasing worldwide. The global prevalence of hyperglycemia during pregnancy has been estimated at 16.9% using the World Health Organization (WHO) criteria (WHO, 2013). In Canada, the prevalence of gestational diabetes is population-specific, varying from 3.8 to 6.5% in the overall population, with higher rates reported among Indigenous patients and those of Latin American, South Asian, Asian, and African descent. Patients with GDM are at significant risk of developing glucose intolerance later in life; about 50% will be diagnosed as having diabetes within 5 to 10 years. Patients whose GDM is diagnosed early in pregnancy and who may be obese are at increased risk of developing sustained glucose intolerance and type 2 diabetes, usually related to the degree of vascular changes that have occurred over time. Current Canadian guidelines strongly recommend universal screening of all pregnant patients for the presence of hyperglycemia (Berger et al., 2019; Feig et al., 2018). Universal screening is important because hyperglycemia is difficult to detect, as it presents without symptoms. Data show that the incidence of adverse maternal and fetal outcomes increase with poorly controlled glucose levels (Berger et al., 2019; Feig et al., 2018).

Maternal and Fetal Risks

Patients with GDM have a higher risk of developing pre-eclampsia or having a birth with shoulder dystocia, a Caesarean birth, or a large-for-gestational-age baby (Berger et al., 2019). GDM places the fetus at increased risk for hypoglycemia, IUGR (related to poor placental function), and intrauterine fetal death.

Screening for Gestational Diabetes Mellitus

Feig et al. (2018) recommend that all pregnant patients be screened for the presence of GDM at 24 to 28 weeks of gestation. Assessment of relevant history, clinical risk factors, and laboratory screening of blood glucose levels should be performed. Patients with multiple risk factors should be screened in the first trimester to identify **hyperglycemia** early. If the initial screening is performed before 24 weeks of gestation and is negative, rescreening between 24 and 28 weeks of gestation is recommended. Risk factors for the development of GDM include the following (Feig et al., 2018):

- Being 35 years of age or older
- Being a member of a high-risk group (African, Arab, Asian, Latin-American, Indigenous, or South Asian)
- Using corticosteroid medication
- Obesity (a body mass index [BMI] greater than or equal to 30)
- Pregestational diabetes
- Gestational diabetes in a previous pregnancy
- Given birth to a baby that weighed more than 4 kg
- A parent, brother, or sister with type 2 diabetes
- Polycystic ovary syndrome or acanthosis nigricans (darkened patches of skin).

The optimal method of screening for GDM has become a controversial topic. There are two types of screening tests for detecting GDM: the sequential test (two-step test) and the one-step test.

All pregnant patients should be offered screening between 24 to 28 weeks using one of the two methods. The two-step screening method is preferred and is shown in Figure 14.5, *A*. In this method, if the value of the plasma glucose is 7.8 – 11.0 when taken at 1 hour, a 2-hour 75-g oral glucose tolerance test should be performed. The alternative one-step method is shown in Figure 14.5, *B*.

Updated national guidelines have endorsed the use of different diagnostic thresholds for the both the two-step screening and one-step screening (Berger et al., 2019). It is recommended that nurses be familiar with both strategies and align their practice to the screening method adopted in their own institution and implement protocols to ensure consistent and uniform reporting of test results.

Nursing care for the pregnant patient with GDM is basically the same as that for patient with pregestational diabetes (see Chapter 15); however, the time frame for planning may be shortened with GDM because the diagnosis is usually made later in pregnancy.

Nursing Care

Antepartum. When the diagnosis of GDM is made, treatment begins immediately, allowing little or no time for the patient and their family to adjust to the diagnosis before they are expected to participate in the treatment plan. This is in contrast to the patient with pregestational diabetes, who may have had years to learn about the disease and adapt to dietary modifications, self-monitoring of glucose, and insulin administration. With each step of the treatment plan, the nurse and other health care providers should educate the patient and their family, providing detailed and comprehensive explanations to ensure understanding of, participation in, and agreement with the necessary interventions. Potential complications should be discussed and the need for testing and maintenance of euglycemia throughout the remainder of the pregnancy reinforced. (See the Nursing Care Plan: The Pregnant Patient with Gestational Diabetes on Evolve.)

As with pregestational diabetes, the aim of therapy in patients with GDM is meticulous blood glucose control. Fasting (preprandial) blood glucose levels should be between 3.8 and 5.2 mmol/L; 1 hour after meals (postprandial) they should be between 5.5 and 7.7 mmol/L; and 2-hour postprandial blood levels should be between 5.0 and 6.6 mmol/L (Berger et al., 2019).

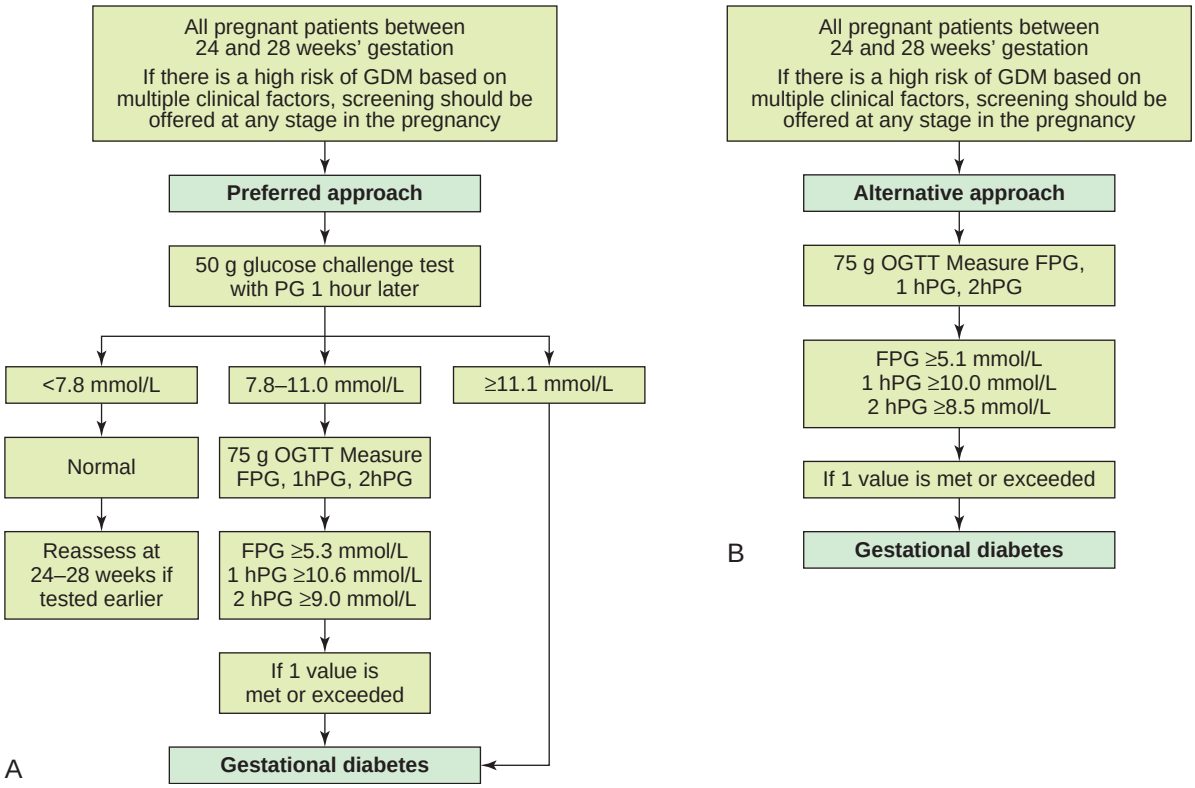

Fig. 14.5 **A:** Preferred "two-step" approach for screening and diagnosis of gestational diabetes. **B**: Alternative approach for screening and diagnosis of gestational diabetes. *1h PG*, 1-hour plasma glucose; *2hPG*, 2-hour plasma glucose; *FPG*, fasting plasma glucose; *GDM*, gestational diabetes mellitus; *OGTT*, oral glucose tolerance test; *PG*, plasma glucose. (From Thompson, D., Berger, H., Feif, D., et al. [2013]. Diabetes and pregnancy. *Canadian Journal of Diabetes, 37*, Supplement 1, S168–S183. Copyright 2013, with permission from Elsevier.)

Diet. Dietary modification is the mainstay of treatment for GDM. The patient with GDM is placed on a standard diabetic diet immediately upon diagnosis. Some authorities recommend fewer calories for overweight patients or patients with obesity, believing that such a diet will cause less hyperglycemia and reduce the need for insulin (Landon et al., 2017). Dietary counselling by a dietitian is recommended.

Exercise. For patients with GDM, exercise appears to be safe. In adults who are not pregnant, exercise increases lean muscle mass and improves sensitivity to insulin. Therefore, a moderate exercise program is recommended for patients with GDM as it may help lower blood glucose levels and may be instrumental in reducing the need for insulin.

Monitoring of blood glucose levels. Regular blood glucose monitoring is necessary to determine if euglycemia can be maintained by diet and exercise. Patients with GDM are taught to perform self-monitoring with blood glucose meters in order to adjust the management plan to achieve near-normal glycemia. Testing may be done at fasting, preprandial, and postprandial times, with values recorded in a log for review by the health care provider. The frequency and timing of blood glucose monitoring should be individualized for each patient.

Pharmacological therapy. Approximately 25 to 50% of patients with GDM require insulin or oral medication during the pregnancy to maintain satisfactory blood glucose levels, despite following a prescribed diet and exercise plan (Landon et al., 2017). The nurse should take a thorough history from the patient with GDM to determine the pattern of increased blood glucose levels.

Up to 20% of patients with GDM require insulin during the pregnancy to maintain adequate blood glucose levels. Patients with repeatedly high glucose thresholds for fasting and 2-hour postprandial values are usually started on insulin therapy. Some cases are managed with a single dose of bedtime NPH insulin to treat isolated fasting hyperglycemia, whereas others require treatment of postprandial hyperglycemia with insulin lispro or aspart at appropriate mealtimes. Up to four injections daily may be necessary to achieve adequate control for some patients (Landon et al., 2017). The patient and their family should be taught the necessary skills to manage insulin administration.

For the past 15 years, oral hypoglycemic therapy has been used as an alternative to insulin in patients with GDM who require medication in addition to diet for blood glucose control. Glyburide and metformin are both used for blood glucose control in patients with GDM and both cross the placenta. While both medications appear to be safe for use during pregnancy, long-term studies are lacking, so the effects of glyburide and metformin over time on patients with GDM and their children are unknown (Balsells et al., 2015).

Glyburide is an oral agent that is frequently prescribed for diabetes. Several studies have shown that glyburide controls blood glucose levels as well as insulin does in patients with GDM. However, other studies have found that glyburide appears to cross the placenta in significant amounts, and increased weight gain in the pregnant patient as well as increased rates of newborn hypoglycemia and increased macrosomia have been reported with its use (Balsells et al., 2015). Glyburide may not work as well in patients with obesity or who experienced higher levels of hyperglycemia early in pregnancy (Landon et al., 2017). Studies have shown that glyburide should be taken at least 30 minutes (preferably 1 hour) before a meal so its peak effect covers the 2-hour postmeal blood glucose level. Because episodes of hypoglycemia can occur

between meals, patients taking glyburide should always carry their glucose meter with them, along with glucose tablets or gel.

Metformin is another oral hypoglycemic agent sometimes used in the management of GDM. The use of metformin compared with insulin in patients with gestational diabetes resulted in less weight gain and less pre-eclampsia than in patients treated with insulin. Infants of mothers using metformin had less newborn hypoglycemia. Although metformin crosses the placenta, it does not appear to be teratogenic. However, glyburide may be better than metformin at controlling blood glucose levels in patients with GDM because glyburide causes the maternal pancreas to produce more insulin, whereas metformin decreases hepatic glucose production and increases peripheral sensitivity to insulin (Landon et al., 2017).

Other antihyperglycemic agents are not recommended for use in pregnancy, as currently there are no human data on the use of non-insulin agents (Feig et al., 2018).

Fetal surveillance. While there is no standard recommendation for fetal surveillance in pregnancies complicated by GDM, patients with blood glucose levels that are well controlled by diet and exercise are at risk for stillbirth related to the presence of gestational diabetes. The SOGC recommends serial ultrasound assessment starting at 28 weeks' gestation and repeating this every 3 to 4 weeks to monitor fetal growth and amniotic fluid levels (Berger et al., 2019). Once the patient reaches 36 weeks of gestation, fetal surveillance weekly with nonstress testing is recommended (Berger et al., 2019). Additional fetal assessments with amniotic fluid index (AFI) or BPP may be considered.

Patients with GDM whose blood glucose levels are not well controlled or who require insulin therapy, have hypertension, or have a history of previous stillbirth generally receive more intensive fetal surveillance. There is no standard recommendation regarding initiation of testing. NSTs and AFI assessment are often recommended twice weekly, beginning from 32 to 36 weeks of gestation, to reduce the risk of stillbirth (Berger et al., 2019; Liston et al., 2018) (see Chapter 13).

Intrapartum. Induction of labour is recommended to be offered to patients with GDM between 38 and 40 weeks of gestation, depending on their levels of blood sugar control and presence of confounding risk factors or comorbidities (Berger et al., 2019).

During labour and birth, blood glucose levels are monitored at least every hour to maintain levels, ideally, at less than 8 mmol/L (Berger et al., 2019). Glucose levels within this range will decrease the severity of newborn hypoglycemia. Patients whose GDM has been managed on insulin can be controlled by a sliding scale of regular insulin that is titrated to blood sugars during labour. Even though IV fluids containing glucose may be given as maintenance fluids during birth, they should not be given as a bolus to the patient who has GDM. Assessment of routine uterine activity and FHR should be done. Although GDM is not an indication for Caesarean birth, it may be necessary, to prevent obstetrical complications related to macrosomia such as shoulder dystocia.

Postpartum. Most patients with GDM return to normal glucose levels after childbirth. However, GDM is likely to recur in future pregnancies, and patients with GDM are at significant risk of developing glucose intolerance or type 2 diabetes later in life (Berger et al., 2019; Feig et al., 2018). Assessment for carbohydrate intolerance can be initiated 6 weeks to 6 months postpartum or after breastfeeding has stopped and should be repeated at regular intervals throughout the patient's life (Berger et al., 2019; Feig et al., 2018). Obesity is a major risk factor for the later development of diabetes. Thus patients with a history of GDM, particularly those who are overweight, should be encouraged to make lifestyle changes that include weight loss and exercise in order to reduce this risk. Because offspring of patients with GDM are at risk of developing obesity and diabetes in childhood or adolescence, regular health care for these children is essential.

Patients with GDM should be encouraged to breastfeed immediately after birth and for at least 4 months postpartum, as this may contribute to the reduction of newborn hypoglycemia and obesity in the child, and prevent the development of metabolic syndrome and type 2 diabetes in themselves. Longer-duration and more intense breastfeeding is associated with less diabetes in the patient (Feig et al., 2018).

HYPEREMESIS GRAVIDARUM

Nausea and vomiting of pregnancy (NVP) is the most common medical condition in pregnancy, affecting 50 to 90% of patients (Campbell et al., 2016). It most commonly occurs between 4 and 8 weeks of gestation with improvement by 16 weeks. However, 10 to 25% of patients still experience symptoms at 20 to 22 weeks of gestation, and some patients will have symptoms throughout pregnancy (see Chapter 12: Nausea and Vomiting). When vomiting during pregnancy becomes excessive enough to cause weight loss, electrolyte imbalance, nutritional deficiencies, and ketonuria, the disorder is termed **hyperemesis gravidarum (HG)**. This disorder occurs in approximately 0.3 to 3% of all pregnancies (London et al., 2017). There are a number of patient characteristics associated with an increased risk for the development of HG, including younger parental age, nulliparity, a BMI less than 18.5 or greater than 25, and low socioeconomic status. Patients with asthma, migraines, pre-existing diabetes, psychiatric illness, hyperthyroid disorders, gastrointestinal disorders, or a previous pregnancy complicated by HG are also more likely to develop hyperemesis. Factors related to the current pregnancy that make a patient more likely to develop HG are carrying a female fetus, multifetal gestation, and gestational trophoblastic disease. Also, a maternal family history of HG is associated with the disorder (Castillo & Phillippi, 2015).

HG can cause complications for both pregnant patients and their newborns. Severe but rare maternal complications of HG include esophageal rupture, pneumomediastinum, and deficiencies of vitamin K and thiamine with resulting Wernicke encephalopathy (CNS involvement) (Kelly & Savides, 2019). Infants born to a parent who had poor pregnancy weight gain because of HG may be small for gestational age, have a low birth weight, or be born prematurely (Castillo & Phillippi, 2015; Kelly & Savides, 2019).

Etiology

The etiology of HG is not well understood. Several theories have been proposed, although none of them adequately explains the disorder in all cases. HG may be related to high levels of estrogen or human chorionic gonadotropin (hCG) and associated with transient hyperthyroidism during pregnancy. Research has found that pregnant patients who have severe nausea and vomiting have a 1.5-fold increased chance of carrying a female infant, supporting the association between increased estrogen exposure and HG (Cunningham et al., 2018; London et al., 2017). Esophageal reflux, reduced gastric motility, and decreased secretion of free hydrochloric acid may contribute to the disorder.

Psychological and social factors can also play a part in the development of HG. Ambivalence toward the pregnancy and increased stress may be associated with this condition (Cunningham et al., 2018). Patients may have to take time away from work, which affects their income and can produce feelings of anxiety. Conflicting feelings about prospective motherhood, body changes, and lifestyle alterations—all normal reactions to pregnancy—may contribute to episodes of vomiting, particularly if these feelings are excessive or unresolved (Campbell et al., 2016).

Clinical Manifestations

HG usually begins in the first trimester. It is characterized by protracted vomiting, retching, severe dehydration, and weight loss requiring hospitalization. The dehydration may lead to electrolyte imbalance, ketosis, and acetonuria (Kelly & Savides, 2019). The patient with HG may have significant weight loss of at least 5% of prepregnancy weight and symptoms of dehydration, such as decreased BP, increased pulse rate, and poor skin turgor (London et al., 2017). The patient is almost always unable to keep down even clear liquids taken by mouth. Laboratory tests may indicate electrolyte imbalances. Other causes of nausea and vomiting must be ruled out, including gastrointestinal, genitourinary, CNS, and toxic or metabolic issues (Campbell et al., 2016). In addition, an interrelated psychological component has been associated with HG and must be assessed (Cunningham et al., 2018).

Nursing Care

Assessment. A thorough assessment to determine the severity of the condition must be completed by the nurse. The frequency, severity, and duration of episodes of nausea and vomiting must be determined. If the patient is vomiting, the assessment should include the approximate amount and colour of the vomitus. Other symptoms such as diarrhea, indigestion, and abdominal pain or distension should also be identified. Assessment of sleep patterns and disruption due to vomiting is important, as sleep deprivation may contribute to how the patient is coping (Campbell et al., 2016). Prepregnancy weight and documented weight gain or loss during the pregnancy are important baseline data to collect. Any effective pharmacological and nonpharmacological interventions that the patient has used should be noted. The pharmacist and dietitian can play an important role in the care of a patient with hyperemesis.

A complete physical examination, including vital signs, should be performed, with attention to signs of fluid and electrolyte imbalance and nutritional status. A urine dipstick test for ketonuria should be obtained, as ketonuria can indicate the need for IV fluids for dehydration. Other laboratory tests that may be ordered include a urinalysis, CBC, electrolytes, renal and liver function tests, assessment of thyroid function, and bilirubin levels. These tests help rule out the presence of underlying diseases, such as pyelonephritis, pancreatitis, cholecystitis, hepatitis, and thyroid dysfunction (London et al., 2017).

Psychosocial assessment includes asking the patient about anxiety, fears, and concerns related to their own health and the effects on pregnancy outcome. Family members should be assessed for anxiety and in regard to their role in providing support for the pregnant patient.

Initial Care. Initially, if the patient can manage their symptoms with clear liquids, their diet can be increased by slowly introducing small, frequent bland meals that are high in protein or carbohydrates but low in fat. The addition of a multivitamin, taken orally if tolerated, has been shown to improve a patient's status. Patients experiencing NVP who are not low in iron stores should stop taking prenatal vitamins with iron during the first trimester and substitute them with folic acid or adult's vitamins that are low in iron (Campbell et al., 2016). Patients should be counselled to avoid odours, tastes, or other activities that can trigger the senses and result in nausea. Examples of triggers include a stuffy room, visually stimulating lights, or strong perfumes (Smith et al., 2020).

Most pregnant patients are reluctant to take medications in pregnancy; therefore, the initial treatment for symptoms of mild NVP include ginger; wrist acupressure at the pressure point of the Nei Guan, which is located three finger-breadths proximal to the wrist (see Figure 12.5); and the use of mindfulness-based cognitive therapy (Campbell et al., 2016; National Institute for Health and Care Excellence [NICE], 2019).

If the patient is unable to maintain clear liquids by mouth, they will require IV therapy for correction of fluid and electrolyte imbalances. In the past, patients needing IV therapy were admitted to the hospital. Today they often are successfully managed on an outpatient basis or at home. Interventions may include initiating and monitoring IV therapy; administering antiemetics, antacids, or nutrition supplements; and monitoring the patient's response to interventions. The nurse needs to observe the patient for any signs of complications, such as metabolic acidosis, jaundice, or hemorrhage, and alert the primary care provider should these occur. Monitoring includes assessment of the patient's nausea, retching without vomiting, and vomiting, since the latter two symptoms, although related, are separate.

Medications may be used if nausea and vomiting are uncontrolled. The current SOGC guidelines for treatment of NVP recommend the use of pyridoxine (vitamin B_6), either alone or in combination with doxylamine as initial medical management (Campbell et al., 2016). A single drug combination of pyridoxine and doxylamine (Diclectin) has been available for use in Canada. Advantages to the use of Diclectin are that it is a single tablet and provides delayed-release effects (Castillo & Phillippi, 2015). Many studies have confirmed the safety of doxylamine/pyridoxine combination in pregnancy (Zhang & Persaud, 2017).

Other frequently prescribed medications include dimenhydrinate or diphenhydramine, which are considered safe in pregnancy. Promethazine, chlorpromazine, and prochlorperazine have also demonstrated benefits and all may be used (Campbell et al., 2016). Metoclopramide accelerates gastric emptying and corrects gastric dysrhythmias. It has been demonstrated in some small studies to be both safe and effective.

Corticosteroids (methylprednisolone [Medrol] or hydrocortisone) may be prescribed for patients who do not respond well to the medications previously discussed. These medications have not been proven to treat hyperemesis effectively in all patients, however. Because exposure to corticosteroids may increase the risk for facial clefting, they should be used with caution and avoided if possible during the first trimester, when fetal organs and organ systems are developing (Campbell et al., 2016; Kelly & Savides, 2019).

In addition to antiemetic drugs, medications to control heartburn or reflux may also be prescribed. Use of antacids, histamine blockers, and proton pump inhibitors has been associated with improved symptom management and quality of life (Castillo & Phillippi, 2015).

If these medications are not effective for controlling nausea and vomiting, the medication of choice is ondansetron (Zofran) (Cunningham et al., 2018; London et al., 2017). Reports of potential safety concerns for fetal congenital malformations with ondansetron use in early pregnancy have not been proven; therefore, ondansetron can be used as an adjunctive therapy for the management of severe NVP when other antiemetic combinations have been unsuccessful (Campbell et al., 2016; London et al., 2017; NICE, 2019).

A standardized assessment tool such as the Pregnancy-Unique Quantification of Emesis (PUQE) Scale allows objective quantification of the presence and severity of the nausea and vomiting and enables accurate monitoring (Table 14.6) (Ebrahimi et al., 2009). A PUQE score of 13 to 15 indicates severe symptoms; 7 to 12, moderate symptoms; and less than 6, mild symptoms. Treatment should be modified according to the score.

Accurate measurement of intake and output, including the amount of emesis, is an important aspect of nursing care. Oral hygiene while the patient is on nothing-by-mouth (NPO) status and after episodes of vomiting helps allay associated discomfort. Assistance with positioning and providing a quiet, restful environment that is free from odours may give the patient some comfort. When the patient begins responding to therapy, limited amounts of oral fluids and bland foods such as crackers, toast, or baked chicken are given. The diet is progressed slowly as

TABLE 14.6 Pregnancy-Unique Quantification of Emesis (PUQE-24) Scale

Motherisk PUQE-24 Scoring System

In the last 24 hours, for how long have you felt nauseated or sick to your stomach?	Not at all	1 hour or less	2–3 hours	4–6 hours	More than 6 hours
	(1)	(2)	(3)	(4)	(5)
In the last 24 hours, have you vomited or thrown up?	7 or more times	5–6 times	3–4 times	1–2 times	I did not throw up
	(5)	(4)	(3)	(2)	(1)
In the last 24 hours, how many times have you had retching or dry heaves without bringing anything up?	None	1–2 times	3–4 times	5–6 times	7 or more times
	(1)	(2)	(3)	(4)	(5)

PUQE-24 Score: ☐ Mild = ≤6 ☐ Moderate = 7–12 ☐ Severe = 13–15
How many hours have you slept out of 24 hours? Why? _____
On a scale of 0 to 10, how would you rate your well-being? _____
0 (worst possible) — 10 (The best you felt before pregnancy)
Can you tell me what causes you to feel that way? _____

Reprinted from Ebrahimi, N., Maltepe, C., Bournissen, F. G., et al. (2009). Nausea and vomiting of pregnancy: Using the 24-hour Pregnancy-Unique Quantification of Emesis (PUQE-24) Scale. Motherisk Program, Hospital for Sick Children, Toronto. *Journal of Obstetrics and Gynaecology Canada, 31*(9), 803–807. Copyright © 2009 Society of Obstetricians and Gynaecologists of Canada, with permission from Elsevier.

tolerated by the patient until they are able to consume a nutritionally sound diet. Patients should be encouraged to eat whatever pregnancy-safe food appeals to them (Campbell et al., 2016). Because sleep disturbances may accompany HG, adequate rest should be promoted. The nurse can assist in coordinating treatment measures and periods of visitation so that the patient has sufficient rest periods.

Follow-up Care. Most patients are able to take nourishment by mouth after several days of treatment. They should be encouraged to eat small, frequent meals consisting of low-fat, high-protein foods; dry, bland foods; and cold foods, and to avoid greasy and highly seasoned foods (Campbell et al., 2016; Smith et al., 2020). A snack before bedtime is also advised. They need to increase their dietary intake of potassium and magnesium. Taking fluids between meals rather than with them sometimes helps lessen nausea, as does drinking liquids from a cup with a lid and drinking tea or water with lemon slices (Smith et al., 2020). See Patient Teaching box: Managing Nausea and Vomiting During Pregnancy, in Chapter 12 for discussion on managing nausea and vomiting during pregnancy. Many pregnant patients find that cooking odours can be nauseating; having other family members cook may decrease nausea. Patients should be counselled to contact their health care provider immediately if the nausea and vomiting recur, especially if accompanied by abdominal pain, dehydration, or weight loss greater than 2.3 kg in 1 week.

The patient with HG needs calm, compassionate, and sympathetic care, with recognition that the manifestations of hyperemesis can be physically and emotionally debilitating to the pregnant person and stressful for their family. Irritability, tearfulness, and mood changes are often consistent with this disorder. Fetal well-being is a primary concern of the pregnant patient. The nurse can provide an environment conducive to discussion of concerns and assist the patient in identifying and mobilizing sources of support. The family should be included in the plan of care whenever possible. Their participation may help alleviate some of the emotional stress associated with this disorder.

HEMORRHAGIC DISORDERS

Bleeding in pregnancy may jeopardize the pregnant patient's and fetal well-being, and an interprofessional approach is warranted to optimize the outcome for both the patient and their fetus. Blood loss decreases vital oxygen-carrying capacity and places the patient at increased risk for **hypovolemia**, anemia, infection, preterm labour, and preterm birth (ACOG, 2008/2019; Gilbert, 2011). Oxygen delivery to the fetus is compromised. Hemorrhage in the pregnant patient increase risks in the fetus and include blood loss or anemia, hypoxemia, hypoxia, anoxia, preterm birth, and stillbirth.

Hemorrhagic disorders in pregnancy are medical emergencies. The incidence and type of bleeding vary by trimester. In the first trimester, most bleeding is a result of spontaneous abortion or ectopic pregnancy. Approximately 50% of bleeding in the third trimester is caused by placenta previa and placental abruption (Gilbert, 2011). Antepartum hemorrhage is a leading cause of death, with ectopic pregnancy rupture, uterine rupture, and placental abruption being responsible for most deaths in pregnant persons.

With approximately 750 to 1 000 mL/min (15% of cardiac output) of blood flow to the uterine vasculature and placenta, disruption of vascular integrity has the potential for the pregnant patient to exsanguinate within 8 to 10 minutes. Prompt, expert teamwork on the part of the health care providers is essential to save the lives of the pregnant patient and fetus.

Early Pregnancy Bleeding

Bleeding during early pregnancy is alarming to the pregnant patient and of concern to health care providers. The common bleeding disorders of early pregnancy include miscarriage, premature dilation of the cervix, ectopic pregnancy, and hydatidiform mole (molar pregnancy). Bleeding can originate from the cervix, caused by sexual intercourse, or by an infection (ACOG, 2008/2019). Pregnant patients with advanced maternal age, smoking exposure, and prior preterm birth are more at risk for vaginal bleeding during pregnancy.

Miscarriage (Spontaneous Abortion). A pregnancy that ends without medical or surgical intervention prior to 20 weeks of gestation or less than 500-g fetal weight is defined as a *miscarriage* or *spontaneous abortion* (Cunningham et al., 2018). The term *miscarriage* rather than *abortion* is used throughout this discussion because it is more appropriate to use with patients. Abortion may be perceived as an insensitive term to use with families who are grieving a pregnancy loss. Therapeutic and elective abortion is discussed in Chapter 8.

Incidence and etiology. Approximately 10 to 15% of all clinically recognized pregnancies end in miscarriage (Simpson & Jauniaux, 2017). The majority—greater than 80% of miscarriages—are early

pregnancy losses, occurring before 12 weeks of gestation (Cunningham et al., 2018). Of all clinically recognized first-trimester losses, 25% result from chromosomal abnormalities (Cunningham et al., 2018). Other possible causes of early miscarriage include endocrine imbalance (as in patients who have luteal phase defects, hypothyroidism, or insulin-dependent diabetes mellitus with high blood glucose levels in the first trimester), immunological factors (e.g., antiphospholipid antibodies), systemic disorders (e.g., lupus erythematosus), and genetic factors. Infections are not a common cause of early miscarriage (Cunningham et al., 2018), but there is an increased risk for a spontaneous miscarriage with varicella infection in the first trimester (Gilbert, 2011). The risk of spontaneous miscarriage is increased in pregnant patients with obesity (Davies et al., 2018; Maxwell et al., 2019).

A late pregnancy loss occurs between 12 and 20 weeks of gestation. It usually results from patient causes such as advanced age and parity in the pregnant person, chronic infections, premature dilation of the cervix or other anomalies of the reproductive tract, chronic debilitating diseases, inadequate nutrition, and recreational drug use (Cunningham et al., 2018). Some of these risk factors cannot be modified, but correction of disorders in the patient, a healthy lifestyle, adequate early prenatal care, immunization against infectious diseases, and treatment of pregnancy complications can do much to prevent other causes of miscarriage.

Clinical manifestations. The types of miscarriage include threatened, inevitable, incomplete, complete, and missed (Figure 14.6). All types of miscarriage can recur in subsequent pregnancies. All types except the threatened miscarriage can lead to infection.

Signs and symptoms of pregnancy loss depend on the duration of the pregnancy. The presence of uterine bleeding, uterine cramping, or low back pain is an ominous sign in early pregnancy and must be considered a threatened miscarriage until proven otherwise. Assessment of beta-human chorionic gonadotropin (β-hCG) blood levels and ultrasound must be performed to confirm a viable pregnancy or pregnancy loss.

If miscarriage occurs prior to the sixth week of gestation, the patient may report a heavy menstrual-like flow. Miscarriage that occurs between weeks 6 and 12 of pregnancy causes moderate discomfort and blood loss. Severe cramping with heavy bleeding is often a sign of later pregnancy loss because the fetus must be expelled. Diagnosis of the type of miscarriage is based on the signs and symptoms present (Table 14.7).

Symptoms of a *threatened miscarriage* (see Figure 14.6, *A*) include mild to moderate spotting of blood with a closed cervical os. Mild uterine cramping may be present.

Inevitable (see Figure 14.6, *B*) and *incomplete* (see Figure 14.6, *C*) miscarriages involve a moderate-to-heavy amount of bleeding with

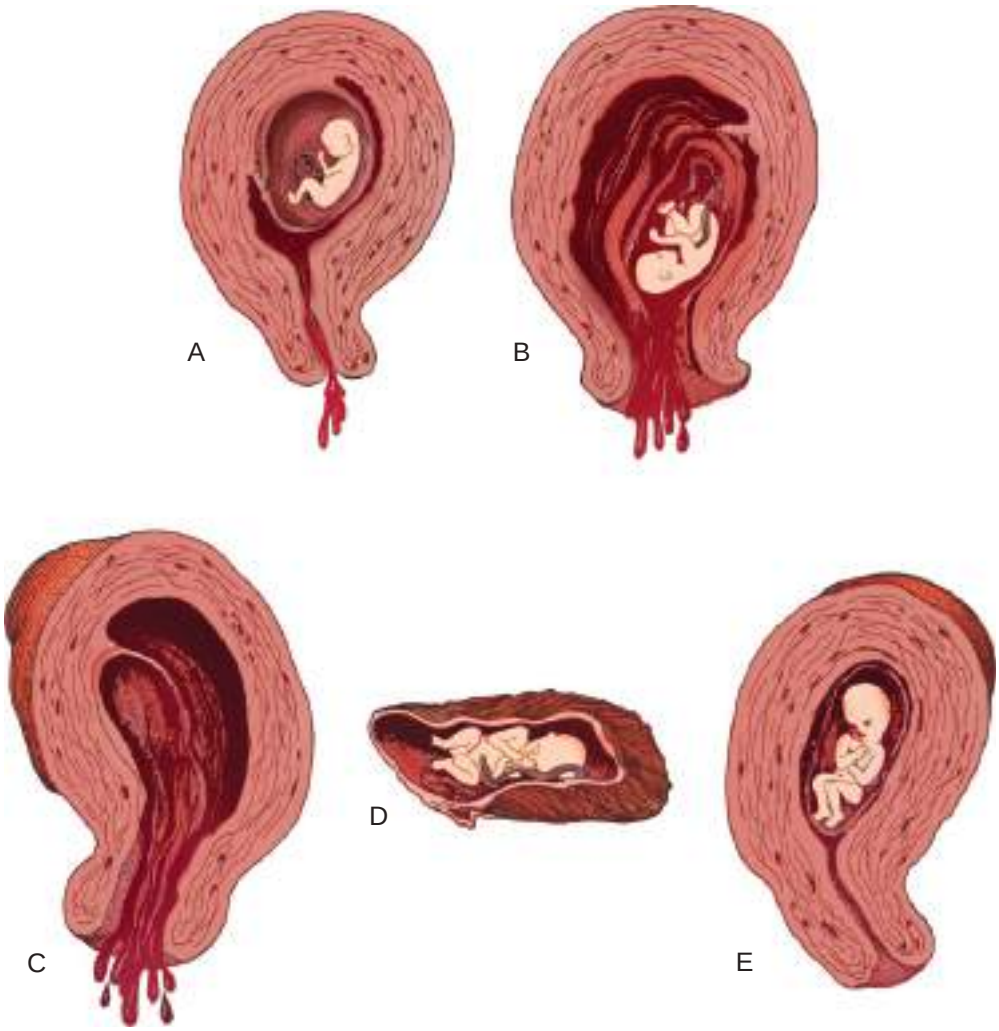

Fig. 14.6 Types of pregnancy loss. **A:** Threatened. **B:** Inevitable. **C:** Incomplete. **D:** Complete. **E:** Missed.

TABLE 14.7 Types of Spontaneous Abortion and Usual Management

Type of Spontaneous Abortion	Amount of Bleeding	Uterine Cramping	Passage of Tissue	Cervical Dilation	Management
Threatened (Figure 14.6 *A*)	Slight, spotting	Mild	No	No	Bed rest is often ordered but has not proven to be effective in preventing progression to actual miscarriage. Repetitive transvaginal ultrasounds and assessment of human chorionic gonadotropin and progesterone levels may be done to determine if the fetus is still alive and in the uterus. Further treatment depends on whether progression to actual miscarriage occurs.
Inevitable (Figure 14.6 *B*)	Moderate	Mild to severe	No	Yes	Bed rest if no pain, fever, or bleeding. If rupture of membranes, bleeding, pain, or fever is present, the uterus is emptied promptly, usually by dilation and curettage.
Incomplete (Figure 14.6 *C*)	Heavy, profuse	Severe	Yes	Yes, with tissue in cervix	May or may not require additional cervical dilation before curettage. Suction curettage may be performed.
Complete (Figure 14.6 *D*)	Slight	Mild	Yes	No	No further intervention may be needed if uterine contractions are adequate to prevent hemorrhage and no infection is present. Suction curettage may be performed to ensure no retained fetal or maternal tissue.
Missed (Figure 14.6 *E*)	None, spotting	None	No	No	If spontaneous evacuation of the uterus does not occur within 1 month, pregnancy is terminated by method appropriate to gestational age. Blood clotting factors are monitored until uterus is empty. Disseminated intravascular coagulation and incoagulability of blood with uncontrolled hemorrhage may develop in cases of fetal death after the twelfth week if products of conception are retained for longer than 5 weeks. May be treated with dilation and curettage, or misoprostol given orally or vaginally.
Septic	Varies, usually malodorous	Varies	Varies	Yes, usually	Immediate termination of pregnancy by method appropriate to duration of pregnancy. Cervical culture and sensitivity studies done, and broad-spectrum antibiotic therapy (e.g., ampicillin) started. Treatment for septic shock initiated if necessary.
Recurrent	Varies	Varies	Yes	Yes, usually	Varies, depends on type. Prophylactic cerclage may be performed if premature cervical dilation is the cause. Tests of value include parental cytogenetic analysis and lupus anticoagulant and anticardiolipin antibody assays on the patient.

Adapted from Cunningham, F., Leveno, K., Bloom, S., et al. (2014). *Williams obstetrics* (24th ed.). McGraw-Hill.

an open cervical os, seen on speculum exam. Tissue may be present with the bleeding. Mild-to-severe uterine cramping may be present. An inevitable miscarriage is accompanied by rupture of membranes and cervical dilation with passage of the fetus and placenta together. An incomplete loss involves the expulsion of the fetus with retention of the placenta (Cunningham et al., 2018). Vaginal bleeding, which may be slight to heavy, is usually malodorous. Surgical evacuation may be required.

In a *complete miscarriage* (see Figure 14.6, *D*) all fetal tissue is passed, the cervix is closed, and there may be slight bleeding. Mild uterine cramping may be present.

The term *missed miscarriage* (see Figure 14.6, *E*) refers to a pregnancy in which the fetus has died but the products of conception are retained in utero for up to several weeks. It may be diagnosed by ultrasonographic examination after the uterus stops increasing or even decreases in size. There may be no bleeding or cramping, and the cervical os remains closed. A missed miscarriage is often simply referred to as an *early pregnancy loss*.

Recurrent pregnancy loss is three or more consecutive pregnancy losses before 20 weeks of gestation. The most widely accepted causes of recurrent miscarriage are parental chromosomal abnormalities, antiphospholipid antibody syndrome, and certain uterine abnormalities (Cunningham et al., 2018).

The evaluation of couples experiencing recurrent pregnancy loss usually includes karyotyping of both partners and miscarriage specimens and assessment of the placenta; evaluating the uterine cavity of the patient; and testing the patient for antiphospholipid antibody syndrome and thyroid disease (Williams & Scott, 2019). Evaluation should also address the psychological response to this diagnosis because patients and their partners often report feelings of guilt, anxiety, and depression. Thus couples experiencing recurrent pregnancy loss should be screened for depression and post-traumatic stress disorder.

Miscarriages can become septic, although this is uncommon. Symptoms of a septic miscarriage include fever and abdominal tenderness. Vaginal bleeding, which may be slight to heavy, is usually malodorous.

Collaborative care.

Initial care. When a patient has vaginal bleeding early in pregnancy, a thorough assessment should be performed (Box 14.6). The data to be collected include pregnancy history, vital signs, type and location of pain, quantity and nature of bleeding, and emotional status. Laboratory tests may include evaluation of β-hCG (pregnancy), hemoglobin level (anemia), and white blood cell (WBC) count (infection).

BOX 14.6 Assessment of Threatened Pregnancy Loss—Early and Late

Initial Database

Chief concern
Vital signs
Number of pregnancies, number of live births
Last menstrual period/estimated date of birth
Pregnancy history (previous and current)
Allergies
Nausea and vomiting
Pain (onset, quality, precipitating event, location)
Bleeding or coagulation issues
Level of consciousness
Emotional status and need for support

Early Pregnancy

Confirmation of pregnancy with laboratory testing
Bleeding (bright or dark, spotting or continuous)
Pain (type, intensity, location, persistence)
Vaginal discharge

Late Pregnancy

Estimated date of birth
Bleeding (amount, pinky, menstrual-like, heavy)
Pain (location, severity, intermittent, continuous)
Vaginal discharge
Amniotic membrane status
Uterine activity
Fetal heart rate present, movement felt

Management depends on the classification of the miscarriage and on signs and symptoms (see Table 14.7). Traditionally, threatened miscarriages have been managed expectantly with supportive care. However, there are no proven effective therapies for this condition. Bed rest, although often prescribed, does not prevent progression to actual miscarriage. Follow-up treatment depends on whether the threatened loss progresses to actual spontaneous abortion or symptoms subside and the pregnancy remains intact. If bleeding and infection do not occur, expectant management is a reasonable option. In approximately half of all threatened miscarriages managed in this way, the pregnancy continues (Cunningham et al., 2018).

Once the cervix begins to dilate, the pregnancy cannot continue, and miscarriage becomes inevitable. If all the products of conception are passed, no surgical intervention is necessary. If heavy bleeding, excessive cramping, or infection is present, however, the remaining embryonic, fetal, or placental tissue must be removed from the uterus, usually by suction curettage. In patients who are clinically stable, expectant management to allow spontaneous resolution of an incomplete miscarriage is another treatment option (Cunningham et al., 2018).

In the past, because suspected fetal death could not be confirmed, expectant management was the only option for missed miscarriages, which eventually ended spontaneously. Because fetal death can now rapidly be confirmed using serial quantitative β-hCG testing and transvaginal ultrasound, many patients choose to have uterine evacuation of a missed miscarriage (Cunningham et al., 2018).

Medical management is another treatment option if bleeding and infection are not present. Outpatient management of first-trimester pregnancy loss is with intravaginal misoprostol (a synthetic prostaglandin E_1 analogue) for up to 2 days (Cunningham et al., 2018) (see Chapters 8 and 20). No difference in short-term psychological outcomes between expectant and surgical management has been found. If there is evidence of infection, unstable vital signs, or uncontrollable bleeding, a surgical evacuation is performed.

For late incomplete, inevitable, or missed pregnancy loss (16 to 20 weeks), misoprostol can be given orally or vaginally to induce labour and achieve vaginal delivery of the fetus(s). Mifepristone can safely be given concomitantly with misoprostol to facilitate cervical preparation and reduces procedure time (Costescu & Guilbert, 2018).

If medical management is chosen, nursing care is similar to the care for any patient whose labour is induced (see Chapter 20). Special care may be needed for management of adverse effects of prostaglandin such as nausea, vomiting, and diarrhea. If the products of conception are not passed completely, the patient may be prepared for manual or surgical evacuation of the uterus.

A third management option, and one that is often chosen, is **dilation and curettage (D&C)**, a surgical procedure in which the cervix is dilated if necessary and a curette is inserted to scrape the uterine walls and remove uterine contents. Uterine contents may also be removed by suction curettage, using a catheter attached to an electric-powered vacuum source (Cunningham et al., 2018). Pain relief during a D&C is usually achieved by administering analgesics or sedatives intravenously or orally (conscious sedation). A paracervical block using a local anaesthetic may also be administered (Cunningham et al., 2018). General preoperative and postoperative care is appropriate for the patient requiring surgical intervention for miscarriage. The nurse reinforces explanations, answers any questions or concerns, and prepares the patient for surgery.

After evacuation of the uterus, oxytocin is often given to prevent hemorrhage. For excessive bleeding, ergot products such as ergonovine or a prostaglandin derivative such as carboprost tromethamine (hemabate) can be given to contract the uterus. Antibiotics are given as necessary. Analgesics such as ibuprofen may decrease discomfort from cramping. Blood transfusion may be required for shock or anemia. The patient who is Rh negative and is not isoimmunized is given $Rh_o(D)$ immune globulin within 48 hours of the pregnancy loss (Cunningham et al., 2018).

Psychosocial aspects of care focus on what the pregnancy loss means to the patient and their family. Grief from perinatal loss is complex and unique to each individual. The care provider and the nurse's provision of explanations of expected procedures, possible complications, and future implications for child-bearing can be helpful and reassuring to the patient and their family. Culturally sensitive education regarding recognition of grief responses and how to manage these responses effectively may also be helpful to the patient and their family (Hendson et al., 2018).

The patient should be offered the choice of spending time with the fetal remains. Depending on the gestational age of the fetus, hospital disposition of the remains may be offered. If the fetus is over 20 weeks' gestation, the family are required to register the birth with Vital Statistics and will need to make arrangements for burial or cremation of fetal remains. See Chapter 24 for further discussion on grief and loss.

! NURSING ALERT

Procedures for disposition of the fetal remains vary according to gestational age between provinces and territories. The nurse should know what the required procedures are in their setting.

Follow-up care. The patient will likely be discharged home within a few hours after a D&C or as soon as their vital signs are stable, vaginal bleeding remains minimal, and they have recovered from anaesthesia. Discharge teaching emphasizes the need for rest. If significant blood loss has occurred, iron supplementation may be ordered. Teaching includes information about normal physical findings such as cramping, type and amount of bleeding, resumption of sexual activity, and family planning (see Family-Centred Care box: Discharge Teaching After Pregnancy Loss). Guidelines suggest that immediate insertion of a levonorgestrel intrauterine system or a copper intrauterine device (IUCD) may be performed, as immediate IUCD insertion post-miscarriage or D&C is safe and does not carry an increased risk of perforation, infection, or discontinuation (see Chapter 8). Expulsion rates may be higher for immediate insertion than with delayed insertion (Costescu & Guilbert, 2018). Follow-up care is needed to assess the patient's physical and emotional recovery. Referrals to local support groups or counselling are provided as necessary.

FAMILY-CENTRED CARE

Discharge Teaching After Pregnancy Loss

- Advise the patient to report any heavy, profuse, or bright red bleeding to their health care provider.
- Reassure the patient that a scant, dark discharge may persist for 1 to 2 weeks.
- To reduce the risk of infection, remind the patient not to put anything into the vagina for 2 weeks or until bleeding has stopped (e.g., no tampons, no vaginal intercourse). They should take antibiotics as prescribed.
- Advise the patient to notify their health care provider if an elevated temperature or a foul-smelling vaginal discharge develops.
- Advise the patient to eat foods high in iron and protein.
- Acknowledge that the patient has experienced a loss and that they may have mood swings and depression. Talking with their family and seeking support from friends will also help them deal with their loss.
- Refer the patient to support groups, clergy, or professional counselling, as needed.
- Advise the patient that attempts at pregnancy should be postponed for at least 2 months to allow their body to recover.

From Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). Mosby.

Follow-up phone calls after a loss are important. The patient may appreciate a phone call on what would have been their due date. These calls acknowledge that the pregnancy existed, validate the patient's experience, and provide opportunities for the patient to ask questions, seek advice, and receive information to help process their grief.

Premature Dilation of Cervix. One cause of late miscarriage is premature dilation of the cervix (**cervical insufficiency**), which has traditionally been defined as passive and painless dilation of the cervix leading to recurrent preterm births during the second trimester in the absence of other causes. It was believed that these criteria defined patients whose early births were caused solely by structural weakness of cervical tissue that could be corrected surgically by cerclage placement. Measurement of cervical length has been used as a way to diagnose cervical insufficiency. However, it is now known that an abnormally short cervix identified during the second trimester can also represent an early step in the process of preterm labour. Therefore, the challenge is to identify patients who have cervical changes because of impaired cervical strength before conception or in early pregnancy, rather than when they are beginning the process of preterm labour (Simhan et al., 2019).

Etiology. Cervical insufficiency may be either acquired or congenital. Congenital risk factors for cervical insufficiency include collagen disorders and uterine anomalies. A risk factor for acquired cervical insufficiency is a history of previous cervical trauma resulting from lacerations during childbirth or mechanical dilation of the cervix during gynecological procedures. Patients who have had prior cervical surgery such as a biopsy in which a large cone specimen was removed or destroyed are also at risk for cervical insufficiency (Ludmir et al., 2017; Simhan et al., 2019).

Diagnosis. Cervical insufficiency is a clinical diagnosis, made by a thorough obstetrical history along with speculum and digital pelvic examinations and a transvaginal ultrasound examination. Short labour and recurring loss of the pregnancy at progressively earlier gestational ages are characteristics of reduced cervical competence. Transvaginal ultrasound examination is recommended to diagnose this condition objectively (Butt & Lim, 2019; Lim et al., 2018). A short cervix (less than 25 mm in length) is indicative of reduced cervical competence. Often, but not always, the short cervix is accompanied by cervical funnelling (beaking) or effacement of the internal cervical os, although the external cervical os remains closed (Cunningham et al., 2018; Ludmir et al., 2017; Simhan et al., 2019).

Collaborative care. Cervical **cerclage** placement has been the treatment of choice for patients with cervical insufficiency due to cervical weakness. Indications for cerclage placement are a poor obstetrical history (three or more previous early preterm births or second-trimester losses), a short (less than 25 mm) cervical length identified on transvaginal ultrasound, and an open cervix found on digital or speculum examination (Simhan et al., 2019). The McDonald technique is often the procedure of choice because of its proven effectiveness and ease of placement and removal. In this procedure, a suture is placed around the cervix beneath the mucosa to constrict the internal os of the cervix (Figure 14.7) (Cunningham et al., 2018).

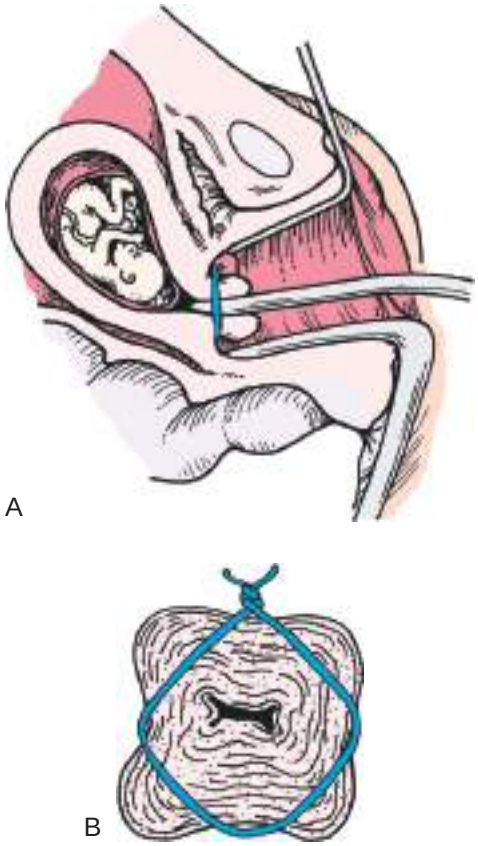

Fig. 14.7 **A:** Cerclage correction of recurrent premature dilation of cervix. **B:** Cross section of closed internal os.

A cerclage may be placed either prophylactically or as a therapeutic or rescue procedure after cervical change has been identified (Cunningham et al., 2018; Simhan et al., 2019). A prophylactic, or history-indicated, cerclage is usually placed at 12 to 14 weeks of gestation. An ultrasound-indicated cerclage may be placed therapeutically at 14 to 23 weeks of gestation in patients with a singleton pregnancy and a history of a prior preterm birth if a short (less than 25 mm) cervix is identified on vaginal ultrasound. Finally, a rescue cerclage may be placed between 16 and 23 weeks of gestation in patients who are found to have cervical change (greater than 1 cm dilated or prolapsed membranes) on physical examination. The cerclage is removed if preterm premature rupture of membranes (PROM) or advanced preterm labour that puts pressure on the stitch occurs. If the pregnancy progresses without further complications, the cerclage is removed when the patient reaches 36 weeks of gestation (Simhan et al., 2019).

The only indication for an abdominal cerclage that has been proven to be of benefit is failure of a prior history-indicated transvaginal cerclage, where spontaneous preterm birth occurred before 33 weeks of gestation. This procedure is usually done at 11 to 12 weeks of gestation or before conception by means of a laparotomy. Suture (Mersilene tape) is placed at the junction of the lower uterine segment and the cervix. Caesarean birth is necessary following an abdominal cerclage, and the suture is left in place if future pregnancies are desired (Ludmir et al., 2017).

The nurse needs to assess the patient's feelings about their pregnancy and their understanding of cervical insufficiency. Evaluating the patient's support systems is also important. Because the diagnosis of cervical insufficiency is usually not made until the patient has lost one or more pregnancies, they may feel guilty or to blame for this impending loss. Therefore, assessing for previous reactions to stresses and appropriateness of coping responses is important. The patient needs the support of their family and health care providers.

If a cervical cerclage has been performed, the nurse monitors the patient after surgery for the presence of uterine contractions, PROM, and signs of infection. Discharge teaching focuses on continued monitoring of these aspects at home. Home follow-up may be provided by nurses through antepartum home care programs.

Follow-up care. Bed rest following cerclage was recommended in the past as a theoretical way to place less pressure on the cervix while in the recumbent position. However, the validity of bed rest has not been scientifically proven. In fact, some data suggest poorer outcomes in patients on bed rest. Progesterone therapy, given either intramuscularly or vaginally, may be recommended for some patients. Decisions about physical activity and intercourse are individualized, based on the status of the patient's cervix, as determined by digital and ultrasound examination (Ludmir et al., 2017).

The patient must understand the need for close observation and supervision for the remainder of the pregnancy. Additional instruction includes the need to watch for and report signs of preterm labour, rupture of membranes, and infection. Finally, the patient should know the signs that would warrant an immediate return to the hospital, including the presence of regular strong contractions, preterm PROM, severe perineal pressure, and an urge to push. If management is unsuccessful and the fetus is born before viability, appropriate grief support should be provided. If the fetus is born prematurely, appropriate anticipatory guidance and support including referral as needed will be necessary (see Chapter 28 for information on high-risk newborns and newborn death and Chapter 24 for information on fetal and early newborn loss and grief).

Ectopic Pregnancy.

Incidence and etiology. An **ectopic pregnancy** is one in which the fertilized ovum is implanted outside the uterine cavity (Figure 14.8). It accounts for 1 in 7 000 to 1 in 30 000 of spontaneously conceived pregnancies (Sepilian, 2017). The frequency is consistent across maternal age ranges and ethnic origins; however, the incidence is increased in patients who have had assisted reproductive therapy (Gilbert, 2011). Ectopic pregnancy is responsible for 9% of pregnancy-related deaths and is the leading cause of infertility (Sepilian, 2017). Patients who have been treated surgically for ectopic pregnancy have a subsequent intrauterine pregnancy rate of 50 to 80%; the recurrent ectopic pregnancy rate is up to 10 to 25% (Cunningham et al., 2018).

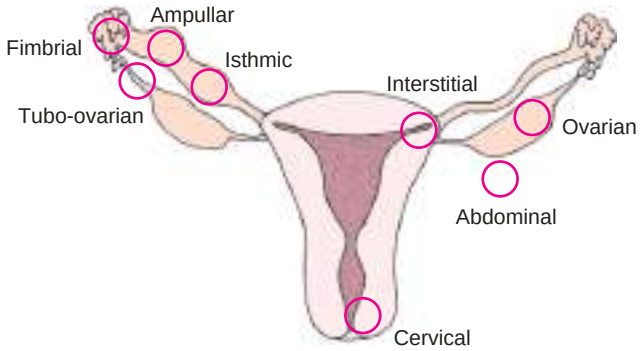

Fig. 14.8 Sites of implantation of ectopic pregnancies. Order of frequency of occurrence is ampullar, isthmic, interstitial, fimbrial, tubo-ovarian ligament, ovarian, abdominal cavity, and cervical (external os).

Some of the increased incidence is likely because of improved diagnostic techniques, such as more sensitive β-hCG measurement and transvaginal ultrasound, resulting in the identification of more cases. Other causes for the rise include an increased incidence of sexually transmitted infections, tubal infection and damage, use of tubal sterilization methods that increase the chance of ectopic pregnancy, increased use of assisted reproductive techniques, and increased use of tubal surgery (Cunningham et al., 2018).

Approximately 95% of ectopic pregnancies occur in the uterine (fallopian) tube, with most located on the ampullar or largest portion of the tube. Other sites include the ovary (0.5%), abdominal cavity (1.5%), and cervix (0.3%) (Gilbert, 2011). Ectopic pregnancy is classified according to site of implantation (e.g., tubal, ovarian, or abdominal). The uterus is the only organ capable of containing and sustaining a term pregnancy. Most abdominal pregnancies are thought to be the result of early tubal rupture, followed by reimplantation. Surgery to remove the embryo or fetus is usually performed as soon as an abdominal pregnancy is identified because of the high risk for hemorrhage at any time during the pregnancy (Figure 14.9). The risk for fetal deformity in an abdominal pregnancy is high as a result of pressure deformities caused by oligohydramnios. The most common concerns include facial or cranial asymmetry, various joint deformities, limb deficiency, and CNS anomalies (Cunningham et al., 2018).

Clinical manifestations. Most cases of ectopic (tubal) pregnancy are diagnosed before rupture, on the basis of three classic symptoms: (1) abdominal pain, (2) delayed menses, and (3) abnormal vaginal bleeding (spotting). Abdominal pain occurs in almost every case. It usually begins as a dull, lower-quadrant pain on one side. The discomfort can progress from a dull to colicky pain when the tube stretches, to sharp, stabbing pain (Cunningham et al., 2018). It progresses to a diffuse, constant, severe pain that is generalized throughout the lower abdomen. The majority of patients with an ectopic pregnancy report a period that is delayed 1 to 2 weeks or is lighter than usual or an irregular period. Mild-to-moderate dark red or brown intermittent vaginal bleeding occurs in many of these patients.

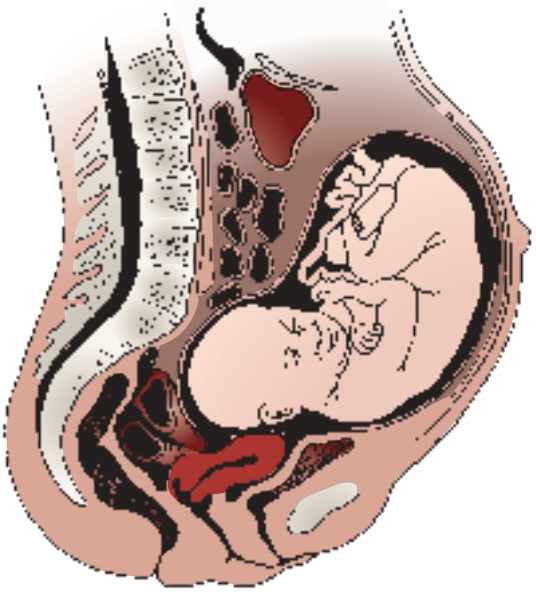

Fig. 14.9 Ectopic pregnancy, abdominal.

If the ectopic pregnancy is not diagnosed until after rupture has occurred, referred shoulder pain may be present in addition to generalized, one-sided, or deep lower-quadrant acute abdominal pain. Referred shoulder pain results from diaphragmatic irritation caused by blood in the peritoneal cavity. The patient may need medication to manage severe, excruciating pain while they are being prepared for surgery. They may exhibit signs of shock related to the amount of bleeding in the abdominal cavity and not necessarily to obvious vaginal bleeding. An ecchymotic blueness around the umbilicus (Cullen sign), indicating hematoperitoneum, may develop in an undiagnosed, ruptured intra-abdominal ectopic pregnancy.

Diagnosis. The differential diagnosis of ectopic pregnancy involves consideration of numerous disorders that share many signs and symptoms. Many of these patients present to the emergency department experiencing first-trimester bleeding or pain. Miscarriage, ruptured corpus luteum cyst, appendicitis, salpingitis, ovarian cysts, torsion of the ovary, and UTI must be considered. The key to early detection of ectopic pregnancy is having a high index of suspicion for this condition. Any patient with symptoms of abdominal pain, vaginal spotting, or bleeding and a positive pregnancy test should undergo screening for ectopic pregnancy.

Laboratory screening includes determination of serum progesterone and β-hCG levels. If either of these values is lower than would be expected for a normal pregnancy, the patient should be asked to return within 48 hours for serial measurements. Transvaginal ultrasonography is done to confirm intrauterine or tubal pregnancy (Butt & Lim, 2019; Lim et al., 2018). Ultrasonographic identification of an intrauterine pregnancy (gestational sac plus yolk sac) rules out ectopic pregnancy in most patients.

The patient should be assessed for the presence of active bleeding, which is associated with tubal rupture. If internal bleeding is present, the patient may have vertigo, shoulder pain, hypotension, and tachycardia. A vaginal examination should be performed only once, and then with great caution. Approximately 20% of patients with tubal pregnancies have a palpable mass on examination. It is possible to rupture the mass during a bimanual examination, thus gentleness is critical.

Medical management. Approximately 40% of patients diagnosed with ectopic pregnancy are appropriate candidates for medical management, which involves giving methotrexate to dissolve the tubal pregnancy (American Society for Reproductive Medicine [ASRM], 2013). Methotrexate is an antimetabolite and folic acid antagonist that destroys rapidly dividing cells. It is classified as a hazardous medication and can cause serious toxic adverse effects even when given in low doses. These adverse effects can cause safety risks for health care providers if the medication is not handled appropriately. Additionally, the Institute for Safe Medication Practices (ISMP) considers methotrexate to be a high-alert drug (Box 14.7) (ISMP, 2018).

Methotrexate therapy can prevent the need for surgery and is a safe, effective, and cost-effective way of managing many cases of tubal pregnancy. The patient must be hemodynamically stable and have normal liver and kidney function to be eligible for methotrexate therapy. The best results following methotrexate therapy are usually obtained if the mass is unruptured and measures less than 3.5 cm in diameter by ultrasound, if no fetal cardiac activity is noted on ultrasound, and if the initial serum β-hCG level is less than 5 000 mIU/L (Cunningham et al., 2018). To be a candidate for medical management the patient must also be willing to follow post-treatment lifestyle restrictions and monitoring. They are informed of how the medication works, possible adverse effects, general self-care guidelines, and the importance of follow-up care (see Family-Centred Care box: Teaching for Patients Receiving Methotrexate Therapy). Patients treated with methotrexate have an intrauterine pregnancy rate of 64%; the recurrent ectopic pregnancy rate is approximately 11% (Sepilian, 2017).

BOX 14.7 Methotrexate Administration

- Obtain the patient's height and weight. These measurements are used to calculate their body surface area in order to determine the correct dose of methotrexate, so they must be accurate.
- The standard dose of methotrexate used to treat ectopic pregnancy is 50 mg/m^2 given intramuscularly, although it may also be ordered as 1 mg/kg.
- The dose of methotrexate should be prepared in the hospital pharmacy under a biological safety cabinet. Syringe(s) containing the methotrexate should be dispensed from the pharmacy no more than three-fourths full in a sealed plastic bag without a needle attached.
- Put on two pairs of gloves before removing the syringe(s) from the sealed plastic bag.
- Remove the syringe cap, and replace with an appropriate needle for intramuscular injection.
- Do not expel air from the syringe or prime the needle because these actions could aerosolize the methotrexate.
- Check the patient's identity and the medication and dosage before injecting the methotrexate. Another nurse should also perform an independent check before the injection is given.
- Dispose of any items worn or used to prepare, dispense, or administer the methotrexate injection in a waste container designated specifically for hazardous drugs.
- Wash your hands thoroughly after removing gloves.

Data from Shastay, A., & Paparella, S. (2010). Ectopic pregnancies and methotrexate: Are you prepared to manage this hazardous drug? *Journal of Emergency Nursing, 36*(1), 57–59.

NURSING ALERT

Patients receiving methotrexate to treat an ectopic pregnancy should refrain from taking any analgesic stronger than acetaminophen. Stronger analgesics can mask symptoms of tubal rupture.

FAMILY-CENTRED CARE

Teaching for Patients Receiving Methotrexate Therapy

- Explain that methotrexate dissolves ectopic (tubal) pregnancies by destroying rapidly dividing cells.
- Explain that urine contains levels of medication metabolite that could be considered toxic for approximately 72 hours after receiving methotrexate. The levels are highest during the first 8 hours after treatment. Teach the patient to avoid getting urine on the toilet seat and to double flush the toilet (with the lid down) after urinating. Also explain that their stools may contain residual medication for up to 7 days.
- Inform the patient of possible adverse effects. Gastric distress, nausea and vomiting, stomatitis, and dizziness are common. Rare adverse effects include severe neutropenia, reversible hair loss, and pneumonitis.

Advise the patient to do the following:

- Avoid intake of foods and vitamins containing folic acid.
- Avoid eating "gas-forming" foods.
- Avoid sun exposure.
- Avoid sexual intercourse until the β-hCG level is undetectable.
- Keep all scheduled follow-up appointments.
- Contact health care provider immediately if experience severe abdominal pain, which may be a sign of impending or actual tubal rupture.

Data from American Society for Reproductive Medicine. (2013). Medical treatment of ectopic pregnancy: A committee opinion. *Fertility and Sterility*, 100(3), 638–644; Shastay, A., & Paparella, S. (2010). Ectopic pregnancies and methotrexate: Are you prepared to manage this hazardous drug? *Journal of Emergency Nursing*, *36*(1), 57–59.

NURSING ALERT

The patient receiving methotrexate therapy who drinks alcohol and takes vitamins containing folic acid (e.g., prenatal vitamins) increases their risk of having medication adverse effects or of exacerbating the ectopic rupture.

Surgical management. Surgical management depends on the location and cause of the ectopic pregnancy, the extent of tissue involvement, and the patient's desires regarding future fertility. One option is removal of the entire tube (salpingectomy). If the tube has not ruptured and the patient desires future fertility, salpingostomy may be performed instead. In this procedure an incision is made over the pregnancy site in the tube, and the products of conception are gently and very carefully removed. The incision is not sutured but left to close by secondary intention, because this method results in less scarring.

If surgery is planned for the patient with an ectopic pregnancy, general preoperative and postoperative care is appropriate. Vital signs (pulse, respirations, and BP) are assessed before surgery every 15 minutes or as needed, based on the severity of the bleeding and the patient's condition. Preoperative laboratory tests include determination of blood type and Rh factor, CBC, and serum quantitative β-hCG assay. Ultrasonography is used to confirm an extrauterine pregnancy. Blood replacement may be necessary. The nurse will verify the patient's Rh and antibody status and administer $Rh_o(D)$ immune globulin, if appropriate. The patient should be encouraged to express their feelings related to the loss. Referral to community resources may be appropriate.

Follow-up care. Patients who have received methotrexate therapy have their β-hCG level measured weekly to make certain that it continues to drop steadily until it becomes undetectable. Complete resolution of an ectopic pregnancy usually occurs in 2 to 3 weeks but can require as long as 6 to 8 weeks (ASRM, 2013).

Whether treated medically or surgically, the patient and their family should be encouraged to share their feelings and concerns related to the loss. Future fertility should be discussed. A contraceptive method should be used for at least three menstrual cycles to allow time for the patient's body to heal. *Every* patient who has been diagnosed with an ectopic pregnancy should be instructed to contact their health care provider as soon as they suspect that they might be pregnant, because of the increased risk for recurrent ectopic pregnancy. These patients may need referral to grief or infertility support groups. In addition to the loss of the current pregnancy, they are faced with the possibility of future pregnancy losses or infertility.

Hydatidiform Mole (Molar Pregnancy). *Hydatidiform mole (molar pregnancy)* is a benign, proliferative growth of the placental trophoblast in which the chorionic villi develop into edematous, cystic, avascular transparent vesicles that hang in a grapelike cluster. Hydatidiform mole is a **gestational trophoblastic disease (GTD)**. GTD is a group of pregnancy-related trophoblastic proliferative disorders without a viable fetus that are caused by abnormal fertilization. In addition to hydatidiform mole, GTD includes invasive mole and choriocarcinoma (a rare form of cancer) (Cunningham et al., 2018).

Incidence and etiology. Hydatidiform mole occurs in 1 in 1 000 pregnancies (Cohn et al., 2019). The etiology is unknown, although there may be an ovular defect or nutrition deficiency. Patients at increased risk for hydatidiform mole formation are those who have had a prior molar pregnancy and those who are in their early teens or older than 40 years of age (Cohn et al., 2019).

Types. A hydatidiform mole may be further categorized as a complete or partial mole. The complete mole results from fertilization of an egg in which the nucleus has been lost or inactivated (Figure 14.10, *A*). The nucleus of a sperm (23,X) duplicates itself (resulting in the diploid number 46,XX) because the ovum has no genetic material or the material is inactive. It is also possible for an "empty" egg to be fertilized by two normal sperm, thereby producing either a 46,XX or 46,XY karyotype. The mole resembles a bunch of white grapes (see Figure 14.10, *B*). The hydropic (fluid-filled) vesicles grow rapidly, causing the uterus to be larger than expected for the duration of the pregnancy. The complete mole contains no fetus, placenta, amniotic membranes, or fluid. Maternal blood has no placenta to receive it; therefore, hemorrhage into the uterine cavity and vaginal bleeding occur. Approximately 15 to 20% of patients with a complete mole have evidence of persistent GTD (Cunningham et al., 2018).

In a partial mole, one apparently normal ovum is fertilized by two or more sperm. Triploidy (69XXY) or quadraploidy (92XXXY) genotypes then result (Moore, 2019). Partial moles often have embryonic or fetal parts and an amniotic sac. Congenital anomalies are usually present. The risk for persistent GTD is much less than with a complete mole. If persistent GTD does occur, it is usually not a choriocarcinoma (Cunningham et al., 2018).

Clinical manifestations. In the early stages, the clinical manifestations of a complete hydatidiform mole cannot be distinguished from those of normal pregnancy. Later, vaginal bleeding occurs in almost 95% of patients. The vaginal discharge may be dark brown (resembling prune juice) or bright red and either scant or profuse. It may continue for only a few days or intermittently for weeks. In early pregnancy, in

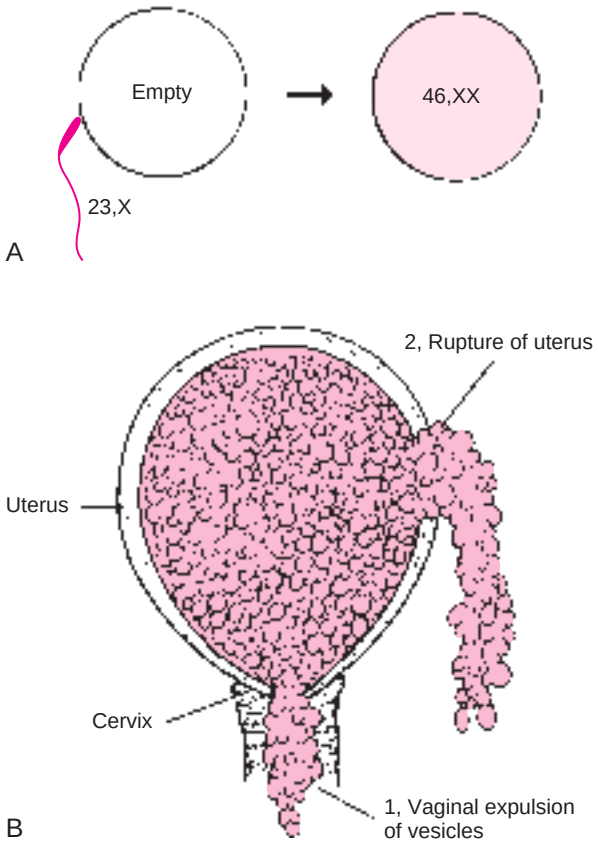

Fig. 14.10 **A:** Chromosome origin of complete mole. Single sperm (in colour) fertilizes an "empty" ovum. Reduplication of the sperm's 23,X set gives completely homozygous diploid 46,XX. A similar process follows fertilization of an empty ovum by two sperm with two independently drawn sets of 23,X or 23,Y; both karyotypes of 46,XX and 46,YY can therefore result. **B:** Uterine rupture with hydatidiform mole. *1,* Evacuation of mole through cervix. *2,* Rupture of uterus and spillage of mole into peritoneal cavity (rare).

about half of affected patients the uterus is significantly larger than expected from menstrual dates. The percentage of patients with an excessively enlarged uterus increases as length of time since the last menstrual period increases. Approximately 25% of affected patients have a uterus smaller than would be expected from menstrual dates.

Anemia from blood loss, excessive nausea and vomiting (hyperemesis gravidarum), and abdominal cramps caused by uterine distension are relatively common findings. Patients may also pass vesicles, which frequently are avascular edematous villi, from the uterus. Preeclampsia occurs in approximately 70% of patients with large, rapidly growing hydatidiform moles and occurs earlier than usual in the pregnancy. If pre-eclampsia is diagnosed before 24 weeks of gestation, hydatidiform mole should be suspected and ruled out. Hyperthyroidism is another serious complication of hydatidiform mole. Usually treatment of the hydatidiform mole restores thyroid function to normal. Partial moles cause few of these symptoms and may be mistaken for an incomplete or missed miscarriage (Cohn et al., 2019; Nader, 2019).

Diagnosis. Transvaginal ultrasound and serum β-hCG levels are used for diagnosis. Transvaginal ultrasound is the most accurate tool for diagnosing a hydatidiform mole. In the past, about half of all molar pregnancies were not diagnosed until molar tissue was passed from the vagina. Currently, however, many patients are diagnosed via ultrasound while asymptomatic or via ultrasound done to evaluate vaginal bleeding or cramping symptoms. A characteristic pattern of multiple diffuse intrauterine masses, often called a *snowstorm pattern,* is seen in place of or along with an embryo or a fetus. The trophoblastic tissue secretes the β-hCG hormone (Cohn et al., 2019; Salani & Copeland, 2017). In a molar pregnancy, β-hCG levels are persistently high or rising beyond the time they would begin to decline in a normal pregnancy.

Medical management. Although most moles pass spontaneously, suction curettage offers a safe, rapid, and effective method of evacuating a hydatidiform mole, if necessary (Cunningham et al., 2018). An alternative management plan for a patient who desires sterilization is hysterectomy. The use of **oxytocic** agents or prostaglandins is not recommended because of the increased risk of embolization of trophoblastic tissue (Salani & Copeland, 2017). Administration of Rh_o(D) immune globulin to patients who are Rh negative is needed to prevent isoimmunization.

Nursing care. The nurse needs to provide the patient and their family with information about the disease process, the necessity of a long course of follow-up, and the possible consequences of the disease. The nurse can help the patient understand and cope with pregnancy loss and recognize that the pregnancy was not normal. The family should be encouraged to express their feelings, and information about support groups or counselling resources should be provided, if needed. The importance of contraceptive counselling and the need to postpone a subsequent pregnancy should also be conveyed.

! NURSING ALERT

To avoid confusion regarding rising levels of β-hCG that are normal in pregnancy but could indicate GTD, pregnancy should be avoided during the follow-up assessment period. Any contraceptive method, except the intrauterine device, is acceptable. Oral contraceptives are highly effective.

Follow-up care. Follow-up management includes frequent physical and pelvic examinations along with measurement of serum β-hCG until the level drops to normal and remains normal for 3 weeks. Monthly measurements are taken for 6 to 12 months. The follow-up assessment period usually continues for a year. During that time a rising titre and an enlarging uterus may indicate GTD (Salani & Copeland, 2017).

Late Pregnancy Bleeding

The major causes of bleeding in late pregnancy are placenta previa and premature separation of the placenta (placental abruption), and variations in the insertion of the cord and the placenta (Figure 14.11). Rapid assessment and diagnosis of the cause of bleeding are essential to reduce maternal and perinatal morbidity and mortality (Table 14.8).

Placenta Previa. In **placenta previa** the placenta is implanted in the lower uterine segment such that it completely or partially covers the cervix or is close enough to the cervix to cause bleeding when the cervix dilates or the lower uterine segment effaces (Figure 14.12).

Sonographers should report the actual distance from the placental edge to the internal cervical os by means of transvaginal sonography (TVS), using standard terminology of millimetres away from the os or millimetres of overlap. A placental edge exactly reaching the internal os is described as 0 mm. When the placental edge reaches or overlaps the internal cervical os on TVS between 18 and 24 weeks' gestation (incidence 2 to 4%), a follow-up examination for placental location in the third trimester is recommended. Overlap of more than 15 mm

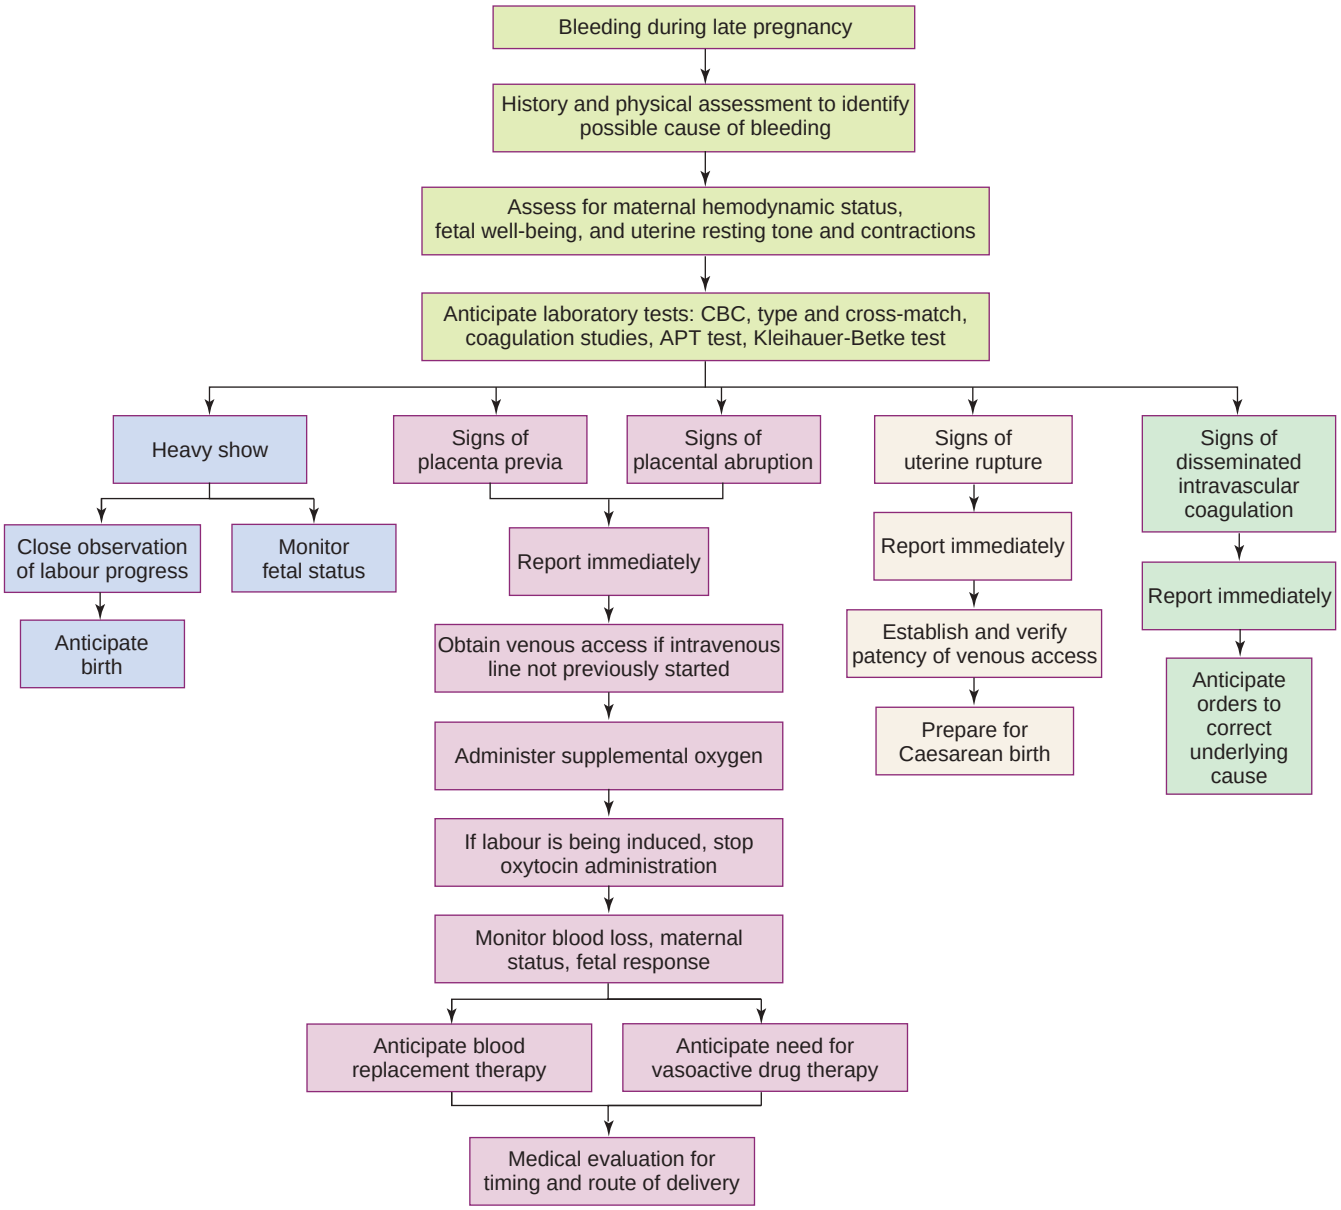

Fig. 14.11 Causes and treatment of bleeding during late pregnancy. *CBC,* Complete blood count.

is associated with an increased likelihood of placenta previa at term (Hobson et al., 2019; Oppenheimer et al., 2007). If the placenta implants in the lower uterine segment, a diagnosis of placenta previa may be made in the second trimester. However, as uterine growth continues throughout gestation, the placenta will usually migrate from the os toward the **fundus**, and the lower uterine segment will develop (Hull et al., 2019; Oppenheimer et al., 2007).

When TVS is used, the placenta is classified as a *complete placenta previa* if it covers the internal cervical os totally. In a *marginal placenta previa* the edge of the placenta is seen on transvaginal ultrasound to be 2.5 cm or closer to the internal cervical os. When the exact relationship of the placenta to the internal cervical os has not been determined or in the case of apparent placenta previa in the second trimester, the term *low-lying placenta* is used (Hull et al., 2019) (see Figure 14.12).

Incidence and etiology. Placenta previa represents a significant clinical concern because the patient may require hospitalization for observation, they may require blood transfusion, and they are at risk for premature birth. The incidence of placenta previa is approximately 0.5% of births (Hull et al., 2019). Some evidence suggests that the incidence of placenta previa is increasing, perhaps as a result of more Caesarean births. In addition to a history of previous Caesarean birth, other risk factors for placenta previa include advanced age of pregnant person (more than 35 to 40 years of age), multiparity, history of prior suction curettage, and smoking (Hull et al., 2019). Maternal race is also associated with placenta previa. It appears that Asian patients have the highest risk for placenta previa. Placenta previa also occurs more frequently in patients carrying male fetuses. A possible explanation for this is that placentas are larger in pregnancies involving male fetuses (Francois & Foley, 2017). Multiple gestation is also a risk factor for placenta previa because of the larger placental area in these pregnancies. Patients who had placenta previa in a previous pregnancy are more likely than others to develop the condition in a subsequent pregnancy, perhaps as a result

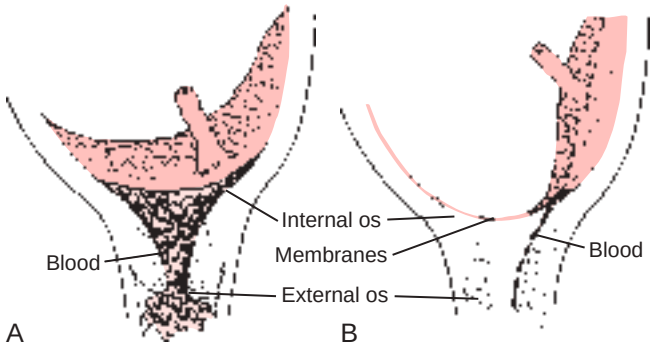

Fig. 14.12 Types of placenta previa. **A:** Complete. **B:** Marginal.

of a genetic predisposition. Previous Caesarean birth and curettage in the past for miscarriage or induced abortion are also risk factors for placenta previa because both result in endometrial damage and uterine scarring (Francois & Foley, 2017; Hull et al., 2019).

Clinical manifestations. Placenta previa is typically characterized by painless bright red vaginal bleeding during the second or third trimester. In the past, placenta previa was usually diagnosed after an episode of bleeding. However, currently most cases are diagnosed by ultrasonography before significant vaginal bleeding occurs. This bleeding is associated with the disruption of placental blood vessels that occurs with stretching and thinning of the lower uterine segment. Between 70 and 80% of patients with placenta previa will have at least one episode of vaginal bleeding. Of patients with vaginal bleeding, one third will present before 30 weeks of gestation, one third between 30 and 36 weeks of gestation, and one third after 36 weeks of gestation (Francois & Foley, 2017) (see Table 14.8).

Vital signs may be normal, even with heavy blood loss, because of the compensatory mechanisms of pregnancy, and up to 40% of blood volume can be lost without showing signs of shock. Clinical presentation and decreasing urinary output are better indicators of acute blood loss than vital signs alone. FHR changes are not usually seen unless there is a major detachment of the placenta.

Abdominal examination usually reveals a soft, relaxed, nontender uterus with normal tone. The presenting part of the fetus usually remains high because the placenta occupies the lower uterine segment. Thus the fundal height is often greater than expected for gestational age. Because of the abnormally located placenta, fetal malpresentation (breech and transverse or oblique lie) is common.

TABLE 14.8 Summary of Findings

Placental Abruption and Placenta Previa

	PLACENTAL ABRUPTION			PLACENTA PREVIA
	Class 1: Mild Separation (10–20%)	**Class 2: Moderate Separation (20–50%)**	**Class 3: Severe Separation (>50%)**	
Bleeding, external, vaginal	Minimal	Absent or moderate	Absent to heavy	Minimal to severe and life-threatening
Total amount of blood loss	<500 mL	1 000–1 500 mL	>1 500 mL	Varies
Colour of blood	Dark red	Dark red	Dark red	Bright red
Shock	Rare; none	Mild shock	Common, often sudden, profound	Uncommon
Coagulopathy	Rare; none	Occasional DIC	Frequent DIC	None
Uterine tonicity	Normal	Increased; may be localized to one region or diffuse over uterus; uterus fails to relax between contractions	Tetanic, persistent uterine contraction; boardlike uterus	Normal
Tenderness (pain)	Usually absent	Present (moderate to severe)	Agonizing, unremitting pain	Absent
Ultrasonographic Findings				
Location of placenta	Normal; upper uterine segment	Normal; upper uterine segment	Normal; upper uterine segment	Abnormal; lower uterine segment
Station of presenting part	Variable to engaged	Variable to engaged	Variable to engaged	High, not engaged
Fetal position	Usual distribution*	Usual distribution*	Usual distribution*	Commonly transverse, breech, or oblique
Other Findings				
Gestational or chronic hypertension	Usual distribution*	Commonly present	Commonly present	Usual distribution*
Fetal effects	Normal fetal heart rate pattern	Atypical fetal heart rate pattern	Abnormal fetal heart rate pattern; death can occur	Normal fetal heart rate pattern

DIC, Disseminated intravascular coagulation.
*Usual distribution refers to the usual variations of incidence seen when there is no concurrent health concern.
Adapted from Gaufberg, S. V. (2011). Emergent management of abruptio placentae. *eMedicine.* http://emedicine.medscape.com/article/795514-overview

Maternal and fetal outcome. The major maternal complication associated with placenta previa is hemorrhage. Another serious complication is development of an abnormal placental attachment (e.g., *placenta accreta, increta*, or *percreta*) (see discussion later in chapter). If excessive bleeding cannot be controlled, hysterectomy may be necessary (Cunningham et al., 2018; Hull et al., 2019). Because most patients with placenta previa have a Caesarean birth, surgery-related trauma to structures adjacent to the uterus and anaesthesia complications are also possible. In addition, blood transfusion reactions, anemia, thrombophlebitis, and infection may occur.

Preterm birth is a major cause of perinatal morbidity and mortality for infants born to patients with placenta previa. IUGR has also been associated with placenta previa, although the risk for developing this condition is low. The incidence of fetal anomalies is increased in pregnancies complicated by placenta previa (Cunningham et al., 2018).

Diagnosis. All patients with painless vaginal bleeding after 20 weeks of gestation should be assumed to have a placenta previa until proven otherwise. A transabdominal ultrasound examination should be performed initially, followed by a transvaginal scan, unless the transabdominal ultrasound clearly shows that the placenta is not located in the lower uterine segment. A transvaginal ultrasound is better than a transabdominal scan for accurately determining placental location (Hull et al., 2019). If ultrasonographic scanning reveals a normally implanted placenta, a speculum examination may be performed to rule out local causes of bleeding (e.g., cervicitis, polyps, carcinoma of the cervix), and a coagulation profile is obtained to rule out other causes of bleeding.

Collaborative care. Once placenta previa has been diagnosed, a management plan is developed. The patient is managed either expectantly or actively, depending on the gestational age, presence of bleeding, and fetal condition.

Expectant management. If the patient is less than 36 weeks of gestation and is not in labour and the bleeding is minimal or has stopped, expectant management (i.e., reduced activity and close observation) is generally the treatment of choice to give the fetus time to mature in utero. The patient may remain in the hospital or be at home if bleeding is stable and the patient has support and lives in proximity to the hospital. Bleeding is assessed by checking the amount of bleeding on perineal pads, bed pads, and linens. Weighing of pads is one way to more accurately assess blood loss; 1 gram is equal to 1 mL of blood.

Ultrasound examinations may be done every 2 weeks. Fetal surveillance may include NST or BPP once or twice weekly. Serial laboratory values are evaluated for decreasing hemoglobin and hematocrit levels and changes in coagulation values. Venous access with an IV infusion or heparin lock may be placed in case blood or blood component therapy is needed. Antepartum steroids (betamethasone) may be ordered to promote fetal lung maturity if the patient is at less than 34 weeks of gestation. No vaginal or rectal examinations are performed, and the patient is placed on pelvic rest (nothing in the vagina). Once the pregnancy is at 37 weeks of gestation and fetal lung maturity is documented, Caesarean birth can be scheduled.

Placenta previa should always be considered a potential emergency because massive blood loss with resulting hypovolemic shock can occur quickly if bleeding resumes. The possibility always exists that the patient may require an emergency Caesarean birth. Placenta previa in a preterm gestation may be an indication for admission to a tertiary perinatal centre because some community hospitals are not equipped to perform emergency Caesarean births 24 hours per day, 7 days per week; nor can they provide neonatal intensive care.

If expectant management is to be implemented, a vaginal speculum examination should be postponed until fetal viability is reached (preferably after 34 weeks of gestation). If a pelvic examination is needed before that time, it is possible that an immediate Caesarean birth may be required. The patient is taken to a delivery room or an operating room set up for Caesarean birth, because profound hemorrhage can occur during the examination. This type of vaginal examination, known as the *double-setup procedure*, is not often performed.

Home care. Criteria for home care management vary among primary perinatal providers and home care agencies and are usually determined on a case-by-case basis. To be considered for home care referral, the patient must, after a period of assessment in hospital, be in stable condition with no evidence of active bleeding and must have the resources to be able to return to the hospital immediately if active bleeding resumes (Francois & Foley, 2017; Oppenheimer et al., 2007).

A patient must have close supervision by family or friends in the home. They should be taught how to assess fetal and uterine activity and bleeding and told to avoid having intercourse, douching, and the use of enemas. They should limit their activities according to the advice of their health care provider and be advised to keep all appointments for fetal testing, laboratory assessments, and prenatal care.

Active management. If the patient is at or beyond 36 weeks of gestation or bleeding is excessive or persistent, immediate Caesarean birth is indicated. Expectant management is terminated as soon as the fetus is mature, if excessive bleeding develops, active labour begins, or any other obstetrical reason to end the pregnancy (e.g., chorioamnionitis) develops (Hull et al., 2019). Caesarean birth is indicated in all patients with ultrasound evidence of placenta previa. In patients with partial or marginal placenta previa (placental edge is greater than 2 mm from the cervical os) who have minimal bleeding, vaginal birth may be attempted (Francois & Foley, 2017; Hull et al., 2019; Oppenheimer et al., 2007).

Acute care of a patient with a diagnosed placenta previa should be carried out in a labour and birth unit with continuous electronic monitoring of the fetus and uterine contractions. Maternal vital signs are assessed frequently for BP changes, increasing pulse rate, changes in level of consciousness, and oliguria. The nurse should continuously assess maternal and fetal status while preparing the patient for surgery.

Blood loss may not stop with the birth of the infant. The large vascular channels in the lower uterine segment may continue to bleed because of the diminished muscle content in that region. The natural mechanism to control bleeding (i.e., the interlacing muscle bundles contracting around open vessels [the "living ligature" characteristic of the upper part of the uterus]) is absent in the lower part of the uterus. Therefore, postpartum hemorrhage may occur even if the fundus is contracted firmly (see Chapter 24).

Emotional support for the patient and their family is extremely important. The actively bleeding patient is concerned not only for her own well-being but for that of the fetus. All procedures should be explained, and a support person should be present. The patient should be encouraged to express their concerns and feelings. If the patient and their support person or family desire spiritual care, the nurse can notify the hospital chaplain service or provide information about other supportive resources. See the Nursing Care Plan, Placenta Previa on the Evolve site.

Placental Abruption (Premature Separation of Placenta).

Premature separation of the placenta, or **placental abruption (abruptio placentae)**, is the detachment of part or all of the placenta from its implantation site (Figure 14.13). Separation occurs in the area of the decidua basalis after 20 weeks of pregnancy and before the birth of the baby.

Fig. 14.13 Placental abruption showing partial and complete placental separation.

Incidence and etiology. Premature separation of the placenta is a serious complication that accounts for significant maternal and fetal morbidity and mortality. The overall incidence of placental abruption is 1 in 100 births, but a range of 1 in 80 to 1 in 250 pregnancies has been reported. The range in incidence likely reflects both variable criteria for diagnosis and an increased recognition of milder forms of abruption. Approximately one third of all antepartum bleeding is caused by placental abruption (Francois & Foley, 2017) (see Clinical Reasoning Case Study: Third-Trimester Vaginal Bleeding).

CLINICAL REASONING CASE STUDY

Third-Trimester Vaginal Bleeding

Ashley is a 29-year-old (G7 T5 P0 A1 L5) who presents to the emergency department with heavy vaginal bleeding and contractions. She has had no prenatal care but is approximately 33 weeks of gestation by her LMP. During her medical screening examination Ashley admitted to cocaine use in the pregnancy and reported that her boyfriend punched her in the abdomen earlier in the day.

Questions

1. Evidence—Is there sufficient evidence to determine the cause of Ashley's bleeding?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Possible diagnoses for Ashley
   b. Laboratory and diagnostic tests necessary to diagnose the cause of Ashley's bleeding
   c. Management options for Ashley
   d. Need for a social work consultation regarding intimate partner violence and use of illicit substances
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?
5. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Ashley's care.

LMP, Last menstrual period.

Maternal hypertension is probably the most consistently identified risk factor for abruption. Cocaine use also is a risk factor because it causes vascular disruption in the placental bed. Blunt external abdominal trauma, most often the result of motor vehicle collisions (MVCs) or the mother being a victim of assault, is another frequent cause of placental abruption. Other risk factors include cigarette smoking, a history of abruption in a previous pregnancy, preterm PROM, and the presence of inherited or acquired thrombophilias (e.g., factor V Leiden mutation or protein C or S deficiency) (Cunningham et al., 2018; Hull et al., 2019). Patients who have had two previous abruptions have a recurrence risk of 25% in the next pregnancy (Hull et al., 2019).

Classification systems. The most common classification of placental abruption is according to type and severity. This classification is summarized in Table 14.8.

Clinical manifestations. The separation may be partial or complete, or only the margin of the placenta may be involved. Bleeding from the placental site may dissect (separate) the membranes from the decidua basalis and flow out through the vagina (70 to 80%), it may remain concealed (retroplacental hemorrhage) (10 to 20%), or it may do both (see Figure 14.13) (Francois & Foley, 2017; Gilbert, 2011).

Clinical symptoms vary with degree of separation (see Table 14.8). Classic symptoms of placental abruption include vaginal bleeding, abdominal pain, uterine tenderness, and contractions (Cunningham et al., 2018; Hull et al., 2019). Bleeding may result in maternal hypovolemia (i.e., shock, oliguria, anuria) and coagulopathy. Mild-to-severe uterine hypertonicity is present. Pain is mild to severe and localized over one region of the uterus or diffuse over the uterus with a boardlike abdomen.

Extensive myometrial bleeding damages the uterine muscle. If blood accumulates between the separated placenta and the uterine wall, it may produce a Couvelaire uterus: the uterus appears purplish and copper coloured, it is ecchymotic, and contractility is lost. Shock may occur and is out of proportion to blood loss as hemoglobin and hematocrit levels decrease, and coagulation factor levels decrease. Clotting defects (e.g., DIC) develop in 10 to 30% of patients, in most cases within 8 hours of hospital admission. A Kleihauer-Betke (KB) test may be ordered to determine the presence of fetal-to-maternal bleeding (transplacental hemorrhage), although it is of no diagnostic value. The KB test may be useful to guide $Rh_o(D)$ immunoglobulin therapy in Rh-negative patients who have had an abruption (Hull et al., 2019).

Maternal, fetal, and newborn outcomes. The patient's prognosis depends on the extent of placental detachment, overall blood loss, degree of coagulopathy present, and the time that passes between placental detachment and birth. Patient complications are associated with the abruption or its treatment. Hemorrhage, hypovolemic shock, hypofibrinogenemia, and thrombocytopenia are associated with severe abruption. Couvelaire uterus, DIC, and infection may occur. Renal failure and pituitary necrosis (Sheehan syndrome) may result from ischemia. In rare cases, patients who are Rh negative can become sensitized if fetal-to-maternal hemorrhage occurs and the fetal blood type is Rh positive.

Fetal complications, which include IUGR, oligohydramnios, preterm birth, hypoxemia, and stillbirth, are related to the severity and timing of the hemorrhage. Fetal survival is related to the size of the hemorrhage. Large (greater than 60 mL) retroplacental hemorrhages have been associated with a fetal mortality rate of 50% or greater (Francois & Foley, 2017). Risks for neurological defects, cerebral palsy, and death from sudden infant death syndrome are greater in newborns following placental abruption (Cunningham et al., 2018; Francois & Foley, 2017).

Diagnosis. Placental abruption should be strongly suspected in the patient who has a sudden onset of intense, usually localized, uterine pain, with or without vaginal bleeding. Initial assessment is much the same as that for placenta previa. Physical examination usually reveals abdominal pain, uterine tenderness, and contractions. The fundal height may be measured over time, because increasing fundal height could indicate concealed bleeding. Approximately 60% of live fetuses exhibit abnormal signs on the electronic fetal heart monitor, such as loss of variability and late decelerations; uterine tachysystole and increased resting tone may also be noted on the monitor tracing (Francois & Foley, 2017; Gilbert, 2011). Many patients demonstrate coagulopathy, as evidenced by abnormal clotting studies (fibrinogen, platelet count, PT, PTT, fibrin split products).

Ultrasound examination is used to rule out placenta previa; however, it is not always diagnostic for abruption. A retroplacental mass may be detected with ultrasonographic examination, but negative findings do not rule out a life-threatening abruption (Cunningham et al., 2018; Hull et al., 2019).

Collaborative care. Management depends on the severity of blood loss and fetal maturity and status. If the abruption is mild, expectant management is implemented if the fetus is less than 36 weeks of gestation and not in distress. The patient is hospitalized and closely observed for signs of bleeding and labour. The fetal status is monitored with intermittent FHR monitoring and NST or BPP until fetal maturity is achieved. If the patient's condition deteriorates, immediate birth is indicated. Use of corticosteroids to accelerate fetal lung maturity is appropriately included in the plan of care for the patient managed expectantly (Goldenberg & McClure, 2015; Hull et al., 2019). Patients who are Rh negative may be given Rh_o(D) immunoglobulin if fetal-to-maternal hemorrhage occurs and the fetal blood is Rh positive.

If the mother is hemodynamically stable, a vaginal birth may be attempted if the fetus is alive and in no acute distress or if the fetus is dead. In the presence of fetal compromise, severe hemorrhage, coagulopathy, poor labour progress, or increasing uterine resting tone, a Caesarean birth is performed. At least one large-bore (16-gauge) IV line should be started. Maternal vital signs should be monitored frequently to observe for signs of declining hemodynamic status, such as increasing pulse rate and decreasing BP. Serial laboratory studies include hematocrit or hemoglobin determinations and clotting studies. Continuous electronic fetal monitoring is mandatory. An in-dwelling Foley catheter can be inserted for ongoing assessment of urine output, an excellent indirect measure of maternal organ perfusion. Fluid volume replacement may be necessary, along with administration of blood products to correct any coagulation defects.

Caesarean birth should be reserved for cases of abnormal electronic fetal monitoring patterns or other obstetrical indications. Caesarean birth should not be attempted when the patient has severe and uncorrected coagulopathy because it may result in surgically uncontrollable bleeding.

Nursing care of patients experiencing moderate-to-severe abruption is demanding because it requires constant close monitoring of the maternal and fetal condition. Information about placental abruption, including the cause, treatment, and expected outcome, is given to the patient and their family. Emotional support for the patient and their family is extremely important. If the patient is actively bleeding, they will be concerned not only for their own well-being but also for that of their fetus. All procedures should be explained, and a support person should be present.

Cord Insertion and Placental Variations. **Placenta accreta** is a serious complication of placenta previa. In this condition, trophoblastic invasion extends beyond the normal endometrial barrier. If the invasion extends into the myometrium, it is called *placenta increta*. *Placenta percreta* exists when the placental invasion extends beyond the uterine serosa (Hobson et al., 2019; Hull et al., 2019). Massive hemorrhage can occur with these conditions. Caesarean birth through a fundal incision, followed by total abdominal hysterectomy, may be indicated (Gagnon, 2017; Hull et al., 2019). The optimal timing of a planned Caesarean birth for a patient with no history of active bleeding is between 34 and 36 weeks' gestation (Hobson et al., 2019).

When fetal vessels lie over the cervical os, the condition is termed **vasa previa**. In vasa previa, the vessels are implanted into the fetal membranes rather than into the placenta. Usually these vessels are protected only by the membranes (not by Wharton's jelly); thus they are at risk for rupture or compression (Hull et al., 2019). In the past, vasa previa was usually diagnosed after rupture of membranes occurred, followed by acute-onset vaginal bleeding caused by a lacerated fetal vessel. Currently, antenatal diagnosis with abdominal and transvaginal ultrasound significantly improve both fetal and maternal outcomes (Gagnon, 2017).

Vasa previa is rare, affecting 0.6 in 1 000 pregnancies (Hull et al., 2019). Risk factors for vasa previa include a history of second-trimester placenta previa or low-lying placenta, pregnancies resulting from assisted human reproduction, and multiple gestations (Francois & Foley, 2017).

There are two variations of vasa previa. In both situations, artificial or spontaneous rupture of the membranes or traction on the cord may rupture one or more of the fetal vessels. As a result, the fetus may rapidly bleed to death (Francois & Foley, 2017; Gagnon, 2017).

One variation of vasa previa, *velamentous insertion of the cord,* occurs when the umbilical vessels begin to branch at the membranes and then course onto the placenta (Figure 14.14, *A*). The other variant of vasa previa occurs when the placenta has divided into two or more lobes rather than remaining as a single mass. This is known as a *succenturiate placenta* (Figure 14.14, *C*). Fetal vessels then run between the lobes of the placenta. The vessels collect at the periphery, and the main trunks eventually unite to form the vessels of the cord. During the third stage of labour, one or more of the separate lobes may remain attached to the decidua basalis, preventing uterine contraction and increasing the risk for postpartum hemorrhage.

Another placental variation is *Battledore* (marginal) insertion of the cord (Figure 14.14, *B*). This variation also increases the risk for fetal hemorrhage, especially after marginal separation of the placenta.

Clotting Disorders in Pregnancy

Normally, a delicate balance (homeostasis) is maintained between the opposing hemostatic and fibrinolytic systems. The hemostatic system stops the flow of blood from injured vessels, first by a platelet plug, then by formation of a fibrin clot. The coagulation process involves an interaction of the coagulation factors in which each factor sequentially activates the factor next in line—the "cascade effect" sequence. The fibrinolytic system is the process by which the fibrin is split into fibrin degradation products and circulation is restored.

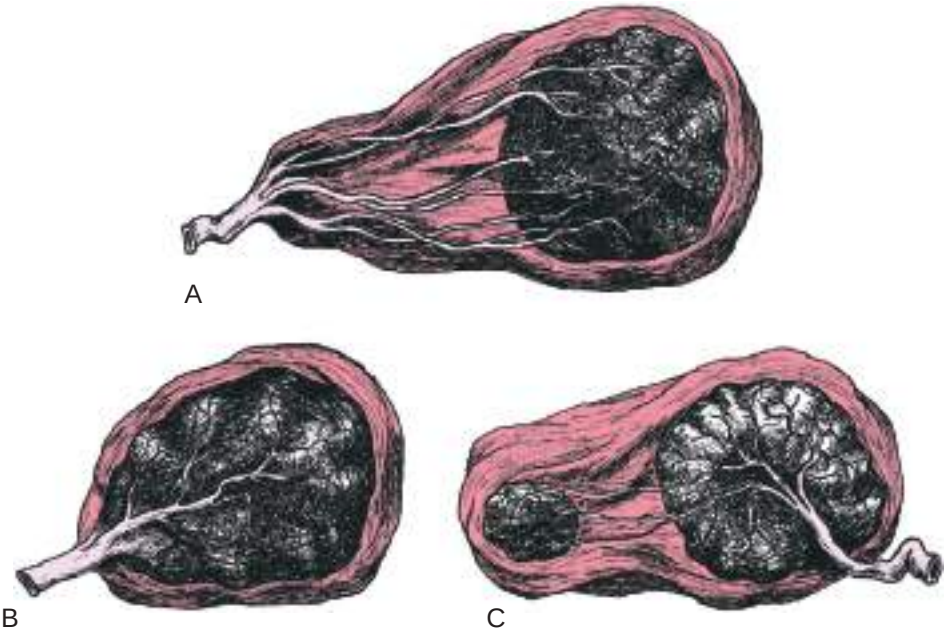

Fig. 14.14 Cord insertion and placental variations. **A:** Velamentous insertion of cord. **B:** Battledore placenta. **C:** Succenturiate placenta.

A history of abnormal bleeding, inheritance of unusual bleeding tendencies, or a report of significant aberrations of laboratory findings indicates a bleeding or clotting issue. For the pregnant patient, bleeding disorders are suspected if the patient has gestational hypertension, HELLP syndrome, retained dead fetus syndrome, amniotic fluid embolism, sepsis, or hemorrhage (Romero et al., 2011). Determination of hemostasis is made by testing the usual mechanisms for the control of bleeding, the function of platelets, and the necessary clotting factors. Most clotting disorders are more a concern in the immediate postpartum period. Recognition in the antepartum period may decrease hemorrhagic issues.

Disseminated Intravascular Coagulation (DIC). Disseminated intravascular coagulation (DIC), or consumptive coagulopathy, is a pathological form of clotting that is diffuse and consumes large amounts of clotting factors, causing widespread external or internal bleeding or both (Cunningham et al., 2018). DIC is never a primary diagnosis. Instead, it results from some condition that triggered the clotting cascade, either extrinsically by the release of large amounts of tissue thromboplastin or intrinsically by widespread damage to vascular integrity.

In the obstetrical population DIC is most often triggered by the release of large amounts of tissue thromboplastin, which occurs in placental abruption (the most common cause of severe consumptive coagulopathy in obstetrics), retained dead fetus syndrome, and amniotic fluid embolus (anaphylactoid syndrome of pregnancy). Preeclampsia, HELLP syndrome, and Gram-negative or Gram-positive sepsis are examples of conditions that can trigger DIC because of widespread damage to vascular integrity (Cunningham et al., 2018). DIC is an overactivation of the clotting cascade and the fibrinolytic system, resulting in depletion of platelets and clotting factors, which causes the formation of multiple fibrin clots throughout the vasculature of the body, even in the microcirculation. Blood cells are destroyed as they pass through these fibrin-choked vessels. Thus DIC results in a clinical picture of clotting, bleeding, and ischemia (Cunningham et al., 2018). Clinical manifestations and laboratory test results are summarized in Box 14.8.

Collaborative care. Medical management in all cases of DIC involves correction of the underlying cause, which may be treatment of existing severe infection, pre-eclampsia, or eclampsia, or removal of a placental abruption or dead fetus. Volume expansion, rapid replacement of blood products and clotting factors, optimization of oxygenation, achievement of normal body temperature, and continued reassessment of laboratory parameters are the usual forms of treatment. Vitamin K administration, recombinant activated factor VIIa,

BOX 14.8 Clinical Manifestations and Laboratory Screening Results for Patients With Disseminated Intravascular Coagulation

Possible Physical Examination Findings	Laboratory Coagulation Screening Test Results
• Spontaneous bleeding from gums, nose • Oozing, excessive bleeding from venipuncture site, intravenous access site, or site of insertion of urinary catheter • Petechiae (e.g., on arm where blood pressure cuff was placed) • Other signs of bruising • Hematuria • Gastrointestinal bleeding • Tachycardia • Diaphoresis	• Platelets: Decreased • Fibrinogen: Decreased • Factor V (proaccelerin): Decreased • Factor VIII (antihemolytic factor): Decreased • Prothrombin time: Prolonged • Partial prothrombin time: Prolonged • Fibrin degradation products: Increased • D-dimer test (specific fibrin degradation fragment): Increased • Red blood smear: Fragmented red blood cells

fibrinogen concentrate, and hemostatic agents should be considered as additional therapies (Francois & Foley, 2017).

Nursing interventions include assessing for signs of bleeding (petechial, oozing from injection sites, hematuria, and hemoptysis) (see Box 14.8) and complications from the administration of blood and blood products, administering fluid or blood replacement as ordered, cardiac and hemodynamic monitoring, and protecting the patient from injury. Because acute renal failure is one consequence of DIC, urinary output needs to be carefully monitored with an in-dwelling catheter. The goal for urine output is 30 mL/hr or greater. Vital signs are assessed frequently. If DIC develops before birth, continuous electronic fetal monitoring is necessary. The patient should be maintained in a side-lying tilt to maximize blood flow to the uterus.

Oxygen may be administered through a tight-fitting rebreathing mask at 8 to 10 L/min or per hospital protocol or health care provider order. To provide oxygen delivery to the tissues, blood products are usually administered. The patient should be kept warm with a forced-air warming system (e.g., Bair Hugger), which is an effective method to maintain normothermia. Other interventions include the use of warmed blankets and fluid warmers, which should be used as needed. DIC is usually corrected with blood and volume replacement, and with resolution of the cause and as coagulation abnormalities resolve (Belfort, 2021).

The patient and their family may be anxious and concerned about the patient's condition and prognosis. The nurse should offer explanations about care and provide emotional support to them through this critical time.

Von Willebrand's Disease. Von Willebrand's disease, a type of hemophilia, is probably the most common of all hereditary bleeding disorders (Demers et al., 2018). It results from a factor VIII deficiency and platelet dysfunction. It is transmitted as an incomplete autosomal dominant trait to both sexes. Although von Willebrand's disease is rare, it is one of the most common congenital clotting defects in North American persons of childbearing age and should be considered in any patient with any type of bleeding disorder, including heavy menstrual bleeding. Symptoms include a familial bleeding tendency, previous bleeding episodes, prolonged bleeding time (the most important test), factor VIII deficiency (mild to moderate), and bleeding from mucous membranes. Factor VIII increases during pregnancy, and this increase may be sufficient to offset danger from hemorrhage during childbirth.

Collaborative care. Von Willebrand's disease is variable in its clinical course, severity, and laboratory values; thus it is possible for this condition to go undetected throughout pregnancy until bleeding issues develop after birth. A primary treatment for many patients is desmopressin (also known as DDAVP), which increases levels of plasma factor VIII and von Willebrand's factor (vWF) (Demers et al., 2018; Rodger & Silver, 2019). If the patient is known to have von Willebrand's disease before labour, factor VIII levels should be monitored and factor VIII/vWF plasma concentrate given as needed to maintain activity at 50% of normal near-term gestation (Demers et al., 2018; Rodger & Silver, 2019). In the intrapartum period, instrumental birth, fetal scalp sampling, and use of fetal scalp electrodes should be avoided to reduce the risks of fetal bleeding during the birth process (Demers et al., 2018). Hemorrhage may occur 4 or 5 days after birth; therefore, the patient should remain in the hospital for several days after birth so they can be monitored for that complication.

Factor V Leiden Mutation. Factor V Leiden (FVL) mutation is an inherited thrombophilia and is estimated to be present in 5% of the White population but is not found in populations of African and Asian descent (Hemsworth et al., 2016). Patients with FVL have an increased risk for venous thromboembolism (VTE) as well as early and late pregnancy loss (Rodger & Silver, 2019). The risk of preterm birth with FVL mutation is less clear, and there is conflicting evidence from research for the risk of preterm birth associated with FVL mutations (Hemsworth et al., 2016).

INFECTIONS ACQUIRED DURING PREGNANCY

Sexually Transmitted Infections

Sexually transmitted infections (STIs) in pregnancy are responsible for significant morbidity rates. Some consequences of maternal infection, such as infertility and sterility, last a lifetime. Psychosocial sequelae may include altered interpersonal relationships and lowered self-esteem. Congenitally acquired infections may affect the length and quality of a child's life. Chapter 7 discusses the diagnosis and management of STIs.

Urinary Tract Infections

Urinary tract infections (UTIs) are a common medical complication of pregnancy, occurring in approximately 20% of all pregnancies. They are also responsible for 10% of all hospitalizations during pregnancy (Duff, 2019). UTIs include asymptomatic bacteriuria, cystitis, and pyelonephritis. They are usually caused by coliform organisms that are a normal part of the perineal flora. By far the most common cause is *Escherichia coli,* a Gram-negative bacterium responsible for at least 80% of initial cases and about 70% of recurrent cases. *Klebsiella pneumoniae* and *Proteus* species are other common pathogens, particularly in pregnant patients with a history of recurrent infections. Up to 10% of infections are caused by Gram-positive organisms such as group B streptococci, enterococci, and staphylococci (Duff & Birsner, 2017).

Asymptomatic Bacteriuria. *Asymptomatic bacteriuria* refers to the persistent presence of bacteria within the urinary tract of patients who have no symptoms. A clean-voided urine specimen containing more than 100 000 colonies per millilitre of a single organism is diagnostic. If asymptomatic bacteriuria is not treated, about one third of pregnant patients will develop acute pyelonephritis. It is recommended that all patients be screened for asymptomatic bacteriuria at their first prenatal visit (Duff & Birsner, 2017). It has been associated with a significant increase in the risk for preterm labour and birth and low-birth-weight infants (Cunningham et al., 2018; Epp & Larochelle, 2017).

Asymptomatic bacteriuria should be treated with an antibiotic. Antibiotics that are often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrodantin), and trimethoprim-sulfamethoxazole (Bactrim DS). Several different regimens, including single-dose or 3-, 7-, and 10-day treatment, may be used (Cunningham et al., 2018). In patients who experience a prompt response to treatment of an initial infection, a urine culture for test of cure may not be clinically necessary or cost-effective. Conversely, urine cultures during or immediately after the completion of therapy are indicated for patients who have a poor response to therapy or a history of recurrent infection (Duff & Birsner, 2017). Patients who have persistent or frequent recurrences of bacteriuria may be placed on suppressive therapy, often nitrofurantoin, each night at bedtime except for the last 4 weeks of pregnancy (Cunningham et al., 2018; Epp & Larochelle, 2017). There is some evidence that cranberry juice or other cranberry products have some effect on reducing the number of symptomatic UTIs (Epp & Larochelle, 2017).

Cystitis. Cystitis (bladder infection) is characterized by dysuria, urgency, and frequency, along with lower abdominal or suprapubic pain. Usually white blood cells (WBCs) and bacteria are found in the urine. Microscopic or gross hematuria may also be present. Typically

symptoms are confined to the bladder rather than becoming systemic. Cystitis is usually uncomplicated, but it may lead to ascending UTI if untreated. Approximately 40% of pregnant patients with pyelonephritis experience symptoms of bladder infection before developing pyelonephritis (Cunningham et al., 2018).

Cystitis is often treated with a 3-day course of antibiotic therapy, which is usually 90% effective in curing the infection. Antibiotics often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrodantin), and trimethoprim-sulphamethoxazole (Bactrim DS) (Cunningham et al., 2018). Phenazopyridine (Pyridium), a urinary analgesic, is often prescribed along with an antibiotic for relief of symptoms caused by irritation of the urinary tract. Although phenazopyridine is effective at relieving dysuria, urgency, and frequency, patients should be taught that the medication colours urine and tears orange. Therefore, they should be instructed to avoid wearing contact lenses while taking this medication and warned that it will stain underwear.

Pyelonephritis. Renal infection (pyelonephritis) is a common serious medical complication of pregnancy and the second most common nonbirth reason for hospitalization (Cunningham et al., 2018). The most common complications associated with pyelonephritis include sepsis, acute respiratory distress syndrome (ARDS), and preterm labour (Duff & Birsner, 2017).

Pyelonephritis develops most often during the second trimester of pregnancy and is usually caused by the *E. coli* organism. Infection develops only in the right kidney in more than half of all cases. The onset of pyelonephritis is often abrupt, with fever, shaking chills, and aching in the lumbar area of the back. Anorexia and nausea and vomiting also can be present. Usually one or both costovertebral angles are tender to palpation.

A patient with mild disease who is hemodynamically stable and has no evidence of preterm labour may be a candidate for outpatient management. They may be treated with oral antibiotics. Alternatively, arrangements may be made for a home care nurse to administer an antibiotic, such as ceftriaxone (Rocephin), either intravenously or intramuscularly (Duff & Birsner, 2017).

Most patients diagnosed with pyelonephritis are usually admitted to the hospital immediately. Treatment with IV antibiotics is started as soon as urine and blood samples for culture and sensitivity have been collected. Ampicillin, gentamicin, cefazolin (Ancef), or ceftriaxone (Rocephin) are often ordered initially because they are broad-spectrum antibiotics that are usually effective. The patient must be monitored closely for the possible development of sepsis (Cunningham et al., 2018).

Clinical symptoms generally resolve within a couple of days after antibiotic therapy is begun. Most patients are afebrile and asymptomatic after 72 hours. If no clinical improvement is seen within 48 to 72 hours, an ultrasound should be performed to assess for a urinary tract obstruction. Once the patient is afebrile, they are changed from IV to oral antibiotics (Cunningham et al., 2018).

Usually antibiotic therapy is continued to complete a total of 7 to 10 days of treatment. Recurrent infection develops in 20 to 30% of pregnant patients after completion of treatment for pyelonephritis. Many patients are maintained on a prophylactic antibiotic (often nitrofurantoin once or twice daily) except for the last 4 weeks of pregnancy (Epp & Larochelle, 2017). Patients receiving antibiotic prophylaxis should have their urine screened for bacteria at each subsequent prenatal appointment and be questioned about symptoms. If symptoms recur or the dipstick test for nitrite or leukocyte esterase is positive, a urine culture should be obtained to determine if retreatment is necessary (Duff & Birsner, 2017).

Patient Education. Nurses are often responsible for teaching pregnant patients about taking medications safely and effectively. This education is especially important in regard to antibiotics because this type of medication is so often misused by the general public. The patient should be instructed to finish the entire course of prescribed antibiotic therapy rather than stopping the medication as soon as they feel better. Failure to complete the entire course can lead to the creation of additional drug-resistant organisms. Antibiotics should be taken on time and around the clock so medication levels in the body remain constant. Finally, many patients develop a yeast infection while taking antibiotics because the medication kills normal flora in the genitourinary tract as well as pathological organisms. They should be encouraged to include yogurt, cheese, or milk containing active acidophilus cultures in their diet while on antibiotics.

The patient should also be taught simple ways to prevent future UTIs. See the Patient Education box: Prevention of Genital Tract Infections, in Chapter 7, for several suggestions.

NONOBSTETRICAL SURGERY DURING PREGNANCY

Approximately 1 in 500 patients require nonobstetrical surgery during pregnancy. However, pregnancy can make the diagnosis more difficult. An enlarged uterus and displaced internal organs may make abdominal palpation more difficult, may alter the position of an affected organ, or may change the usual signs associated with a particular disorder. The most common conditions necessitating abdominal surgery during pregnancy are appendicitis, cholecystitis, trauma, and gynecological issues (Schwartz & Ludmir, 2017). The rate of premature labour induced by nonobstetrical surgical intervention is 3.5% and occurs more often following appendectomy than with any other type of surgery.

Appendicitis

Appendicitis is the most common nongynecological cause of an acute surgical abdomen during pregnancy, occurring in about 1 in 1 000 pregnancies (Cappell, 2017a). The diagnosis is often delayed because the usual signs and symptoms mimic some normal changes of pregnancy, such as nausea and vomiting and increased WBC count. As pregnancy progresses, the appendix is pushed upward and to the right from its usual anatomical location (see Figure 10.16). Because of these changes, appendix rupture and peritonitis occur in up to 25% of pregnant patients with appendicitis (Cappell, 2017a).

The most common symptom of appendicitis in pregnancy is right lower quadrant pain, regardless of gestational age. Nausea and vomiting are often present, but loss of appetite is not a reliable indicator of appendicitis. Fever, tachycardia, a dry tongue, and localized abdominal tenderness are commonly found in nonpregnant people with appendicitis, but they are less likely indicators for the disorder in pregnant patient. Because of the physiological increase in WBCs that occurs in pregnancy, this test is not helpful in making the diagnosis. A urinalysis and a chest X-ray should be performed to rule out UTI and right lower lobe pneumonia, given that both of these conditions can cause lower abdominal pain (Kelly & Savides, 2019). Appendicitis can also be confused with other disorders such as cholecystitis, preterm labour, pyelonephritis, or placental abruption (Cunningham et al., 2018).

Radiological imaging is necessary if appendicitis is suspected after history, physical examination, and laboratory studies have been completed. Although computed tomography (CT) is the imaging test of choice in nonpregnant patients because it is highly accurate, the use of ultrasonography during pregnancy is preferred to avoid fetal

exposure to radiation from CT (Cappell, 2017a). Magnetic resonance imaging (MRI) may be used if appendicitis has not been confirmed by other imaging techniques (Cappell, 2017a; Kelly & Savides, 2019).

Prompt surgical intervention to remove the appendix is still the standard treatment (Kelly & Savides, 2019). Laparoscopic surgery may be performed during the first and second trimesters of pregnancy if the appendix has not ruptured or the diagnosis is uncertain. Antibiotics are often administered for uncomplicated appendicitis and are definitely necessary if rupture, abscess, or peritonitis has occurred. Clindamycin and gentamicin are often prescribed because they are considered both effective and safe. The maternal mortality rate from ruptured appendix is about 4%. The fetal mortality rate from ruptured appendix is much higher, more than 30% (Cappell, 2017a).

Intestinal Obstruction

The second most common nonobstetrical abdominal emergency in pregnancy is intestinal obstruction. The incidence of intestinal obstruction during pregnancy is estimated at 1 in 2 500 pregnancies (Cappell, 2017a). Any patient with a laparotomy scar is more likely to have an intestinal obstruction (adynamic ileus) during gestation. Adhesions as a result of previous surgery or pelvic inflammatory disease, an enlarging uterus, and displacement of the intestines are etiological factors.

Symptoms of an intestinal obstruction include abdominal pain, emesis, and constipation (Cappell, 2017a). Immediate surgical intervention is required for release of the obstruction. Pregnancy is rarely affected by the surgery, assuming the absence of complications such as peritonitis.

Cholelithiasis and Cholecystitis

Cholelithiasis (the presence of gallstones in the gallbladder) occurs more often in women than in men. Its incidence increases during pregnancy, probably because of increased hormone levels and pressure from the enlarged uterus that interferes with the normal circulation and drainage of the gallbladder. Most gallstones are asymptomatic during pregnancy. Usually the first symptom of cholelithiasis is biliary colic, epigastric, or right upper-quadrant pain that can radiate to the back or shoulders. Pain may occur spontaneously or after eating a high-fat meal. Approximately two thirds of patients with biliary colic have recurrent attacks (Cappell, 2017b).

Cholecystitis (inflammation of the gallbladder) is usually caused when a gallstone obstructs a cystic duct and may also occur during pregnancy, due to increased pressure of the enlarged uterus interfering with the normal circulation and drainage of the gallbladder. As in biliary colic that occurs with cholelithiasis, epigastric or right upper-quadrant pain is present, but the pain is usually more severe and prolonged. Nausea, vomiting, and fever may also be present. Acute cholecystitis is the third most common indication for nonobstetrical surgical intervention in pregnancy, occurring in about 4 cases per 10 000 pregnancies (Cappell, 2017b).

Often gallbladder surgery is postponed until the puerperium. The patient can usually be managed conservatively for the remainder of the pregnancy (see Patient Teaching box: Nutrition Counselling for the Pregnant Patient with Cholecystitis or Cholelithiasis). However, patients with recurrent biliary colic or acute cholecystitis generally require immediate cholecystectomy. Although the second trimester has traditionally been considered the safest time for this surgery, it is increasingly performed at any time during pregnancy because of improved surgical techniques and outcomes. Both laparoscopic and open cholecystectomy procedures are acceptable during pregnancy (Cappell, 2017b; Cunningham et al., 2018).

PATIENT TEACHING

Nutrition Counselling for the Pregnant Patient with Cholecystitis or Cholelithiasis

- Assess diet for foods that cause discomfort and flatulence and omit foods that trigger episodes.
- Reduce dietary fat intake to 40 to 50 g/day.
- Limit protein to 10 to 12% of total calories.
- Choose foods so that most of the calories come from carbohydrates.
- Prepare food without adding fats or oils, as much as possible.
- Avoid eating fried foods.

Gynecological Concerns

Pregnancy predisposes a patient to ovarian issues, especially during the first trimester. Ovarian cysts and twisting of ovarian cysts or adnexal tissues may occur. Other concerns include retained or enlarged cystic corpus luteum of pregnancy and bacterial invasion of reproductive or other intraperitoneal organs.

Laparotomy or laparoscopy may be required to discriminate between ovarian conditions and early ectopic pregnancy, appendicitis, or an infectious process.

Nursing Care

Initial assessment of the pregnant patient requiring surgery focuses on presenting signs and symptoms. A thorough history and physical examination should be performed. Laboratory testing includes, at a minimum, a CBC with differential and a urinalysis. In addition, FHR and uterine activity should be monitored, and constant vigilance is required in watching for symptoms of impending obstetrical complications. The extent of preoperative assessment is determined by the immediacy of surgical intervention and the specific condition that requires surgery.

Hospital Care. When surgery becomes necessary during pregnancy, the patient and their family will be concerned about the effects of the procedure and medication on fetal well-being and the course of pregnancy. An important part of preoperative nursing care is encouraging the patient to express their fears, concerns, and questions.

Preoperative procedures such as preparation of the operative site and time of insertion of IV lines and urinary retention catheters vary with the surgeon and the facility. However, in every instance there is a total restriction of solid foods and liquids or a clear specification of the type, amount, and time at which clear liquids may be taken before surgery. Some bowel preparation such as clear liquids and laxatives may be required before surgery. Food by mouth is restricted for several hours before a scheduled procedure. If the patient experiences a prolonged nothing-by-mouth (NPO) status, IV fluids with dextrose should be given. Even if they have had nothing by mouth but, more important, if surgery is unexpected, the patient is in danger of vomiting and aspirating; special precautions are taken before anaesthetic is administered (e.g., administering an antacid).

Intraoperatively perinatal nurses may collaborate with the surgical staff to increase their knowledge about the special needs of pregnant patients undergoing surgery. One intervention to improve fetal oxygenation is positioning the patient on the operating table with a lateral tilt to avoid compression of the maternal vena cava. Continuous FHR and uterine contraction monitoring during surgery may be ordered because of the risk of preterm labour. Monitoring may be accomplished by using sterile Aquasonic gel and a sterile sleeve for the transducer. During abdominal surgery, uterine contractions may be palpated manually.

However, many practitioners simply monitor the fetus before and after the procedure.

In the immediate recovery period, general observations and care pertinent to postoperative recovery should be initiated. Frequent assessments should be carried out for several hours after surgery. Whether the patient is cared for in the surgical postanaesthesia recovery area or in a labour and birth unit, continuous fetal and uterine monitoring will likely be initiated or resumed because of the increased risk of preterm labour. **Tocolysis** may be necessary if preterm labour occurs (see Chapter 20).

The use of pneumatic compression devices on all pregnant patients undergoing surgery is recommended (Chan et al., 2014). The need for pharmacological thromboprophylaxis should be determined on a case-by-case basis, taking into account the expected scope and length of the procedure and whether the patient has risk factors for venous thrombosis in addition to the pregnancy (e.g., thrombophilia, prolonged immobilization, past history of venous thrombosis, malignancy, diabetes mellitus, varicose veins, paralysis, or obesity). For laparoscopic procedures (gynecological or general surgical) predicted to last greater than 45 minutes, use of LMWH is suggested; mechanical thromboprophylaxis is a reasonable alternative for shorter procedures (Chan et al., 2014).

Home Care. Plans for the patient's return home and for convalescent care should be completed as early as possible before discharge. The patient and other support persons must be taught signs of infection. Box 14.9 lists information that should be included in discharge teaching for the postoperative patient. The patient may also need referrals to various community agencies for evaluation of the home situation, child care, home health care, and financial or other assistance.

TRAUMA DURING PREGNANCY

Trauma can be a complication during pregnancy and may be caused by vehicular crashes, falls, burns, industrial mishaps, violence, gunshot wounds, and other injuries in the home and community. In order to optimize the outcomes for both pregnant patient and fetus in severe trauma cases, it is important to have a interprofessional team approach that involves trauma surgeons, emergency medicine physicians, obstetricians, neonatologists, and nursing staff experienced in perinatal care (Jain et al., 2015).

Trauma during pregnancy is the leading cause of nonobstetrical maternal mortality, with 20% of maternal deaths directly attributable to injuries (Jain et al., 2015). Nonlethal injuries occur in 1 in every 12 pregnant patients and are most commonly the result of an MVC or intimate partner violence (IPV). Other common causes of trauma in a pregnant patient are penetrating injuries and falls, assaults, gunshot wounds, and burns. Approximately 80% of fetal deaths associated with maternal trauma are from MVCs (Ruth & Miller, 2013). Maternal death caused by trauma is usually the result of head injury or hemorrhagic shock. Fetal death usually occurs as a sequelae to maternal death or as a result of placental abruption.

Acts of violence are a significant health concern for pregnant patients. The risk of trauma caused by abuse is increased during pregnancy, and rates of recurrence are high. IPV during pregnancy has been reported to range from 6 to 22%, and up to 45% of pregnant patients report a history of IPV at some time during their lifetime. IPV is most likely to occur during the first 3 months of pregnancy (Brown, 2017). See Chapter 5: Intimate Partner Violence.

A recent study showed that obstetrician have suboptimal practice when it comes to asking pregnant patients about IPV and a history of abuse (Long et al., 2019). Multiple barriers (cultural, societal, economic, and institutional) prevent pregnant patients from being screened for IPV and receiving appropriate support services, which may contribute to an unrecognized pregnancy at risk.

Trauma increases the incidence of miscarriage, preterm labour, placental abruption, and stillbirth (Plante, 2019). The effect of trauma on pregnancy depends on the length of gestation, type and severity of the trauma, and degree of disruption of uterine and fetal physiological features. Fetal death as a result of trauma is more common than the occurrence of both maternal and fetal death. Less serious trauma is associated with numerous complications in pregnancy, including fetomaternal hemorrhage, placental abruption, intrauterine fetal death, and preterm labour and birth (Jain et al., 2015). Careful evaluation of mother and fetus after all types of trauma is imperative.

Multisystem trauma during pregnancy is usually the result of a serious MVC, especially if the patient is not wearing a seat belt with a shoulder harness and is ejected from the vehicle. To improve chances of survival for both the pregnant patient and the fetus in a potential crash, pregnant persons should wear properly positioned restraints at all times when in a motor vehicle (see Figure 11.16) (Cunningham et al., 2018).

Special considerations for the pregnant patient and their fetus are necessary when trauma occurs, because of the physiological alterations that accompany pregnancy and the presence of the fetus. Fetal survival depends on maternal survival; therefore, the pregnant patient must receive immediate stabilization and appropriate care for optimal fetal outcome.

BOX 14.9 Discharge Teaching for Home Care

- Care of incision site
- Diet and elimination related to gastrointestinal function
- Signs and symptoms of developing complications (wound infection, thrombophlebitis, pneumonia)
- Equipment needed and technique for assessing temperature
- Recommended schedule for resumption of activities of daily living
- Treatments and medications ordered
- List of resource persons and their telephone numbers
- Schedule of follow-up visits

If birth has not occurred:

- Assessment of fetal activity (kick counts)
- Signs of preterm labour

Maternal Physiological Characteristics

Optimal care for the pregnant patient after trauma depends on having an understanding of the physiological state of pregnancy and its effects on trauma. The pregnant patient's body exhibits responses that are different from those of a nonpregnant person to the same traumatic insults. Because of the different responses to injury during pregnancy, management strategies must be adapted for appropriate resuscitation, fluid therapy, positioning, assessments, and most other interventions. Significant adaptations required for treatment of trauma in the pregnant patient are summarized in Table 14.9.

The uterus and bladder are confined to the bony pelvis during the first trimester of pregnancy and are at reduced risk for injury in cases of abdominal trauma. After pregnancy progresses beyond the fourteenth week, the uterus becomes an abdominal organ, and the risk for injury increases in cases of abdominal trauma. During the second and third trimesters, the distended bladder becomes an abdominal organ and is at increased risk for injury and rupture. Bowel injuries occur less often during pregnancy because of the protection provided by the enlarged uterus.

TABLE 14.9 Adaptations in Pregnant Patients and Relation to Trauma

System	Alteration	Clinical Responses
Respiratory	↑ Oxygen consumption	↑ Risk of acidosis
	↑ Tidal volume	↑ Risk of respiratory mismanagement
	↓ Functional residual capacity	
	Chronic compensated alkalosis ↓ $Paco_2$ ↓ Serum bicarbonate	↓ Blood-buffering capacity
Cardiovascular	↑ Circulating volume, 1 600 mL ↑ Cardiac output ↑ Heart rate ↓ Systemic vascular resistance ↓ Arterial blood pressure Heart displaced upward to left	Can lose 1 000 mL of blood No signs of shock until blood loss >30% total blood volume ↓ Placental perfusion in supine position Point of maximal impulse, fourth intercostal space
Renal	↑ Renal plasma flow Dilation of ureters and urethra Bladder displaced forward	 ↑ Risk of stasis, infection ↑ Risk of bladder trauma
Gastrointestinal	↓ Gastric motility ↑ Hydrochloric acid production ↓ Competency of gastroesophageal sphincter	↑ Risk of aspiration Passive regurgitation of stomach acids if head lower than stomach
Reproductive	↑ Blood flow to organs Uterine enlargement	Source of ↑ blood loss Vena caval compression in supine position
Musculoskeletal	Displacement of abdominal viscera Pelvic venous congestion Cartilage softened Fetal head in pelvis	↑ Risk of injury, altered rebound response Altered pain referral ↑ Risk of pelvic fracture Centre of gravity changed ↑ Risk of fetal injury
Hematological	↑ Clotting factors ↓ Fibrinolytic activity	↑ Risk of thrombus formation

The elevated levels of progesterone that accompany pregnancy relax smooth muscle and profoundly affect the gastrointestinal tract. Gastrointestinal motility decreases, with a resultant increased time required for gastric emptying; the production of hydrochloric acid increases in the last trimester, and the gastroesophageal sphincter relaxes. Because of these changes, airway management of the unconscious pregnant patient's airway is critically important.

! NURSING ALERT

The unconscious pregnant patient is at increased risk for regurgitation of gastric contents and aspiration whenever their head is positioned lower than the stomach or if abdominal pressure is applied.

A pregnant patient has decreased tolerance for hypoxia and apnea because of their decreased functional residual capacity and increased renal loss of bicarbonate. Acidosis develops more quickly in the pregnant patient than in the nonpregnant state.

Cardiac output increases 30 to 50% over prepregnancy values and is position dependent in the third trimester. Because of compression of the inferior vena cava and descending aorta by the pregnant uterus, cardiac output decreases dramatically if the patient is placed in the supine position. Thus the supine position must be avoided, even in patients with cervical spine injuries. It is of utmost importance that lateral uterine displacement be accomplished without any head movement. As soon as the neck is immobilized, the stretcher should be tilted laterally (Brown, 2017; Jain et al., 2015).

Circulating blood volume increases 40 to 50% during gestation. As a result, significant intra-abdominal or intrauterine blood loss can occur with only minimal changes in vital signs (Brown, 2017). By the time maternal tachycardia and hypotension, which are considered hallmark symptoms of blood loss, are evident, massive hemorrhage has likely already occurred (Ruth & Miller, 2013).

Fetal Physiological Characteristics

Perfusion of the uterine arteries, which provide the primary blood supply to the uteroplacental unit, depends on adequate maternal arterial pressure because these vessels lack autoregulation. Therefore, maternal hypotension decreases uterine and fetal perfusion. Maternal shock results in splanchnic and uterine artery vasoconstriction, which decreases blood flow and oxygen transport to the fetus. Electronic fetal monitoring tracings can assist in the evaluation of fetal status after trauma to assess for hypoxia and hypoperfusion, including tachycardia or bradycardia, decreased or absent baseline variability, and late decelerations.

Careful monitoring of fetal status assists greatly in maternal assessment because the fetal monitor tracing works as an "oximeter" of internal maternal well-being. Hypoperfusion can be present in the pregnant patient before the onset of clinical signs of shock. The electronic fetal monitoring tracings may show the first signs of maternal compromise, such as when maternal heart rate, BP, and colour appear normal yet the electronic fetal monitoring printout shows signs of fetal hypoxia (Brown, 2017; Jain et al., 2015).

Mechanisms of Trauma

Blunt Abdominal Trauma. Blunt abdominal trauma is most commonly the result of MVCs but also may be the result of battering or falls. Maternal and fetal morbidity and mortality rates associated with MVCs are directly correlated with whether the mother remains inside the vehicle or is ejected. Maternal death is usually the result of a head injury or exsanguination from a major vessel rupture. Serious retroperitoneal hemorrhage after lower abdominal and pelvic trauma is reported more frequently during pregnancy. Serious maternal abdominal injuries are usually the result of splenic rupture or liver and renal injury.

Blunt trauma to the patient's abdomen is an important cause of placental abruption. Placental separation is thought to be a result of deformation of the elastic myometrium around the relatively inelastic placenta. Shearing of the placental edge from the underlying decidua basalis ensues and is worsened by the increased intrauterine pressure caused by the impact. It is imperative that all pregnant victims be evaluated carefully for signs and symptoms of placental abruption after even minor blunt abdominal trauma.

! NURSING ALERT

Signs and symptoms of placental abruption include uterine tenderness or pain, uterine irritability, uterine contractions, vaginal bleeding, leaking of amniotic fluid, or a change in FHR characteristics.

Pelvic fracture can result from severe injury and produce bladder trauma or retroperitoneal bleeding with two-point displacement of pelvic bones. One point of displacement is common at the symphysis pubis, and the second point is posterior because of the structure of the pelvis. Careful evaluation for clinical signs of internal hemorrhage is indicated.

Direct fetal injury as a complication of blunt trauma during pregnancy most often involves the fetal skull and brain. Most commonly, this injury accompanies maternal pelvic fracture in late gestation after the fetal head becomes engaged. When the force of the impact is great enough to fracture the maternal pelvis, the fetus often sustains a skull fracture. Evaluation for fetal skull fracture or intracranial hemorrhage is then indicated.

Uterine rupture as a result of trauma is rare, occurring in less than 1% of severe cases. Rupture is more likely to occur in a previously scarred uterus. When uterine rupture occurs, it is usually associated with a direct blow delivered with substantial force (Cunningham et al., 2018). Traumatic uterine rupture almost always results in fetal death. Death in the pregnant patient occurs less frequently, in about 30% of cases (Ruth & Miller, 2013).

Penetrating Abdominal Trauma. Bullet and stab wounds are the most frequent causes of penetrating abdominal trauma in pregnant patients. When the uterus sustains penetrating wounds, the fetus is more likely than the pregnant patient to be seriously injured. The enlarged uterus may protect other organs in the patient, particularly the bowel, but the fetus is more vulnerable (Brown, 2017).

Numerous factors determine the extent and severity of injuries to the fetus and patient from a bullet wound, including size and velocity of the bullet, anatomical region penetrated, angle of entry, path of the bullet, organs damaged, gestational age, and exit wound. Once the bullet enters the body, it may ricochet several times as it encounters organs or bone, or it may sever a large blood vessel. During the second half of pregnancy, the fetus usually sustains a direct injury from the bullet. Gunshot wounds require surgical exploration to determine the extent of injury and repair damage as needed.

Stab wounds are limited by the length and width of the penetrating object and are usually confined to the pathway of the weapon. Injuries to the pregnant patient and fetus are less if the stab wound is located in the upper abdomen and is from movement of the penetrating object from above the head downward toward the abdomen rather than from movement from the ground upward toward the lower abdomen. Stab wounds usually require surgical exploration to clean out debris, determine extent of injury, and repair damage.

Thoracic Trauma. Thoracic trauma is reported to produce 25% of all trauma deaths. Pulmonary contusion results from nearly 75% of blunt thoracic trauma and is a potentially life-threatening condition. Pulmonary contusion can be difficult to recognize, especially if flail chest is also present or if there is no evidence of thoracic injury. It should be suspected in cases of thoracic injury, especially after blunt acceleration or deceleration trauma such as that occurring when a rapidly moving vehicle crashes into an immovable object.

Penetrating wounds into the chest can result in pneumothorax or hemothorax. This type of injury is usually caused by a vehicular crash that results in impalement by the steering column or a loose article in the vehicle that becomes a projectile with the force of impact. Stab wounds into the chest also may occur as a result of violence.

Collaborative Care

Immediate Stabilization. Immediate priorities for stabilization of the pregnant patient after trauma should be identical to those of the nonpregnant trauma patient. Pregnancy should not result in any restriction of the usual diagnostic, pharmacological, or resuscitative procedures or manoeuvres (Jain et al., 2015). The initial response of many trauma team members when caring for the pregnant patient is to assess fetal status first because of the concern for a healthy newborn. Instead, the trauma team should follow a methodical evaluation of the pregnant patient's status to ensure complete assessment and stabilization of the patient. Fetal survival depends on the patient's survival, and stabilization of the patient improves the chance of fetal survival.

! NURSING ALERT

Priorities of care for the pregnant patient after trauma must be to resuscitate the patient and stabilize their condition first and then consider fetal needs.

In cases of minor trauma, the patient is evaluated for vaginal bleeding, uterine irritability, abdominal tenderness, abdominal pain or cramps, and evidence of hypovolemia. A change in or absence of FHR or fetal activity, leakage of amniotic fluid, and presence of fetal cells in the maternal circulation (Kleihauer-Betke) are also included in the assessment.

Primary Survey. The systematic evaluation begins with a *primary survey* and the initial *CABDs* of resuscitation: *compressions*, *airway*, *breathing*, and *defibrillation*. Increased oxygen needs during gestation necessitate a rapid response (see Cardiopulmonary Resuscitation for the Pregnant Patient later in the chapter). The presence of a cervical spine injury is always assumed.

Signs of bleeding may be more difficult to recognize in the pregnant patient because a 30 to 35% loss of maternal blood volume may produce only a minimal change in maternal mean arterial pressure.

Hypovolemia can be detrimental for the fetus because the vascular bed of the uterus is a low-resistance system that depends on adequate maternal cardiac output and arterial pressure to maintain uterine and fetal perfusion. Maternal hypovolemia can be fatal for the fetus.

! NURSING ALERT

Hyperextension of the neck should be avoided; instead, jaw thrust is used to establish an airway for the trauma victim.

Once an airway is established, assessment should focus on adequacy of oxygenation. The chest wall should be observed for movement. If breathing is absent, ventilations and endotracheal intubation are initiated. Supplemental oxygen should be administered with a tight-fitting, nonrebreathing face mask at 10 to 12 L/min to maintain oxygen saturation greater than 95% to optimize maternal and fetal status. The chest wall should be assessed for a penetrating chest wound or flail chest. Breathing with a flail chest will be rapid and laboured; chest wall movements will be uncoordinated and asymmetrical; crepitus from bony fragments may be palpated.

Rapid placement of two large-bore (14- to 16-gauge) IV lines is necessary in most seriously injured patients. It is important to place the lines while veins are still distended. Cardiac arrest during the immediate stabilization period is usually the result of profound hypovolemia, necessitating massive fluid resuscitation. Infusion of crystalloids such as Ringer's solution or normal saline solution should be given as a 3:1 ratio; that is, 3 mL of crystalloid replacement to 1 mL of the estimated blood loss is given over the first 30 to 60 minutes of acute resuscitation. Because of the 50% increase in plasma blood volume during pregnancy, published formulas for nonpregnant adults used for estimating crystalloid and blood replacement to counter blood loss must be adjusted upward for pregnancy. When severe hemorrhage exists, transfusion with fresh frozen plasma, platelets, and packed red blood cells at a 1:1:1 ratio lowers the rate of coagulopathy and may increase the chance of survival (Mendez-Figueroa et al., 2013; Ruth & Miller, 2013).

Replacement of red blood cells and other blood components should be anticipated and blood drawn for type, cross-match, CBC, and platelet count. Infusion of type-specific packed red blood cells is usually necessary to improve fetal oxygenation status and to replace blood lost. During an extreme emergency, type O Rh-negative blood may be administered without matching. Massive transfusion protocols (MTPs) are established to provide rapid blood replacement in a setting of severe hemorrhage; it is important for nurses to be aware of the MTP in their institutions.

If possible, vasopressor medications to restore maternal arterial BP should be avoided until volume replacement is administered. These medications may significantly reduce uterine blood flow and thus decrease oxygen delivery to the fetus. In addition, their use does not address the cause of the hypovolemia (Ruth & Miller, 2013).

After 20 weeks of gestation, venous return to the heart is best accomplished by positioning the uterus to one side to eliminate the weight of the uterus compressing the inferior vena cava or the descending aorta. This facilitates efforts to establish the forward flow of blood through resuscitation and stabilization. If a lateral position is not possible because of resuscitative efforts or cervical spine immobilization, the uterus can be manually deflected to the left, or a wedge can be inserted underneath the right side of the backboard or stretcher.

Establishing a baseline neurological status (level of consciousness, pupil size, and reactivity) is essential. The Glasgow Coma Scale is commonly used at the scene of the accident to help determine the extent of a head injury.

Secondary Survey. After immediate resuscitation and successful stabilization measures are employed, a more detailed *secondary survey* of the trauma patient and fetus should be accomplished. A complete physical assessment to include all body systems is performed.

The maternal abdomen should be evaluated carefully because a large percentage of serious injuries involve the uterus, intraperitoneal structures, and retroperitoneum. The pregnant patient's stomach is assumed to be full. A nasogastric tube can be used to empty the stomach to help prevent acid aspiration syndrome. An empty stomach facilitates respiratory efforts. The uterus should be evaluated for evidence of gross deformity, tenderness, irritability, or contractions.

The greatest clinical concern after an MVC is placental abruption, as the rate of abruption is 40 to 50% in these patients (Brown, 2017). Assessments should focus on recognition of this complication, with careful evaluation of fetal monitor tracings, uterine tenderness, labour, or vaginal bleeding. Ultrasonographic examination may be performed to determine gestational age, viability of fetus, and placental location. However, ultrasound studies cannot exclude placental abruption.

Peritoneal lavage for the pregnant patient after blunt abdominal trauma has proven to be a safe procedure and can be helpful in the early diagnosis of intraperitoneal injury or hemorrhage. Under direct visualization, the peritoneum is incised, and a peritoneal dialysis catheter is positioned. If aspiration yields free-flowing blood, the test is considered positive, and a laparotomy should be performed. This procedure is not necessary before laparotomy if intraperitoneal bleeding is clinically apparent. Indications for peritoneal lavage include abdominal symptoms or signs suggestive of intraperitoneal bleeding, alteration in mental status, unexplained shock, and severe multiple injuries (Cunningham et al., 2018).

If trauma is the result of a penetrating wound, the patient should be completely undressed and carefully examined for all entrance and exit wounds. Exploratory laparotomy is necessary after a gunshot wound to explore the abdominal cavity for organ damage and to repair any damage present, with careful examination of all organs, the entire bowel, and posterior vessels. If uterine injury is determined, the risks and benefits of Caesarean birth are quickly evaluated. A Caesarean birth is desirable if the fetus is alive and near term and may be necessary for the preterm fetus because of the high incidence of fetal injury in these cases. The fetus usually tolerates surgery and anaesthesia if adequate uterine perfusion and oxygenation are maintained. Tetanus prophylaxis guidelines are not changed by pregnancy.

Trauma may affect numerous systems in the maternal body and may affect more than the pregnancy. External signs of trauma should suggest the possibility of internal trauma. Back and neck pain suggest spine injury, abrasions on the chest suggest chest injury, and limb pain and malposition suggest limb fractures. If head injury results in nonresponsiveness, spinal, thoracic, and abdominal injuries are suspected. Hypovolemic shock can occur with internal hemorrhage, fracture of long bones, ruptured liver or spleen, hemothorax, or arterial dissection.

All female trauma victims of childbearing age should be considered pregnant until proven otherwise. Determination of the health history and a history of the events preceding the trauma are important components of care. If the pregnant patient was involved in an MVC, it should be determined whether they were the driver or a passenger and if they were ejected from the vehicle or were wearing a seat belt and remained within the vehicle.

In addition to helping to stabilize the patient, the nurse can provide emotional support to them and their family. If the trauma is the result of an MVC, other family members may also have been critically injured or killed. The nurse should collaborate with other staff to make sure that questions are answered and consistent information given. Grief support may be necessary.

Fetal maternal hemorrhage. The potential for fetal–maternal hemorrhage exists after trauma. Hemorrhage can lead to fetal anemia, distress, or even death. If the pregnant trauma victim is Rh negative, fetal–maternal hemorrhage can result in sensitization and hemolytic disease of the newborn. The KB assay is often performed in pregnant patients after blunt abdominal trauma to estimate the amount of fetal blood within the maternal circulation. However, because most cases have less than 30 mL of hemorrhage, KB test results seldom alter management (Cunningham et al., 2018). Usually the routine administration of 300 mcg of Rh_o(D) immunoglobulin is sufficient to protect almost all Rh-negative pregnant trauma patients from alloimmunization (Brown, 2017).

Radiation exposure. If the pregnant patient has sustained serious injuries, any necessary radiographic examination should be performed, regardless of fetal exposure. If radiographic examination would be performed for the nonpregnant trauma victim, it also should be performed for the pregnant patient. Abdominal or pelvic CT scanning can be used to visualize extraperitoneal and retroperitoneal structures and the genitourinary tract. No single diagnostic procedure provides a radiation dose sufficient to threaten the well-being of the developing embryo or fetus, especially in the mid to late weeks of gestation (Brown, 2017). Blunt head trauma and loss of consciousness necessitate skull films and CT assessment with neurosurgical consultation. MRI can also be used safely to assess injuries because it does not produce ionizing radiation (Brown, 2017).

Ultrasound. Ultrasound after trauma is not as sensitive as electronic fetal monitoring for diagnosing placental abruption. It may be useful to help establish gestational age, locate the placenta, evaluate cardiac activity (to determine whether the fetus is alive), and determine amniotic fluid volume. It may also be used to evaluate the presence of intra-abdominal fluid that would suggest the presence of intra-abdominal hemorrhage.

Fetal health surveillance. External FHR and contraction monitoring is recommended after blunt trauma in a viable gestation for a minimum of 4 hours, regardless of injury severity. Continuous electronic fetal monitoring may show early signs of placental abruption, including a change in baseline rate, loss of accelerations, and the presence of late decelerations (Liston et al., 2018). If the estimated gestational age is 24 weeks or greater, fetal monitoring should be initiated soon after the patient is stable, because placental abruption usually becomes apparent shortly after the injury. Fetal monitoring should be continued and further evaluation initiated if any of these signs occur. Palpation is required to evaluate the intensity of contractions and the uterine resting tone. It is important to palpate between contractions to verify that the uterus is well relaxed. If the uterus does not relax between contractions, placental abruption could be present. Occasional uterine contractions are the most common finding with trauma during pregnancy, occurring in 40% of cases and resolving in 90% of cases with no adverse fetal outcome. The intensity and frequency of contractions are predictive of complications such as placental abruption and preterm labour. Elevated basal uterine tone also raises suspicion for traumatic placental abruption. Placental abruption occurring after trauma may be delayed for up to 48 hours after the incident.

The exact duration of FHR and contraction monitoring required after blunt abdominal trauma is not known. Monitoring should be continued indefinitely if uterine contractions, abnormal FHR characteristics, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes are present. Most physicians recommend continuous monitoring for at least 24 hours (Jain et al., 2015). Most abruptions develop soon after the traumatic event, although in rare cases abruption has developed days afterward (Cunningham et al., 2018).

Discharge Planning. Following minor trauma, the patient may be discharged home, after several hours of evaluation. Their vital signs should be stable, with no evidence of bleeding at the time of discharge. The fetal tracing should be normal before monitoring is discontinued and the patient is discharged. Education for the patient and their family is very important. They should be instructed to contact their health care provider immediately if changes in fetal movement or signs and symptoms indicative of preterm labour, PROM, or placental abruption develop. If the trauma occurred as a result of IPV, the patient may need information about the abuse cycle; referral to a crisis centre, law enforcement agency, or counselling centre; and help in forming a safety plan (see Box 5.11: Safety Strategies).

Cardiopulmonary Resuscitation of the Pregnant Patient

Trauma, cardiac abnormalities, embolism, magnesium overdose, sepsis, intracranial hemorrhage, anaesthetic complications, eclampsia, and uterine rupture are common causes of cardiac arrest in a pregnant patient. Various protocols exist for cardiopulmonary resuscitation (CPR) during pregnancy. The most widely used guide is the American Heart Association (AHA) advanced cardiac life support (ACLS) protocol (Jeejeebhoy et al., 2015). This protocol recommends standard CPR with the uterus displaced laterally, fluid-volume restoration, and defibrillation, if indicated. The decision for Caesarean birth should be made within 4 to 5 minutes of the mother's cardiac arrest. No matter what protocol is used, nurses and other health care providers must be prepared if CPR is to be successful.

Special modifications are necessary when CPR is performed during the second half of pregnancy. In nonpregnant patients chest compressions produce a cardiac output of only about 30% of normal. Cardiac output in pregnant patients may be even less as a result of aortocaval compression caused by the gravid uterus. Therefore, uterine displacement during resuscitation efforts is critical (Cunningham et al., 2018; Lavonas et al., 2015). To prevent supine hypotension, the patient is placed on a flat, firm surface, ideally a spine board, with the uterus displaced laterally manually. Administration of 100% oxygen by face mask to treat or prevent hypoxemia is recommended (Lavonas et al., 2015). Compressions should be provided at the depth of 5 centimetres at a rate of 100 times per minute (Lavonas et al., 2015).

Defibrillation with an automated external device (AED) is also key to increasing the chance of survival. If defibrillation is needed, the paddles, or AED pads must be placed one rib interspace higher than usual because the heart is slightly displaced by the enlarged uterus. The same currently recommended defibrillation protocol should be used in the pregnant patient as in the nonpregnant patient. If possible, the fetus should be monitored during the cardiac arrest (see Emergency box).

EMERGENCY

Cardiopulmonary Resuscitation of the Pregnant Patient in the Hospital

Assessment
- Determine unresponsiveness and no breathing or no normal breathing.
- Activate emergency call system and get the emergency response cart.
- Position patient on a flat, firm surface with the uterus displaced laterally with a wedge if possible (e.g., a rolled towel placed under her hip).

Circulation
- Assess for the presence of a pulse by feeling carotid pulse for no longer than 10 seconds.
- If there is no pulse, begin chest compressions at rate of a minimum of 100/min at a compression depth of at least 5 cm. Allow the chest to completely recoil (re-expand) completely after compression. Chest compressions may be performed slightly higher on the sternum if the uterus is enlarged enough to displace the diaphragm into a higher position.

Airway
- Open airway with head tilt–chin lift manoeuvre.

Breathing
- Assess for presence of breathing (look, listen, feel) for no longer than 8 seconds.
- If the patient is not breathing, give two slow breaths using a bag-mask device; ensure that the chest rises with each breath.
- Rescue breathing without chest compressions should be given at a rate of 10 to 12 breaths/min.
- After five cycles of 30 compressions and two breaths (or approximately 2 minutes), check for a pulse. If pulse is not present, continue cardiopulmonary resuscitation.

Defibrillation
- Use a defibrillator according to standard protocol to analyze heart rhythm, and deliver shock if indicated.

Birth
- Consider perimortem Caesarean birth within 5 minutes if chest compressions are unsuccessful.

Relief of Foreign-Body Airway Obstruction
- If the pregnant patient is unable to speak or cough, perform chest thrusts.
- Stand behind the patient and place your arms under their armpits to encircle the chest. Press backward with quick thrusts until the foreign body is expelled (Figure 14.15).

Unconscious Foreign-Body Airway Obstruction
- If a pregnant patient becomes unresponsive place them on their back with a rolled blanket under their hip to ensure the uterus is displaced laterally and kneel at their side.
- Open the patient's mouth with the tongue-jaw lift and remove the obstruction if it is visualized and can be done safely and attempt rescue breathing.
- If unable to ventilate, position hands for chest compressions. Deliver 30 chest compressions firmly, check mouth again for presence of obstruction, and attempt to provide rescue breathing. Continue sequence until the patient's airway is clear of obstruction.
- If the patient is unconscious, give chest compressions as for a patient without a pulse.

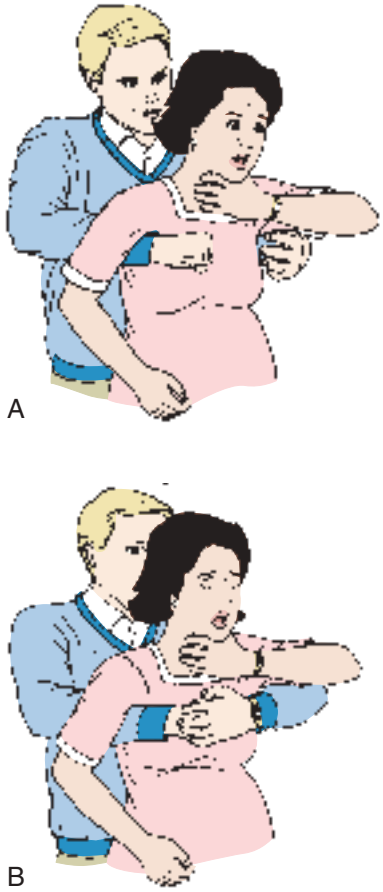

Fig. 14.15 Heimlich manoeuvre. Clearing airway obstruction in a person in the late stages of pregnancy. **A:** Standing behind victim, place your arms under the person's armpits and across the chest (between nipples). Place thumb side of your clenched fist against the middle of the sternum and place other hand over fist. **B:** Perform backward chest thrusts until foreign body is expelled or person loses consciousness.

Complications that may be associated with CPR of a pregnant patient include laceration of the liver, rupture of the uterus, hemothorax, and hemoperitoneum. Fetal complications, including cardiac arrhythmia or asystole related to maternal defibrillation and medications and CNS depression related to antiarrhythmic medications and inadequate uteroplacental perfusion, with possible fetal hypoxemia and acidemia, also may occur.

If resuscitation is successful, the patient and their fetus must receive careful monitoring. The patient remains at increased risk for recurrent pulmonary arrest and dysrhythmias (ventricular tachycardia, supraventricular tachycardia, and bradycardia). Therefore, their cardiovascular, pulmonary, and neurological status should be assessed continuously. If the pregnancy remains intact, uterine activity and resting tone must be monitored. Fetal status and gestational age should be determined and used in decision making regarding continuation of the pregnancy or the timing and route of birth.

Another common reason for performing CPR on a pregnant patient is airway obstruction caused by choking. Clearing an airway obstruction is usually accomplished by performing abdominal thrusts. However, during the second and third trimesters of pregnancy, chest thrusts (Heimlich manoeuvre) rather than abdominal thrusts should be used (see Emergency box and Figure 14.15).

Perimortem Caesarean Birth

In the presence of multisystem trauma, perimortem Caesarean birth may be indicated. Removal of the stressor of pregnancy early in the process of resuscitation may increase the chance for an intact newborn outcome and also improve maternal resuscitative efforts. Therefore, if the pregnancy is at or beyond fetal viability (23 to 24 weeks of gestation) a Caesarean birth should be performed after 4 minutes of resuscitative efforts if there is no spontaneous return of circulation (Brown, 2017; Lavonas et al., 2015). It should be emphasized that perimortem Caesarean birth is rarely successful, especially when the maternal arrest is related to trauma (Jain et al., 2015; Ruth & Miller, 2013).

KEY POINTS

- Hypertensive disorders of pregnancy are a leading cause of maternal and perinatal morbidity and mortality worldwide.
- Pre-eclampsia/eclampsia is a multisystem disease, and the pathological changes are present long before clinical manifestations, such as hypertension, are evident.
- Once pre-eclampsia becomes clinically evident, therapeutic interventions may slow the progression of the disease, allowing the pregnancy to continue, but the underlying pathology continues.
- HELLP syndrome, which is a complication of pre-eclampsia/eclampsia, is considered life-threatening.
- Magnesium sulphate, the anticonvulsant of choice for preventing or controlling eclamptic seizures, requires careful monitoring of reflexes, respirations, and renal function; its antidote, calcium gluconate, should be at the bedside.
- Intent of emergency interventions for eclampsia is to prevent self-injury, enhance oxygenation, reduce aspiration risk, and establish control with magnesium sulphate.
- Diagnosis of gestational diabetes mellitus is important to ensure glycemic control for patients and thus improve perinatal outcomes.
- Ectopic pregnancy is a significant cause of maternal morbidity and mortality, even in developed countries.
- Placental abruption and placenta previa are differentiated by type of bleeding, uterine tonicity, and presence or absence of pain.
- Clotting disorders are associated with many obstetrical complications.
- The physiological adaptations of pregnancy mask warning signs and changes in vital signs during early shock state.
- Preoperative care for a pregnant patient differs from that for a nonpregnant patient in one significant aspect: the presence of the fetus.
- Trauma from accidents is the most common cause of death in patients of childbearing age.
- Fetal survival depends on maternal survival. After trauma occurs, the first priority is resuscitation and stabilization of the mother before consideration of fetal status.
- Minor trauma is associated with major complications for the pregnancy, including placental abruption, fetomaternal hemorrhage, preterm labour and birth, and fetal death.
- In the case of cardiac arrest in a pregnant patient, the advanced cardiac life support (ACLS) guidelines should be implemented without modification.

Pregnancy at Risk: Pre-existing Conditions

Melanie Basso

Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Differentiate the types of diabetes mellitus and their respective risk factors in pregnancy.
2. Compare insulin requirements during pregnancy, the postpartum period, and lactation.
3. Identify pregnant patient and fetal risks and possible complications associated with pregestational diabetes in pregnancy.
4. Develop a plan of care for the pregnant patient with pregestational diabetes.
5. Understand the pathophysiology and management of hyperthyroidism and hypothyroidism in a pregnant patient.
6. Differentiate the management of various cardiovascular disorders in pregnant patients.
7. Describe the care of the pregnant patient with obesity.
8. Describe the different types of anemia and their effects during pregnancy.
9. Describe the care of pregnant patients with pulmonary disorders.
10. Review the effects of neurological disorders on pregnancy.
11. Describe the care of patients whose pregnancies are complicated by autoimmune disorders.
12. Explain the effects on and the management of pregnant patients with human immunodeficiency virus (HIV).
13. Describe care of a pregnant patient with a spinal cord injury.
14. Discuss the care of pregnant patients who have issues related to substance use.

For most patients, pregnancy is a normal and healthy life event. However, for some, pregnancy can be a time of significant risk due to the presence of a chronic illness. Patients need to actively participate in self-management of their illness along with the interprofessional team to manage the changes in pregnancy to promote the best pregnancy outcomes.

The goal of the health care team is to work with patients to foster as normal a pregnancy experience as possible, while supporting the unique maternal and fetal needs prompted by the coexistence of chronic conditions. Nurses are key members of the health care team who guide and support the patient and their family in achieving optimal outcomes for both themselves and their fetus.

This chapter focuses on nursing care for patients with metabolic disorders, including diabetes mellitus and thyroid disorders; cardiovascular disorders; selected disorders of the respiratory, gastrointestinal, integumentary, and central nervous systems; and autoimmune disorders. Key elements of care for patients with substance use issues, human immunodeficiency virus (HIV) infection, spinal cord injury, and obesity are also discussed. For each disorder, management throughout the entire perinatal period (antepartum, intrapartum, and postpartum) is discussed; thus all of the information for each condition is located in one place in the text.

METABOLIC DISORDERS

Diabetes Mellitus

Worldwide, the incidence of diabetes mellitus is increasing at a rapid rate. *Pre-existing* or *pregestational diabetes mellitus (PGDM)* is an umbrella term that includes patients who have either type 1 or type 2 diabetes diagnosed prior to pregnancy. The prevalence of PGDM has increased in Canada from 0.7 to 1.5%, likely because of an increase in type 2 diabetes (Feig et al., 2014). Advances in knowledge about the effects of pregnancy on diabetes care have improved the outcomes for patients. Patients with diabetes who become pregnant have improved outcomes when they work together with an interprofessional team involving an obstetrician, internist or endocrinologist, pediatrician, nurse, and dietitian. These patients require education regarding the effects that pregnancy can have on their diabetes management in order

to prevent complications in themselves and the fetus. Patients with type 1 and type 2 diabetes must have frequent prenatal health care visits to support their knowledge about necessary changes to their diet and the importance of increased requirements for self-monitoring of blood glucose levels. More frequent laboratory evaluation and more intensive fetal surveillance and, occasionally, hospitalization may be required to achieve optimal pregnancy outcomes.

Before becoming pregnant, individuals with diabetes are strongly encouraged to have preconception counselling to optimize glycemic control, assess for presence of complications, review medications, and begin folate supplementation (Feig et al., 2018). Patients with PGDM have increased risks for adverse pregnancy outcomes including perinatal mortality, congenital malformations, hypertension, preterm birth, and large-for-gestational age infants (Berger et al., 2019; Feig et al., 2018).

Nurses who provide care to pregnant patients with diabetes must fully understand both the normal physiological responses to pregnancy and the physiological effects and psychosocial implications of diabetes in order to accurately assess the needs of the individual patient, help them plan for their care, and intervene, when appropriate.

Pathogenesis. Diabetes mellitus is a group of metabolic diseases characterized by **hyperglycemia** resulting from defects in insulin secretion, insulin action, or both. *Insulin*, produced by beta cells in the islets of Langerhans of the pancreas, regulates blood glucose levels by enabling glucose to enter adipose and muscle cells, where it is used for energy. Insulin stimulates protein synthesis and the storage of free fatty acids. When insulin is insufficient or ineffective in promoting glucose uptake by the muscle and adipose cells, glucose accumulates in the bloodstream, resulting in hyperglycemia. Hyperglycemia causes hyperosmolarity of the blood, which attracts intracellular fluid into the vascular system, resulting in cellular dehydration and expanded blood volume. Consequently, the kidneys function to excrete large volumes of urine (*polyuria*) in an attempt to regulate excess vascular volume and excrete the unused glucose (**glycosuria**). Polyuria and cellular dehydration cause excessive thirst (*polydipsia*).

The body compensates for its inability to convert carbohydrate (glucose) into energy by burning proteins (muscle) and fats. The end products of this metabolism are **ketones** and fatty acids, which in excess quantity produce ketoacidosis and acetonuria. Weight loss occurs because of the breakdown of fat and muscle tissue. This tissue breakdown causes a state of starvation that compels the individual to eat excessive amounts of food (*polyphagia*).

Over time, diabetes that is not well controlled causes significant changes in both the microvascular and macrovascular circulations. These structural changes affect a variety of organ systems—primarily the heart, eyes, kidneys, and nerves. Complications resulting from diabetes include premature atherosclerosis, retinopathy, nephropathy, and neuropathy.

Diabetes may be caused either by impaired insulin secretion, when the beta cells of the pancreas are destroyed by an autoimmune process, or by inadequate insulin action in target tissues at one or more points along the metabolic pathway. Both of these conditions are commonly present in the same person, and determining which, if either, abnormality is the primary cause of the disease is difficult.

Classification. Diabetes during pregnancy is currently classified into two categories: pregestational diabetes and gestational diabetes. *Pregestational diabetes* applies to patients with type 1 or type 2 diabetes that existed before pregnancy (Berger et al., 2019; Feig et al., 2018).

People with type 1 diabetes have an absolute insulin deficiency caused by pancreatic islet beta-cell destruction, which makes them prone to ketoacidosis. Type 1 diabetes includes cases thought to be caused by an autoimmune process and those for which the cause is unknown (Landon et al., 2017).

Type 2 diabetes is the most prevalent form of the disease and affects individuals who have insulin resistance and relative (rather than absolute) insulin deficiency. Although type 2 diabetes was once believed to affect mostly older individuals, increasing numbers of children and adolescents have been diagnosed with the disorder since the early 1990s (Moore, T. R., et al., 2019). Specific causes of type 2 diabetes are unknown at this time. It often goes undiagnosed for years because hyperglycemia develops gradually and is often not severe enough for the person to recognize the classic signs of polyuria, polydipsia, and polyphagia. Other risk factors for the development of type 2 diabetes include aging, a sedentary lifestyle, family history and genetics, puberty, hypertension, and prior gestational diabetes. Type 2 diabetes often has a strong genetic predisposition (Feig et al., 2018; Moore, T. R., et al., 2019).

Gestational diabetes mellitus (GDM) is the classification for patients who have carbohydrate intolerance that is discovered during pregnancy. GDM is any degree of glucose intolerance with its onset or first recognition during pregnancy. This definition applies regardless of whether insulin is used for treatment or whether the diabetes persists after pregnancy. It does not exclude the possibility that glucose intolerance preceded the pregnancy. Patients who experience gestational diabetes should be assessed for the presence of underlying disease no more than 6 months after the pregnancy ends (Berger et al., 2019; Feig et al., 2018) (see Chapter 14 for further discussion of GDM).

Metabolic Changes Associated With Pregnancy. Normal pregnancy is characterized by complex alterations in maternal glucose metabolism, insulin production, and metabolic homeostasis. During normal pregnancy, adjustments in maternal metabolism allow for adequate nutrition for both the mother and the developing fetus. Glucose, the primary fuel used by the fetus, is transported across the placenta through the process of carrier-mediated facilitated diffusion. This means that the glucose levels in the fetus are directly proportional to maternal levels. Although glucose crosses the placenta, insulin does not. Around the tenth week of gestation, the fetus secretes its own insulin at levels adequate to use the glucose obtained from the pregnant parent. Thus, as the pregnant parent's glucose levels rise, fetal glucose levels are increased, resulting in increased fetal insulin secretion.

During the first trimester and early second trimester of pregnancy, the pregnant patient's metabolic status is significantly influenced by the rising levels of estrogen and progesterone. These hormones stimulate the beta cells in the pancreas to increase insulin production, which promotes increased peripheral use of glucose and decreased blood glucose, with fasting levels reduced by approximately 10% (Figure 15.1, *A*). At the same time, an increase in tissue glycogen stores and a decrease in hepatic glucose production occur, which together further encourage lower fasting glucose levels. As a result of these normal metabolic changes of pregnancy, patients with type 1 and type 2 diabetes are prone to **hypoglycemia** (low blood glucose) during the first trimester.

During the latter part of the second trimester and the third trimester, pregnancy exerts a **diabetogenic** effect on the maternal metabolic status. Because of the major hormonal changes, there is decreased tolerance to glucose, increased insulin resistance, decreased hepatic glycogen stores, and increased hepatic production of glucose. Rising levels of human chorionic somatomammotropin, estrogen, progesterone, prolactin, cortisol, and insulinase increase insulin resistance through their actions as insulin antagonists. Insulin resistance is a glucose-sparing mechanism that ensures an abundant supply of glucose for the fetus. The patient's insulin requirements gradually increase from about 18

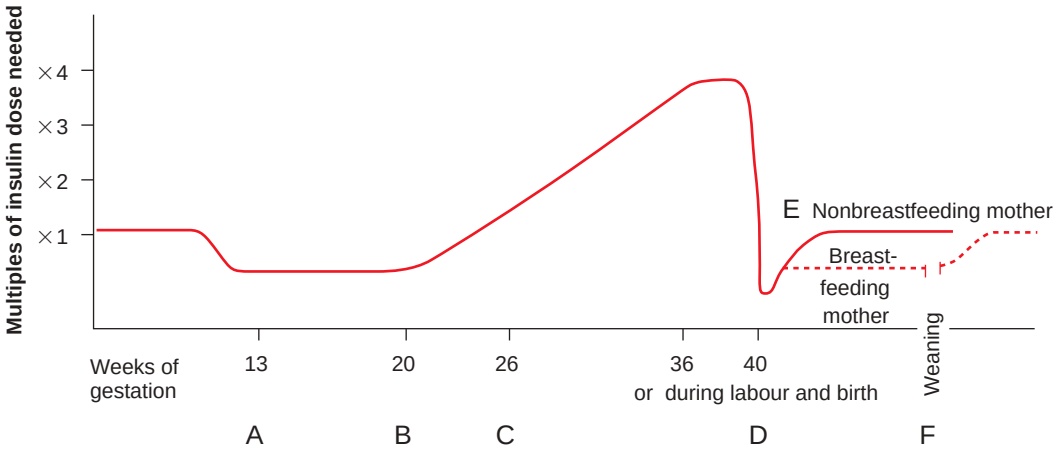

Fig. 15.1 Changing insulin needs during pregnancy. **A:** First trimester/early second trimester: Insulin need is reduced because of increased insulin production by the pancreas and increased peripheral sensitivity to insulin; nausea, vomiting, and decreased food intake by mother and glucose transfer to the embryo or fetus contribute to hypoglycemia. **B:** Late second trimester: Insulin need increases as placental hormones, cortisol, and insulinase act as insulin antagonists, decreasing the effectiveness of insulin. **C:** Third trimester: Insulin requirements gradually increase until about 36 weeks of gestation. **D:** Day of birth: Maternal insulin requirements drop drastically to approach prepregnancy levels. **E:** Breastfeeding mother maintains lower insulin requirements, as much as 25% less than prepregnancy; insulin need of nonbreastfeeding mother returns to prepregnancy levels in 7 to 10 days. **F:** At weaning of breastfeeding infant, mother's insulin need returns to prepregnancy levels.

to 24 weeks of gestation to approximately 37 weeks of gestation with a gradual decline thereafter (Moore, T. R., et al., 2019) (see Figure 15.1, *B* and *C*).

At birth, expulsion of the placenta prompts an abrupt decrease in levels of circulating placental hormones, cortisol, and insulinase (see Figure 15.1, *D*). Maternal tissues quickly regain their prepregnancy sensitivity to insulin. For the nonbreastfeeding mother, the prepregnancy insulin–carbohydrate balance usually returns in about 7 to 10 days (see Figure 15.1, *E*). Lactation uses maternal glucose; thus the breastfeeding mother's insulin requirements remain low as long as they are nursing (see Figure 15.1, *E*). On completion of weaning, the patient's prepregnancy insulin requirement is re-established (see Figure 15.1, *F*).

Pregestational Diabetes Mellitus (PGDM)

Pregestational diabetes (type 1 and type 2) has increased from 3.1 per 1 000 births to 4.7 per 1 000 births, primarily as a result of an increased number of patients of childbearing age with type 2 diabetes (Feig et al., 2014). Patients who have PGDM may have vascular disease, retinopathy, or nephropathy. The diabetogenic state of pregnancy imposed on the compromised metabolic system of the patient with pregestational diabetes has significant implications. The normal hormonal adaptations of pregnancy affect glycemic control, and pregnancy may accelerate the progress of vascular complications. Almost all patients with PGDM are insulin dependent during pregnancy.

During the first trimester, when maternal blood glucose levels are normally reduced and the insulin response to glucose is enhanced, glycemic control is improved. The insulin dose for the pregnant patient with well-controlled diabetes may have to be reduced to prevent hypoglycemia. Nausea, vomiting, and cravings typical of early pregnancy result in dietary fluctuations that influence maternal glucose levels and may also necessitate a reduction in insulin dosing.

Insulin requirements steadily increase after the first trimester, so the insulin dose must be adjusted accordingly to prevent hyperglycemia. Insulin resistance begins as early as 14 to 16 weeks of gestation and continues to rise until it stabilizes during the last few weeks of pregnancy.

Preconception Counselling. Preconception counselling is recommended by the Canadian Diabetes Association (CDA) and the Society of Obstetricians and Gynaecologists of Canada (SOGC) for all patients of reproductive age with diabetes in order to support improved pregnancy outcomes (Berger et al., 2019; Feig et al., 2018). Preconception care provides the opportunity to evaluate the patient's health status, plan the optimal time for pregnancy, improve self-management of optimal glycemic control before conception, and stabilize any vascular complications of diabetes (retinopathy, nephropathy, neuropathy, and cardiovascular disease). However, it is estimated that fewer than 50% of patients with type 1 diabetes plan their pregnancies and seek preconception counselling, and this figure is even lower for patients with type 2 diabetes (Feig et al., 2018). Preconception counselling is particularly important because strict metabolic control before conception and in the early weeks of gestation during organogenesis is instrumental in decreasing the risk of congenital anomalies and spontaneous abortion (Box 15.1).

BOX 15.1 Goals for Self-Monitored Glucose Levels in the Preconceptual Period

Recommended glycemic targets for preconception and during pregnancy:

Prepregnancy A_{1C}	<7%*
Pregnancy A_{1C}	≤6.0%

*Ideally, A_{1C} ≤6.0% if this can be safely achieved. In some patients, particularly those with type 1 diabetes, higher targets may be necessary to avoid excessive hypoglycemia. Regular measurements of glycated hemoglobin provide data for altering the treatment plan and lead to improvement of glycemic control. A hemoglobin A_{1C} of 6 to 7% is the desired goal, which correlates with an average glucose of 5.5 to 7.7 mmol/L (Thompson et al., 2013).

A_{1C} = glycated hemoglobin: With prolonged hyperglycemia, some of the hemoglobin remains saturated with glucose for the life of the red blood cell. Therefore, a test for glycated hemoglobin provides a measurement of glycemic control over time, specifically over the previous 8 to 12 weeks.

Preconception counselling includes providing information about medications being used for glycemic control. The use of oral antihyperglycemic medications alone for patients with PGDM during pregnancy is not recommended by the CDA (Feig et al., 2018; Thompson et al., 2013). Currently, research is being conducted to assess the effectiveness of adding oral antihyperglycemic agents such as metformin in addition to insulin therapy, but there is insufficient evidence to recommend this at this time (Feig et al., 2018). Patients with type 2 diabetes who conceive on oral hypoglycemic medications can continue these medications until insulin is initiated (Feig et al., 2018).

The patient's partner should be included in preconception counselling to improve support for the patient and understanding of potential complications of pregnancy as a result of diabetes. The couple also should be informed of anticipated alterations in the management of diabetes during pregnancy and the need for an interprofessional team approach to pregnancy care. Financial implications of the diabetic pregnancy and other demands related to frequent maternal and fetal surveillance should be discussed. Contraception is an important aspect of preconception counselling to assist the couple in planning the timing of pregnancy.

Maternal Risks and Complications. Although morbidity and mortality rates have improved significantly for pregnant patients with diabetes, they remain at risk for the development of significant complications during pregnancy. Poor glycemic control around the time of conception and in the early weeks of pregnancy is associated with an increased incidence of spontaneous miscarriage. Patients with good glycemic control before conception and in the first trimester are no more likely to miscarry than patients who do not have diabetes (Moore, T. R., et al., 2019).

Poor glycemic control later in pregnancy increases the likelihood of fetal macrosomia. *Macrosomia* has been defined as a birth weight more than 4 000 to 4 500 g or greater than the ninetieth percentile. It occurs in up to 50% of pregnancies in patients with gestational diabetes and in 40% of pregestational diabetic pregnancies (Berger et al., 2019; Landon et al., 2017). These large infants tend to have a disproportionate increase in shoulder and trunk size; consequently, the risk of shoulder dystocia is greater in these babies than in other macrosomic infants. Thus patients with type 1 and type 2 diabetes face an increased probability of Caesarean birth because of failure of fetal descent or slowed labour progress or of operative vaginal birth (use of forceps or vacuum extraction) (Feig et al., 2018; Moore, T. R., et al., 2019).

Pregnant patients with nephropathy and hypertension in addition to diabetes are also increasingly likely to have hypertension and are at increased risk for developing superimposed pre-eclampsia. The rate of hypertensive disorders in all types of pregnancies complicated by diabetes is 15 to 30%. Chronic hypertension occurs in 10 to 20% of all pregnant patients with diabetes and in up to 40% of patients who have pre-existing renal or retinal vascular disease (Magee et al., 2014; Moore, T. R., et al., 2019). Patients with PGDM should be counselled to start taking low-dose Aspirin prior to the sixteenth week of pregnancy to reduce the risks of developing pre-eclampsia (Butalia et al., 2018; Magee et al., 2014).

Hydramnios (polyhydramnios) frequently develops during the third trimester of pregnancy in patients with diabetes. While the cause is unknown, one theory is that hydramnios in patients with diabetes is caused by an increased glucose concentration in amniotic fluid resulting from maternal and fetal hyperglycemia, which induces fetal polyuria. The complications most frequently associated with hydramnios (usually defined as a deepest pocket of fluid greater than 8 cm) are placental abruption, uterine labour dysfunction, and postpartum hemorrhage (Cunningham et al., 2018).

Infections are more common and more serious in pregnant patients with diabetes. Disorders of carbohydrate metabolism alter the body's normal resistance to infection. The inflammatory response, **leukocyte** function, and vaginal pH are all affected. Vaginal infections, particularly monilial vaginitis, are more common, as are urinary tract infections (UTIs). Infection is serious because it causes increased insulin resistance and may result in ketoacidosis. Postpartum infection may also occur among patients who have poorly controlled blood glucose.

Ketoacidosis (accumulation of ketones in the blood resulting from hyperglycemia and leading to metabolic acidosis) occurs most often during the second and third trimesters, when the diabetogenic effect of pregnancy is greatest. When the maternal metabolism is stressed by illness or infection, the patient is at increased risk for **diabetic ketoacidosis (DKA)**. Patients who have been given steroids as a result of risk for preterm birth may be at increased risk for DKA because steroids cause a significant increase in blood glucose levels. DKA may also occur because of the over- or under-administration of insulin.

DKA may occur with blood glucose levels barely exceeding 11 mmol/L because of an increase in the body's resistance to insulin in pregnancy; nonpregnant thresholds are higher, at 16.7 to 19.5 mmol/L. In response to stress factors such as infection or illness, hyperglycemia occurs, with a resulting increase in hepatic glucose production and decreased peripheral glucose use. The presence of nausea, vomiting, and fever can lead to ketoacidosis. Stress hormones, which can impair insulin action and further contribute to insulin deficiency, are released. Fatty acids are mobilized from fat stores into the circulation. As they are oxidized, ketone bodies are released into the peripheral circulation. The patient's buffering system is unable to compensate, and metabolic acidosis develops. The excessive blood glucose and ketone bodies result in osmotic diuresis, with subsequent loss of fluid and electrolytes, volume depletion, and cellular dehydration (Table 15.1). Prompt treatment of DKA is necessary to avoid maternal coma or death. Ketoacidosis at any time during pregnancy can lead to intrauterine fetal death and may stimulate preterm labour. The incidence of DKA has decreased in recent years because of advances in clinical management and blood glucose monitoring (Berger et al., 2019). Currently it affects only about 1 to 2% of pregnant patients with diabetes (Cunningham et al., 2018). The rate of intrauterine fetal demise (IUFD) with DKA, formerly approximately 35%, is 10% or less (Moore, T. R., et al., 2019).

The risk of *hypoglycemia* (a less than normal amount of glucose in the blood) is also increased during pregnancy. Early in pregnancy, when hepatic production of glucose is diminished and peripheral use of glucose is enhanced, hypoglycemia occurs frequently, often during sleep. Later in pregnancy, hypoglycemia may also result as insulin doses are adjusted to maintain **euglycemia** (a normal blood glucose level; also called *normogylcemia*). Patients with a prepregnancy history of severe hypoglycemia are at increased risk for severe hypoglycemia during gestation. Episodic and nonsevere hypoglycemic episodes do not appear to have significant deleterious effects on fetal well-being (see Table 15.1).

The rare but important concern in pregnancy is the patient's loss of hypoglycemic awareness, a condition in which early symptoms of hypoglycemia are not recognized. Frequent episodes of hypoglycemia can dull the body's normal responses to hypoglycemia and lead to lack of the patient's ability to recognize hypoglycemia. This is more common in patients with long-standing diabetes and creates safety concerns for the mother, especially at times when concentration is required, such as driving a car. Strict avoidance of hypoglycemia by the patient for a period of time has been associated with improvement in the recognition of severe hypoglycemia; therefore, tight control of blood glucose levels in the normal range is critical in pregnancy (Yale et al., 2018).

TABLE 15.1 Differentiation of Hypoglycemia (Insulin Shock) and Hyperglycemia (Diabetic Ketoacidosis)

Causes	Onset	Symptoms	Interventions
Hypoglycemia (Insulin Shock)			
Excess insulin Insufficient food (delayed or missed meals) Excessive exercise or work Indigestion, diarrhea, vomiting	Rapid (regular insulin) Gradual (modified insulin or oral hypoglycemic agents)	Irritability Hunger Sweating Nervousness Personality change Weakness Fatigue Blurred or double vision Dizziness Headache Pallor; clammy skin Shallow respirations Rapid pulse Laboratory values • Urine: Negative for sugar and acetone • Blood glucose: ≤3.3 mmol/L	• Check blood glucose level when symptoms first appear. • Eat or drink 15 g fast sugar (simple carbohydrate) immediately. • 175 mL (3/4 c) unsweetened fruit juice or regular pop • 15 mL (1 tbsp) or 3 packets of table sugar dissolved in water • 5 to 6 Life Savers candies • 15 mL (1 tbsp) honey • 15 g glucose in glucose tablet form • Recheck blood glucose level in 15 minutes and eat or drink another 15 g fast sugar (simple carbohydrate) if glucose remains low. • Recheck blood glucose level in 15 minutes. • Notify primary health care provider if there is no change in glucose level. • If person is unconscious, administer 50% dextrose IV push, 5 to 10% dextrose in water IV drip, or 1 mg glucagon subcutaneously. • Obtain blood and urine specimens for laboratory testing.
Hyperglycemia (DKA)			
Insufficient insulin Excess or wrong kind of food Infection, injuries, illness Emotional stress Insufficient exercise	Slow (hours to days)	Thirst Nausea or vomiting Abdominal pain Constipation Drowsiness Dim vision Increased urination Headache Flushed, dry skin Rapid breathing Weak, rapid pulse Acetone (fruity) breath odour Laboratory values • Urine: Positive for sugar and acetone • Blood glucose: ≥11 mmol/L	• Notify primary health care provider. • Administer insulin in accordance with blood glucose levels. • Give IV fluids such as normal saline solution or one-half normal saline solution; potassium when urinary output is adequate; bicarbonate for pH <7. • Monitor laboratory testing of blood and urine.

DKA, Diabetic ketoacidosis; *IV*, intravenous.

Fetal and Neonatal Risks and Complications. Despite improvements in the care of pregnant patients with diabetes, sudden and unexplained stillbirth is still a significant risk (Berger et al., 2019; Feig et al., 2018; Landon et al., 2017). In addition, the perinatal mortality rate is three times higher for patients with diabetes than for patients who do not have this disease. Miscarriage rates for patients with PGDM are as high as 30%. Major causes of perinatal mortality are congenital malformations, respiratory distress syndrome, and extreme prematurity. IUFD (sometimes called *stillbirth*) remains a major concern. Approximately 4% of all stillbirths occur in patients whose pregnancies are complicated by pre-existing diabetes. Poor glycemic control is the most consistent finding in patients who had a stillbirth. In addition to hyperglycemia, other causes of stillbirth include congenital abnormalities, placental insufficiency or fetal growth restriction, macrosomia or polyhydramnios, or obstructed labour (intrapartum stillbirth) (Inturrisi, 2017; Reddy & Silver, 2019).

Hyperglycemia during the first trimester of pregnancy, when organogenesis is occurring, is a primary contributor to diabetes-associated birth defects. Central nervous system (CNS) defects (e.g., anencephaly, open spina bifida) are increased ten-fold. Cardiac defects, especially ventricular septal defects (VSDs) and transposition of the great vessels, are increased five-fold (Inturrisi, 2017; Moore, T. R., et al., 2019). Infant morbidity and mortality rates associated with diabetic pregnancy are significantly reduced with strict control of maternal glucose levels before and during pregnancy.

The fetal pancreas begins to secrete insulin at 10 to 14 weeks of gestation. The fetus responds to maternal hyperglycemia by secreting large amounts of insulin (*hyperinsulinism*). Insulin acts as a growth

hormone, causing the fetus to produce excess stores of glycogen, protein, and adipose tissue and leading to increased fetal size, or *macrosomia*. Birth injuries are more common in infants born to mothers with diabetes than in those born to mothers who do not have diabetes, and macrosomic fetuses have the highest risk for this complication. Common birth injuries associated with diabetic pregnancies include brachial plexus palsy, facial nerve injury, humerus or clavicle fracture, and cephalohematoma. Most of these injuries are associated with difficult vaginal birth and shoulder dystocia (Berger et al., 2019; Moore, T. R., et al., 2019).

Hypoglycemia at birth is also a risk for infants born to mothers with diabetes. The degree of hypoglycemia is influenced by maternal glucose control during the latter weeks of pregnancy and during labour and birth (Landon et al., 2017). (For further discussion of newborn complications related to maternal diabetes, see Chapter 28.)

Nursing Care. Nurses play a key role in helping patients who are diabetic to understand how pregnancy affects their management of diabetes. Patients require an individualized plan of care that builds on their in-depth knowledge of their own disease management to achieve euglycemia and prevent complications (see Nursing Care Plan, Pregnancy Complicated by Pregestational Diabetes on Evolve). The initial prenatal visit is the optimal time to assess the patient's knowledge regarding diabetes and pregnancy, review potential maternal and fetal complications, and begin the initial plan of care with the patient and their family. In addition to the routine prenatal examination, specific efforts are made to assess the effects of the diabetes, especially retinopathy, nephropathy, peripheral and autonomic neuropathy, peripheral vascular, and cardiac involvement. Nurses are well positioned to promote preventive and positive behaviours, thus improving patient outcomes (Azami et al., 2018). Subsequent visits are important for monitoring a patient's progress and identifying further learning needs. Teaching should include family members.

Routine prenatal laboratory tests are performed, and baseline renal function may be assessed with a 24-hour urine collection for total protein excretion and creatinine clearance. Urinalysis and culture are performed to assess for the presence of a UTI, which is common in diabetic pregnancy. Because of the risk of coexisting thyroid disease, thyroid function tests may also be performed (see later discussion of thyroid disorders). The **glycated hemoglobin $A1_c$** level may be measured to assess recent glycemic control. With prolonged hyperglycemia some of the hemoglobin remains saturated with glucose for the life of the red blood cell (RBC). Therefore, a test for glycated hemoglobin provides a "diabetic report card," an evaluation of glycemic control over the previous 4 to 6 weeks. Hemoglobin $A1_c$ levels greater than 6.0 indicate elevated glucose levels during the previous 4 to 6 weeks (Berger et al., 2019). Fasting blood glucose or random (1 to 2 hours after eating) glucose levels may be assessed during antepartum visits. Self-monitoring blood glucose records may also be reviewed.

Antepartum care. The presence of risk factors for the patient and their fetus means that the patient with diabetes is monitored more frequently than a patient with a low-risk pregnancy. During the first and second trimesters of pregnancy, their routine prenatal care visits may be scheduled every 1 to 2 weeks. In the last trimester they will likely be seen one or two times each week. Most pregnant patients with diabetes are managed on an outpatient basis.

Achieving and maintaining euglycemia with blood glucose levels in the range of 3.4 to 6.7 mmol/L (Table 15.2) is the primary goal of medical therapy for the pregnant patient with diabetes (Feig et al., 2018). Euglycemia is achieved through a combination of diet, insulin, exercise, and frequent blood glucose monitoring. Nurses with expert knowledge in the management of diabetes in pregnancy can provide the patient with individualized information on the changes to their diabetes management, to help them achieve and maintain excellent blood glucose control.

TABLE 15.2 Target Blood Glucose Levels During Pregnancy

During Pregnancy	
Fasting and preprandial PG	3.8–5.2 mmol/L
1 hr postprandial PG	5.5–7.7 mmol/L
2 hr postprandial PG	5.0–6.6 mmol/L

PG, Plasma glucose.

Clinical practice guidelines: Diabetes and pregnancy. *Canadian Journal of Diabetes, 37*(1), S168–S183; Feig, D., Berger, H., Donovan, L., Godbout, A., Kader, T., Keely, E., & Sanghera, R. (2018). Diabetes and pregnancy 2018 clinical practice guidelines. *Canadian Journal of Diabetes, 42,* s255–s282.

Because the patient with diabetes is at risk for infections, eye conditions, and neurological changes, foot care and general skin care are important. A daily bath should include good perineal and foot care. Lotions, creams, or oils can be applied to dry skin. The patient should avoid wearing tight clothing. They should always wear shoes or slippers that fit properly, preferably with socks or stockings. Feet should be inspected regularly, toenails should be cut straight across, and professional help should be sought for any foot issues.

The patient should wear a medic alert bracelet at all times and carry their glucose meter, insulin, syringes or pens, and food to treat hypoglycemia, such as a fast-acting glucose along with a protein and a starch (see Community Focus box). The pregnant patient should be informed of how to report conditions such as nausea, vomiting, and infections and should know how to reach their health care provider at all times (see Table 15.1).

COMMUNITY FOCUS

Accessibility of Diabetes Supplies

It is very important that health care providers be aware of the realities of the cost and availability of diabetes equipment. Visit the local pharmacy and examine the diabetes equipment and supplies that are available. Locate glucose meters, urine test strips, insulin syringes, and insulin pens. How much does each of these items cost? Check to see which items are covered by health insurance. Read the directions for use of each item. How easy are the instructions to follow? Could a person with low literacy skills read and understand them? Do the directions have illustrations? Are the directions available in more than one language in addition to English? Does the pharmacy have someone who can teach patients? How will this information be helpful in patient teaching?

Diet. The patient with PGDM has usually had previous nutrition counselling regarding the management of diabetes. The pregnant patient needs to learn to incorporate changes into dietary planning, as pregnancy precipitates special nutrition concerns and needs. Nutrition counselling is primarily provided by a registered dietitian. Counselling should address general nutrition principles appropriate for all pregnant patients as well as diabetes-specific nutritional needs.

Dietary management during diabetic pregnancy must be based on blood glucose levels. The diet is individualized to allow for increased fetal and metabolic requirements, with consideration of such factors as prepregnancy weight and dietary habits, overall health, ethnic background, lifestyle, stage of pregnancy, knowledge of nutrition, and

insulin therapy. The dietary goals are to have weight gain consistent with a normal pregnancy, prevent ketoacidosis, and achieve euglycemia through consistency in carbohydrate intake.

For patients with a body mass index (BMI) of 22 to 27, dietary counselling includes advice to consume about 35 kcal/kg of ideal body weight per day with the average diet including 2 200 kilocalories (first trimester) to 2 500 kilocalories (second and third trimesters). For patients with a BMI greater than 30, experts recommend that the caloric intake total 25 kcal/kg/day (Moore, T. R., et al., 2019). Total calories should be distributed among three meals and at least two snacks. Meals should be eaten on time and never skipped. Going more than 4 hours without food intake increases the risk for episodes of hypoglycemia. Snacks must be carefully planned in accordance with insulin therapy to avoid fluctuations in blood glucose levels. A large bedtime snack of at least 25 g of carbohydrate with some protein is recommended in order to help prevent hypoglycemia and starvation ketosis during the night.

In general, people with diabetes should follow the healthy diet recommended for the general population in *Canada's Food Guide* (see Appendix A). This involves consuming a variety of foods. This diet will ensure an adequate intake of carbohydrate (CHO), fibre, fat and essential fatty acids, protein, vitamins, and minerals (see Patient Teaching box: Dietary Management of Diabetic Pregnancy). Simple carbohydrates are limited. Complex carbohydrates that are high in fibre content are recommended because the starch and protein in such foods help regulate the blood glucose level by more sustained glucose release (Moore, T. R., et al., 2019). Folic acid supplements of 1 mg/day are recommended for 3 months prior to conception and throughout the first trimester to reduce the risk of neural tube defects (Keely et al., 2018).

PATIENT TEACHING

Dietary Management of Diabetic Pregnancy

- Follow healthy eating for pregnancy based on *Canada's Food Guide*.
- Divide daily food intake between three meals and two to four snacks, depending on individual lifestyle, hunger, blood glucose, ketones, insulin regime, and pregnancy-related factors, such as nausea, vomiting, heartburn, and constipation.
- Eat a substantial bedtime snack to prevent a severe drop in blood glucose level during the night.
- Limit the intake of fats if weight gain occurs too rapidly.
- Take daily vitamins and iron as prescribed by the health care provider. Folic acid supplementation should be 1 mg/day for the first trimester and then decreased to 0.4 mg/day.
- Avoid foods high in refined sugar.
- Never skip meals or snacks.
- Reduce intake of saturated fat and cholesterol.
- Eat foods high in dietary fibre.
- Avoid drinking alcohol and limit caffeine to 300 mg/day.

Exercise. Being active for 30 to 60 minutes per day is encouraged for all pregnant patients. Daily activity has been shown to increase insulin sensitivity, thus lowering blood glucose levels; increase utilization of glucose, especially after a meal; improve glucose control, perhaps eliminating the need for insulin therapy; and reduce the risk for excessive weight gain. Although exercise enhances the utilization of glucose and decreases insulin need in nonpregnant patients with diabetes, there are limited data regarding the benefits of exercise during pregnancy for the pregnant patient with types 1 or 2 diabetes (Brown et al., 2017). Physical activity can be divided into 10- to 20-minute periods after each meal (Inturrisi, 2017) (see also Patient Teaching box: Exercise Tips for Pregnancy, in Chapter 11).

For patients with PGDM who have poorly controlled blood sugar or have vascular disease, only mild exercise is recommended because exercise causes a redistribution of blood flow, which increases the potential for ischemic injury to the placenta and already compromised organs. Walking and swimming are two forms of exercise with minimal risk and may be the exercises of choice for previously sedentary patients. Patients should check their blood glucose levels before, during, and after exercising.

Self-monitoring of blood glucose. Blood glucose testing at home is the most important tool available for assessing the patient's degree of glycemic control. Blood glucose levels are routinely measured at various times throughout the day, such as before breakfast, lunch, and dinner; 2 hours after meals; at bedtime; and in the middle of the night (see Patient Teaching box: Testing Blood Glucose Level). In addition, this monitoring provides feedback on how well their insulin-dose treatment is working. The newer meters are calibrated to provide plasma (rather than whole blood) glucose values. The nurse needs to be knowledgeable about the specific glucose meter that the patient uses in order to troubleshoot problems, assess accuracy of technique, and determine accuracy of reported results. The data obtained facilitate interaction with the health care team in maintaining glycemic control and maximizing pregnancy outcomes.

PATIENT TEACHING

Testing Blood Glucose Level

Blood sugar testing requires the use of a blood sugar meter. The meter measures the amount of sugar in a small sample of blood, usually from your fingertip, that you place on a disposable test strip.

Follow the instructions that come with your blood sugar meter. In general, here's how the process works:

1. Wash and dry your hands well. (Food and other substances can give you an inaccurate reading.)
2. Insert a test strip into your meter.
3. Prick the side of your fingertip with the needle (lancet) provided with your test kit.
4. Touch and hold the edge of the test strip to the drop of blood.
5. The meter will display your blood sugar level on a screen after a few seconds.

Some meters can test blood taken from an alternate site, such as the forearm or palm. But these readings may not be as accurate as readings from the fingertips, especially after a meal or during exercise, when blood sugar levels change more frequently.

! NURSING ALERT

Hyperglycemia may occur in the 2-hour postprandial values because blood glucose levels peak about 2 hours after a meal.

Special circumstances may require more frequent testing. Pregnant patients are instructed to check glucose levels at any sign of hypoglycemia or hyperglycemia. When there is any readjustment in insulin dosage or diet, more frequent measurement of blood glucose is warranted. If nausea, vomiting, or diarrhea occurs or if any illness is present, the patient will have to monitor their blood glucose levels more closely.

Target levels of blood glucose during pregnancy are lower than nonpregnant values (see Table 15.2). Acceptable fasting levels are generally between 3.8 and 5.2 mmol/L, and 2-hour postprandial levels should be less than 6.7 mmol/L (Feig et al., 2018). The patient should be told to report episodes of hypoglycemia (less than 3.2 mmol/L) and hyperglycemia (greater than 11 mmol/L) to their health care provider immediately so that adjustments in diet or insulin therapy can be made.

Pregnant patients with diabetes are much more likely to develop hypoglycemia than hyperglycemia because the goal of therapy is to maintain the blood glucose in a narrow, low-normal range of 3.8 to 5.2 mmol/L. Most episodes of mild or moderate hypoglycemia can be treated with oral intake of 10 to 15 g of simple carbohydrates (see Table 15.1). If severe hypoglycemia occurs in which the patient experiences a decrease in or loss of consciousness or an inability to swallow, they will require a parenteral injection of **glucagon** or intravenous (IV) glucose. Because hypoglycemia can develop rapidly and impaired judgement can be associated with even moderate episodes, it is vital that family members, friends, and work colleagues be able to recognize signs and symptoms quickly and initiate proper treatment, if necessary.

Although hyperglycemia is less likely to occur, it is still a dangerous complication. Hyperglycemia can rapidly progress to DKA, which is associated with an increased risk for fetal death (Inturrisi, 2017). Patients and their family members should be alert for signs and symptoms of hyperglycemia, especially when infections or other illnesses occur (see Patient Teaching box: What to Do When Illness Occurs).

PATIENT TEACHING

What to Do When Illness Occurs

Continue to Take Insulin

- Be sure to take insulin even though appetite and food intake may be less than normal. (Insulin needs are increased with illness or infection.)

Contact Your Health Care Provider

- Call your health care provider and relay the following information:
  - Symptoms of illness (e.g., nausea, vomiting, diarrhea)
  - Elevated temperature
  - Most recent blood glucose level
  - Urine ketones
  - Time and amount of last insulin dose

Take Preventive Measures

- Increase oral intake of fluids to prevent dehydration.
- Rest as much as possible.

Seek Emergency Treatment if Needed

- If you are unable to reach your health care provider and blood glucose exceeds 11.0 mmol/L with urine ketones present, seek emergency treatment at the nearest health care facility. Do not attempt to self-treat.

Insulin therapy. All type 1 and almost all type 2 diabetic patients will use insulin during pregnancy. Adequate insulin is the primary factor in the maintenance of euglycemia during pregnancy, thus ensuring proper glucose metabolism of the patient and fetus. Insulin requirements during pregnancy change dramatically as the pregnancy progresses, necessitating frequent adjustments in the dose.

Patients with type 2 diabetes who were on oral antihyperglycemic diabetic medications are usually switched to insulin, as currently these agents are not recommended for managing patients with PGDM as lone treatment by the CDA (Feig et al., 2018). See discussion in Chapter 14 on pharmacological therapy for further information regarding oral hypoglycemic therapy in pregnancy. Insulin therapy must be individualized and adjusted to ensure proper glucose metabolism of the mother and fetus.

The goal of administration of exogenous insulin during pregnancy is to achieve diurnal glucose levels that are similar to those of a nondiabetic pregnant patient. The insulin regimen for a pregnant patient will differ from that which was effective in the nonpregnant state in combinations and timing of insulin injections (Feig et al., 2018; Landon et al., 2017). A patient with type 1 PGDM who has typically been accustomed to one injection per day of intermediate-acting insulin may have to adjust to multiple daily injections of mixed insulin.

The patient with type 2 diabetes previously treated with oral hypoglycemic agents must learn to self-administer injections of insulin. The nurse is instrumental in providing education and support regarding insulin administration and the adjustment of insulin dosage to maintain euglycemia.

Since 1982 most insulin preparations have been produced by inserting portions of DNA ("recombinant DNA") into special laboratory-cultivated bacteria or yeast cells. The cells then produce synthetic human insulin (Humulin), which is less likely to cause antibody formation than animal-derived (beef or pork) insulin. More recently, insulin products called *insulin analogues,* in which the structure differs slightly from that of human insulin, have been produced. This small alteration in insulin structure results in changes in the onset and peak of action of the medication. The most commonly used insulin preparations include rapid-acting, short-acting, intermediate-acting, and long-acting (Feig et al., 2018; Landon et al., 2017) (Table 15.3). Mixtures of short- and intermediate-acting insulins in several proportions are also available.

Lispro (Humalog) and aspart (NovoRapid) are commonly prescribed rapid-acting insulins with a shorter duration of action than that of regular insulin. They are preferred for use during pregnancy (Feig et al., 2018; Landon et al., 2017). Advantages of rapid-acting insulins include convenience because they are injected immediately before mealtime, less hyperglycemia after meals, and fewer hypoglycemic episodes and improvement in blood glucose control. Because their effects last only 3 to 5 hours, most patients require a longer-acting insulin in addition to the rapid-acting insulin to maintain optimal blood glucose levels (Feig et al., 2018; Moore, T. R., et al., 2019) (see Table 15.3).

Glargine (Lantus) and detemir (Levemir) are long-acting insulin analogues that have been designed to more accurately mimic basal

TABLE 15.3 Insulin Types

Expected Time of Action

Type of Insulin	Examples Generic (Trade) Name	Onset of Action	Peak of Action	Duration of Action
Rapid-acting	Lispro (Humalog)	10–15 min	1–2 hr	3–5 hr
	Aspart (NovoRapid)	10–15 min	60–90 min	3–5 hr
Short-acting	Humulin R	30 min	2–3 hr	6.5 hr
	Novolin R	30 min	2.5–5 hr	6–8 hr
Intermediate-acting	Humulin N	1–3 hr	5–8 hr	Up to 18 hr
	Novolin NPH	1.5 hr	4–20 hr	24 hr
	Humulin Lente	1–3 hr	6–12 hr	18–24 hr
	Novolin L	2.5 hr	7–15 hr	22 hr
Long-acting	Humulin Ultralente	4–6 hr	8–20 hr	>36 hr
	Glargine (Lantus)	90 min	None	16–24 hr

L, Lente; *NPH* (or *N*), neutral protamine Hagedorn; *R,* regular.
Data from Thompson, D., Berger, H., Feig, D., et al. (2013). Clinical practice guidelines. Diabetes and pregnancy. *Canadian Journal of Diabetes, 37,* S168–S183.

insulin secretion. Small amounts of these insulins are released slowly, with no pronounced peak. Glargine and detemir insulins appear to be safe for use during pregnancy. When administered with rapid-acting or short-acting insulin there is less maternal hypoglycemia (Feig et al., 2018; Landon et al., 2017) (see Table 15.3).

Most pregnant patients with diabetes manage their insulin with two to three injections per day. Usually, two thirds of the daily insulin dose, with longer-acting (glargine or detemir) and short-acting (aspart or lispro) insulin combined in a 2:1 ratio, is given before breakfast. The remaining one third, again a combination of longer- and short-acting insulin, is administered in the evening before dinner. To reduce the risk of hypoglycemia during the night, separate injections are often administered, with short-acting insulin given before dinner, followed by longer-acting insulin at bedtime. An alternative insulin regimen that works well for some patients is to administer short-acting insulin before each meal and longer-acting insulin at bedtime (Feig et al., 2018).

Although subcutaneous insulin injections are most commonly used, increasing numbers of pregnant patients are using continuous subcutaneous insulin infusion (CSII) systems. The insulin pump is designed to mimic more closely the function of the pancreas in secreting insulin (Figure 15.2). This portable, battery-powered device is worn like a pager during most daily activities. The pump infuses rapid-acting insulin (usually lispro) (Feig et al., 2018; Landon et al., 2017) at a set basal rate and has the capacity to deliver up to four different basal rates in 24 hours. It also delivers bolus doses of insulin before meals to control postprandial blood glucose levels or to correct elevations in blood glucose. A fine-gauge plastic catheter is inserted into subcutaneous tissue, usually in the abdomen, and attached to the pump syringe by connecting tubing. The subcutaneous catheter and connecting tubing are changed every 2 to 3 days. Although the insulin pump is convenient and generally provides good glycemic control, complications such as pump failure, precipitation of insulin inside the pump mechanism, abscess formation, and poor uptake from the infusion site can still occur. To safely use the pump during pregnancy, the patient must monitor their blood glucose levels frequently. Therefore, use of the insulin pump requires a knowledgeable, motivated patient and skilled health care providers (Feig et al., 2018; Landon et al., 2017).

Urine testing. Urine testing for glucose is not beneficial during pregnancy. Because of the lowered renal threshold for glucose, the degree of glycosuria does not accurately reflect the blood glucose level. However, urine testing for ketones continues to have a place in diabetic management. Testing may also be performed when illness occurs or when the blood glucose level is 14 mmol/L or greater, because of the increased risk for ketoacidosis. The patient should be taught to report moderate levels of urine ketones to their health care provider (Daley, 2014).

Fig. 15.2 Insulin pump shows basal rate for pregnant patients with diabetes. (Courtesy of MiniMed, Inc., Sylmar, CA)

Complications requiring hospitalization. Occasionally, pregnant patients who are diabetic require hospitalization to regulate insulin dosage and stabilize glucose levels. Nursing care during hospitalization provides continuous support and education for regulating insulin therapy and blood glucose. Infection can lead to hyperglycemia and DKA and may require hospitalization, regardless of gestational age. Hospitalization during the third trimester for close maternal and fetal observation may be indicated for patients whose diabetes is poorly controlled or who also have hypertension.

Fetal surveillance. Diagnostic techniques for fetal surveillance are often performed to assess fetal growth and well-being. The goals of fetal surveillance are to detect evidence of fetal compromise as early as possible and prevent IUFD or unnecessary preterm birth.

Early in pregnancy the estimated date of birth is determined. A baseline ultrasound is obtained during the first trimester to assess gestational age. Follow-up ultrasonography examinations are usually performed during the pregnancy (as often as every 4 to 6 weeks) to monitor fetal growth; estimate fetal weight; detect hydramnios or macrosomia; and assess for the presence of congenital anomalies. An integrated pregnancy screen (IPS) and detailed ultrasound are performed at 18 to 22 weeks (see Chapter 13) to assess for neural tube defects.

Fetal echocardiography may be performed between 20 and 22 weeks of gestation to detect cardiac anomalies, especially in patients who had poorer glucose control early in pregnancy, as demonstrated by a hemoglobin $A1_c$ level above 6% at the first prenatal visit (Moore, T. R., et al., 2019). Doppler studies of the umbilical artery may be performed in patients with vascular disease to detect placental compromise (see discussion in Chapter 13).

Most fetal surveillance measures are concentrated in the third trimester, when the risk of fetal compromise is greatest. The goals of antepartum testing during the third trimester are to prevent IUFD and maximize the opportunity for the patient to safely give birth vaginally to a live baby. Pregnant patients who are diabetic should be taught how to do daily fetal movement counts, beginning at 26 to 32 weeks of gestation (see Chapter 13) (Liston et al., 2018; Moore, T. R., et al., 2019).

The nonstress test (NST) is the preferred primary method to evaluate fetal well-being. It is usually begun by 36 weeks of gestation and performed weekly. If the NST is abnormal, a biophysical profile (BPP) or contraction stress test (oxytocin challenge test) will be performed. Testing often begins earlier in patients who have vascular disease or poor glucose control (Berger et al., 2019; Landon et al., 2017) (see Chapter 13).

Determination of date and mode of birth. Pregnant patients who have diabetes often progress to term when good metabolic control is maintained and all parameters of antepartum fetal surveillance remain within normal limits. Reasons to consider birth before term include poor metabolic control, worsening hypertensive disorders, fetal macrosomia, prior stillbirth, fetal growth restriction or abnormal fetal heart tracing (Berger et al., 2019; Landon et al., 2017; Liston et al., 2018).

Induction of labour is often planned between 38 and 40 weeks, provided maternal glucose levels are well controlled (Berger et al., 2019). To confirm fetal lung maturity an amniocentesis may be performed when birth will occur before 38.5 weeks of gestation. For the pregnancy complicated by diabetes, fetal lung maturation is better predicted by the amniotic fluid phosphatidylglycerol (greater than 3%) (see Chapter 13). If the fetal lungs are still immature, birth should be postponed as long as the results of fetal assessment remain normal. Induction of labour despite fetal lung maturity may be required on the basis of assessment of fetal compromise or if severe pre-eclampsia, deteriorating vision

resulting from proliferative retinopathy, or worsening renal function develops. Involvement of the obstetrical team is critical to making the best decision for each individual patient (Berger et al., 2019).

A planned vaginal birth is the preferred mode of birth for patients with PGDM. Caesarean birth should only be performed for obstetrical reasons, such as when antepartum testing suggests a compromised fetal status. Induction of labour may be planned at term for the patient who has well-controlled blood glucose levels.

Intrapartum care. During the intrapartum period, the patient with pregestational diabetes must be monitored closely to prevent complications related to dehydration, hypoglycemia, and hyperglycemia. Most patients use large amounts of energy (kilocalories) to accomplish the work and manage the stress of labour and birth; however, this energy expenditure varies with the individual. Blood glucose levels and hydration must be controlled carefully during labour. An IV line is inserted for infusion of a maintenance fluid such as 5% dextrose in normal saline or lactated Ringer's solution. Insulin is administered by intermittent subcutaneous injection. In patients who have difficulty regulating their blood glucose, a continuous insulin infusion may be required. Blood glucose levels are assessed every hour in active labour. Fluids and insulin levels are adjusted to maintain blood glucose levels at between 4 and 7 mmol/L (Feig et al., 2018). It is essential that these target glucose levels be maintained because hyperglycemia during labour can cause metabolic issues in the newborn, particularly hypoglycemia (Feig et al., 2018; Landon et al., 2017). During labour, continuous fetal heart monitoring is recommended for patients who are receiving insulin (Liston et al., 2018). Labouring patients are encouraged to be mobile in labour; **telemetry** monitoring can be used to monitor the fetus remotely. Side-lying positions are preferred for the patient labouring in bed, to prevent supine hypotension due to a large fetus or polyhydramnios. Labour progresses without intervention, provided normal rates of cervical dilation, fetal descent, and fetal well-being are maintained. **Epidural** anaesthesia may be provided to patients who require pain relief. Labour dystocia may occur because of a macrosomic infant or cephalopelvic disproportion, necessitating Caesarean birth. Labouring patients with diabetes are monitored for diabetic complications, such as hyperglycemia, ketones in the urine, and ketoacidosis. During second-stage labour, the nurse should be alert for the possibility of shoulder dystocia if the birth of a macrosomic infant is attempted and should be prepared to assist with manoeuvres to free the fetal shoulder lodged behind the symphysis pubis (see Chapter 20). Depending on the gestational age of the fetus at birth, a neonatologist or pediatrician may need to be present at the birth to provide newborn care.

If a Caesarean birth is planned, it should be scheduled in the early morning to facilitate glycemic control. Patients should take their full dose of insulin the night before surgery. No morning insulin is given on the day of surgery, and the patient is given nothing by mouth. Regional anaesthesia (epidural or spinal) is recommended because hypoglycemia can be detected earlier if the patient is awake.

Postpartum care. During the first 24 hours postpartum, insulin requirements decrease substantially because the major source of insulin resistance, the placenta, has been removed. Patients with PGDM may require only one half the prenatal insulin dose on the first postpartum day, provided that they are eating a full diet. It takes several days after birth to re-establish carbohydrate homeostasis. Blood glucose levels are monitored in the postpartum period, and insulin dosage is adjusted accordingly. Blood glucose levels do not require such tight control after birth. Usually insulin is not given until the blood glucose level is greater than 11.0 mmol/L. Many patients with type 2 diabetes do not require insulin at all for the first 1 to 2 days after giving birth, and some patients require no insulin in the postpartum period and are able to maintain euglycemia through diet alone or with return to management with oral hypoglycemic medications (Feig et al., 2018; Landon et al., 2017). Patients who give birth by Caesarean may require an IV infusion of glucose and insulin until they resume a regular diet. After birth, several days may be required to re-establish carbohydrate homeostasis (see Figure 15.1, *D* and *E*). Blood glucose levels are monitored carefully in the postpartum period; the insulin dose is adjusted, often using a sliding scale (the amount of insulin to be administered is determined by the patient's blood glucose level at the time the dose is given).

Possible postpartum complications include pre-eclampsia or eclampsia, hemorrhage, and infection. Hemorrhage is a possibility if the mother's uterus was overdistended (by polyhydramnios or a macrosomic fetus) or overstimulated (by oxytocin induction). Postpartum infections such as endometritis are more likely to occur in a patient with diabetes.

Mothers who choose to breastfeed are encouraged to start right away. Breastfeeding has an antidiabetogenic effect for the children of patients with diabetes and for the patients themselves (Berger et al., 2019; Moore, T. R., et al., 2019). This effect is important because a child born to a mother with type 2 diabetes has a 70% chance of also developing type 2 diabetes later in life. In addition, there may be an association between prenatal exposure to hyperglycemia and an increased risk for obesity in childhood (Inturrisi, 2017). Infants who are exclusively breastfed are less likely to develop diabetes; exposure to breastmilk substitutes may be an important risk factor for the development of type 2 diabetes (Feig et al., 2018).

The mother may have early breastfeeding difficulties. Poor metabolic control may delay lactogenesis and contribute to decreased milk production. Initial contact and opportunity to breastfeed the infant may be delayed because of institutional practices of separating mothers and babies post-Caesarean or placing infants of mothers with diabetes in special care nurseries for observation during the first few hours after birth. Support and assistance from nursing staff and lactation specialists can facilitate the mother's early experience with breastfeeding and encourage them to continue.

Insulin requirements in breastfeeding patients may be one half of prepregnancy levels because of the carbohydrate used in human milk production. Because glucose levels are lower than normal, breastfeeding patients are at increased risk for hypoglycemia, especially in the early postpartum period and after breastfeeding sessions, particularly after late-night nursing (Moore, T. R., et al., 2019). Breastfeeding patients with diabetes may be at increased risk for **mastitis** and yeast infections of the breast. Insulin dosage, which is decreased during lactation, must be readjusted at the time of weaning (see Figure 15.1).

The postpartum parent needs information about family planning and contraception. While family planning is important for all patients, it is essential for the patient with diabetes, to safeguard their own health and promote optimal outcomes in future pregnancies. Excellent glucose control at conception is crucial for all patients with diabetes; therefore, the importance of conscientiously using a reliable contraceptive method until another pregnancy is desired should be stressed. No one best form of contraception exists for patients with diabetes. Emphasis should be placed on consistent use of a reliable and effective birth control method. The risks and benefits of contraceptive methods should be discussed with the mother and their partner before discharge from the hospital. Barrier methods are often recommended as safe, inexpensive options that have no inherent risks for patients with diabetes. The intrauterine device (IUD) may also be used without concerns about an increased risk of infection (Landon et al., 2017).

The use of oral contraceptives is controversial because of the risk of thromboembolic events and vascular complications and the effect on carbohydrate metabolism. In nonsmoking patients who are younger than 35 years old and do not have vascular disease, combination low-dose oral contraceptives may be prescribed. Progestin-only oral

contraceptives also may be used because they affect carbohydrate metabolism minimally, if at all (Cunningham et al., 2018). Close monitoring of blood pressure and lipid levels is necessary to detect complications (Landon et al., 2017).

Opinion is divided over the use of long-acting parenteral progestins such as medroxyprogesterone (Depo-Provera). Some health care providers recommend their use, especially in patients who may have difficulty with daily dosing of oral contraceptives. In contrast, other health care providers believe this method may adversely affect glycemic control. In addition, although Depo-Provera may lower serum triglyceride and high-density lipoprotein (HDL) cholesterol levels, it does not lower total cholesterol or low-density lipoprotein (LDL) levels. For this reason it is not recommended as a first-choice method of contraception for patients with diabetes (Thompson et al., 2013).

The transdermal (patch) and transvaginal (vaginal ring) are newer contraceptive methods that are particularly effective in patients who prefer weekly or every-third-week dosing, respectively. For patients weighing more than 90 kg (198 lb) the contraceptive failure rate with transdermal administration is higher than in lower-weight patients. Therefore, this method would be contraindicated in patients with obesity. Patients who choose the patch as their contraceptive method should have no risk factors for cardiovascular or thromboembolic disease (Cunningham et al., 2018).

The patient and their partner should be informed that the risks associated with pregnancy increase with the duration and severity of the diabetic condition and that pregnancy may contribute to vascular changes associated with diabetes. Thus, the option of tubal ligation should be discussed with the patient who has completed their family or who has significant vasculopathy.

Thyroid Disorders

Hyperthyroidism. Hyperthyroidism occurs in approximately 1 to 4 of every 1 000 persons (Mestman, 2017). Identification of hyperthyroidism in a pregnant patient is important because adverse outcomes can occur in both the mother and the offspring (Ross, 2020a). Graves' disease, which is autoimmune in nature, is the usual cause; but hyperthyroidism in pregnancy can be caused by other causes (e.g., toxic nodular goitre, functioning adenoma, excessive thyroid hormone intake, and thyroiditis) (Mestman, 2017; Ross, 2020a). Symptoms of hyperthyroidism can be difficult to detect as they may mimic those of early pregnancy, such as an increased heart rate, sensitivity to hot temperatures, and fatigue. Other symptoms of hyperthyroidism include the following: irregular heartbeat, feeling of anxiety severe nausea or vomiting, shaky hands (slight tremor), and difficulty sleeping (Ross, 2020a).

Because of the timing of the symptoms, hyperemesis gravidarum may be considered as the diagnosis. Careful assessment by the primary health care provider is necessary, with blood work that includes thyroid levels, to get an accurate diagnosis. Laboratory findings include elevated thyroxine (T_4) and triiodothyronine (T_3) levels and greatly suppressed serum thyroid-stimulating hormone (TSH) levels. It is important to differentiate subclinical, mild hyperthyroidism from moderate to severe disease. Pregnant patients with minimal or mild symptoms—low TSH and mildly elevated T_4 levels—may be monitored without intervention (Nader, 2019). Signs that may help differentiate moderate to severe hyperthyroidism from normal pregnancy symptoms include unplanned weight loss, onycholysis (loose nails), and a pulse rate greater than 100 beats/min (Nader, 2019). The best possible outcomes can be achieved when hyperthyroidism is diagnosed and treated prior to pregnancy. Untreated moderate and severe hyperthyroidism can be detrimental during pregnancy, resulting in infants with low birth weight, intrauterine growth restriction (IUGR), prematurity, stillbirth, goitre, and hyper- or hypothyroidism (Nader, 2019). However, most newborns of patients with hyperthyroidism have normal thyroid function. Patients with hyperthyroidism are at increased risk of pre-eclampsia, heart failure, premature birth, stillbirth, fetal growth restriction, thyroid storm, and miscarriage (Nader, 2019). Patients should be started on low-dose Aspirin before 16 weeks of pregnancy to reduce the risks of developing pre-eclampsia (Butalia et al., 2018; Magee et al., 2014).

Most pregnant patients diagnosed with thyroid disease will have received treatment for the condition prior to conception. Generally, medication therapy alone is considered for control of hyperthyroidism in pregnancy; radioiodine treatment is not used because of destruction of the fetal thyroid gland, resulting in permanent hypothyroidism in the newborn.

The treatment options are limited because of the fetal risks of the currently available pharmacological treatments. There are two primary choices of medications to treat hyperthyroidism, propylthiouracil (PTU) and methimazole (MM). PTU was considered the medication of choice throughout pregnancy for patients with hyperthyroidism, as a result of concerns for teratogenicity of MM. More recently, reports of severe PTU-related liver failure have raised concerns about the routine use of PTU, including the use of PTU in pregnancy (Mestman, 2017; Ross, 2020a). As a result, in pregnant patients with hyperthyroidism, PTU use is limited to the first trimester only. The teratogenic effects of MM are to be avoided in the first trimester during fetal organogenesis. Patients are directed to switch to MM after the first trimester to avoid the potential risk of longer-term PTU-associated hepatotoxicity. Thyroid function testing should be performed 2 to 4 weeks after switching to MM to ensure that a euthyroid state has been maintained. Hyperthyroid patients treated with MM should be switched to PTU at the time of the positive pregnancy test (Mestman, 2017; Ross, 2020a).

Both medications work well and are well tolerated by most patients. The most common maternal adverse effects of both PTU and MM are pruritus and skin rash. Other possible adverse effects include drug-related fever, bronchospasm, migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice (Mestman, 2017; Ross, 2020a). The most severe adverse effect is agranulocytosis, which occurs rarely and usually develops only in older patients and in those taking high doses of the medication. Symptoms of agranulocytosis are fever and unexpected sore throat, which should be reported immediately to the health care provider; the patient should stop taking the medication (Mestman, 2017; Nader, 2019).

Beta-adrenergic blockers such as propranolol or atenolol may be used in patients with severe hyperthyroidism symptoms. Long-term use is not recommended because of the potential for IUGR and altered response to anoxic stress, postnatal bradycardia, and hypoglycemia (Nader, 2019; Ross, 2020a).

In severe cases, hyperthyroidism may be treated surgically with subtotal thyroidectomy during the second or third trimester. Because of the increased risk of miscarriage and preterm labour associated with major surgery, this treatment is usually reserved for patients with severe disease whose medication therapy does not control the disease. Risks associated with the surgery are hypoparathyroidism, recurrent laryngeal nerve paralysis, and anaesthesia-related complications (Nader, 2019).

Postoperative hypothyroidism is common, occurring in at least 20% of patients with hyperthyroidism. Graves' disease may worsen in the postpartum period and increased doses of anti-thyroid medications may be required to manage this disorder. Close monitoring of thyroid function testing is required. If a mother taking hyperthyroid medication chooses to breastfeed they need to be aware that physiologically significant doses of the medication are passed to the infant through the breast milk. The infant's thyroid status should be monitored periodically so that newborn hypothyroidism can be prevented.

! NURSING ALERT

A serious but uncommon complication of undiagnosed or partially treated hyperthyroidism is thyroid storm, which may occur in response to stresses such as infection, pre-eclampsia, birth, or surgery. Symptoms of this rare condition include sudden fever, restlessness, tachycardia, vomiting, hypotension, or stupor. Heart failure may also occur. Prompt treatment is essential to ensure a good maternal outcome; IV fluids and oxygen are administered along with high doses of PTU. Potassium iodide, antipyretics, glucocorticoids, and beta-adrenergic blockers may also be given; sedation may be necessary for extreme restlessness (Mestman, 2017; Nader, 2019; Ross, 2020a).

Hypothyroidism. Hypothyroidism is a condition that results from an underactive thyroid gland and may be present during pregnancy. Many symptoms of hypothyroidism are similar to pregnancy symptoms such as fatigue and weight gain. Hypothyroidism is diagnosed in 2.2 to 2.5% of pregnant patients (Ross, 2020b). Hypothyroidism is usually the result of Hashimoto's disease (autoimmune thyroiditis), thyroid gland ablation by radiation, previous surgery, or not taking enough antithyroid medications. Iodine deficiency in patients living in developed countries is rare (Nader, 2019; Ross, 2020b), but in the rest of the world, the most common cause of thyroid conditions is iodine deficiency. Symptomatic pregnant patients should be screened for the presence of hypothyroidism (Mestman, 2017). Untreated hypothyroidism may result in poor obstetrical maternal and fetal outcomes: pre-eclampsia, low birth weight, placental abruption, spontaneous pregnancy loss, premature birth, and perinatal morbidity (American College of Obstetricians and Gynecologists [ACOG], 2015; Nader, 2019).

Characteristic symptoms of hypothyroidism include maternal fatigue, weight gain, cold intolerance, decrease in exercise capacity, constipation, cool and dry skin, coarsened hair, and muscle weakness. Laboratory findings during pregnancy include elevated levels of TSH (above 6 mU/L), with or without low T_4 levels (ACOG, 2015; Nader, 2019).

Diagnosis and treatment of pregnant patients with overt hypothyroidism are important, as thyroid deficiency has been shown to cause impaired neurological development during early fetal development. The fetus is dependent on the maternal transfer of thyroid hormones, specifically T_4. If the mother is iodine deficient, fetal brain development can be impaired. Infants born to mothers with hypothyroidism may be of low birth weight and may be at risk for further cognitive deficits if born premature. Patients with subclinical hypothyroidism have not been shown to have adverse pregnancy outcomes and therefore do not require treatment (ACOG, 2015).

Thyroid hormone supplements are used to treat hypothyroidism. Levothyroxine (e.g., T_4 [Synthroid]) is the treatment of choice for treatment of hypothyroidism during pregnancy (Alexander et al., 2017; Orlander, 2021). Levothyroxine is considered safe and is not **teratogenic**.

As pregnancy progresses, the patient requires increased amounts of thyroid replacement hormone, usually increasing dosing up by 50% (Orlander, 2021). The aim of medication therapy is to maintain the TSH level at the lower end of the normal range for pregnant patients. Patients with little or no functioning thyroid tissue require higher doses of levothyroxine. In addition, as pregnancy progresses increased doses of thyroid hormone are usually required. This increased demand during pregnancy is probably related to increased estrogen levels (Cunningham et al., 2018; Nader, 2019). Because of increased absorption in the small intestine, taking the medication on an empty stomach is recommended. Prenatal vitamins may inhibit absorption of thyroid replacements because of the presence of iron and calcium (Orlander, 2021).

! NURSING ALERT

Pregnant patients should be instructed to take thyroid replacement hormone 4 hours before or after iron tablets because ferrous sulphate lowers the effectiveness of the medication (Orlander, 2021).

Nursing Care. A pregnant patient with thyroid dysfunction requires education to ensure the best outcomes for themselves and their fetus. This education should include information about the disorder and its potential impact on the patient and their fetus, the medication regimen and possible adverse effects, the need for continuing medical supervision, and the importance of maintaining consistent levels of thyroid hormone. The family should be incorporated into the plan of care to foster support among the members.

The patient often needs the nurse's help to cope with the discomforts and frustrations associated with symptoms of the disorder. For example, the patient with hyperthyroidism who has nervousness and hyperactivity along with weakness and fatigue can benefit from suggestions to channel excess energies into quiet diversional activities such as reading or crafts. Discomfort associated with hypersensitivity to heat (hyperthyroidism) or cold intolerance (hypothyroidism) can be minimized by wearing appropriate clothing, regulating environmental temperatures, and avoiding temperature extremes, when possible.

Nutrition counselling with a registered dietitian is an important component of management of symptoms. The patient with hyperthyroidism who has increased appetite and poor weight gain and the hypothyroid patient who has anorexia and lethargy need counselling to ensure adequate intake of nutritionally sound foods to meet both maternal and fetal needs.

CARDIOVASCULAR DISORDERS

Heart disease is a common cause of nonobstetrical morbidity and mortality for patients during pregnancy. The major cardiovascular changes that occur during pregnancy affect the patient with cardiac disease as a result of increased intravascular volume, decreased systemic vascular resistance, cardiac output increases of 30 to 50% during pregnancy, labour, and birth, as well as the intravascular volume changes that occur just after childbirth (Linley & Williams, 2018). The normal heart can compensate for the increased workload, so pregnancy, labour, and birth are generally well tolerated, but the diseased heart is hemodynamically challenged.

If the cardiovascular changes are not well tolerated, cardiac failure can develop during pregnancy, labour, or the postpartum period. In addition, if cardiomyopathy develops, valvular disease exists, or a congenital heart defect is present, cardiac decompensation (inability of the heart to maintain a sufficient cardiac output) may occur. Fever and infection are the major causes of cardiac decompensation during pregnancy (Anthony & Sliwa, 2016; Deen et al., 2017).

From 0.5 to 4% of pregnancies are complicated by heart disease. Thanks to better management of congenital heart disease in childhood, pregnancy outcomes for patients with these conditions have improved. However, cardiac disease still remains a leading cause of maternal mortality during pregnancy (Silversides et al., 2018). Box 15.2 lists maternal cardiac disease risk groups and their related mortality rates. Pregnancy is not advised in patients who have the following cardiac conditions: pulmonary hypertension, Marfan syndrome with aortic involvement, and Eisenmenger syndrome, because the associated maternal mortality rate related to ventricular failure is extremely high, up to 50% (Anthony & Sliwa, 2016; Deen et al., 2017; Gaddipati & Troiano, 2013).

BOX 15.2 Maternal Cardiac Disease Risk Groups

Group 1 (Mortality Rate <1%)
Atrial septal defect
Ventricular septal defect (uncomplicated)
Patent ductus arteriosus (uncomplicated)
Tetralogy of Fallot (corrected)
Pulmonic and tricuspid disease
Mitral stenosis or aortic regurgitation (NYHA class I and II)
Biosynthetic valve prosthesis
Mitral valve prolapsed with regurgitation

Group II (Mortality Rate 5 to 15%)
Aortic stenosis
Coarctation of aorta without valve involvement
Artificial heart valve
Mitral stenosis (NYHA class III and IV) or with atrial fibrillation
Tetralogy of Fallot (uncorrected)
Previous myocardial infarction
Marfan syndrome with normal aorta

Group III (Mortality Rate 25 to 50%)
Pulmonary hypertension
Coarctation of the aorta with valvular involvement
Marfan syndrome with aortic involvement
Endocarditis
Eisenmenger syndrome
Peripartum cardiomyopathy with persistent left ventricular dysfunction

Sources: Gaddipati, S., & Troiano, N. H. (2013). Cardiac disorders in pregnancy. In N. H. Troiano, C. J. Harvey, & B. F. Chez (Eds.), *AWHONN's high risk and critical care obstetrics* (3rd ed.). Lippincott Williams and Wilkins; Gilbert, E. S. (2011). Cardiac disease. In E. S. Gilbert (Ed.), *Manual of high risk pregnancy and delivery* (5th ed.). Mosby.

The degree of limitations in activity experienced by the patient with cardiac disease is important to understand in relation to the treatment and prognosis during pregnancy. The New York Heart Association (NYHA) functional classification of heart disease is a widely accepted standard:

- Class I: Asymptomatic without limitation of physical activity
- Class II: Symptomatic with slight limitation of activity
- Class III: Symptomatic with marked limitation of activity
- Class IV: Symptomatic with inability to carry on any physical activity without discomfort

No classification of heart disease can be considered rigid or absolute, but the NYHA classification system is a clear, practical guide for cardiac classification that can inform appropriate obstetrical care. Medical therapy is provided by an interprofessional team approach that includes the patient, cardiologist, obstetrician, anaesthesiologist, and nurses. The pregnant patient may experience a change in their functional classification because of the hemodynamic changes that occur in the cardiovascular system during pregnancy. There is a 30 to 45% increase in cardiac output over nonpregnancy resting values, with most of the increase occurring in the first trimester and the peak at 20 to 26 weeks of gestation (Linley & Williams, 2018). The functional classification of the patient's disease is determined at 3 months and again at 7 or 8 months of gestation. Pregnant patients may progress from class I or II to III or IV during pregnancy as cardiac output increases and more stress is placed on the heart. Patients with cyanotic congenital heart disease do not fit into the NYHA classification because their exercise-induced symptoms have causes unrelated to heart failure.

A diagnosis of cardiac disease depends on the history, physical examination, radiographic and electrocardiographic findings, Holter monitoring, and, if indicated, ultrasonographic results. Most diagnostic studies are noninvasive and can be safely performed during pregnancy. The differential diagnosis of heart disease also involves ruling out respiratory conditions and other potential causes of chest pain.

Pregnancy in a patient with heart disease is associated with increased risks for decompensation of maternal cardiac status and pregnancy complications, including maternal arrhythmias, heart failure, preterm birth, fetal growth restriction, and a small but significant risk for maternal and fetal death (Deen et al., 2017). The highest risk for complications or death occurs in patients with pulmonary hypertension, complicated coarctation of the aorta, and Marfan syndrome with aortic involvement (Blanchard & Daniels, 2019).

Cardiac diseases vary in their effect on pregnancy depending on whether they are acute or chronic conditions. The following discussion focuses on selected congenital and acquired cardiac conditions and other cardiac disorders. A review of the care of the pregnant woman who has had a heart transplant concludes this section.

Congenital Cardiac Diseases

Congenital heart disease is classified as acyanotic or cyanotic. Patients at increased risk for a cardiac event in pregnancy include those with a prior cardiac event or arrhythmia, NYHA functional class greater than II, or cyanosis, left heart obstruction, and systemic ventricular dysfunction.

Acyanotic Cardiac Lesions

Atrial septal defect. Atrial septal defect (ASD) is one of the most common of the congenital heart diseases (Bredy et al., 2018; Gaddipati & Troiano, 2013). It is an abnormal opening between the atria and is one of the causes of left-to-right shunting resulting in increased pulmonary blood flow. This defect may go undetected because the patient is usually asymptomatic. The pregnant patient with an ASD usually has an uncomplicated pregnancy. However, some patients may develop heart failure or arrhythmias as the pregnancy progresses, as a result of increased plasma volume. Another possible complication is the development of emboli (blood clots) (Canobbio et al., 2017).

Ventricular septal defect. Ventricular septal defect (VSD), an abnormal opening between the right and left ventricles, is another cause of a left-to-right shunt (see Box 47.2). It may occur as a single lesion or in combination with other cardiac anomalies such as tetralogy of Fallot. The defect is usually diagnosed and corrected early in life. As a result, a VSD is not very common in pregnancy (Canobbio et al., 2017). Patients with small, uncomplicated VSDs usually do not have pregnancy complications. For patients with a large VSD, there is a higher risk for heart failure or pulmonary hypertension. Medical management includes administration of anticoagulants if indicated, along with rest and decreased physical activity (Canobbio et al., 2017; Gaddipati & Troiano, 2013).

Patent ductus arteriosus. This condition is rarely seen in adults, as most people with a patent ductus arteriosus (PDA) have it corrected as a newborn or as a child (see Box 47.2). Patients with a corrected PDA do well in pregnancy, and patients with an uncorrected PDA who have a small to moderate size ductus and who have normal pulmonary arterial pressures are likely to experience few or no complications with pregnancy related to their cardiac defect (Canobbio et al., 2017; Davies & Herbert, 2007a).

Coarctation of the aorta. Coarctation of the aorta is a localized narrowing of the aorta near the insertion of the ductus (see Box 47.3). Patients with this lesion have hypertension in their upper extremities but hypotension in the lower extremities. In most patients, the lesion has been surgically corrected in childhood. Pregnancy is typically relatively safe for the patient with uncomplicated, uncorrected coarctation. The maternal mortality rate is approximately 3 to 5% if it is not repaired (Blanchard & Daniels, 2019).

Complications that can occur for patients with coarctation of the aorta include hypertension, heart failure, cerebrovascular accident (stroke), aortic dissection, rupture of associated aneurysms, and increased risk of pre-eclampsia (Blanchard & Daniels, 2019; Deen et al., 2017). The mainstays of treatment for uncorrected coarctation of the aorta during pregnancy are rest and treatment of hypertension; therefore, antihypertensive medications, preferably beta-adrenergic blocking agents, are key to management of this condition. Vaginal birth is usually recommended, with Caesarean birth performed only for obstetrical indications. If bacteremia is suspected, antibiotic prophylaxis is given during labour and birth (Cunningham et al., 2018).

Pulmonic stenosis. Patients with severe pulmonic stenosis (see Box 47.3) are encouraged to have surgical correction before pregnancy in order to improve their outcomes of pregnancy (Davies & Herbert, 2007a). As with other cardiac disorders, patients with mild-to-moderate disease do well in pregnancy. However, those with severe disease have a higher risk of right-sided heart failure, resulting in higher rates of pregnancy loss and poor maternal outcomes.

Cyanotic Congenital Cardiac Lesions

Tetralogy of Fallot. Tetralogy of Fallot is the most common cyanotic heart disease observed during pregnancy (Blanchard & Daniels, 2019). Components of tetralogy of Fallot include a VSD; pulmonary stenosis; overriding aorta; and right ventricular hypertrophy leading to a right-to-left shunt (see Box 47.4). Patients with tetralogy of Fallot are encouraged to have surgical repair prior to attempting conception because pregnancy outcomes are better once the VSD and pulmonary stenosis have been repaired (Gaddipati & Troiano, 2013). Patients with uncorrected tetralogy of Fallot experience more right-to-left shunting during pregnancy, resulting in reduced blood flow through the pulmonary circulation and increasing hypoxemia, which can cause syncope or death (Davies & Herbert, 2007a; Gaddipati & Troiano, 2013). Maintenance of venous return in patients with uncorrected tetralogy of Fallot is critical. Therefore, the most dangerous time for these patients is the late third trimester of pregnancy and the early postpartum period, when venous return is reduced by the large pregnant uterus and peripheral venous pooling after birth. Use of pressure-graded support hose is recommended. Blood loss during birth may also adversely affect venous return; thus blood volume must be adequately maintained.

Acquired Cardiac Disease

Mitral Valve Stenosis. Mitral stenosis is almost always caused by rheumatic heart disease (RHD), a consequence of rheumatic fever (Blanchard & Daniels, 2019; Siu, 2019). Rheumatic fever develops suddenly, often several symptom-free weeks after an inadequately treated group A beta-hemolytic streptococcal throat infection. Episodes of rheumatic fever create an autoimmune reaction in the heart tissue, leading to permanent damage of heart valves (usually the mitral valve) and the chordae tendineae cordis. This damage is classified as RHD. RHD may be evident during acute rheumatic fever or discovered years later. Recurrences of rheumatic fever are common, each with the potential to increase the severity of heart damage.

Mitral valve stenosis (narrowing of the opening of the mitral valve caused by stiffening of valve leaflets, thereby obstructing blood flow from the atrium to the ventricles) is the characteristic lesion often resulting from RHD. As the mitral valve narrows, cardiac output decreases and dyspnea worsens, occurring first on exertion and eventually at rest. A tight stenosis plus the increase in blood volume and required cardiac output demands of normal pregnancy and birth may cause pulmonary edema, atrial fibrillation, right-sided heart failure, infective endocarditis, pulmonary embolism, and massive hemoptysis (Blanchard & Daniels, 2019; Cunningham et al., 2018). Approximately 25% of patients with mitral valve stenosis may become symptomatic for the first time during pregnancy. Maternal mortality is related to functional capacity. Almost all maternal deaths related to mitral stenosis occur in patients who are classified as NYHA class III or IV (Cunningham et al., 2018). Patients with mild-to-moderate stenosis usually tolerate pregnancy well (Davies & Herbert, 2007a; Siu, 2019).

Patients with a history of RHD are no longer recommended to receive prophylactic antibiotics (Linley & Williams, 2018; Siu, 2019). Patients with mitral stenosis may require diuretics such as furosemide (Lasix) to prevent pulmonary edema, and beta blockers or calcium channel blockers to prevent tachycardia (Deen et al., 2017; Linley & Williams, 2018). Cardioversion may be needed for new-onset atrial fibrillation, a complication associated with mitral stenosis. Patients who have chronic atrial fibrillation may need digoxin or beta blockers to control the heart rate. In addition, anticoagulant therapy may be needed to prevent embolism (Blanchard & Daniels, 2019; Linley & Williams, 2018).

The care of the patient with mitral stenosis is typically managed by reducing their activity and restricting dietary sodium, in addition to the pharmacological management discussed previously (Cunningham et al., 2018). The pregnant patient with mitral stenosis should be monitored clinically for symptoms and with echocardiography to assess the atrial and ventricular size and heart valve function.

Intrapartum care for patients with severe disease includes invasive hemodynamic monitoring during labour and birth, with a goal toward maintaining adequate ventricular filling and cardiac output (Davies & Herbert, 2007b). During labour, adequate pain control is required to prevent tachycardia. Epidural analgesia for labour is preferred (Deen et al., 2017; Siu, 2019). The patient should be encouraged to labour and give birth in the side-lying position and avoid the supine and lithotomy positions. Shortening the second stage of labour by vacuum- or forceps-assisted birth is also important, to decrease the cardiac workload. Caesarean birth should be performed only for obstetrical indications. Aggressive diuresis is initiated immediately after birth because fluid shifts can place the patient at risk for pulmonary edema (Deen et al., 2017; Linley & Williams, 2018). Management by skilled providers who are alert to the signs of cardiac decompensation is critical.

For patients with NYHA class III or IV cardiac disease, surgical intervention may be necessary. Valve replacement and mitral valve repair have been performed successfully during pregnancy. Currently, balloon valvotomy is likely to be the procedure of choice and would optimally be performed after 20 weeks of gestation to decrease radiation risks to the fetus. Surgical intervention should be considered only when symptoms cannot be controlled by medical therapy (Blanchard & Daniels, 2019).

Aortic Stenosis. *Aortic stenosis* is a narrowing of the opening of the aortic valve leading to an obstruction to left ventricular ejection. Pregnancy outcomes are poor for patients with severe aortic stenosis. As with other valvular diseases, the highest risk time is late pregnancy, during labour and birth, and in the initial days postpartum (Linley & Williams, 2018). Maternal mortality is low; however, preterm birth

and low birth weight are potential adverse fetal outcomes. Medical management is similar to that for mitral stenosis.

Mitral Valve Prolapse. Mitral valve prolapse (MVP) is a common, usually benign condition occurring in less than 1% of patients (Blanchard & Daniels, 2019). In MVP the mitral valve leaflets prolapse into the left atrium during ventricular systole, allowing some backflow of blood. Midsystolic click and late systolic murmur are hallmarks of this syndrome. Most cases are asymptomatic. A few patients have atypical chest pain (sharp and located in the left side of the chest) that occurs at rest, is unrelated to exercise, and unresponsive to nitrates. Patients may experience anxiety, palpitations, dyspnea on exertion, and syncope. If patients are symptomatic, beta-blocking drugs are given to relieve chest pain and palpitations and reduce the risk of life-threatening arrhythmias (Cunningham et al., 2018). If symptoms are unusually severe, thyroid function should also be checked (Blanchard & Daniels, 2019). Pregnancy and its associated hemodynamic changes may change or alleviate the murmur and click of MVP as well as its symptoms. Pregnancy is usually well tolerated. Antibiotic prophylaxis is no longer recommended for invasive procedures for at-risk patients and for complicated vaginal births in patients with MVP (Cunningham et al., 2018).

Ischemic Heart Disease

Myocardial Infarction. Myocardial infarction (MI), an acute ischemic event, rarely occurs in patients of childbearing age. It is estimated to occur in only 1 of 16 000 pregnancies (Blanchard & Daniels, 2019). However, the incidence may continue to rise, considering the number of patients who delay childbearing until later in life. Patients with coronary artery disease often have classic risk factors such as diabetes, hypertension, cigarette smoking, hyperlipidemia, and obesity (Cunningham et al., 2018; Davies & Herbert, 2007c). The cardiac changes that normally occur in a pregnant patient may provoke symptoms for the first time. It is also possible for patients with a history of MI to become pregnant (Gaddipati & Troiano, 2013).

MI occurs most frequently in the last trimester of pregnancy and in patients older than 30 years. The maternal mortality rate from an MI during pregnancy is approximately 20%. Patients are most likely to die at the time of the infarction or during labour and birth (Blanchard & Daniels, 2019). The risk of maternal death increases if the patient gives birth within 2 weeks of having an MI (Deen et al., 2017). Fetal loss is also high in this population.

Medical management for pregnant patients with MI is the same as that for nonpregnant patients and includes the administration of morphine, nitrates, lidocaine, beta blockers, Aspirin, magnesium sulphate, and calcium antagonists (Deen et al., 2017). Coronary angioplasty and stenting procedures have been performed during pregnancy. These procedures should not be avoided if they are considered to be appropriate for treating the woman (Deen et al., 2017). Thrombolytic agents such as urokinase, streptokinase, and tissue plasminogen activator (tPA) do not appear to cross the placenta. However, their use is considered to be relatively contraindicated in pregnancy because of the risk for subsequent maternal and fetal hemorrhage (Gaddipati & Troiano, 2013). Because pain can lead to tachycardia and increased cardiac demands, pain control during labour is crucial. The side-lying position is preferred to prevent pressure on the vena cava. Vaginal birth is preferable, with avoidance of maternal pushing and a vacuum- or forceps-assisted birth (Deen et al., 2017).

Other Cardiac Conditions

Peripartum Cardiomyopathy. Peripartum cardiomyopathy (PPCM) is heart failure with cardiomyopathy. The classic criteria for the diagnosis of PPCM include development of heart failure during the last month of pregnancy or within the first 6 postpartum months; absence of heart disease before the last month of pregnancy; a left ventricular ejection fraction of less than 45%; and, most important, lack of another cause for heart failure (Anthony & Sliwa, 2016; Sliwa et al., 2010). The etiology of the disease is unknown. The incidence in North America is 1 in 3 000 live births, with the maternal mortality rate estimated to be in the range of 25 to 50%; the infant mortality rate is approximately 10% (Deen et al., 2017; Kolte et al., 2014).

Associated risks include maternal age over 30, hypertension, multifetal pregnancies, pre-eclampsia, and African descent (Anthony & Sliwa, 2016; Blanchard & Daniels, 2019). Clinical findings include breathlessness, dyspnea, cough, orthopnea, tachydysrhythmias, and edema, with radiological findings of cardiomegaly. Maternal death is usually caused by thromboembolism, arrhythmia, or progressive heart failure. The prognosis is good if cardiomegaly does not persist after 6 months postpartum. Patients whose hearts remain enlarged after 6 months postpartum are at increased risk to have PPCM in future pregnancies (Anthony & Sliwa, 2016; Blanchard & Daniels, 2019; Kolte et al., 2014). Given the recurrence risk of 30 to 50%, patients are counselled against subsequent pregnancies.

Medical management of cardiomyopathy during pregnancy includes treatment similar to that for heart failure and the potential for thromboembolism: diuretics, sodium restriction, afterload-reducing agents, anticoagulants, and digoxin. Anticoagulation may be necessary if the cardiac chambers are significantly dilated and contract poorly because of the increased risk for clot formation. Angiotensin-converting enzyme inhibitors, often prescribed to achieve afterload reduction, can be used only in the postpartum period because they are teratogenic agents and have been associated with severe fetal renal toxicity and stillbirth (Davies & Herbert, 2007c). During labour, epidural anaesthesia is often used for pain control to decrease the cardiac workload and reduce tachycardia. Caesarean birth should be performed only for obstetrical indications (Anthony & Sliwa, 2016; Deen et al., 2017).

Infective Endocarditis. Infective endocarditis is inflammation of the innermost lining—the endocardium—of the heart, caused by invasion of microorganisms. In North America, women at greatest risk for developing infective endocarditis are those who have congenital heart lesions, degenerative valve disease, have intracardiac devices in place or who use drugs intravenously (Cunningham et al., 2018). Bacterial endocarditis, leading to incompetence of heart valves and thus heart failure and cerebral emboli, can result in death. Treatment is with antibiotics. Prophylactic treatment with antibiotics is used only for patients at highest risk for this condition.

Primary Pulmonary Hypertension. Patients with primary pulmonary hypertension have constriction of the arteriolar vessels in the lungs, leading to an increase in the pulmonary artery pressure. As a result of this pathology, there is right ventricular hypertension, right ventricular hypertrophy and dilation, and right ventricular failure with tricuspid regurgitation and systemic congestion. The primary challenge is maintaining blood flow to the lungs. Any event that significantly decreases venous return to the heart, such as hypotension, impairs the ability of the right ventricle to pump blood through the pulmonary vessels with their high, fixed vascular resistance. Hypotension must be avoided at all costs (Deen et al., 2017). Symptoms may be nonspecific, such as fatigue and shortness of breath. Dyspnea on exertion is the most common symptom (Cunningham et al., 2018).

Primary pulmonary hypertension is diagnosed by electrocardiography. The diagnosis is confirmed by right-sided cardiac catheterization, which may be deferred during pregnancy (Cunningham et al.,

2018). Mortality rates reported during pregnancy are as high as 50%; thus pregnancy is not advised (Blanchard & Daniels, 2019; Davies & Herbert, 2007a). In patients who choose to become pregnant, the most dangerous time is the intrapartum and early postpartum periods because of increases in cardiac output and fluid shifts.

Medical management of primary pulmonary hypertension during pregnancy includes treatment in a tertiary centre with cardiac critical care support, limiting the patient's activity, and avoiding supine positioning. Diuretics, supplemental oxygen, and vasodilator medications are also ordered. During labour and birth, hypotension must be avoided, by carefully establishing epidural analgesia and preventing blood loss (Cunningham et al., 2018).

Eisenmenger Syndrome. Eisenmenger syndrome is caused by a congenital communication between the systemic and pulmonary circulations and elevated pulmonary vascular resistance, which can result in right-to-left shunting. It is associated with an underlying structural cardiac defect, either a VSD (most common) or a patent ductus arteriosus (Blanchard & Daniels, 2019). When there is more extensive left-to-right shunting, the hemodynamic changes in pregnancy can result in high morbidity and mortality for both the mother and fetus. Patients in this situation are often encouraged to terminate the pregnancy. Although sudden death can occur at any time, the intrapartum and early postpartum periods seem to be the most dangerous (Blanchard & Daniels, 2019).

In patients who continue pregnancy despite the risks, management includes measures to maintain pulmonary blood flow. Physical activity is strictly limited. Other interventions include the use of pressure-graded elastic support hose and oxygen therapy. Hospitalization is often necessary to provide optimal care (Davies & Herbert, 2007a). During labour and birth, opioid-based regional anaesthesia provides pain relief without causing excessive hemodynamic instability. Hypotension must be prevented at all costs because it results in more right-to-left shunting, thereby increasing hypoxemia, increasing pulmonary vascular resistance, and worsening the shunt. Volume overload or excessive systemic resistance must also be prevented because it further stresses the failing right side of the heart. Caesarean birth should be performed only for obstetrical indications and avoided whenever possible (Deen et al., 2017).

Marfan Syndrome. Marfan syndrome is an autosomal dominant condition characterized by generalized weakness of the connective tissue, resulting in the characteristic feature of the disease, aortic wall and root dilation. Other signs and symptoms associated with Marfan syndrome include dislocation of the optic lens, deformity of the anterior thorax, scoliosis, long limbs, joint laxity, and arachnodactyly. Diagnosis is usually based on family history and physical examination, including ocular, cardiovascular, and skeletal features (Deen et al., 2017).

The majority of deaths from Marfan syndrome are caused by aortic dissection and rupture. Overall, the maternal mortality rate associated with Marfan syndrome is greater than 50%. However, it is significantly increased if the aortic root diameter measures more than 4 cm (Blanchard & Daniels, 2019; Goland & Elkayam, 2017). Approximately 90% of these patients have mitral valve prolapse, and 25% have aortic insufficiency with an increased risk of aortic dissection and rupture during pregnancy and birth. Excruciating chest pain and cardiac decompensation are the first signs of aortic rupture, which can occur primarily in the third trimester or the postpartum period.

Preconception counselling for patients with Marfan syndrome is essential to make patients aware of the risks of pregnancy with this disease. An accurate assessment of the aortic root using noninvasive imaging with transesophageal echocardiography, computed tomography (CT), or magnetic resonance imaging (MRI) must be obtained to assess the patient's specific risk and make management recommendations. Elective repair of the aorta is recommended when the aortic root diameter measures 55 to 60 mm. Therefore, patients with an aortic root diameter greater than 55 mm should be counselled to have it repaired before becoming pregnant. On the other hand, patients with an aortic root diameter less than 40 mm can attempt pregnancy with only modest risk (Goland & Elkayam, 2017). Pregnancy outcomes in patients with Marfan syndrome may have a high rate (up to 40%) of obstetrical complications, such as premature birth, mainly due to premature rupture of membranes, IUGR, small size for gestational age, and newborn mortality (Goland & Elkayam, 2017). Because the condition is inherited, each child born to a patient with Marfan syndrome has a 50% chance of having the disorder (Gaddipati & Troiano, 2013; Goland & Elkayam, 2017).

Therapy includes limiting of physical activity, prevention of hypertensive or hypotensive complications, and administration of beta blockers as needed to maintain a resting heart rate of approximately 70 beats/min. Pregnant patients with Marfan syndrome should be cared for collaborative by their obstetrician and cardiologist. Tachycardia should be prevented during labour. Patients with aortic root diameters less than 40 mm can give birth vaginally, reserving Caesarean birth for obstetrical indications. Some authorities believe that patients with larger aortic root diameters should give birth by elective Caesarean because of concerns about increased pressure in the aorta during labour. However, data do not exist to make this a firm recommendation (Blanchard & Daniels, 2019).

Valve Replacement. Pregnant patients with mechanical or bioprosthetic heart valves require specialized care for this high-risk situation. The primary medical management, anticoagulation, is both controversial and complicated. A high risk for thromboembolism exists because of the hypercoagulability of pregnancy. At the same time, the use of anticoagulants during pregnancy presents the possibility of maternal and fetal hemorrhage. Some oral anticoagulants pose a significant risk to the fetus for abnormalities and intracranial hemorrhage. However, prosthetic heart valve thrombosis is a life-threatening emergency during pregnancy and requires clot removal surgery, which carries a high mortality rate (Roos-Hesselink et al., 2013).

Patients with bioprosthetic heart valves usually do not require anticoagulation during pregnancy. This type of valve may be used in patients of childbearing age because it has a relatively low rate of complications during pregnancy. However, bioprosthetic valves are not as durable as mechanical valves. In addition, pregnancy accelerates the deterioration of bioprosthetic valves (Deen et al., 2017).

Anticoagulation is required with a mechanical valve. Management of anticoagulation during pregnancy is quite controversial because commonly used medications have significant maternal and fetal adverse effects, and no single agent is safe for use throughout the entire prenatal period. Often low-molecular-weight heparin (Lovenox) is used during the first trimester. In the second and third trimesters, warfarin (Coumadin) may be used instead. If Lovenox is used during the second and third trimesters, it should be discontinued several weeks before the anticipated date of birth and the patient started on heparin. Anticoagulation therapy should be discontinued during labour and resumed in

the postpartum period. Warfarin is generally used for long-term postpartum anticoagulation. Warfarin is safe for use in breastfeeding patients (Deen et al., 2017).

Heart Transplantation. Increasing numbers of heart transplant recipients are successfully completing pregnancies. It is recommended that pregnancy be avoided for at least 1 year after the transplant because by that time the risk for acute rejection and the intensity of immunosuppression are considerably less (Blanchard & Daniels, 2019). Before conception, the patient should be assessed for quality of ventricular function and potential rejection of the transplant. Additionally, they should be stabilized on their immunosuppressant regimen. Patients who have no evidence of rejection and have normal cardiac function at the beginning of the pregnancy appear to do well during pregnancy, labour, and birth. Research has shown that the transplanted heart responds normally to pregnancy-related changes. Complications that are common in patients who have had a heart transplant include hypertension and at least one episode of rejection (Cunningham et al., 2018).

LEGAL TIP: Cardiac Emergencies
The management of cardiac emergencies such as maternal cardiopulmonary distress or arrest should be documented in policies, procedures, and protocols. Nursing scope of practice and independent nursing actions should be clearly identified.

Nursing Care

The presence of cardiac disease is a significant influencing factor in the decision-making process for a patient with heart disease who is considering a pregnancy. Patients and their partners must understand the individualized risks involved in the patient's clinical situation. If the pregnancy is unplanned, the nurse should explore the couple's desire to continue once they have been counselled on the full extent of the risks of ongoing pregnancy. Pregnancy termination is one option, depending on the severity of the cardiac defect. The family may need further information to make an informed decision about carrying on with the pregnancy.

Nursing care of the pregnant patient with a cardiovascular disorder combines routine perinatal care with care specific for the cardiac diagnosis and function. The interprofessional team must work with the patient and their family in an environment that has the required resources to provide appropriate maternal hemodynamic monitoring, and the patient's condition may need to be assessed as often as weekly. See the Evolve website for the Nursing Care Plan, The Pregnant Patient with Heart Disease.

Antepartum

Nursing care for the pregnant patient with heart disease is focused on minimizing stress on the heart and ensuring that the pregnant patient and fetus have a healthy outcome. Cardiac stress is greatest between 25 and 30 weeks as the hemodynamic changes reach their maximum (Antony et al., 2017; Linley & Williams, 2018). Factors that increase the risk for cardiac decompensation need to be avoided. The workload of the cardiovascular system can be reduced by appropriate treatment of any coexisting emotional stress, hypertension, anemia, hyperthyroidism, or obesity.

Signs and symptoms of cardiac decompensation are taught at the first prenatal visit and reviewed at each subsequent visit (Box 15.3 and Patient Teaching box: The Pregnant Patient at Risk for Cardiac Decompensation).

The pregnant patient with cardiovascular disease often requires some modification of their activities. Reduced activity level during pregnancy affects all of the organ systems, but especially the cardiovascular and musculoskeletal systems. In addition, psychological adverse effects can be debilitating (Cunningham et al., 2018). The community health nurse, social worker, and physiotherapist or occupational therapist are key resource people whose services may be incorporated into the plan of care.

Symptoms of cardiac decompensation may appear abruptly or gradually. Medical intervention must be instituted immediately to maintain optimal cardiac status. Dyspnea, palpitations, syncope, and edema commonly occur in pregnant patients and can mask the symptoms of a developing or worsening cardiovascular disorder (Anthony & Sliwa, 2016; Pieper, 2012). A patient's sudden inability to perform activities that they were previously comfortable doing may indicate cardiovascular decompensation (see Box 15.3).

BOX 15.3 Signs of Potential Complications

Cardiac Decompensation

Pregnant Patient: Subjective Symptoms

Increasing fatigue, difficulty breathing, or both with usual activities
Feeling of smothering
Frequent cough
Palpitations; feeling that her heart is racing
Generalized edema: swelling of face, feet, legs, fingers (e.g., rings do not fit anymore)

Nurse: Objective Signs

Irregular weak, rapid pulse (100 or more beats/min)
Progressive, generalized edema
Crackles at base of lungs after two inspirations and exhalations that do not clear with coughing
Orthopnea; increasing dyspnea
Rapid respirations (25 or more breaths/min)
Moist, frequent cough
Cyanosis of lips and nail beds

PATIENT TEACHING

The Pregnant Patient at Risk for Cardiac Decompensation

Instruct the patient to do the following:

- Watch for and immediately report signs of cardiac decompensation or heart failure: generalized edema; distension of neck veins; dyspnea; frequent, moist cough; or palpitations.
- Watch for and immediately report signs of thromboembolism: pain, redness, tenderness, or swelling in extremities or chest pain.
- Avoid constipation and thus straining with bowel movements (Valsalva manoeuvre) by taking in adequate fluids and fibre. A stool softener may also be helpful.

Teach the importance of the following:

- Daily weighing. Sudden weight gain indicates fluid retention.
- Keeping all prenatal visit appointments, although they will be scheduled more frequently than for pregnant patients who are not at risk.
- Limiting activity (depending on classification of her heart disease). Patients with class I or II cardiac disease need 10 hours of sleep every night and 30 minutes of rest after meals. Patients with class III or IV cardiac disease usually need bed rest for most of each day.

Modified from Gilbert, E. S. (2011). *Manual of high risk pregnancy and delivery* (5th ed.). Mosby.

Infections should be treated promptly because they can complicate the condition by accelerating the heart rate and by direct spread of organisms (e.g., streptococci) to the heart structure. Infections are a major cause of cardiac decompensation during pregnancy. Bacteriuria screens should be performed. The patient should be instructed to notify their health care provider at the first sign of an upper respiratory infection, especially if fever is present. Vaccination against influenza and pneumococci are appropriate (Deen et al., 2017).

Many patients with heart disease are at risk for iron-deficiency anemia. Iron and folate supplementation may help to prevent anemia and thus decrease cardiac workload (Deen et al., 2017).

Nutrition counselling is necessary, optimally with the patient's family present. The pregnant patient needs a well-balanced diet with iron and folic acid supplementation, high protein levels, and adequate calories to gain weight. Iron supplements tend to cause constipation; thus the patient should increase their intake of fluids and fibre. A stool softener may also be prescribed. It is important that the patient with a cardiac disorder avoid straining during defecation, thus causing the Valsalva manoeuvre (forced expiration against a closed airway, which when released, causes blood to rush to the heart and overload the cardiac system). Sodium restriction may be necessary. The patient's intake of potassium may be monitored to prevent hypokalemia, especially if they are taking diuretics. Depending on the specific cardiac condition, some patients may be limited in their total daily fluid intake. A referral to a dietitian may be necessary for a nutritional plan of care.

Cardiac medications are prescribed as needed, with attention to fetal well-being. The hemodynamic changes that occur during pregnancy, such as increased plasma volume and increased renal clearance of medications, can alter the amount of medication needed to establish and maintain a therapeutic level. Therefore, monitoring medication levels during pregnancy is crucial to maintain effective therapy for the patient while minimizing risk to the fetus.

Anticoagulant therapy may be prescribed during pregnancy for several conditions such as recurrent venous thrombosis, pulmonary embolus, RHD, prosthetic valves, or cyanotic congenital heart defects. If anticoagulant therapy is required during pregnancy, several different medications may be recommended (see the section on valve disorders for more discussion of anticoagulant therapy). The patient may need to learn to self-administer injectable agents such as heparin or low-molecular-weight heparin (Lovenox). A patient taking warfarin requires specific nutritional teaching to avoid eating foods high in vitamin K, such as raw, dark green leafy vegetables, which counteract the effects of warfarin. In addition, they will require a folic acid supplement.

Tests for fetal maturity and well-being and placental sufficiency may be necessary. Other therapy is directly related to the functional classification of heart disease. The nurse must reinforce the need for close medical supervision.

Heart Surgery During Pregnancy. Ideally, surgery to correct a cardiac lesion should be performed prior to pregnancy. In some patients, however, cardiac disease is diagnosed for the first time during pregnancy. The maternal mortality risk does not increase, but there is a fetal mortality risk of 10 to 15% if heart surgery is performed, especially if cardiopulmonary bypass is used. If possible, surgery should be postponed until the third trimester of pregnancy, when the risk to the fetus is considerably decreased (Blanchard & Daniels, 2019).

Intrapartum

For all pregnant patients the intrapartum period is the one that evokes the most apprehension in patients and caregivers. The patient with impaired cardiac function may have increased anxiety and fear because labour and birth places additional stress on their already compromised cardiovascular system, which can result in a poor maternal outcome. General intrapartum management for cardiac disease focuses on strict fluid management, preventing hypotension and maternal tachycardia (>110 beats/min), and optimizing cardiac output. Induction of labour at or near term may be indicated.

Assessments include the routine assessments for all labouring patients, as well as assessments for cardiac decompensation. In addition, arterial line placement and arterial blood gas evaluations may be needed to assess for adequate oxygenation. Pulmonary artery catheters (Swan-Ganz catheter), although used consistently in past practice to monitor hemodynamic status during labour and birth, are currently used less frequently, with no changes in maternal outcomes (Robertson et al., 2012). Electrocardiographic telemetry monitoring and continuous monitoring of blood pressure and pulse oximetry should be instituted for all patients with cardiac issues, and the fetus should be continuously monitored electronically.

! NURSING ALERT

A pulse rate above 100 beats/min or a respiratory rate of 25 breaths/min, particularly when associated with dyspnea, may indicate impending ventricular failure. The nurse needs to check the respiratory status frequently for developing dyspnea, coughing, or crackles at the base of the lungs. The colour and temperature of the skin should also be noted. Pale, cool, clammy skin may indicate cardiac shock.

Nursing care during labour and birth focuses on the promotion of cardiac function. A calm atmosphere in the labour and birth rooms can help minimize anxiety. The nurse can provide anticipatory guidance by keeping the patient and their family informed of labour progress and events that will probably occur and by answering any questions they have. The patient's childbirth preparation method should be supported to the degree feasible for her cardiac condition. Nursing techniques that promote comfort, such as back massage, may also be used.

Cardiac function is supported by keeping the patient's head and shoulders elevated and body parts resting on pillows. The side-lying position usually facilitates hemodynamics during labour. Discomfort is relieved with medication and supportive care. Physiologically, the ideal labour for a patient with heart disease is one that is short and pain-free. Therefore, use of epidural analgesia is encouraged, although care must be taken to avoid hypotension, a common adverse effect of regional anaesthesia (Deen et al. 2017; Gaddipati & Troiano, 2013; Robertson et al., 2012).

Beta-adrenergic agents such as terbutaline are associated with various adverse effects, including tachycardia, irregular pulse, myocardial ischemia, and pulmonary edema. Therefore these medications should be used judiciously in patients with known or suspected heart disease (Blanchard & Daniels, 2019). If evidence of cardiac decompensation appears, the physician may order furosemide (Lasix) for rapid diuresis and oxygen by intermittent positive pressure to decrease the development of pulmonary edema.

Spontaneous or induced (with a favourable cervix) labour followed by vaginal birth is preferred for patients with cardiac disease (Pieper, 2012; Robertson et al., 2012). If no obstetrical concerns exist, vaginal birth may be accomplished with the patient in the side-lying position to facilitate uterine perfusion. The supine position should be avoided. If it is used, a pad or small wedge is placed under one hip to displace the uterus laterally and minimize the danger of supine hypotension. The patient can flex their knees and place their feet flat on the bed. The use of stirrups is contraindicated because stirrups can compress the popliteal veins, thereby increasing the blood volume in the chest and trunk as a result of the effects of gravity. Open-glottis pushing is

recommended. The patient should avoid the Valsalva manoeuvre when pushing in the second stage of labour because it reduces diastolic ventricular filling and obstructs left ventricular outflow. Oxygen via face mask is administered. Vacuum extraction or outlet forceps are often used to decrease the length of the second stage of labour and the heart's workload at that time. Caesarean birth is not routinely recommended for patients who have cardiovascular disease because of the risks of dramatic fluid shifts, sustained hemodynamic changes, and increased blood loss.

Bacterial endocarditis prophylaxis is not recommended, as the risk of bacteremia is low (Allen & Canadian Paediatric Society, 2010; Linley & Williams, 2018; Siu, 2019). Dilute IV oxytocin immediately after birth may be used to prevent hemorrhage. Ergot products should not be used because they cause an increase in blood pressure. Fluid balance should be maintained and blood loss replaced. If tubal sterilization is desired, it is best to delay surgery until the patient is hemodynamically near normal, afebrile, nonanemic, and able to ambulate normally (Cunningham et al., 2018).

Postpartum

Monitoring for cardiac decompensation in the postpartum period is essential. The first 24 to 72 hours postpartum are the most hemodynamically difficult for the patient. During the immediate postpartum period, diuretic therapy may be required. Hemorrhage, infection, or both may worsen the cardiac condition. The patient with a cardiac disorder may continue to require an arterial catheter for monitoring of arterial blood gases and blood pressure. Discharge should be delayed up to 72 hours to allow time to assess for complications (Linley & Williams, 2018; Pieper, 2012).

! NURSING ALERT

The immediate postbirth period is hazardous for a patient whose heart function is compromised. Cardiac output increases rapidly as extravascular fluid is remobilized into the vascular compartment. At the moment of birth, intra-abdominal pressure is reduced drastically; pressure on veins is removed, the splanchnic vessels engorge, and blood flow to the heart is increased. When blood flow increases to the heart, a reflex bradycardia may result.

Care in the postpartum period is tailored to the patient's functional capacity. Postpartum assessment of the patient with cardiac disease includes vital signs, oxygen saturation levels, lung and heart auscultation, presence of edema, amount and character of bleeding, uterine tone and fundal height, urinary output, pain (especially chest pain), the activity–rest pattern, dietary intake, parent–infant interactions, and emotional state. The head of the bed should be elevated and the patient encouraged to lie on their side. Progressive ambulation is encouraged as tolerated. The patient may require assistance with grooming and hygiene needs and other activities. Bowel movements without stress or strain are promoted with stool softeners, diet, and fluids.

The patient may need assistance from family members to help in the care of the newborn. While breastfeeding is not contraindicated, some patients with heart disease (particularly those with life-threatening disease) may be unable to breastfeed, and some patients may not wish to breastfeed their newborn. The patient who chooses to breastfeed requires support from their family and the nursing staff to assist in positioning the patient or the infant for feeding. The infant should be brought to the mother and taken from them after the feeding to conserve the mother's energy. Patients who are breastfeeding may require less cardiac medication, especially diuretics, for the treatment of their condition. Most medications used to manage cardiac disorders are compatible with breastfeeding. However, thiazide diuretics may suppress lactation (Blanchard & Daniels, 2019). Because diuretics can cause newborn diuresis that can lead to dehydration, lactating patients must be monitored closely to determine if medication doses can be reduced and still be effective. Nurses caring for the newborn should be alerted to watch for voiding patterns and amounts and to monitor the infant closely for signs of dehydration.

Patients who are too ill to care for and feed their babies should be provided with opportunities to have the baby at the bedside so they can look at and touch the baby to establish an emotional bond. Having the baby skin-to-skin with the mother gives them a powerful opportunity to get to know the baby while expending little energy. If the mother is unable to hold the infant, the nurse or a family member can hold the infant at the mother's eye level and close enough for the mother to touch.

Discharge should be carefully planned with the patient and family. A clear plan to support the mother's need for a balance between rest and sleep periods along with activity must be discussed. The role of relatives, friends, and others in assisting with meal preparation and household duties as well as child-care responsibilities must be addressed. The family may be referred to community resources (e.g., homemaking services) for additional support, as appropriate. Rest and sleep periods, activity, and diet must be planned. The nurse should provide information to the couple about their re-establishing sexual relations and contraception needs or answer questions about tubal ligation or vasectomy.

In general, the complications associated with pregnancy are usually greater than the risks associated with any form of contraception (Deen et al., 2017). Patients at particular risk for thromboembolism should avoid using combined estrogen-progestin oral contraceptives, but progestin-only pills may be used. Parenteral progestins (e.g., medroxyprogesterone [Depo-Provera]) are safe for use by patients with cardiac disease and are extremely effective. However, they cause irregular bleeding, which may be problematic for patients on anticoagulant therapy. An IUD may be used by some patients with congenital heart lesions (Deen et al., 2017). Both the patient and their partner should discuss the options together in order to make the best choice for their individual situation.

Medical assessment and community health nurse follow-up are important after discharge to continue monitoring for cardiac decompensation, through the first few weeks after birth, because of hormone shifts that affect hemodynamics. Few data are available regarding how quickly cardiac output returns to normal after giving birth. Older studies suggested that this occurred by 8 to 10 weeks postpartum. However, a longitudinal study that followed patients before, during, and after pregnancy found that both nulliparous and multiparous patients had significantly higher cardiac outputs above their prepregnancy values even at 1 year after giving birth (Isley & Katz, 2017).

Men and women with a congenital heart defect are at increased risk for having children who also have a defect. The risk for affected mothers is greater, approximately two to more than three times that of affected fathers. Children born with a congenital heart defect to parents with congenital heart defects appear to inherit the risk for cardiac maldevelopment in general rather than a specific defect, because they often do not have the same defect as the parent (Deen et al., 2017). Therefore, preconception and genetic counselling before a subsequent pregnancy are essential.

OBESITY

Excessive weight is an increasingly serious health concern among children, adolescents, and adults living in affluent nations, and

pregnant patients are no exception. The BMI is used to define obesity. Persons with a BMI of 25 or greater are categorized as overweight, whereas those with a BMI of 30 or greater are considered obese. Individuals with a BMI of 40 or greater are classified as severely or morbidly obese (Denison et al., 2018; Picklesimer & Dorman, 2013). Patients who are overweight or obese and their fetuses and infants are at increased risk of experiencing health complications during and after pregnancy (ACOG, 2013; Gunatilake & Perlow, 2011; Maxwell et al., 2019).

Maternal physiological changes are the product of hormonal influences and mechanical effects. In patients with obesity, the weight of fat tissue and the subsequent added metabolic demands also affect maternal physiology. Both pregnancy and obesity cause blood volume and cardiac output to increase, and in the obese patient these levels expand in proportion to the amount of fat tissue. During labour and vaginal birth and in the immediate postpartum period, blood values and cardiac output in obese patients can reach levels 80% greater than prelabour values. The enlarged uterus and abdominal fat mass also further increase the possibility of aortocaval compression.

The gastric emptying time is delayed, the tone of the cardiac sphincter is decreased, and the gastric contents are hyperacidic in all pregnant patients. The patient with obesity is more likely to have a hiatal hernia and a marked increase in intragastric pressure and volume; therefore, these patients are at great risk for regurgitation and aspiration. Comprehensive care of the bariatric patient is essential to ensure optimum outcomes for both mother and fetus (Maxwell et al., 2019).

Antepartum Risks

Patients with obesity often have difficulty becoming pregnant and may require assisted human reproduction. Once they are pregnant, patients with obesity may have difficulty maintaining the pregnancy. There is an increased risk of spontaneous abortions, as well as increased rate of recurrent pregnancy loss (Maxwell et al., 2019). Increased BMI also leads to a higher risk of stillbirth; patients with a BMI greater than 35 have an almost three times greater rate of stillbirth after 28 weeks (Maxwell et al., 2019).

It is recommended that patients who are overweight or obese attempt to obtain an ideal body weight before conception, to improve their own health as well as pregnancy outcomes (Maxwell et al., 2019). Once the patient is pregnant, a weight loss program may have limited effect on reducing maternal and newborn complications (Maxwell et al., 2019). Regular exercise during pregnancy has many benefits and has been shown to improve pregnancy outcomes in patients with obesity (Maxwell et al., 2019).

Increasing numbers of patients of reproductive age are undergoing various types of bariatric reduction surgery (ACOG, 2013; Maxwell et al., 2019). Patients must be counselled to defer pregnancy for up to 24 months after bariatric surgery, to reduce the rates of newborn complications (Maxwell et al., 2019). Overall pregnancy outcomes are improved for patients who become pregnant post–bariatric surgery—for example a reduction in pregestational diabetes, hypertensive disorders, and pre-eclampsia, and a decreased risk of having a large-for-gestational-age infant (Maxwell et al., 2019).

During pregnancy, patients with obesity require increased surveillance and care. GDM screening should be done early in the pregnancy, as the risk for GDM and type 2 diabetes is increased (Berger et al., 2019). A dating ultrasound by transvaginal measurement is recommended between 7 and 14 weeks' gestation to confirm the estimated date of birth (Maxwell et al., 2019). During the routine 18- to 22-week ultrasound examination, it can be difficult to visualize fetal structure, and repeated ultrasound scans may be required to assess fetal anatomy. This assessment is important, as infants of obese mothers have an increased rate of undetected chromosomal abnormality. Noninvasive prenatal testing results have a higher failure rate than that of patients of normal weight (Maxwell et al., 2019). Congenital anomalies such as neural tube, heart, ventral wall, and cardiac defects are also increased (Maxwell et al., 2019).

Patients with obesity have an increased prevalence of pre-existing hypertension or risk of developing hypertensive disorder of pregnancy (Magee et al., 2014). It is recommended that low-dose Aspirin (acetylsalicylic acid) be initiated prior to 16 weeks' gestation as prophylaxis for pre-eclampsia (Brown et al., 2018; Butalia et al., 2018; Maxwell et al., 2019).

Nursing Care

Caring for the bariatric patient during the perinatal period requires a caring, knowledgeable approach. Appropriate-sized equipment is required. A large manual blood pressure cuff is required, as automated blood pressure machines may not be accurate for blood pressure assessment. It is important to have bariatric equipment such as appropriate-sized beds, operating room tables, stretchers, and wheelchairs and to determine the manufacturer's weight limit on equipment prior to use. Bathrooms and shower stalls may require wider doors. It is also important to ensure that there is access to larger gowns, weight scales, and epidural needles. Nurses need to use appropriate mechanical lifts when necessary, as no patient lifting is permitted by institutional protocols and work-safe procedures. Care of the patient with obesity during labour and postpartum is discussed further in Chapter 20.

OTHER MEDICAL CONDITIONS IN PREGNANCY

Anemia

Anemia is the most common medical disorder of pregnancy, affecting up to 50% of pregnant patients (Samuels, 2017). It results in a reduction of the oxygen-carrying capacity of the blood; thus the heart tries to compensate by increasing the cardiac output. This effort increases the workload of the heart and stresses ventricular function. Therefore, anemia that occurs with any other complication (e.g., pre-eclampsia) may result in heart failure.

An indirect index of the oxygen-carrying capacity is the packed RBC volume, or hematocrit level. The normal hematocrit range in nonpregnant patients is 0.37 to 0.47. Normal values for pregnant patients with adequate iron stores may be as low as 0.32. This decreased level has been explained by the blood volume expansion of approximately 50% and total RBC mass expansion of approximately 25%. This *hydremia* (dilution of blood) is also called the **physiological anemia of pregnancy**.

Anemia in pregnancy is defined as a hemoglobin level of less than 110 g/L or a hematocrit of less than or equal to 0.32 (Samuels, 2017). When a patient has anemia during pregnancy, the loss of blood at birth, even if minimal, is not well tolerated. The patient is at increased risk for requiring blood transfusions. Patients with anemia have a higher incidence of puerperal complications such as infection than do pregnant patients with normal hematological values. *Severe anemia*, defined as a hemoglobin level of less than 60 g/L, has been associated with decreased fetal oxygen levels that result in abnormal fetal heart rate patterns, decreased amniotic fluid volume, and fetal death.

Nursing care of the pregnant patient with anemia requires that the nurse be able to distinguish between the normal physiological anemia of pregnancy and the disease states. The majority of cases

of anemia in pregnancy are caused by iron deficiency. The other types include a considerable variety of acquired and hereditary anemias such as folic acid deficiency, sickle cell anemia, and thalassemia.

During prenatal visits, the nurse should take a diet history and provide dietary teaching as appropriate. Pregnancy may cause increased fatigue, stress, and financial difficulties for a patient with anemia as they cope with activities of daily living. The nurse should assess the pregnant patient's needs and provide appropriate resources or referral.
